[12366.]—**Pianofortes without Strings.**—If Mr. Fennessy will take the trouble to look into several articles lately printed, he will find pianos without strings are no novelty, a patent for one by Dr. Clegget dating 1788. They are now in rather common use, but were never extensively adopted, probably because the tones of most of them are very short, but this I believe to be only the result of the bad proportions of their forks or vibrating parts, for the sounds of a good tuning fork are anything but "short," certainly not so short as in Mr. Bottone's words to "require no dampers." Mr. Goldsworthy's—I should have written Goldsworthy Gurney's—piano was mentioned by me as being one of the best and simplest arrangements I have seen, and because it promises to obtain the greatest possible resonance any such instrument seems likely to get from a soundboard. Other varieties are rather numerous, as Mr. Fennessy will find by "reading up" "our" journal. Mr. Llewellyn informs me he constructed pianofortes whose sounds were obtained from steel wires coiled like a catherine wheel, the straight ends of which fitted tightly in a hole formed in the bridge on the soundboard. He tuned them by forming a screw on the straight part which projected above the bridge, and by means of a rather tight fitting nut (it was fitted rather tightly to avoid jarring) he tuned these springs, *à la* American clock "bells." To raise their pitches, he drew more of the straight parts through the bridge, thereby shortening the lengths of their vibrating portions. To flatten them the reverse operation served. I think very similar means have been employed for varying the pitches of harmonium reeds, and now are for organ reeds.—The Harmonious Blacksmith.

[12368.]—**Imitation Bronze.**—There is a practice that I condemn—viz., using corrosive sublimate for bronzing. It is, in the first place, very pernicious, and will make brass work as rotten as a biscuit. It, therefore, endangers the public safety if used in gas-fittings. Use sulphate of ammonia and sweat with acid.—Jack of All Trades.

[22368.]—**Imitation Bronze.**—Powder the corrosive sublimate; if it well blackens the brass that is sufficient.—W. Bolton.

[12374.]—**Ancient Wrought Iron.**—Is not the diameter of the base of this column a little overstated. 14ft. 4in. seems rather out of proportion for the base of a column probably not much longer than its visible portion, which is stated to be 48ft., and only 12in. diameter at top. Should it not have been $14^4/_{10}$in. at bottom. If this wrought (?) iron column be a mere relic of a past civilisation, like Cleopatra's needle, and no longer serves any useful purpose where it stands, although as a rule I abhor robbing ruins, I yet think it would be worth while to bring it to England, and if somewhat too large and heavy for the East India Museum, it might be sent to that interesting refuge for destitute curiosities, South Kensington Museum, and again subjected to the influence of (Henry) King Cole.—The Harmonious Blacksmith.

[12384.]—**Coppering Carbon.**—Place a piece of zinc in the porous pot, with one part of sulphuric acid and seven parts of water, and in the outer cell a saturated solution of sulphate of copper with a few extra crystals added to keep up the strength. Twist a piece of copper wire round the carbon, and connect to the zinc, allowing the carbon to dip in the copper solution as far as required. Metallic copper will shortly be deposited on the carbon, to which you can easily solder, using chloride of zinc, otherwise killed spirits of salts. I think this will also suit "D. J." (query 12453).—W. Bolton.

[12397.]—**Boat Building.**—Having built a small boat for my own amusement (though not a boat builder) it gives me pleasure to write what I know of it, in the hope of imparting some benefit to "W. S." and others. The kind of boat I wanted was such as one person could easily row for six or eight miles, and if necessary carry two or three persons. Having by visiting the quay decided on her dimensions—namely, 12ft. keel, 3ft. 9in. beam, and about 16in. deep amidships—to build one of these dimensions the following materials are required:—One piece of oak 12ft. by 3in. by 1½in. keel, one ditto 2ft. by 1ft. 4in. by ¾in. stern board, one ditto 2ft. 4in. by 3in. by 1½in. stern post, one ditto 2ft. 4in. by 4in. by 1½in. (curved) stem, two best quality yellow pine battens 14ft. by 7in. by 3in. free from shakes, or bad knots, and not dry—cut seven boards out of each; planking, twelve pieces green ash 5ft. by 1in. by ¾in. ribs, two pieces of ash 14ft. by 1½in. by 1¼in. gunwales, three dozen 1¼in. brass screws No. 14, 3lb. 1in. copper nails and washers, 5lb. or 6lb. paint. In addition to the ordinary tools used for planing and cutting timber when boat building, half a dozen pairs of what are termed tongs will be found very useful for gripping the planks together until shaped and secured. To make them, get two pieces of oak 18in. by 2in. by 1¼in., taper from 12in. back on outside at one end, and at the other taper them 6in. back, or inside, to give room for a wedge; strap together, secure each on a pivot, and by driving in a wedge at short end the jaws firmly hold the planks together. To build the boat, or rather the way I built it, was, having planed up the stuff, I half checked the stem and sternposts on keel, nailed on sternboard, rebated keel for edge of first board, placed this frame on a couple of stools about 20in. high, and stayed it securely in an upright position; cut one of the boards 14ft. long up the centre; these formed the first planks on each side; nailed three or four pieces 6in. by 3in. by ¾in. across keel to keep first planks horizontal amidships. While bending them into stem and sternposts, tapered planks on each edge to fit, painted rebate in keel and edges of planks, and secured them with copper nails; applied next plank, overlapping edge of first ¾in., gripped them together with tongs, tapered edge to fit, and reduced top edge at stem and stern, as at those points I had less space to cover than amidships, riveted planks and proceeded to third, which I had to cut and splice again to get it to assume a proper curve; a splice of 2½in. long, having a piece of brown paper painted on each side, and well nailed together, suited me. When the planks had been brought up to the required depth and shape of boat the gunwale was put in, and inside of boat painted two coats, a piece of ordinary 4in. down spout, stopped at one end, served me for steaming chest to soften and supple ribs, the sooner these were secured to planks after coming out of "chest" the better job; mine were put in 12in. apart; three seats 8in. by 1in., a flooring-board 14in. by ¾in. shaped to ribs, four coats of paint on outside; then a launch. It answers my purpose well.—H., Belfast.

[12417.]—**Hardening Spiral Springs.**—You have probably been using mild steel, such as pianoforte strings; it won't harden or temper to speak of. Get good cast steel, and you will certainly succeed.—T. S. USBORNE.

[12419.] — **Photography.** — Water alone. — S. BOTTONE.

[12427.]—**Entomological.**—The maggot is very like an ordinary cheese maggot, about ¼in. long, but stouter. It is found singly or by twos and threes in the sap-vessels of the leaf-stem or midrib of the leaves that are turning yellow in various species of Brassicæ. —MIMOSA.

[12428.]—**Air Vessel for Pump.**—The size, shape, and material are of no moment, so that they are big enough. It may be necessary to provide for the periodical supply of fresh air into a pressure pot. A vacuum pot will take care of itself.—T. S. USBORNE.

[12429.]—**An Engineering Inquiry.**—There is no royal road for a practical engineer to attain even a partial knowledge of his profession. At the same time, if J. A. P. Spence is in earnest, let him engage for two years in a marine engineer's erecting shop, but he must make up his mind to rough it, but "Dum spiro spero."—LUFFRA.

[12432.]—**Testing Beer and Spirits.**—Sykes' hydrometer as used by the Excise is the only reliable one for alcoholic strength, price, 15s. to 25s.—M. A. B.

[12439.] — **Working Plane Surfaces.** — R. Roberts asks for an impossibility. Theoretically, a perfect plane surface cannot be obtained; practically, Sir J. Whitworth first brought into fashion a means of getting a plane surface. Mr. Roberts should purchase a pair of Sir J. Whitworth's plane surfaces, of a size rather larger than he requires for his instrument. Then scrape a surface as true as he can on the face of his instrument, take one of the plane surfaces, cover with some colour which can be removed easily; on bringing this into contact with the scraped surface, the high parts will be covered with the colour whilst the low parts remain uncoloured; scrape away the high parts. Try again with the coloured plane surface, and so on, till the colour is distributed equally all over the surface. He will then have obtained as true a plane surface, as mechanics at present can make.— C. H. W. B.

[12439.]—**Working Plane Surfaces.**—Cannot R. Roberts use the method employed by the glass polishers? I will describe it. Two plates are employed rough, just as they come from the annealing furnace, one three or four times smaller than the other. The larger plate is imbedded in gypsum in a perfectly horizontal position upon the grinding bench, a table of about 2ft. high, resembling a billiard table. The smaller plate is fixed into the muller or upper stone, a movable box made heavy by weights, but in such a manner that the plates shall present opposite surfaces to each other, that is a rough (rolled) towards a smooth (from the casting plate) surface. When all is thus prepared, coarse sand and water is applied, and the upper stone is set in motion over the whole surface, round its axis, and backwards and forwards at the same time, either by the hand or machinery. When the sand has become too fine, the next size or number is applied (at Newhaus, in the Austrian States, seven kinds of sand, of different degrees of fineness, are employed), and this is continued until the grinding is finished—*i.e.*, until the ground plate exhibits a perfectly horizontal and plane surface. The process is then repeated with emery, which is renewed fifteen times at some places, gradually growing finer, until at last the glass becomes smooth as well as even, but is still dull and incapable of reflection. For this purpose it next requires polishing, which is done either by machine or by hand, the machine producing the best plane surface, but, nevertheless, it can be done by hand good enough. The powder employed is oxide of iron or crocus, also called colcothar (prepared by roasting green vitriol and washing). This is rubbed gently over the glass by means of a weighted board covered with woollen cloth. This process might easily be applied to metal, and I think with the same success.— P. W. H. J.

[12442.]—**Indigestion.**—Drink a tumbler of cold water containing a tablespoonful of lime water as you rise and go to bed. Eat brown bread made from the whole of the wheat ground, no bran being removed; avoid made dishes, spices, or sauces. Early to bed and early to rise. As much open-air exercise as possible. Never eat to repletion, but leave off whilst you could still eat a little more; no raw vegetables (salad, celery, &c.); avoid any vegetable that disagrees or causes flatulence. Indigestion is curable by proper diet, not by medicine.—M. A. B.

[12443.]—**The Tremolo.**—"Corelli" must have long practice to give that beautiful tremolo which he asks for; it is produced by the trembling or quivering of the single finger which stops the note. I was years before I could accomplish it properly, although I have scraped a fiddle for the past 22 years. Persevere, and you can accomplish great things; if a scraper, purchase Kreutch's Exercises (1s. 6d.), you will find many good exercises in it.—W. CLARKE.

[18443.]—**The Tremolo.**—It is difficult to explain, in writing, how the tremolo is produced, but, in a general way, it may be described as the shake, without removing the finger from the string, and this may be done by the fingers only, or by a free movement of the upper part of the hand in connection with the particular finger required.—F. F. C.

[12444.]—**Day and Night Telescope.**—The erecting eyepiece of most telescopes (spy-glasses) consists of four lenses, these are contained in the last draw of the instrument, two at one end in a small tube inside the draw and two at the other end; there is a stop in each of these inner tubes to cut off the wandering rays. To convert such a telescope into a night glass unscrew the first draw (the one nearest the eye), and unscrew from it the inner tube farthest from the eye and remove it; screw on the draw and focus again; the focus is much shorter; the object appears unveiled, but brighter, as it is not so much magnified, and besides, the loss of light incurred in passing through two lenses is avoided. Most small telescopes magnify greatly in proportion to the size of their object-glasses, and show darkly as day telescopes, and do not do well at night.—PHILANTHROPIST.

[12445.]—**Rotten Silk.**—Where dust is allowed to accumulate it breeds a species of fungus similar to mildew or must, which will very soon rot the best of fabrics.—JACK OF ALL TRADES.

[12447.]—**Employment for a Retired Tradesman.**—This all depends upon a person's taste. A good garden will afford you a vast fund of amusement. Mechanics are all very well; but some spend their life in such things without knowing, or being able to drive a nail properly. If "A Retired Tradesman" is determined to go in for mechanics, and has the means, get a good lathe, not less than 6in., with tools and slide-rest. Joiner's tools to consist of brace and bits; planes, smooth, jack, and trying; chisels, firmers from ⅛in. to 1½in., mortice tools from ⅛in. to ⅝in., beads, hollows, and moulding planes as you want them, bradawls and gimlets, a carpenter's bench, fret and circular saw, table for lathe, oval chuck, with other chucks; in fact, there is no knowing what you want until you start. I should recommend you to get the back numbers of the ENGLISH MECHANIC, in which all these things are treated on. If a start is made there is not the least doubt but that you will find by applying here that you will find plenty able and willing to give you tips. Never use a good lathe for grinding and polishing, but in some out-of-the-way place fit a temporary affair up for the purpose.—JACK OF ALL TRADES.

[12447.]—**Employment for a Retired Tradesman.**—A work-room with lathe and joiner's bench is all very well, but hardly enough for an active-minded man, accustomed to employment. A garden is a capital resource, so is an aquarium, especially if "A Retired Tradesman" has a microscope, he will find his aquarium almost as interesting as a Zoological Garden, he may be constantly finding something wonderful and strange. The study of some branch of natural history will be a more enduring pleasure than a tool bench. Geology is, perhaps, the most suitable for "A Retired Tradesman," but he cannot go wrong with any, if studied properly, not contenting himself, as many do, with learning merely the names (say) of the insects he collects; he must try to observe their manners and customs, to get all the good they can teach, which is a great deal. There is no need for a student of nature to travel far or incur much cost in finding objects of interest. They may be found everywhere by those who know where to look, and the habit of observing quickly increases the power of observation; those who have not acquired it, have little idea how much pleasure they miss. Many of the very commonest objects are, when properly examined, amongst the most wonderful; for instance, what fisherman's net is half as skilfully constructed as a spider's web; what building built with such economy of material as a honeycomb, and we shall be lucky indeed if "our" lifeboat is as complete a success as a gnat's egg-raft. —PHILO.

[12447.]—**Employment for a Retired Tradesman.**—I think photography would prove very interesting after the first difficulties of the art were surmounted, these are sometimes vexatious; and if necessary a few lessons might be taken from a professional photographer. Chemistry is a very interesting study, but some of its experiments are not devoid of danger; however, by far the greater portion of them are quite safe. Roscoe's "Chemistry" for study, and Francis' "Chemical Experiments" might suit.—PHILANTHROPIST.

[12450.]—**Beehives.**—The hive described in p. 806, Vol. XIV., is not the hive which I prefer above all others; but for those who prefer the Woodbury hive it is, in practice, the very best I know of, and with the improvements suggested at the end of the letter, and description, it will be perfect as a Woodbury hive. My objections to the Woodbury are described on p. 533, same volume, and my new hive is there roughly shadowed forth, and I have been promising to send an accurate description of all its parts ever since, but really cannot find the time to do it. However, I will endeavour to do so in time to enable bee-keepers to arrange for next year. But to return to "S. R. S. B. G." and p. 806. Fig. 1 shows ground plan. The blocks go down to within one-sixteenth of an inch of the bottom, and come up to within ⅛in. of top, and on them is laid ⅛in. deal to fill up the spaces, which said ⅛in. stuff is nailed in through both inner and outer skins of hive. The notches, as in the Woodbury, are cut into, and not through, the front and back inner skins only, which are of ⅜in. stuff for the purpose. My reply to first question makes it unnecessary to reply to the last one. As regards my new hive, results are bearing out all my anticipations. Swarms of this year are filling them, and the difference of the appearances at the entrances of them as compared with the Woodbury is most decidedly in their favour—no idling or outside clustering; no fanning at entrance, which is 9in. wide and ¾in. high; no difficulty about the ventilation, as the top board being in pieces, ventilation can be regulated to a nicety.—C. N. ABBOTT.

[12452.]—**Building on Sand.**—Sand is one of the best of foundations if properly drained. The first thing to be done would be to ascertain what is the nature of the stratum beneath; if it is at all soft, building should be proceeded with very cautiously. One of the worst situations for a sand foundation is at the side of a hill.—P. W. H. J.

[12452.]—**Building on Sand.**—If "Inquirer" wants a good job, by all means put in a concrete foundation; it is not only a better job, but it can be done for less money. A more powerful recommendation I cannot call to mind at present.—LUFFRA.

[12456.]—**Fuel for Steam-Engine.**—Use slack and coke in preference.—JACK OF ALL TRADES.

[12458.]—**Blowing Apparatus.**—The pressure required to force air through the syrup would be nearly 1½lb. A fan would not be able to force that pressure economically, though it would force it. The plan that I should recommend would be this: Get an iron or brass ring or tube ¾in. diameter, internal 16in. diameter, in which pierce fifty or sixty small holes that would let a knitting-needle go through them. This is to be fastened to the bottom of the cistern, and to have the straight portion of the pipe passing out at the side. This will do better than the Bessemer plan for a small thing like this, as in the former there would only be needless complication. There then wants a cylinder, 5in. stroke, and 3in. diameter. This is to be made like a double-action air-pump, and will require considerable care in its construction. It will be best made of brass. The air-vessel is to be a tin cylinder 10in. diameter, and the same high, which is to be connected with the ring by a pipe. To the piston-rod of the air-vessel there is to be fastened a lever-handle to work up and down like a pump. Instead of an air-pump, you might meet with an old engine-cylinder, second-hand, with slide-valve attached. This might be made into a pump by arranging so that the valve moves in opposite directions to the piston, by fixing the valve-rod to a pin on lever. An arrangement will be sent if desired.— P. W. H. J.

[12459.]—**Bending Laths.**—If you only want slight work, make saw cuts across your wood on concave side—one inch or less apart, and two-thirds of an inch through; and before bending wet the convex side only with hot water; but you must fix the ends in position permanently. If you want strong work you must give more particulars—viz., length of chord, rise of arch from chord, kind of wood, and hint of the purpose in view. I am supposing deal; but you can buy of a cooper a hoop of ash to make two much stronger and cheaper than you can make one.—CABINET MAKER.

[12459.]—**Bending Laths.**—If birch, beach, ash, &c., boil them and bend upon blocks. Oak, lime, poplar, willow, &c., will retain their shape. With the fir tribe it is a difficult job not to bend them, but to get them to retain their shape, unless put into a groove or fixed in some way.—JACK OF ALL TRADES.

[12461.]—**Threads in Gas-pipe.**—If "A Subscriber" will furnish himself with either Greenwood's or Martin's book upon "Screw Cutting," he will have all he wants, and will never have cause to regret the trifling outlay. They both advertise in "ours"—JACK OF ALL TRADES.

[12461.]—**Threads in Gas-pipe.**—1in. and upwards = 11; ¾in. and ⅝in. = 14; ⅜in. and ¼in. = 18; ⅛in. and all sizes of ordinary brass tube, 26.—W. BOLTON.

[12462.]—**Electrotyping.**—Copies can be taken off the plaster if it is properly prepared. They must first be dipped in melted wax and allowed to remain for a few minutes. After they are cool they are to be blackleaded with a soft brush. This wants to be done so that the blacklead is scarcely visible. They will then be ready for copying. They will return a fair medal, but there are many substances more suitable. Guttapercha serves the purpose admirably. The method adopted is to heat the guttapercha in boiling water, or in a chamber heated to the temperature of boiling water which makes it soft and pliable. The plaster casts are to be fitted with rims made of stout tin or pasteboard, bound round with wire. The guttapercha is then to be gently kneaded in and worked round until it has penetrated into the hollows of the plaster. They are then each to have weights loaded on the guttapercha and set aside until it is cool. Another plan is to place the plaster casts, if medals, or small ones, each at the bottom of a separate saucer, and surround it with well-kneaded clay flush with surface of medal, allow this to dry and press the guttapercha into it. To obtain a wax mould, the plaster cast is first brushed over with boiled linseed oil until it is perfectly saturated; this succeeds best when plaster is gently heated. Another plan is to saturate with water, and another with milk. To cast, the rim is to be ¼in. above medal, and before the wax is quite cool undo the rim or else it will stick to the wax. Care must be taken not to pour on the wax too hot, as that is one great cause of failure in getting good moulds, it should be poured on just as it is beginning to set in the dish. Put the medal and wax in a cool place, and in about an hour the two will separate easily; when they adhere, the cause is either that the plaster has not been properly prepared, or that the wax has been poured too hot.— P. W. H. J.

[12462.]—**Electrotyping.**—I should recommend the use of guttapercha in preference to wax, the latter being much more difficult to manipulate, on account of the formation of air bubbles, and other inconveniences. The guttapercha must be boiled in water until quite soft. The object to be copied, if plaster, should be slightly rubbed over with sweet oil, and should be provided with a rim of cardboard, or very thick drawing paper, allowing sufficient depth in the rim to hold a requisite quantity of the material. This may be conveniently secured with sealing-wax or strong gum. A rim of thin tin will answer the purpose very well if properly secured by means of a fine wire. To lay the plumbago on the mould, you need only to use a camel's-hair brush and rub on the plumbago (which must be very freely pulverised) in very small quantities, working round in circles, until the mould has acquired a metallic lustre. I have tried the above method, and have always found it to answer admirably.—W. H. H. C.

[12462.]—**Electrotyping.**—Take a piece of cardboard and tie round the edge of casts, either wetting or oiling before pouring the wax, or standing the whole in a little water in a saucer. To make the blacklead adhere evenly, wash the face with turps, and let dry; then apply the plumbago with a soft camel's-hair brush.—JACK OF ALL TRADES.

[12463.]—**Vision.**—There is another theory for the correction of the inverted image—viz., at the optic commissure or junction of the two optic nerves, there are three sets of fibres—decussating, non-decussating, and commissural. It is supposed that inverted vision is corrected here by the lower fibres passing upwards, and the upper downwards. A perfectly satisfactory reason, however, has never been given.—M. A. B.

[12463.]—**Vision.**—Perhaps visible direction has something to do with the inverted image, as evidently the eye receives the rays of light proceeding from an object above it in a direction slanting downwards, and we may thus be enabled to judge of the position of the object; a similar reasoning will apply to the case of objects situated below the eye.—PHILANTHROPIST.

[12463.]—**Vision.**—"H. Science" asks for the most probable cause of the inversion of images on the retina, but as the cause of that is nearly self-evident, I think he must mean to ask why do objects, the images of which are inverted on the retina, appear to us upright. The difficulty I feel in removing this difficulty, which many have, is in understanding what is the difficulty they find. We are entirely unconscious of the image which is formed on the retina; all that we learn by direct sensation is that we see when there is nothing between our eyes and objects giving off or reflecting light; that we see most distinctly the objects at which we direct our eyes, and that when we try to see parts of objects above or below, or at the side of that immediately in front, we have to turn our eyes upwards, downwards, or sideways respectively; and we have learned to do that just as we have learned to raise or depress our hands by the action of muscles, the action of which is quite unconscious to us, unless, indeed, the muscles are injured or fatigued so that their action gives us uneasiness. This is, I think, the most probable way in which the real position of objects seen by us is learned; but it may have been learnt, as it is now known to us, by our observing, as we often may without moving the eyes, that the part of the object the image of which is highest is nearest to the floor, which we know is below us. Thus, when we are lying down on (say) the right side, the lowest part of an object we look at forms its image on the part of the retina, where an object to our right would form its image if we were upright; but we find no difficulty in deciding its position with respect to ourselves, if we know our own position; nor should we find any difficulty by looking at objects when standing on our heads, and knew we were doing so.—PHILO.

[12470.]—**Separating Salts Produced from Kelp.**—The question put by "A Tyro" is one of those which it is difficult to answer, owing to their indefiniteness. The method to be pursued will depend very much upon the proportion of the salts contained. I should say that from a solution of potassium chloride, sodium carbonate, and sodium sulphate, if the proportion of the two latter be large, the best plan would be to concentrate by boiling. Upon cooling a crystalline mixture of sodium sulphate and carbonate would be obtained, such as sold by the name of grocers' soda crystals. From the mother liquor crude potassium chloride might be obtained by a second concentration and crystallisation. But I must confess that as I see no method by which they may be neatly separated, I think it would never pay unless the proportion of potassium chloride be large, in which case it might be crystallised out from the original liquor. I should advise the querist to concentrate some of the solution, and see of what the crystals obtained on cooling are composed, when he will have a better idea how to set about it.—ANALYST.

[12473.]—**Printers' Rollers.**—To mix composition for rollers: Summer use, 1½lb. best glue and 4lb. treacle; winter use, 1lb. best glue and 4lb. treacle. Soak the glue about one hour and a half if thick, if thin one hour. Take it out of the water, lay it on a board until next day, then melt down in proper melting-pot, or put it in a saucepan and place it in another containing water (be sure and not let the water run over into your glue; one great secret in roller casting is to have as little water in your glue as possible), then add treacle as above, let boil once, then keep it just under boiling point until cooked, which takes about two hours, more or less; pour out into moulds, well cleaned and greased; if left too long on the fire it will get thick and spoil. The above is sufficient for an 18in. roller; other sizes in proportion. From long experience I find the above is the best for both machine and press. Any further information to "A Tyro" I shall be happy to give. Perhaps the following may be of use to him and others. French compo. prevents damp rollers. For a 24in. roller, take ½oz. Russian isinglass, ½oz. gelatine, dissolve the two in ½ pint of water. When the usual composition is ready for pouring, add the above to it, let all boil ¼ hour longer, and cast in usual way.—W. CLARKE.

[12475.]—**Removing Whitewash.**—I should advise "S., Colombo, Ceylon," to try dilute hydrochloric acid for the removal of whitewash from stone and woodwork, subsequently washing with water.—ANALYST.

[12475.]—**Removing Whitewash.**—Take a bass scrubbing-brush and elbow grease. — JACK OF ALL TRADES.

[12482.]—**Integral and Differential Calculus.**—It would be difficult to mention any branch of science where the calculi are of no use, and it would really take up too much time and space to show where, when, and how used. The student, before commencing differential calculus, ought to have a good knowledge of trigonometry, and some knowledge of conics. Of course, a slight, yet useful, knowledge of this branch of mathematics may be obtained without so very extended acquaintance with the above subjects. (See Mr. Proctor's articles on the Calculus in Vol. XII.) I (personally) think Mr. Todhunter's books the best that any student can use. They are published by Macmillan, 10s. 6d. each. A book has lately been published by Messrs. Longmans, written by Professor Williamson, but I cannot say anything about it as I have not seen it.—C. H. W. B.

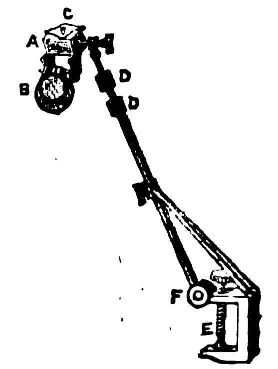
[12484.] — **Inorganic Chemistry.** — Get the "Science Directory" from South Kensington Museum. The syllabus for chemistry, first stage, second stage, and honours, will be found therein, also the books recommended by the examiner.—C. H. W. B.

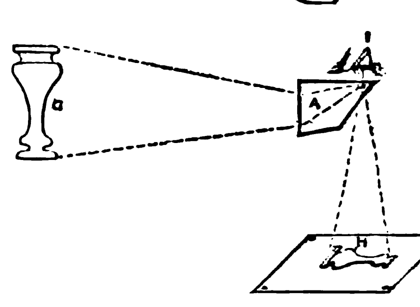
[12484.]—**Inorganic Chemistry.**—If "Science and Art" is ignorant of the science he desires to study, I should recommend him to begin by attending some regular course of lectures on chemistry, such as are given in most towns by certificated science teachers. If he prefers, or is compelled, to study privately, let him begin by reading Roscoe's "Science Primer," price 1s., published by Macmillan, carefully performing the experiments therein described. Then read Houghton Gill's "Chemistry for Schools," experimenting in the same way. If the student's object were to acquire a good knowledge of the science, I would then advise him to study Roscoe's "Elementary Chemistry," and the first two volumes of Miller's "Elements of Chemistry," but as his object is to pass the science and art examinations, he must read the book and master the chemical gymnastics of the examiner, Dr. Frankland. I am afraid "Science and Art" has fallen a victim to the intricacies of the "Science Directory" when he writes of wishing to pass "first-class in the third stage for honours." The lowest or elementary stage has two classes, first and second; so has the advanced stage; and so has the highest or "honours" stage. When obtained, the "honours" consist of a piece of brown card with your name written on it. There are very few honours to give away as the department has little to spare, its breaches of contract and "mistakes" being not unfrequent. The teachers of chemistry working under the department do their best, but their pay being dependent on "results," they are compelled to cram their pupils with the questionable theories of the examiner to the exclusion of much more valuable information and sound knowledge. If you want to learn chemistry for its own sake, and independently of the "honours," attend a class not connected with the department.—ALFRED H. ALLEN.

[12486.]—**Machine for Cleaning Boots.**—In reply to "S. J. R." first black your boots by hand, then polish with a revolving brush fixed to the head-stock of a lathe, or to cog-wheels, and a weight over pulley.—R. A. H.

[12504.]—**Sketching from Nature.**—Take a picture frame about 18in. square, or thereabouts, tie across the frame threads of cotton, both perpendicular and horizontal, about 2in. apart, like a gravel sieve; mount the whole upon a leg and fix it in the ground. Sit at a distance of 5ft. to 10ft., you will then see the place each object of the landscape occupies in relation to the cross lines, which serves to measure the position and space each require. The paper you sketch upon should be the same size as the frame, and should be attached to a board with pins. Dots at the end of the paper and across the top indicate the whereabouts of the threads on the frame; and the position each object must be placed in is easily found by the use of the T square, which serves, with the aid of the before-mentioned dots, to divide the paper into small squares in the same manner that the cotton threads divide the view of the landscape. This apparatus can be constructed for 1s. In sketching it is required to sit in one position until the outlines are taken. I would add a sketch as desired if I thought it necessary. You will probably understand it without, if not I will send sketch.—JOHN HOPKINS.

[12504.]—**Sketching from Nature.**—In answer to Thomas King (query 12504, p. 497), I do not think that anything better can be recommended for sketching from nature than the camera lucida; it can be obtained cheaply, and is certainly portable. I know people who have bought it second-hand for 12s., and as there is some exactness required, am inclined to think it would not be easy for ordinary persons to make. Both the camera obscura and the lucida have been tried by myself, and the palm belongs to the lucida for usefulness—but, "aye, there's the rub," it wants practice, and, possibly, a peculiar fitness of vision to use it. I am justified in saying this, because I know talented artists among my own acquaintance who cannot work with it. I have employed it for some years, find it a good servant, and therefore recommend it to others. Mine cost (new) £2 5s. The whole principle of the instrument lies in a nutshell: a prism, through which the images of the objects to be delineated are carried; these are seen reflected by the eye perpendicularly underneath the prism on a sheet of paper which is placed there. The eye then is held over the edge of glass, the hand with pencil delineates the outline of the landscape or object to be represented. The difficulty is in being able to see both the image of the object to be drawn and the pencil point at the same time—though some appear to surmount this vexatious trouble (for such it is), very quickly. After buying my lucida I laid it by in disgust for more than ten years, till a happy thought occurred to me to try it once more—and successfully. But for absolute truth I have more confidence in my own correct eye than in any optical appliance whatever. Many otherwise excellent photographs are notoriously distorted. The camera lucida has this fault, but with care it may be made to speak correctly. The following description, with reference to the diagrams, will explain it. A, prism; B, two eyepieces to assist defective vision; D, clamps to secure the elongating and telescopic rods, which thus increase or decrease size of image on paper; E, screw





for fastening on to edge of table or board; F is a pivot by which means the lengthening rod can be placed at any desired angle; C is a movable eyehole, of great advantage in confining the field of vision. The other diagram will show the principle still clearer. A, the prism; G, object to be drawn; H, image reflected; I, the eye. If Thomas King will turn to my answer to "Poloski" (12393), he will have the other requisite for sketching from nature.—A WORKING B.

[12511.]—**Gas.**—The following table will furnish "A., Liverpool," with the information he requires, and be useful to others. It is from the "Gas-Manager's Handbook." Wigan cannel and coal produce on an average:—

	Cannel		Coal
Gas	10,900	..	9,980 cubic feet
Illuminating power..	21·25	..	11·4 sperm candles
Coke	1,486	..	1,517lb.
Tar	17	..	11 gallons
Ammoniacal water ..	18	..	20 gallons

—SAUL RYMEA.

[12511.]—**Gas.**—In reply to "A., Liverpool," I learn that about 8,000 feet of really brilliant gas can be obtained from a ton of the best cannel coal; but if it is allowed to remain in the retort to be still further exhausted, then ten, twelve, and fourteen thousand feet of poorer stuff can be obtained, but the coke is then nearly unfit for household use. Ordinary coal, of course, will render a less and poorer quantity in proportion; but the larger the quantity of vapour obtained the greater is the profit the gas companies derive. It is a pity that our meters only register the quantity, without indicating the quality, so that we are now made to pay as much per thousand for the poorer stuff as the good, and are compelled to open our taps wider to burn a larger quantity, to obtain the light which a less quantity of the best gas would give. The complaints of poorness of light and increase of bills are getting so universal that it is time this subject was thoroughly ventilated.—R. A. H.

[12517.]—**Mathematical Machines and Tables.**—Babbage's extreme ambition unhappily did so overleap itself that the lesser of his proposed engines, the "Difference engine," a part of which was at South Kensington, is neither finished, nor, I believe, has yet produced any kind of table. The simpler of its purposes were meanwhile carried out by Scheutz, a Swede, whose machine was employed at Somerset House to calculate and print most of Dr. Farr's "English Life-Table," the volume mentioned in reply

12415, p. 495; and is now, I believe, manipulating the data of the 1871 census into a new edition of those tables. Babbage's complete design, the "Analytical Engine," which is to tabulate any function whatever, expressible by any algebraic formula, remains on paper only. Had he been content to execute either of them, as a first specimen, on a scale registering to ten decimal figures only, it seems he would have been enabled to carry out even this marvellous "Analytical Engine;" but he insisted on twenty figure results, as alone worthy of a national engine, and had to leave posterity to grow to his opinion. The little substitute of Scheutz was a quite independent invention; so admitted, I believe, by the philosopher, and without jealousy, welcomed and introduced to the country by him.—E. L. G.

[12520.]—**Fluid Lens for Photography.**—It would certainly be possible to construct a camera according to the diagram, but it possesses so many objections that no good could come of such an arrangement. 1. The loss of light by reflection from four mirrors would be very considerable. 2. The sulphuric acid would be constantly absorbing water, thus increasing its bulk, and altering its density and reflective power. 3. The water would rapidly evaporate from the proximity of the sulphuric acid. The focus would be best found by experiment with a piece of tissue paper or ground glass. It would vary with the distance of the object. Better buy a common sixpenny lens and fit it in a cigar box, than construct such an arrangement as in the diagram.—ALFRED H. ALLEN.

[12526.]—**Camera Lucida.**—The simplest so-called *camera lucida* for the microscope is Dr. Lionel Beale's neutral tint reflector. It consists of a piece of glass of a neutral tint inclined at 45° in front of the aperture in the cap of the eyepiece, and answers the purpose of Sömmerling's mirror or Wollaston's camera very satisfactorily. It may be purchased of any optician for a few shillings. The form introduced some years since by Mr. Collins is, in my opinion, the best. A substitute which will serve for rough work may be easily devised. Take a pill-box which will just slip on to the eyepiece in place of the usual cap, make an aperture in the bottom of the box the size of the eye-lens of the eyepiece, fix in a frame, which may be made of wood, cardboard or cork, two pieces of thin glass with a piece of thin tracing paper between them, or a little slightly coloured water may be run in in such fashion that the glasses shall be inclined at 45° to the face of the bottom of the pill-box. A piece of neutral tinted glass substituted for the thin glasses will, of course, form the orthodox article and may be very easily made by a person possessing very ordinary ingenuity at a trifling cost.—H. P. H.

[12567.]—**Chalk for Microscope.**—The plan I have adopted with very fair success is simple. I take a piece of the chalk I wish to examine, and immersing it in a small basin of water scrub it energetically with a tooth brush, or small nail brush, until the water has become tolerably turbid. I set the water aside until it has had time to allow the heavier particles to subside, when I pour off the water to about an inch of the bottom and fill up afresh with clean water. I then usually transfer the whole to a glass vessel, the better to see how things go on. This process of decanting and refilling must be repeated a score or more times, and the deposit after (say) the twentieth washing treated with soda, and then rewashed until all traces of soda are removed. The deposit, if now collected, will usually be found to consist of little else than foraminiferæ, coccoliths, &c. Another plan, which I sometimes follow, but do not like, is to pound the chalk tolerably fine, place it in a muslin bag and wash in water in the fashion a laundress "blues" her linen with the "blue bag," proceeding later as in the preceding plan.—H. P. H.

UNANSWERED QUERIES.

The numbers and titles of queries which remain unanswered for five weeks are inserted in this list. We trust our readers will look over the list, and send what information they can for the benefit of their fellow contributors.

Since our last "Jack of All Trades" has answered 12057, 12063, 12064, 12067, 12071, 12075, 12076, 12082, 12083, 12085, 12087, 12088, 12091, 12095, 12103, 12107, 12109, 12119; Joseph William Fennell, 12067; "P. W. H. J.," 12071, 12107; W. M. Colles, 12085; "Suffolk Amateur," 12087; "J. R. F.," 12087; "Vexed Violinist," 12087.

QUERIES.

[12537.]—**Compressing Air.**—If I take a cylindrical vessel—diameter a little over 13½in., so that the area of a piston moving in it is exactly one square foot, said vessel one foot deep—and press the piston downwards 6in., 7in., 8in., 9in., 10in. and 11in., what will be the work expended in compressing the above cubic foot of air—suppose at freezing temperature and 30in. of barometric pressure — into the corresponding new volumes indicated above—that is, ½, 5/12, ⅓, ¼, ⅙, and 1/12 of a cubic foot? The relative pressures in atmospheres will be 2, 3, 4, 5, 6, and 12, including the ordinary atmospheric pressure. At these particular volumes and corresponding pressures, what will be the temperature of the compressed air at the moment of compression, the sides of the cylinder being untraversable, or impermeable to heat either from without or from within, not taking into consideration the increase of elasticity of the confined air, which must inevitably take place by the heat generated? Again, supposing the length of the vessel is infinite, what will be the temperature of the air when the piston is raised 1ft.—which will, of course, double its volume—then 2ft., 4ft., 8ft., 16ft., 32ft., 64ft., 128ft., 256ft., and 492ft., then raised to infinity? Also, what would be the work expended in raising the piston to those various points? I know it will involve the use of the higher branches of mathematics, but I shall not be afraid of that. Will "E. L. G." kindly help me, or any other competent to do so?—MECHANICAL EQUIVALENT.

[12538.]—**Electrotyping.**—Will any experienced hand in this art tell me why I cannot get the deposit to take in the deep cavities of my moulds, but only on the flat or raised surfaces? It seems to thicken round the edges and branch out like rock coral.—DUPLEX.

[12539.]—**House Fly.**—Can the common house fly bite or sting?—GEO. A. AMES.

[12540.]—**Poultry.**—I should be thankful for the advice of any of our friends who have knowledge of the diseases of poultry and their remedy, in the following case. A cock bird has lately manifested great difficulty in swallowing, and, on examination, I discovered a white substance towards the root of the tongue. This substance continues to enlarge, and is now quite apparent through the sides of the beak, which the bird cannot perfectly close. I have tried various things which friends have advised, but none seem to do any good. The bird does not seem ill otherwise, inasmuch as he perseveres at the food, and with difficulty passes sopped bread and barleymeal. I should like to save him, as he is valuable.—H. G. W.

[12541.]—**Fish Culture.**—I live on the bank of a small river which is thinly stocked with trout. Would it be advisable and possible to introduce dace to the higher parts of the river; also the best way to do so? There are dace twelve miles lower down, which is as far as the tide comes.—GREEN DRAKE.

[12542.]—**Luminous Tubes.**—I extract the following from *Engineering*, of June 28, p. 435:—"Another curious discovery of Dr. Geissler was, that mercury, when shaken in a rarefied glass tube, would also become luminous, and emit a strong light, so that in a perfectly dark room all objects could be distinctly seen; the colour of the mercurial light could be modified by the presence of small traces of gases in tubes. A minimum of nitrogen shows an intense red, and hydrogen a yellow light. The capacity of mercury for producing light seems to depend on its purity, so much so that it was not luminous when it contained an admixture of tin, lead, zinc, or bismuth, but gold or silver did not affect it. It would be possible to utilise this peculiar quality of mercury for lighting up chambers filled with explosive gases, such as some parts of mines or powder magazines, instead of using the Davy lamp." I should like to know if any of "our" readers have ever made this tube in the form of an hour-glass, and with what result. In this way the mercury could be kept in motion for a considerable time, and for that time would, I conceive, be a self illuminating lamp.—PEGASUS.

[12543.]—**Light Shifting Hoist.**—Will any brother reader of our excellent journal kindly aid me in the following difficulty?—In the course of my work I have to lift a box 4ft. × 2ft., containing 36 bottles, in divisions, on to a slab 2ft. high. The bottles I fill with oil (2lb. in each), and have then to lift all down again on to a trolley to be wheeled away. The box, with bottles empty, weighs over 90lb., and when the latter are filled the weight is more than 160lb. I want some contrivance by which I can raise the box 2ft. 6in., push it forward, say 3ft. in a straight line, and, and bottles filled, vice versâ. Ceiling with strong joists, 9ft. high. A crane would be too much in the way, and the ordinary pulley blocks are inadequate, as with them one cannot well shift the load far enough from the point of suspension.—S. SELWYN.

[12544.]—**Taraxacum.**—I shall feel obliged if any one will inform me how to make taraxacum or dandelion coffee? I can't afford to buy it from the chemist.—WELSHMAN.

[12545.]—**Comet.**—I shall feel greatly obliged if any of "our" astronomical contributors will inform me when the next comet which will be visible to the naked eye is expected to appear in England.—GRAYSON GOLCAR.

[12546.]—**Protection for Steam Boilers.**—Would any of your correspondents inform me what is the best covering for steam boilers exposed to the air? I have seen a composition of manure, clay, &c., and should like to know the exact proportion of each, and how it is used.—WM. FELLOWS.

[12547.]—**Pasting Cloth to Maps.**—Will some one inform me how to paste cloth to maps? I have tried to do some and they crimp, the cloth runs in. I pasted both the paper and cloth. What sort of cloth should be used?—C. W. I.

[12548.]—**Flexible Black Varnish for Leather.**—I should be thankful for a recipe for making this. It is required for the folding head of a cabriolet. Brilliancy, flexibility, and resistance of wet are the desiderata.—LAMBDA.

[12549.]—**Field-glasses.**—To "F. R. A. S." or MR. OLDFIELD.—In looking through these on a blank light sky a darkened zone occupying the middle two-fourths of diameter of field of view is observable. Is this in the eye or field lenses? Is it a fault or a failing?—LAMBDA.

[12550.]—**Seaweeds.**—How can seaweeds be nicely dried for show?—B.

[12551.]—**Picture Framing.**—Would some practical person kindly inform me, through the medium of this paper, the simplest way and the neatest to cut and join the angles of picture frames, and it will greatly oblige—JIM.

[12552.]—**Aquarium.**—I am about making an aquarium, and if one of "our" ingenious subscribers would supply the following information, I should be glad. Size to be 2ft. × 1ft. 8in. × 1ft. 3in. What should be the material for bottom? What cement for fixing glass? What glass should be used? What fish would be best to stock it with when finished? Any other information which they may think necessary would oblige—W. R.

[12553.]—**Electro Magnetism.**—I have an electro-magnetic engine which is useful to me in doing light work, but the contact breaker is a constant source of annoyance, as the platinum points are continually burning or being oxidised. I have partly remedied the destructive effect of the spark by putting an extra coil of wire round the magnet and joining the ends of it together, thereby forming a complete circuit in itself. This, I suppose, acts as an induction coil does, and lessens the spark, but what I wish to know is, if the contact breaker known as the mercury and alcohol one, will be better than a platinum one. I should feel very much obliged if Mr. Sprague would describe minutely the action of one of these, and say how the oxide that is formed upon breaking contact is got rid of. A small sketch would, I think, interest many of your readers. I should also like to know how it is that my plan of an extra coil lessens the burning effect of the spark, and also if it lessens the power of the magnet at all.—CONTACT BREAKER.

[12554.]—**Graphite Battery.**—I should feel obliged if Mr. Sprague would inform me what purpose the glass tube is for in the graphite battery, described on p. 423, and whether to use acid or saline solution in the manganese cell?—WALTER WINNING.

[12555.]—**Packfong or Chinese White Copper.**—Can any follow reader inform me the composition of this alloy? I have some reason to suspect it contains nickel, and resembles the so-called albata or German silver in its composition and properties. Also, what articles do the Chinese construct with it, its specific gravity, and price?—THE HARMONIOUS BLACKSMITH.

[12556.]—**Soda-water.**—Would some of your readers inform us if soda-water be really a weakening beverage? My impression is it is a vulgar error.—A. B. C.

[12557.]—**Nickel Silver.**—There is advertised pure nickel silver, and nickel silver plated (spoons, teapots, &c.) What I want to know is, is it the pure metal nickel, or is it a mixture of nickel with other alloy—white metal, in fact?—NICKEL SILVER.

[12558.]—**Boot and Shoemaking.**—Thanks to the correspondents who replied to me on this painful subject. I have been directed to a more scientific man than I have met hitherto. He modelled my old lasts with leather to very near the pattern of my feet, and the boots made on them are an improvement, but not all I require. I find my problem is not so easily solved, for my foot, as I said, measures more at big toe joint than at instep, and if made sufficiently wide at former part to take off pressure from that tender spot, he says it would be impossible to get the last out of the boot when finished. I find the only boots I can wear without pain are a very old pair which have worked into the very cast of the sole, and in the same way the maker I refer to models his lasts, so that bulges on the sole will have a corresponding hollow in the insole of the boot, but then he cannot give me sufficient width in the upper. Can any one solve this problem for the shoemaker? Also, is there any remedy for swollen tender joints, besides taking the pressure off?—IRISH MECHANIC.

[12559.]—**Cleaning Oil Painting.**—I wish to clean an oil painting that is dirty with age, can any one give me a trustworthy recipe that has been proved?—SEMPER PARATUS.

[12560.]—**Varnish for Marbled Edges.**—I have marbled some book edges by the transfer process, but they are dull. Is there any varnish or gloss that will not stick them together?—SEMPER PARATUS.

[12561.]—**Curving Book Edges.**—Will some one inform me how to bend the fore edge of books, and at what stage of the process of bookbinding it should be done, as I cannot curve them well, they run in steps?—SEMPER PARATUS.

[12562.]—**Tar Pavement.**—Will "Philo" or any other correspondent of "ours" inform me the proportion of pitch to coal tar for making the tar pavement I intend boiling the coal tar. Would small sea shingle do instead of gravel, for our gravel is simply soft granite which works up pasty after a little wear and exposure to wet? The only objection to sea shingle is, its being salted would take the damp in changes of weather, but I do not know if it would do so if mixed with boiled coal tar and pitch. An answer much wanted.—HORTI.

[12563.]—**Rough Skin.**—I have for some months past been troubled with a roughness of the skin of my face, and have tried several would-be remedies, but without the desired effect. The skin of the cheeks and forehead is in a perpetual state of small white flakes or scales, and there is no soreness. I seldom eat salt meat and have never been a sea voyage. I should be glad of a recipe for this irregularity.—F. ACE.

[12564.]—**Photographic.**—Will some kind reader of "our" MECHANIC inform me the cause of my Carter negatives giving a dark shade on the faces of each person I take. Is it the want of proper knowledge of the arrangement of light on the sitter or some other defect? My negatives seem clean and sharp, but still the faces are dark, apparently dirty when printed.—J. H. WILLIAMS.

[12565.]—**Sticks.**—Can any reader tell me how to bend the handles of sticks? I want to use rough blackthorn to make sticks for "hockey," &c.—W. M. COLLES.

[12566.]—**Bees.**—If a swarm of bees take possession of an empty hive, does the swarm become the property of the owner of the hive?—W. M. COLLES.

[12567.]—**Brick and Tile Glazing.**—Can any of "our" readers inform me how the above named things are glazed for roof and flooring purposes?—For a Friend in the Colonies.

[12568.]—**Smoke and Light.**—How is it that tobacco smoke looks brown on a white background, and blue on a dark?—A. B. M.

[12569.]—**Consumption of Alcohol.**—Can any reader inform me what quantity of alcohol is yearly consumed in this country per head of the population?—Inquirer.

[12570.]—**Sunrise and Sunset.**—Will some kind correspondent give me the formula to calculate sunrise and sunset for any particular day? Will the same rule answer for the moon and planets? A short example will render great assistance to—Delta.

[12571.]—**Brake for Bicycle with Indiarubber Tires.**—Having just purchased a bicycle with indiarubber tires but without a brake, I am about to have one added. Will any correspondent kindly inform me if the ordinary wooden block wears out the rubber, and if the roller sometimes used has the same disadvantage?—E. B. Shaw.

[12572.]—**Piano Construction.**—Will the "Harmonious Blacksmith" please to enlighten me on the following points in his No. 8 Piano Action, given at p. 95, No. 368. 1. Are the hammer shanks there represented the proper length? 2. Would it be best to employ a metal rail for hammer butts to centre in, or wood, so that each hammer can be taken out singly? 3. Are the dowels which fasten on the slanting part of the hopper to be in a vertical or horizontal plane? If vertical, how is the wire spring to pass between them? If horizontal, how is it possible to get two dowels 5/32in. diameter with room for the wire spring to pass between them in ⅜in.? 4. In what manner is the hopper kept from sliding sideways from under the hammer butt? 5. Is the set off screw attached to the hammer butt, or as the hammer strikes the string, does it force the hopper from under the notch in the hammer butt by the set off screw coming in contact with the lower end of the hammer butt? 6. How is the forte pedal placed to lift the dampers from the wires? With respect to wire bridges, would it not be equally as well to make them in lengths for one note, to insure their being properly bedded?—Pianette.

[12573.]—**Hygrometer.**—Can any one describe an instrument called a hygrometer, invented by Sir John Leslie, by which mercury and water may be converted into ice?—C. T. E.

[12574.]—**Calculus.**—Will some kind correspondent solve the following question for me? A gentleman had a circular fishpond, the diameter of which was 100ft. He wished to inclose it by a fence in the form of an isosceles triangle, the sides of which shall be tangent to the circle. Required the length of the sides so as to inclose the least possible land.—W. H. H. C.

[12575.]—**Angles of Incidence and Reflection.**—Can any of your readers give me any information about the result of the discovery of the inequality of the angles of incidence and reflection? The author of this discovery, Mr. Brine, of King's College, Cambridge, had a machine made to test the thing, and thereby proved his assertion to be true. This machine was taken to the Nautical Office and examined, but no fault could be found with its construction. I should like to know what became of the discovery, if it is one.—R. P.

[12576.]—**Buffalo Pickers.**—Will any one oblige by describing the process how leather is tanned for these pickers?—Linum.

[12577.]—**The Iris or Rainbow.**—Will one of your astronomical or meteorological readers kindly inform me why it is that the rainbow appears of a circular shape? I have referred to many books on the subject, but can only find that the reason of the rainbow appearing as a segment, is in consequence of the refracted rays of light being only visible at certain determinate angles. This is by no means a lucid explanation to my mind, and hence my desire to obtain further information from some of your many talented contributors.—A Young Astronomer.

[12578.]—**Medical Coil.**—I have a medical coil which is worked by six Smee's cells, zinc plates 4½in. × 3in., the silver of one connected with the zinc of the next, and of course the extreme ends of the battery terminate in a silver at one end and a zinc at the other. The binding screw on the coil which connects the wire coming from the extreme silver is marked N, which I take for negative, and the other end P, which is positive. Now what I want to know is, if the electricity flows first from the zinc through the fluid to the copper, and from the copper to the zinc through the connecting wire above, how is it that the copper extreme is the negative? I suppose that all the electricity in the battery is given off into the coil from the zinc or positive end of the battery, and I cannot understand how it is that it is so, as from what I read I understand it quite the reverse. Perhaps I am mistaken in regard to the circulating electricity, as I suppose that when the body is placed in the circuit, it returns by negative pole back into the battery. I am using my machine for rheumatism of five years standing, and have not been able to work for over seven months. It is principally in my feet, and I am not able to stand long without a deal of pain. I have no pain when I am off my feet, and I feel anxious to know the most beneficial way to use my machine to bring about a cure. I might say that I apply the positive on the spine and the negative to my feet.—S. A. Z.

[12579.] —**Counting Envelopes.**—Is there any machine for counting envelopes? I know that there are many machines employed in making them. Would such a machine be useful?—Philanthropist.

[12580.]—**Photo-Lithography.**—Can any of your readers inform me of any process by which positive pictures can be used directly for reproduction by photolithography? As far as I can learn only negatives (photographic) are at present employed with the prepared stone or transfer paper. If any one can give me the formula for such process, or will indicate to me to what person or books I can apply, he would much oblige —Amateur Photo-Litho.

[12581.]—**Tests for Flour.**—I am much pleased with the alum test for bread flour, and request the favour of two more tests—viz., one for rice and one for china clay, as I have suspected some biscuits—sea biscuits commonly called—containing one or both these ingredients. —Ohio.

[12582.]—**Paper Clothes.**—The Japanese, it is well known, are the best paper makers in the world. They use paper advantageously in a thousand ways unknown to western civilisation, and I saw lately in an American paper, that paper suits, cool, light, waterproof, and not easily to be torn, are imported into New York, and sold there from half a dollar upwards. Can any American subscriber give any information about these paper clothes. We have done a good deal in England in the way of collars, curtains, and other articles in paper, and ought to be able to compete with the Japanese, or at any rate to be able to import some of their productions. Fancy the luxury of paper suits this weather! The thoughts of them almost tempt me to tear my black cloth coat into fifty pieces!—Kappa.

[12583.]—**Electro - Plating and Coppering.**—Will "Jack of All Trades," or some of our electro-plating friends, put me right in the following:—1st. I have some cutter-knives (steel blades), they have been plated, but the silver is worn off. I have placed them in the outer cell of Daniell's battery, and cannot copper them. Is this the right way to copper articles before plating them? 2nd. Is the cyanide solution the best for plating? I mix together 8oz. of cyanide to 1 quart of rain-water, and add ½oz. of nitrate of silver. Is this right?—Anxious.

[12584.]—**Bee-Keeping.**—"Phan" wishes to know whether she may continue to put on fresh super room after the drones are killed? The cottagers here, who all keep bees on the old burning principle, have a strong prejudice against supers, and argue that when the super-honey is taken the bees rob their neighbours' hives to replace what has been taken away from them. "Phan" would be glad of any remarks to prove the folly of this.

[12585.]—**Thermo-Electric Pile.**—I should esteem it a great favour if some practical correspondent will give me any information concerning the construction of the above. I have bismuth and antimony, and want to know (1) what size to make the bars? (2) In what mould, and how to cast them? (3) What solder, or how otherwise to unite the ends? Any other information respecting same or galvanometer.—Robert Knight.

[12586.]—**Magnetine or Improved Skeuasma.**—I wish some able correspondent would inform me how the above are made. What is their principle of action? What form should they take to be suitable for the various complaints they are intended to cure? Have they been patented; if so, when? Directions how to construct similar to that given for Pulvermacher's chain bands some time back would greatly oblige.—J. R. L.

[12587.]—**Lamp for Blow-pipe.**—I am a working jeweller, and am working in a small country town where there is no gas. Will any of your readers kindly recommend the best lamp to work by, and for the blowpipe?—Standstill.

[12588.]—**Railway Metals.**—I am informed that on a railway running north and south the rails wear most on the west side, while on a railway running east and west there is no perceptible difference. Can any of "our" correspondents say anything about this?—Luffra.

[12589.]—**Lapidary's Wheel.**—Could any reader give me a few hints as to size of lapidary's wheel for cutting and polishing stones, speed run at, &c.—A Subscriber.

[12590.]—**Glues.**—Will any of your numerous readers or correspondents inform me how it is that some glues after being used for a very little time in the glue-pot get frothy, and that others preserve the black colour as it is in the cake? I have got a supply of glue at present, but experience difficulty, or rather annoyance, in using it from its frothy nature; it clogs the brush, and does not work freely. Is there any cure for this? Or is the glue inferior in quality?—A Country Bookbinder.

[12591.]—**Harvest Moon.**—Can any one inform me why "the harvest moon," as it is called, looks larger than at other times?—A. S.

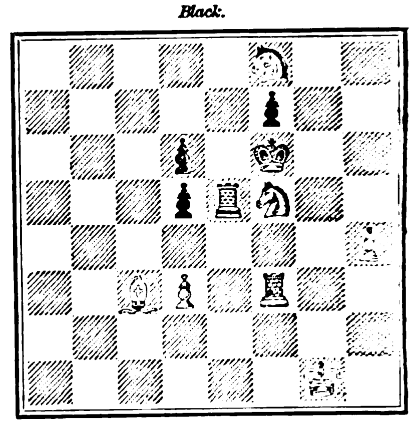
CHESS.

All communications intended for this department to be addressed to J. W. Abbott, 7, Claremont-place, Loughborough-road, Brixton, S.W.

The "Chess Tournament," under the auspices of the British Chess Association, was held at the Crystal Palace, on July the 18th, 19th, and 20th inst., and met with all the success that was anticipated, and although the heat was excessive, and very much against the prosecution of a sedentary game like chess, the meeting was attended by a large assemblage of players and visitors from all parts of the country. The programme of the first day's proceedings consisted of blindfold, consultation, and simultaneous games. Blackburne conducted ten games at the same time blindfold, and actually succeeded in winning six, drawing three, and lost only one. Lowenthal played twenty-five simultaneous games against as many amateurs, winning seventeen, losing one and drawing the remainder. Two consultation games were played, the combatants being Steinitz and Tuckertort against De Vere and Wisker, while in the other Boden and Duffy were matched against Merchin and another. On Friday, Captain Kennedy gave a lecture on the "History and Antiquities of Chess." The discourse was interesting and seemed to be appreciated by the audience. On Saturday the programme was of a varied and attractive kind. Tuckertort conducted ten games blindfold, and although hardly so successful as Blackburne on the previous Thursday, he played the games with great precision and rapidity. The Telegraphic Match against the Clubs of Birmingham, Bristol, Hull, Glasgow, and Nottingham was highly interesting, and created much interest among the numerous visitors present. Unfortunately, owing to the lateness of the hour, but few of the games were finished. The Congress throughout has undoubtedly been of a successful character; the greatest harmony and good-will has pervaded the entire proceedings from first to last.

Problem IX.—By A. W. Cooper.

Black.



White.

White to play and mate in four moves.

Solution to Problem VIII.

White.	*Black.*
1. R to Kt 3	1. P to R 5
2. R to Kt 8	2. Anything
3. Kt or R mates acc.	

W. Nash (S. Neots).—Problems of five and six moves deep, and upwards, are appreciated only by enthusiasts, and such compositions are altogether out of place in a newspaper column. Many of our correspondents find *three* move problems quite difficult enough, and judging by the moves you send as the solution of W—'s problem, your advocacy in favour of more complicated positions is surely somewhat premature on your part.

R. S. (Edinburgh).—Look again attentively at Problem VII., and you will discover that the diagram is perfectly correct, as is the printed solution.

Inductorium.—Your problem is sound, but it is rather too easy for publicity.

G. J. Slater (Bolton).—Both the positions appear to be sound now, and they are accordingly marked for insertion.

Argo (Yarmouth).—We shall avail ourselves of one of your problems in due course.

J. C. S.—Correct, but too late for notice in the customary list.

Problems received with thanks from W. S. P—, B. Horwitz, A. W. Cooper, and C. W. (of Sunbury).

Correct solutions to Problem VII. (continued).—G. F. Grand (Gateshead); Argo (Yarmouth); Wiseaf (D—wich); G. J. Slater (Bolton); J. R. (Lincoln).

Correct solutions to Problem VIII. have been received from A. W. Cooper, R. A. Proctor, H. Cherry, and Beresford (Vauxhall). All others are wrong.

Experiments with Dynamite in Italy.—A series of trials of dynamite as a blasting agent were made during the past year at the Biassa tunnel, on the line of railway now in course of construction between Genoa and Spezzia, and which fully show the superiority of that substance over ordinary blasting powder, and especially when water is met with. Eastern end.—Compact limestone and hard dolomite. 1st. With ordinary blasting powder, 203 metres of tunnel driven 7·50 square metres in section in 200 days, or at the rate of 1·015 metres per day of 24 hours. 2nd. With dynamite, 300·80 metres run of equal section in 160 days, or at the rate of 1·88 per day of 24 hours, showing a superiority in favour of dynamite of 0·865 per day. Western end.—Rock, clayey schist, with beds of sandstone and abundant filtration water. 1st. With ordinary blasting powder, 80·75 metres run of tunnel, 7·050 square metres in section, driven in 190 days, or 0·425 per day of 24 hours. 2nd. With dynamite, 107·10 metres run of tunnel of the same section in 170 days, or 0·63 per day, showing 0·205 per day in favour of dynamite. From a careful estimate made as to the relative cost of blasting with gunpowder, as compared with dynamite, a saving of 4 francs per cubic metre was found to be obtained when the latter substance had been used.

JETHRO FROST, New York, John Baynes, Manchester.—See "Hints to Correspondents," No. 4.

NON SCIENCE.—Your query is too vague. You must say more particularly for what purpose you require to raise water. See also back volumes.

Communications which can only appear as advertisements to hand from Shamrock, W. A. G., Athelstane, P. E. M., An Improver, R. M. M. S., One in the Trade.

THE DISTRESSED ONE, Rodger, F. R. C. P., John Smith, Banjo, F. R. L., Water, W. W., Esam, R. B., are referred to indices to back volumes.

DAVID JACOB.—See back volumes, if nothing there suits you write again and say plainly what you want. Your telegram was too ambiguously worded, and besides arrived to late. Your letter since to hand shall appear next week.

PRENTICE.—Build and try your steam carriage. When successful, write us again.

BENDING AMBER.—"Out of Pocket" writes that "Jack of All Trades'" plan for bending amber has proved a failure. The amber cracks under the process.

G. W. K. L.—Your wit is of the heaviest character, and we cannot spare space for the insertion of a letter which does nothing but "chaff," in a rather stupid mauner, one of our oldest contributors.

OUTGENIOUS WHITESMITH.—Never mind your compound medicine.

LINUM.—We do not think "J. K. P." would do what you ask. At any rate, your request cannot appear as a query. You might advertise your request and ask him to send you his address.

S. SEBASTIAN BAZLEY, M.A.—The book on turning to hand. Thanks.

CHINCHEY.—Our opinion is that Condy's fluid has been very much overrated.

J. D.—Your eighth paper on the organ next week.

E. WOODWARD.—No stamps inclosed.

GEO GILLUS.—See "Hints to Correspondents," No. 4.

L. S. (Dublin).—We cannot inform you.

HY. HORSMAN.—Recipes for making vesuvians were given in last volume, pp. 202, 207.

W. T. R.—The only way to prevent any one pirating your invention, is to patent it. That involves expense and will, till we have a reform of our patent laws.

F. CHESHIRE.—Such questions are no doubt asked both for exercise and to elicit information.

STELLA.—Do you want the skin of your face destroyed?

R. JOHNSON.—Your sketch and description are scarcely correct.

E. J. H., Paper Stainer, J. S. Wilson, and Bird Fancier.—Your queries are advertisements.

E. W. B.—An American paper.

J. M. G BROOKWOOD.—Your letter on Moses or Samuel is rather out of date, and rather too Biblical.

THE WELSH SHEPHERD says:—"Allow me to correct a printer's error in my last letter (4566, p. 465). In line 35 downwards: Not parallel to the glass plate must converge to the same point, &c., ought to be: to some point, &c."

HY. CLARK (Derby).—You speak of the brain as if its parts could be counted, measured, and separated like a box of dominoes. Be assured the brain of man is a much more mysterious thing than you and some other professed phrenologists think. We have frequently seen men who knew next to nothing of physiology or the properties of matter, or of vital forces, and who were profoundly ignorant of physical geography even, talk of the brain as if they understood the mysteries of existence; and we occasionally let one of these correspondents display his ignorance in our pages with the hope that some one who knows a little about mind and matter might enlighten him. But we suppose our chief correspondents think it would be a waste of their time and our space, and hence they let the subject pass. As Henry Clark speaks with great confidence, we will venture to give him a challenge; and we beg to suggest that he should *manipulate* the heads of ten men in the dark. The possessors of the heads should have decided intellectual biases. One should be a poet, another a farmer, another an engineer, another a musician, another a bricklayer, another a clergyman, another a mathematician, and so on; and we undertake to say that our friend the phrenologist would not be able, by feeling their heads, to distinguish one from the other. Will Henry Clark accept the challenge? If so we will do our best to assist him in trying the experiment.

MR. WM. TONKES writes to say that he is and has been for some time ill, and is "prohibited under medical advice from even reading." This is the reason of his late silence. He is, however, improving, "and hopes shortly to take his place once more in our columns." We heartily wish his health may be speedily restored.

THOMAS BUCHANAN has sent us the following in reply to our note last week, p. 499:—"Permit me to thank you for your editorial courtesy in having extracted a single sentence from my paper, and so produced it as to hold me up to 'inextinguishable laughter.' I shall not avail myself of your kind permission to ask 'F.R.A.S.' what those 'eternal fires' mean. The question of my lecture was merely a rhetorical *erotesis*, not needing an answer, since it was the mental soliloquy of the Chaldean shepherd 4,000 years ago, the expression of philosophic wonder, which, as I attempted to show, culminated in the apotheosis of humanity, in the Eleusinian mysteries and Freemasonry—to wit, the Deism which elaborates a religion apart from revelation. The last two topics I did not name, except so far as they are included in the Egyptian worship of Isis and Osiris—the Buddhism of India, and the parallel system of Confucius in China. But I merely glanced at the poetical aspect of the subject, which Byron has embellished, and which so long, as astrology, enthralled nations; and at the theory which represents the constellations as a panoramic picture, on which, in fiery etchings, the record of the Noachian deluge and the Ark were preserved." As we have given the whole of Mr. Buchanan this time he cannot complain of our only making an extract. We shall be glad to hear from Mr. Buchanan again on some less speculative subject.

THE INVENTOR.

APPLICATIONS FOR LETTERS PATENT DURING THE WEEK ENDING JULY 23, 1872.

2132 D. Cunningham, Dundee, for improvements in the construction and working of caissons, which improvements are also applicable to movable bridges and the gates of docks and canal locks.

2133 H. A. Bonneville, Piccadilly, for improvements in the manufacture of imitations of tapestry. A communication.

2134 J. Ashwell, Highgate-road, Kentish Town, for improvements in the construction of furnaces, and in the arrangement of flues or passages for economising fuel therein.

2135 B. Brower, New York, U.S., for an improvement in card holders.

2136 J. B. Robertson, Manchester, for improvements in steam traps.

2137 J. Dale, Manchester, for improvements in the manufacture of oxylates of soda and potash.

2138 R. M. M. Alloway, Torquay, Devonshire, for an improved process for desiccating oak bark, flax, hemp, tobacco plat, mustard, and other substances by atmospheric evaporation.

2139 G. Newsome, Hunslet, Leeds, for improvements in machinery for lithographing and letter-press printing.

2140 B. Blair, Belfast, Dublin, for improvements in axles and axle-boxes for carriages and other vehicles.

2141 H. S. Copland, Duke-street, Strand, for an improved apparatus for mixing precipitating materials with sewage, and removing deposits, which apparatus is applicable also for other purposes.

2142 J. Imray, Southampton-buildings, for improvements in apparatus for supporting respiration and light in suffocating or explosive atmospheres. A communication.

2143 L. Bradley, Park-place, Regent's-park, and J. Speight, Leeds, for improvements in forming roads and other ways.

2144 S. S. Bateson, Bolton-street, Mayfair, for improvements in the treatment of hides and skins.

2145 M. A. Wier, Great Winchester-street, City, for an apparatus for registering and checking entries and exits to and tramway cars, omnibuses, or other carriages.

2146 E. Brooks, Birmingham, for improvements in brooms and brushes.

2147 H. Cheery, Handsworth, Staffordshire, for improvements in punching and shearing machines.

2148 W. Jenkins, Leamington, for improvements in machinery for rolling leather.

2149 J. Bidder, Islington, A. C. L. Lamb, Twickenham, and W. O. Scrivener, Westminster, for an improved clasp or fastener for necklaces and other personal ornaments and wearing apparel.

2150 W. E. Gedge, Wellington-street, Strand, for an improved machine for splitting wood and cutting it into lengths. A communication.

2151 C. J. Tiehoff and E. Voss, Holland, for improvements in apparatus for ventilating ships, railway carriages, houses, and other buildings.

2152 C. W. Siemens, Great George-street, Westminster, for improvements in regenerative gas furnaces for the manufacture of glass. A communication.

2153 W. Paterson, W. A. Sanderson, R. Sanderson, and J. Sanderson, Galashiels, Scotland, for improvements in the treatment of wool in process of manufacture, and in the preparation of materials therefor.

2154 C. G. Hill, Nottingham, for improvements in machinery for goffering, fluting, and crimping net and other fabrics.

2155 J. W. Melling, Wigan, for improvements in engines actuated by steam or other elastic fluid.

2156 F. J. Cheesbrough, Liverpool, for improvements in evaporating and concentrating sulphuric and other acids, also salt, sulphur, and other substances capable of evaporation, and in the apparatus to be used therein. A communication.

2157 G. D. Hughes, Nottingham, for improvements in steam-engine or other motive-power governors, and apparatus connected therewith.

2158 C. de Negri and G. Herrmann, Hornsey-road, and W. Guest, Great Saffron-hill, Middlesex, for improvements in machinery for braiding whips or other articles.

2159 J. G. Smeaton, Harwood-road, Walham-green, for an improved apparatus for the generation of steam and the circulation of heated water.

2160 W. N. Hutchinson, Wellesbourne, Devonshire, for improvements in railway engines, carriages, and vehicles, and in permanent way therefor.

2161 D. Timiriazeff, Southampton-buildings, for improvements in machinery for forming stereotype moulds or matrices.

2162 W. Linney, Bedworth, Warwickshire, for propelling looms, winding engines, and various other machines.

2163 J. Pullen, sen., and J. Pullen, jun., Camden-street, Walworth, for a new and improved method of casting and making lead D traps.

2164 R. Payne, Frome, for indicating the variations of heat in holds of vessels, rooms, or other places at a distance. A communication.

2165 H. Robinson, Skipton, Yorkshire, for improvements in the construction of railway waggons.

2166 W. Eades and W. T. Eades, Birmingham, for an improved tube cutter and wrench.

2167 J. Richardson, Lincolnshire, for improvements in arranging, actuating, and controlling cut-off slide valves of steam and other engines.

2168 J. Lake, Manchester, for improvements in steam boilers.

2169 M. Henry, Fleet-street, for improvements in apparatus for measuring and indicating time. A communication.

2170 J. Hopkinson, jun., Birmingham, for improvements in apparatus for giving motion to the revolving lights of lighthouses.

2171 J. Knott, Sheffield, for improvements in furnaces for economising fuel and preventing the generating of smoke. A communication.

2172 J. Knott, Sheffield, for an improved lubricator for machinery and axles. A communication.

2173 A. Krieger, Borough, Surrey, for a new or improved apparatus to be applied to street tramway carriages for facilitating the traffic.

2174 R. W. Eddison, Leeds, for improvements in platform lifts or hoists. A communication.

2175 F. Ayckbourn, North Brixton, for a new or improved arm for discharging or impelling missiles or projectiles for offensive, defensive, sporting, and other purposes.

2176 A. M. Clark, Chancery-lane, for a new or improved expansible pivot.

2177 L. C. Warneck, Paris, for a new or improved arrangement of shifting screw propeller.

2178 A. Ray, Guildford, for an improved mechanical mover. A communication.

2179 P. Love, Bedford, for improvements in machinery or apparatus for excavating, especially applicable for drainage purposes.

2180 P. R. Couron, Lewisham, for improvements in the washing and stirring apparatus employed in brewing, distilling, and other like processes.

2181 J. Robey, Manchester, for improvements in the manufacture of a substitute for animal charcoal, to be used for purifying sewage and various other substances.

2182 G. Goold, Handsworth, Birmingham, for improvements in apparatus for regulating the draught in the chimneys of fireplaces, stoves, or ranges, also applicable for other purposes.

2183 T. N. Palmer, Dalston, for an improved catamenial belt, which may also be used for other purposes. A communication.

2184 R. Hutton, Sheffield, for improvements in steam boiler and other furnaces.

2185 W. R. Lake, Southampton-buildings, for improvements in hoists or elevators. A communication.

2186 J. Thom, Chorley, Lancashire, and J. Stenhouse, Pentonville, London, for improvements in treating fatty substances containing colouring matters, and in obtaining useful products therefrom.

2187 A. M. Clark, Chancery-lane, for improvements in the manufacture of ornamental tiles or slabs. A communication.

2188 W. R. Lake, Southampton-buildings, for improvements in apparatus for raising liquids, grain, and other materials, parts of which improvements are applicable to the construction of rotary engines. A communication.

PATENTS SEALED.

187 S. R. Smyth, for a new self-acting machine or apparatus for working sewing or other similar machines that are worked by foot treadles or by hand, or by other power.

191 E. T. Hughes, for improvements in the preparation of wool, either pure or mixed with other fibrous materials, intended to be spun into threads or yarns to be used for weaving.

203 Count di Tergolina, for improvements in the construction of bits for horses and animals.

210 W. Bradburn, for a new application of the gases and vapours or fumes resulting from the burning of pyrites, cinders, and of the acid liquid produced by the absorption thereof.

211 A. Wood, for improvements in cleaning tramways and in apparatus employed therefor.

212 R. J. Wood, for improvements in sweeping streets or roads and in the machinery or apparatus employed therefor.

213 A. Wood, for improvements in tramway cars.

232 H. Jones, for a new or improved moustache protector and trainer.

235 A. Budenberg, for improvements in sugar refining and in the centrifugal machines employed therein.

247 R. J. Bills and G. Dobson, for an improved composition for preventing incrustation and corrosion in steam boilers and other apparatus for generating steam.

258 J. L. Tonkys, for an improvement in lamps for burning hydrocarbon spirit or oils.

259 W. Walton, for improvements in the manufacture of wire cards.

277 J. E. T. Woods, for improvements in reverberatory and other furnaces for chemical purposes.

Terms of Subscription,

PAYABLE IN ADVANCE.

6s. 6d. for Six Months and 11s. for Twelve Months, Post Free to any part of the United Kingdom.

Volumes V., VI., VII., VIII., IX., X., XI., XII., XIII., and XIV. bound in cloth, 7s. each.

Indexes for each half-yearly volume, up to Vol. X. (except Vols. II., V., and X.) inclusive, 2d.; Post Free, 2½d. Cases for Binding, 1s. 6d. each.

*** Subscribers are requested to order Cases and Vols through their booksellers, and not to send direct. The new regulations of the Post-office prevent their transmission through the Post.

To American and Belgian Subscribers.

☞ American and Belgian Subscribers, *especially when renewing their subscriptions*, are *particularly requested* to advise the Publisher of the transmission of the Post-office Order, and the exact amount for which it is made payable.

Subscribers in the United States and Belgium can be supplied with the ENGLISH MECHANIC post free from this Office, for the sum of 18s. (3 dols. 25 c. gold, or 15fr. 60c.) per annum, payable in advance.

The remittance should be made by International Post-office Order. Back numbers cannot be sent by the ordinary newspaper post, but must be remitted for at the rate of 5d. each to cover extra postage.

Notice to Subscribers.

Subscribers receiving their copies direct from the office, are requested to observe that the last number of the term for which their Subscription is paid, will be forwarded to them in a *coloured wrapper*, as an intimation that a fresh remittance is necessary, if it be desired to continue the Subscription.

Charges for Advertising.

	s.	d.
ALL ADVERTISEMENTS (except in the Exchange Column), per line of Eight Words	0	6
Every additional line	0	6
(No advertisement inserted for less than 1s.)		
Larger Advertisements Contracted for.		
ADVERTISEMENTS in EXCHANGE COLUMN for Sixteen Words	0	6
For every succeeding Eight Words	0	6

Front Page Advertisements 9d. per line.

The address is included as part of the advertisement and charged for.

Advertisements must reach the office by mid-day on Tuesday to ensure insertion in the following Friday's number.

OUR EXCHANGE COLUMN.

EXCHANGE *Advertisements are charged at the rate of Sixpence for the first Sixteen Words, and Sixpence for every succeeding Eight Words.*

Patent SODAWATER APPARATUS; for good Glazier's Diamond or offers.—B., Post-office, St. George's, Oakengates, Salop.

LANDSCAPE STEREO. Set (Ross and Ottewill), and Tourist's Glass for good 3in. Telescope.—Mr. LARKIN, Bilston.

For exchange, "CASSELL'S POPULAR EDUCATOR," the last edition, well bound, for work on "Mine Surveying and Dialing" or "Mechanical Drawing;" or offers.—Apply, D. THOMAS, Platt-lane Colliery, Wigan.

In exchange for a good CONCERTINA, Shakespeare's Works, complete, in two volumes, gilt edged and illustrated, nearly new.—A. FELTON, High-street, Sandwich, Kent.

Fine VIOLONCELLO and Bow, with good strong case complete; for large Bicycle, in good working order.—J. TURNBULL, at Mr. Forbes, Swinton-row, Edinburgh.

AIR GUN, never been used (value £3 3s.) will be exchanged for Sewing Machine.—Apply, A. THORN, 77, Stamford-street, London.

Wanted, a good Set of PHOTOGRAPHIC APPARATUS for Velocipede to carry 3 persons, new principle; a bargain.—JAMES HILL, Chertsey Foundry, Surrey.

A 36in. BICYCLE, in first-class condition, hickory wheels, brass bearings, &c., quite equal to new (cost £8); for Gold Albert, or offers.—D. LYNCH, Town-lane, Dunkinfield.

An excellent 36in. BICYCLE (cost £6 10s.); offers solicited.—W. L. BREARE, Moor-lane, Burley-in-Wharfedale, via Leeds.

"REMARKABLE VERY REMARKABLE INDEED," are the effects of LAMPLOUGH'S PYRETIC SALINE in Preventing and Curing Smallpox, Fevers, and Skin Diseases. Specially refreshing and invigorating during hot weather. Sold by all Chemists, and the Maker, 113, Holborn-hill, London.—[ADVT.]

AMATEUR TURNERS.—Ornamental Lathes purchased or sold on commission at G. H. BUCK'S Tool Manufactory, 312, Euston-road, near the Hampstead-road. Fret Cutting Machines, the best out, 5 guineas.

MACHINERY DEPOT, LEEDS.—BENJAMIN MILLER, Licensed Valuer of Machinery. Engineers' Tools.—N.B.—New and Second-hand Engineers' and Machine-makers' Tools always in stock for immediate delivery at 11, Hunslet road, Leeds.

IRON FRAME PIANOFORTES.—Every player who is desirous of some better quality of tone than that which he can obtain from that improved Dulcimer called the Modern Pianoforte, should try Hargreaves's American Iron Frame, cross-strings pianoforte, which will give him a new quality of tone appreciably superior in brilliancy in the upper octaves, and in roundness in the lower octaves. New overstrung scale, suspended soundboard, newly-invented action.—Sole importer, WILLIAM HARGREAVES, 61, Dale-street, Manchester.

NOTICE!—ABSCONDING APPRENTICE.—FREDERICK WEEKS, Iron Moulder, from TAYLOR & BODLEY'S, Engineers, Exeter. Employers will please note this and refuse employment. Age 19 years, short, thick set.

FOR SALE.

MACHINERY to be SOLD CHEAP.—New Deal Frame (by Parsons); Self-acting Saw Bench (by Chambers); General Joiners' Saw Bench (by Powis); other benches and sawing machines; Steam Winch; Portable Engines 25 and 8 h.-p.; Stationary Engines 2½ to 20 h.-p.; Boilers 2½ to 14 h.-p.; Sets of Pumps, &c.—JOHN FRANCE, Ada House, Carter-street, Walworth.

MARTIN & SON, Engineers, Iron, Brass, and Malleable Iron Founders, Vine-street, York-rd., Lambeth. Ten horse-power Horizontal Engine, from £40 to £50; 5in. Lathe, £8; Bench Drilling Machines; 13in Silent Fan, £4; Blocks, Couplings, Shafting, Copying and Stamping Presses, Fret-cutting Machines, Single and Double Purchase Crabs, Band, Fly Spur, Bevel, Cone, and Train Wheels, Points, Curves, Crossings, Axle Boxes, Brasses, and General Castings, Malleable Iron Lathe Carriers, Screw Stocks, and Spanners.

AMERICAN DRILL CHUCKS (Beach Patent), 21s. each. Warwick Chuck, 24s. each, post free.—BOOTH BROTHERS, Dublin.

BICYCLE REGISTERS, specially adapted for attaching to the handle so that the rider can observe the progress without getting off. Price 21s. Stamped envelope for illustrated description.—R. K. JONES, 168, Grange-lane, Birkenhead.

VELOCIPEDES at 1s. 2d. per inch diameter of Driving Wheel, at G. WOOTTON, Bedford. Lists one stamp.

HORIZONTAL ENGINE CASTINGS (½ H.-P.) 16s. 6d. per set. Brass Castings and Forgings. Pump 4s. 6d. Full-size Working Drawings, 1s.—NEAL, 71A, Princess-street, Manchester.

COMPOUND SLIDE REST (6in. centre), good design, and well fitted. Price £3 10s.—As above.

A BARGAIN.—BICYCLE for Sale, 36in., nearly new, ironwork all bright, warranted perfect. Particulars on application. Price £3.—Address, J. FLEMING, Woolshops, Halifax.

CONJURING APPARATUS, PUZZLES, &c., of the best make. Send two stamps for descriptive catalogue, including all the latest novelties from 6d. upwards. Full explanation sent with each trick.—PROFESSOR DE VERE, 295, Strand, London, W.C.

THE ENCHANTED FLOWER.—At word of command a Beautiful Flower appears in your button-hole, and will remain there as long as you please. Carriage free, 14 stamps.—PROFESSOR DE VERE, 295, Strand, London, W.C.

MAGIC.—Professor De Vere's BOX OF MAGIC, containing full instructions and every apparatus for performing ten new and marvellous conjuring tricks, as now being exhibited at the Egyptian Hall, carriage free, fourteen stamps.—295, Strand, London, W.C.

COPPER WIRE, Silk and Cotton Covered. Good insulation. Guaranteed conductivity 90 per cent.—J. & W. RICKARD, Ashbourne-road Mills, Derby.

ENGRAVE YOUR OWN NAME.—All the necessary chemicals post free 8 stamps.—TUCKEY & MOORE, Devizes.

GOOD DOUBLE-BARREL MUZZLE-LOADING GUN for Sale.—Address, F. MILLER, 4, Jassemine-terrace, Oval-road, E. Croydon.

BIRD ORGANS for Teaching Birds to sing and whistle various popular airs, comprising "God Save the Queen," "Rule Britannia," "Annie Laurie," "Champagne Charlie." The organs play 8 different popular airs, exactly imitating the notes of singing birds, and the facility and celerity with which birds imitate the airs after being played a few times is marvellous. Catalogue 4 stamps.—MILLIKIN & LAWLEY, 168, Strand.

A SPLENDID BICYCLE, 36in., £3.—HENRY NEWTON, 18, William-street, Stepney, E.

HARMONIUM, walnut case, new, £3 15s.; large ditto, 7 stops, £7. New music, £1 worth 2s. post free. £6 for 10s.—W. LEA, 56, Melville-place, Liverpool.

A FIRST-CLASS CARTE CAMERA (Bellows), by Garland, London, fitted with Grubb's A 8 Quick-acting Carte Lens. A trial allowed.—PHOTO., Moor-lane, Burley-in-Wharfedale.

SEWING MACHINE MAKERS AND AMATEURS.—Parts of the Wheeler-Wilson accurately Machined supplied.—W. WILLIAMS, 7, William-street, Blackfriars-road, London. Enclose stamp for list.

HARMONIUMS, £4, full compass, walnut cases, warranted; 5 stop ditto, 5 guineas. List one stamp.—W. TEMLETT, 95, Union-street, Borough, S.E.

ABYSSINIAN GOLD ALBERTS 6s. each.—Magnificent designs, and as good as gold. Also Lockets, Ear-rings, Brooches, Scarf Pins, &c.—Sole Manufacturers, L. & A. PYKE, 32, Ely-place, Holborn. City Depots:—153, Cheapside; 153A, Cheapside; 68, Fleet-street.

AS GOOD AS GOLD!—The New Metal called Abyssinian Gold. The Prices are so Cheap, and the appearance is so good, combined with the fact of its Durability. To be had in every variety of Personal Jewellery.—Sole Manufacturers, L. & A. PYKE, 32, Ely-place, Holborn. City Depots:—153, Cheapside; 153A, Cheapside; 68, Fleet-street.

THE BEST THING EVER INVENTED.—Abyssinian Gold in all kinds of Personal Jewellery at prices that astonish. Handsome Alberts, Newest Designs, 6s. each.—Sole Manufacturers, L. & A. PYKE, 32, Ely-place, Holborn. City Depots:—153, Cheapside; 153A, Cheapside; 68, Fleet-street.

THE GREATEST DISCOVERY.—Abyssinian Gold.—Sole Manufacturers, L. & A. PYKE, 32, Ely-place, Holborn. City Depots:—153, Cheapside; 153A, Cheapside; 68, Fleet street.

ABYSSINIAN GOLD is one of the greatest inventions. All manner of personal Jewellery. The Alberts at 6s. each are the wonder of the day.—Sole Manufacturers, L. & A. PYKE, 32, Ely-place, Holborn. City Depots:—153, Cheapside; 153A, Cheapside; 68, Fleet-street.

PRICES PLEASE ALL.—ABYSSINIAN GOLD JEWELLERY.—Sole Manufacturers, L. & A. PYKE, 32, Ely place, Holborn. City Depots:—153, Cheapside; 153A, Cheapside; 68, Fleet-street.

AS GOOD AS GOLD is the character of the New Metal, ABYSSINIAN GOLD. We invite inspection of the many Handsome Articles of Jewellery made from it.—Sole Manufacturers L. & A. PYKE, 32, Ely place, Holborn. City Depots:—153, Cheapside; 153A, Cheapside; 68, Fleet-street.

Important Sale of Optical, Mathematical, and other Scientific Property.

MR. J. C. STEVENS has received Instructions from the Executors to SELL by AUCTION at his Great Rooms, 38, King-street, Covent-garden, on Thursday and Friday, August 15 and 16, at half-past 12 precisely each day, the Surplus Stock of SCIENTIFIC INSTRUMENTS of the late Mr. PETER FRITH, of Sheffield, consisting of Portable, Ship, Astronomical, and other Telescopes—Microscopes, Drawing Instruments, Magnifiers, Spectacles, Lenses, &c. Full particulars in Catalogues, which will be ready about a week before.

BREECH-LOADING Double-barrel GUN (first-class maker), surest killer cartridge-making machines, measures, cleaning apparatus. When new cost 21 guineas. Price now only 7 guineas.—KEEPER, 7, John-street, North Heigham, Norfolk.

BICYCLE for Sale, first-class maker, 30s.: great bargain.—18, Lamb's Conduit street, Holborn, W.C.

TO AMATEUR ENGINEERS.—Some beautiful Model Steam Engines, nearly completed, for Sale.—Address, W. F. E., 10, Frith-street, Soho.

BEAM ENGINE, new Cylinder, 3in. diameter, 5in. stroke, complete; 1 H.-P. Boiler, locomotive principal, nearly finished, £15. Sold together or separate; no reasonable offer refused.—6, Hotspur-street, Kennington road, S.E.

STEAM BOATS, (Working Models), for Sale, Exchange, or Given Away.—NAUTICUS, 21, Clerkenwell-green.

DISSOLVING VIEWS, (pair Newton's), mahogany bodies, lanterns, 3½ double condensors, rackwork adjustment.—69, Winchester street, Salisbury.

LATHE, (4½ centre), on iron standards, with rests, chucks, &c., complete; also small Drilling Machine. Price together, £7.—Apply, 20, Northampton-square, Clerkenwell.

WHOLE PLATE PORTRAIT LENS, £3. 15 by 12 Porcelain Bath, 12s.; or offers.—FRED. GARTHWAITE, Headingley Hill, Leeds.

A FINE-TONED EBONY CONCERT FLUTE, with eight silver-plated keys; a 9in. polished Glass Reflector, ready for silvering, with cast-iron tool, and wood pattern for same, ditto for 12in. tool, 6in. glass disc, two &c. barometer tubes, and a small lot of chemicals in stoppered bottles; cheap.—19, Victor-street, Lower Broughton, Manchester.

WANTED.

SITUATIONS.

AGENTS WANTED EVERYWHERE. £3 and upwards earned weekly without risk. New Articles required by everybody. Great demand. Rare chance for earning money.—All having spare time should call or address E. W. BACON and Co., 127, Strand, London.

WANTED AGENTS to sell Birmingham goods. Wholesale List sent.—Apply to J. PELL, Birmingham.

YOUTH (intelligent) as OUT-DOOR APPRENTICE to Mathematical and Philosophical Instrument Maker's. Premium required.—Address, OMEGA, Mr. Pratt, 35, Hunter-street, Brunswick square.

TO MILL SAWYERS.—WANTED, a MAN who understands Circular and Frame Saw Mill, able to read and write.—Apply G. S. ARNALL, Timber Merchant, Truro and Redruth.

THE ADVERTISER seeks a SITUATION as FOREMAN SMITH. Is well up in engines both stationary and portable; builder's, waggon, quarry, and general smith's work. 13 years' reference.—Address, J. SHAW, 47, Napier street, Leicester.

ADDRESSES.

WOULD any kind reader give me the ADDRESS of MAKERS of best kind of hand ladder for general purposes in a large house?—G. W. WHITAKER, Helmshore, near Manchester.

ADDRESS WANTED "TYNE ENGINEER," re Tannate of Soda reply.—W. M., Post-office Seaforth, near Liverpool.

WILL "J. B." (Query 12363, Recovering Indigo) send his ADDRESS to G. E. A., Post-office, East Grinstead.

TO MILLERS and MILLWRIGHTS.—Would an Apparatus that would entirely remove back lash from millstones that are driven by engines by gearing be likely to be taken up by millers. Those interested in the question are requested to write to GEO. CORMACK, Beechville, Oxford Co., Ontario Canada.

WANTED, the ADDRESS of a Firm who make Bagpipes, either in London or Glasgow.—E. DOW, Rough Lee, Marsden, Huddersfield.

WANTED to PURCHASE, PLATE ELECTRICAL MACHINE, with Apparatus, Tate's Air Pump, Induction Coil.—Letters, with particulars, to be addressed F. M., Post-office, Victoria-road, Brighton.

THE LONDON AND GENERAL PERMANENT LAND, BUILDING, AND INVESTMENT SOCIETY. Shares, £40. Monthly subscription, 5s. Entrance Fee, 1s. per share. 337, Strand, W.C.

TRUSTEES.

The Right Hon. the Earl of Lichfield.
Thomas Hughes, Esq., Q.C., M.P.
The Hon. H. F. Cowper, M.P.

CHAIRMAN OF DIRECTORS.

Thomas Hughes, Esq., Q.C., M.P.

Large or small sums received on deposit, repayable at short notice. Shares may be taken at any time—no back payments. Money ready to be advanced on Freehold or Leasehold Security.

W. R. SELWAY, Managing Director.

DEATH or INJURY from ACCIDENT, with the consequent LOSS of TIME and MONEY, provided for by a policy of the RAILWAY PASSENGERS' ASSURANCE COMPANY, against ACCIDENTS of ALL KINDS.—An Annual Payment of £3 to £6 5s. insures £1,000 at Death, or an allowance at the rate of £6 per week for injury. £650,000 have been paid as Compensation, one out of every 12 Annual Policyholders becoming a claimant each year. For particulars apply to the Clerks at the Railway Stations, to the Local Agents, or at the Offices, 64, Cornhill, and 10, Regent-street London.

WILLIAM J. VIAN, Secretary.

The English Mechanic
AND
WORLD OF SCIENCE AND ART.

FRIDAY, AUGUST 9, 1872.

ARTICLES.

THE DETECTION OF ADULTERATION OF ARTICLES OF FOOD.

By Alfred H. Allen, F.C.S.,
Lecturer on Chemistry at the Sheffield School of Medicine.

THE adulteration of food is a subject which has been written on by many, and the public are now pretty well aware what articles of food are most subject to admixture. But most writers on adulteration have been content with stating their results, without describing the methods used in detecting admixture. Even those who do describe their processes do so in most cases in such a manner as will only be understood by scientific men, omitting the minute precautions, the observance of which will alone enable a beginner to obtain satisfactory results.

Many articles of food are used but in small quantity, and the fee to a professional analyst for the examination of a sample would often exceed the saving that would result from the use of a purer article, and in many cases the only satisfaction the consumer would obtain would be the knowledge that the article he was accustomed to purchase was grossly impure, while he would have no certainty of procuring a superior quality by changing his shop. If the detection of admixture were more readily effected, and more generally understood, there are many who would be only too glad to examine their purchases. It is usual to assume the necessity of employing complex chemical tests and a powerful microscope in detecting adulteration, and although there are certainly many admixtures which can only be recognised by these means in the hands of an expert operator, there are, on the other hand, many adulterations which can be readily detected by any intelligent person who possesses a small microscope and a dozen or two of bottles, with reagents.

It is my intention in this article to describe minutely the simple methods of detecting the adulteration of food, avoiding, as far as possible, the employment of technical terms, and I hope in this manner to place the readers of the English Mechanic in a position to examine many articles for themselves, and so learn which are the best shops to make their purchases, while at the same time I give them the results obtained by myself in the examination of a considerable number of specimens.

Adulterations of Mustard.

Mustard is a condiment very commonly adulterated with wheaten flour or starch, turmeric, cayenne, &c. Ground mustard seeds give a somewhat pasty flour, owing to the large quantity of oil present. To prevent the tendency to cake, flour or starch is added, 10 or 12 per cent. being amply sufficient, though the quantity is often increased to 50 or 60 per cent. In the best quality of mustard prepared by one of the best-known makers, no starch is used, the tendency to cake being got over by the extraction of a large proportion of the fixed oil. The presence of *flour or starch may be detected* by boiling a small quantity of the mustard with water, and gradually adding to the thick liquid a solution of iodine in alcohol (or in water to which iodide of potassium has been added). A blue or violet colour will be produced if starch or flour be present, as it almost invariably is. Genuine mustard seed contains no appreciable quantity of starch, and does *not* give a blue colour with solution of iodine.* The presence of starch or flour can also be readily ascertained by the microscope, the granules of starch being readily recognisable; they are turned blue by addition of iodine solution. The shape and size of the starch granules, as seen under the microscope, indicate the kind of starch employed for adulteration. Wheat flour is commonly used, but I have also found potato starch.

Turmeric is seen under the microscope of a bright yellow colour and characteristic structure. It may be detected with certainty by the following test, even when present in very small quantity. Shake half a teaspoonful of the mustard in the cold with two or three times its bulk of methylated spirits. Filter the solution and evaporate one-half of the liquid to dryness at a steam heat in a porcelain basin, in which is placed a piece of filter paper about the size of a penny. When all the alcohol has been driven off, moisten the paper with a strong aqueous solution of boracic acid, and again evaporate completely.* In presence of turmeric the paper will acquire a reddish colour; but, as a further proof, drop on it some solution of caustic potash or soda, which will produce a very beautiful series of colours, in which green and purple are most evident. On then adding hydrochloric acid, a red colour will be produced, which can be again turned green and blue by addition of excess of alkali. The colours are very vivid and characteristic, pure mustard giving no such result. Turmeric is very frequently added to mustard to give it that bright yellow colour which the public seem to expect, but which is not natural to pure mustard. Turmeric is not injurious, and is not generally used in quantities sufficiently large to appreciably affect the weight of the article.

Gamboge is said to be sometimes used for colouring mustard. Its employment is highly reprehensible, as it is a violent purgative. It may be detected in the same way as turmeric, but gives a bright red instead of a green or blue colour on treatment with caustic soda, and on adding excess of hydrochloric acid the paper becomes merely yellow instead of the orange red colour produced in presence of turmeric.

Cayenne Pepper, or Capsicum, is often added to mustard to increase its pungency. It is best detected by evaporating to dryness the other portion of the spirituous solution used for testing for turmeric. On heating the residue in a porcelain dish very pungent fumes are evolved, which irresistibly compel coughing, and produce a sense of heat in the lungs.

Charlock Seeds are sometimes used for mixing with mustard. The charlock is very closely allied to the mustard, its botanical name being *Sinapis arvensis*, while white and black mustard are respectively *Sinapis alba* and *Sinapis nigra*. The charlock grows in corn-fields, and bears a large yellow flower. The taste of the seed is not so pungent as that of the true mustard, but agreeable and somewhat similar. There exists at present no means of detecting its presence in manufactured mustard, but admixture with it is by no means so reprehensible as most adulterations.

Plaster of Paris is said to have been used in adulterating mustard, but I never met with an instance. It could only be used to increase the weight, and, therefore, would be employed in some quantity, so that a sample of the mustard would leave an excessive proportion of ash after ignition. Mustard usually leaves about 3 per cent. of ash, and any proportion exceeding 5 per cent. may be looked upon as indicating adulteration by mineral matter.

Chalk, if present, would be at once detected by addition of an acid (hydrochloric) to some of the mustard, when effervescence would be produced.

The recent examination of seven samples of mustard, purchased in Sheffield, has given me the following results:—

No. 1.—Price, 6d. per ¼lb. canister. Free from starch, flour, and turmeric, but cayenne was present, and a sensible quantity of husk. The taste was extremely pungent—far more so than the other samples.

No. 2.—Price, 2oz. for 1½d. Contained *no* cayenne, and but very little turmeric. Potato starch was present in some quantity.

No. 3.—Price, 1½d. an ounce. Contained starch or flour, turmeric, and cayenne.

No. 4.—Price, 1½d. an ounce. "Warranted free from all impurities and adulterations." Contained starch or flour, turmeric, and cayenne.

No. 5.—Price, 1d. an ounce. Contained much starch, turmeric, and cayenne.

No. 6.—Price, 1d. an ounce. Contained starch or flour, turmeric, and cayenne.

No. 7.—Price, 1d. an ounce. Contained starch or flour, cayenne, and a little turmeric.

From these results it will be seen that all seven samples contained admixture of some kind. All but No. 1 had their strength materially reduced by admixture with starch or flour. All but one contained cayenne. All except No. 1 had more or less turmeric in them. It may be thought that the addition of flour, or starch, to mustard is of a very excusable nature, but the admixture of excessive quantities not only cheats the consumer by selling him flour at the price of mustard, but is highly reprehensible in a medical point of view. Suppose a child poisons itself, and while the medical man is on his way a dose of mustard and water is given to produce sickness, but in consequence of the adulteration of the mustard the emetic refuses to act and the child dies; who is to blame here, and can the admixture of flour with mustard be considered legitimate? Undoubtedly the consumer will do well to purchase his mustard free from starch or flour, with which he can easily mix it for himself, if he fancies it too strong or too dear. When one well-known firm sells five or six different qualities of mustard it is evident they are not all likely to be the pure article. In this, as in other cases, the best is the cheapest.

Adulterations of Ginger.

The additions to ground ginger are very similar to those of mustard. Turmeric may be detected by the microscope, or as described under "Mustard." Cayenne *must* be searched for by the microscope. As ginger naturally contains a large proportion of starch the iodine test is inapplicable, and the addition of the various farinas can only be ascertained by careful microscopic examination.

Adulterations of Vinegar.

Vinegar is an article very often adulterated, the more common impurities being sulphuric and hydrochloric acids, and cayenne, with accidental contamination by zinc, copper, and lead. Oxalic and tartaric acids are also said to be occasionally present. Vinegar is essentially a weak, impure, acetic acid, of very variable strength. Its strength may be ascertained by the usual processes of acidimetry. A more simple but less exact method is to weigh carefully a small, dry, white lump of marble, and place it in a known weight or measure (500 grains) of the vinegar until effervescence has entirely ceased. (In presence of sulphuric acid a little barium chloride should first be added.) The marble is then rinsed, dried, and re-weighed, when every five grains of loss indicates the presence of six grains of real acetic acid in the sample of vinegar. The vinegar of commerce is either fermented or distilled vinegar; the latter variety is obtained by the distillation of wood, and the former derived from either sugar, malt, or wine. The percentage of real acetic acid in vinegar varies from 2·38 to 5·66 per cent. Very weak vinegars should be rejected, as they are unable to prevent the decomposition of meat and vegetables, while the extremely pungent varieties are open to the suspicion of containing cayenne or sulphuric acid. One part in a thousand of sulphuric acid may be legally added to vinegar to increase its keeping properties, but this proportion is often greatly exceeded. If addition of solution of barium chloride occasions more than a very slight cloud, the presence of free sulphuric acid may be suspected, and searched for by the following tests:—

1. Write letters with the vinegar on white paper by means of a clean quill pen or splinter of wood. On strongly drying the paper before a fire the letters will become charred if sulphuric acid was present in the vinegar to the extent of 2 per cent.

2. Dissolve a lump of white sugar in thirty parts of water, and dip into the solution a porcelain capsule or basin, so that it remains wet. Then dry by placing on a vessel containing boiling water, and while in this position allow a drop of the vinegar to fall upon the porcelain, and let it dry up completely. If sulphuric acid was present only to the extent of a 300th part of the vinegar, a black spot will be produced on the basin where the vinegar fell. With very minute quantities of sulphuric acid the spot has a green colour.

* In a recent trial in America, a Dr. Doremus stated that genuine mustard contained starch, and that the iodine reaction failed, owing to the presence of the essential oil of mustard. But the intentional addition of a very small quantity of starch to a sample of genuine mustard is readily detected by the blue colour produced on gradual addition of the iodine solution in sufficient quantity, though the first few drops produce no effect. The starch in mustard would also be discerned by the microscope, if really present. A *few* scattered granules are alone visible in the genuine substance.

* A solution of borax mixed with hydrochloric acid may be employed in place of the boracic acid, but is scarcely so satisfactory. The test detailed in the text is there published in a new form, and is the only one by which turmeric can be readily and certainly detected without the aid of the microscope.

3. If it be desired to determine the free sulphuric acid, 8oz. of the vinegar are concentrated, the liquid mixed with twice its bulk of alcohol, filtered, acidified with hydrochloric acid, and precipitated with barium chloride. 233 grains of the ignited precipitate correspond to 98 parts of concentrated sulphuric acid.

The other adulterations of vinegar may be detected in the following manner:—Boil down 4 ounces of the sample to about an ounce, and divide into four portions, Nos. 1, 2, 3, and 4.

1. Evaporate nearly to dryness, add methylated spirits, stir well, and filter. Evaporate the clear alcoholic solution to dryness and heat. Very pungent fumes, which produce irresistible coughing and sense of heat in the lungs, indicate the *presence of cayenne*. (Ginger, which is occasionally present in vinegar, gives a similar result. The only way of distinguishing it from cayenne is to carefully neutralise the vinegar with sodium carbonate, when the *taste* of the liquid will generally settle the question.)

2. Add a strong solution of potassium carbonate, then more of the original vinegar (so that the reaction is strongly acid), and stir with a glass rod. A white crystalline precipitate, giving streaks on the sides of the vessel in the track of the glass rod, indicates the *presence of tartaric acid*. Vinegars obtained from wine contain tartaric acid as a normal constituent.

3. Evaporate to complete dryness, and ignite the residue in a porcelain crucible till no longer black. (The ignition may be greatly expedited by addition of a crystal or two of potassium chlorate.) Boil the ignited residue with a little nitric acid, add water, and filter. To the clear solution add excess of ammonia and carbonate of ammonium, boil and filter. If the filtered liquid has a blue tint, *copper is present*. To the hot liquid add a solution of ferro-cyanide of potassium, when the production of a white precipitate shows the *presence of zinc*. Pour acetic acid on the filter containing the precipitate produced by ammonia and ammonium carbonate, and to the liquid which runs through add chromate of potassium. A chrome-yellow precipitate will be produced if *lead is present*.

4. Dilute with water, and add a solution of calcium sulphate (plaster of Paris.) A white turbidity shows the *presence of oxalic acid*.

If the original vinegar gives more than a slight milkiness with a solution of nitrate of silver, the *presence of hydrochloric acid* is indicated.

I have recently examined four samples of vinegar by the above method, with the following results:—

No. 1.—Price, 8d. a quart. Adulterated with cayenne.

No. 2.—Price, 4d. a quart. Contained cayenne and a small quantity of free sulphuric acid.

No. 3.—Price, 5d. a quart. Contained cayenne, and small quantity of free sulphuric acid. A suspicious precipitate with nitrate of silver.

No. 4.—Price, 8d. a quart. Unadulterated.

Adulterations of Pepper.

Dr. Hassall found pepper adulterated with wheat and pea-flour, ground rice, ground mustard seeds, linseed meal, and pepper dust. The examination cannot be made satisfactorily without a good microscope, and then requires care and skill to successfully detect the admixture of the various starches, &c. I do not believe that actual dust or dirt is ever intentionally mixed with pepper, its adulterations being the above farinas, &c., added as make-weights. As pepper naturally contains a large quantity of starch the iodine test cannot be used for detecting admixture. Four samples of black pepper recently purchased in Sheffield have proved free from foreign admixture.

Adulterations of Cayenne Pepper.

Cayenne pepper (ground capsicums) is sometimes adulterated with common salt, various kinds of starch, sawdust, turmeric, red ochre, red lead, and vermilion. The addition of salt gives cayenne a bright red colour, and renders it less liable to fade on exposure to light. Salt is sometimes present in very considerable amount, and is used to cover other additions. The above adulterations may be detected in the following manner:—Boil some of the cayenne pepper in water, *decant* some of the liquid from the undissolved portion, and test the solution for starch by means of iodine solution. A blue or violet colour indicates the *presence of starch*. The particular kind of starch present can only be ascertained by the microscope. Filter the remainder of the water in which the cayenne has been boiled, and to the clear liquid add some silver nitrate. A white curdy precipitate, not dissolved on adding nitric acid, is produced if *common salt is present*. Boil some of the cayenne in strong hydrochloric acid for some minutes, then add a a few drops of nitric acid, and boil again. Dilute the acid liquid with some water,* filter, and divide the clear liquid into three portions, which test in the following manner:—

1. Add potassium ferro-cyanide. A Prussian blue precipitate indicates the *presence of iron*. Traces of iron are naturally present in cayenne, but a distinct precipitate proves adulteration by red ochre, rouge, or other ferruginous matter.

2. Add ammonia till alkaline. Then acidify with acetic acid, and add chromate of potassium. A chrome-yellow precipitate proves the *presence of lead*, probably as red lead, in which case the original solid particles will be darkened on moistening with dilute nitric acid.

3. Pour the liquid on a clean penny or piece of copper, and after standing some minutes wash the metal and polish with a cloth. If *vermilion* was present in the cayenne the copper will appear white and amalgamated.

Sawdust and turmeric are best detected by the microscope, or the latter addition may be readily discovered by the method described under "Mustard."

Four recent examinations of cayenne pepper resulted in the detection of salt and a small quantity of starch in two, the other samples being genuine. Dr. Hassall found only four genuine specimens in a series of twenty-eight, one half of which contained one of the poisonous metals—lead or mercury.

(*To be continued.*)

* If the insoluble residue has a reddish colour which is persistent after ignition, *the presence of brick-dust* may be assumed.

TECHNOLOGICAL EXAMINATIONS.

THE Society of Arts has formulated a programme of work which, even if the results fail to come up to the sanguine expectations of many, cannot but be productive of much good as far as the manufacturing interests of this country are concerned; for if it is backed up, as it should be, by those who are in possession of the requisite means, and can impart the needed stimulus, it will go a great way towards enabling us to retain the supremacy in the industrial world which we at present look upon almost as our birthright, and even if neglected and left out in the cold will still assist in a measure to keep what may be termed the science of manufacture and the necessity of a knowledge of it prominently before the public. The scheme, which may be considered to have been fairly started at the recent Conference of the Society of Arts, under the patronage of the most distinguished notabilities, had its origin in a proposal of Major Donnelly, R.E., that the Society should undertake the examination of artisans in the scientific principles which underlie the various industries in which they are engaged or are likely to be engaged, and award certificates of proficiency and prizes for those found to be accomplished. These certificates will be of three grades, and will probably be divided into first and second class, and the degrees of proficiency, or grades, will be apportioned, and certificates awarded as follows:—No. 1 will be the elementary grade, or what may be termed the ordinary "workman's" certificate; 2, the advanced, or "foreman's" certificate; and 3 the honours grade, or "manager's" certificate, which may be assumed to imply that the holder has been examined and found to be acquainted with all that is known of the scientific principles on which his special art or manufacture is founded. The first of these "technical examinations" is proposed (we hope soon to be enabled to state that the scheme has passed this stage) to be held in May, 1873, and to take up two of the most important manufactures—viz., cotton and paper, the idea being to follow as closely as possible the line taken by the annual International Exhibitions. It would be premature to speak of the minor rules and regulations which will govern the working of these examinations, but the committee appointed to shape a programme for the proposed examinations of artisans employed in the cotton manufacture was read at the conference, and the following will convey an idea of what is required of the candidates. The examination, then, will be divided into three parts, the first of which will be concerned with those branches of science a knowledge of which may be considered necessary as a foundation for sound technical instruction, regard being had to the acknowledged difficulties of obtaining a scientific education. The second part will be concerned with the "technology" of the manufacture, or the special application of the different branches of science to it. The third will be concerned with the practical skill shown in the manufacture itself. The knowledge of the candidates will be tested, as far as concerns Part I., general science, by the ordinary May examinations of the Science and Art Department; and as concerns Part II., technology, by special papers, set immediately afterwards; while the qualifications of the candidates as regards Part III., practical skill, will be judged by the returns of their employment in cotton mills. The outline of the scheme as applied to the cotton manufacture may be taken as a rough guide as to what will be required in the technical examinations connected with other industries, but special subjects, will of course, be introduced to suit the requirements and peculiarities of other trades or professions. The committee consider that the following subjects are more or less connected with or involved in the manufacture of cotton: practical plane or solid geometry, machine construction and drawing, building construction, pure mathematics, theoretical mechanics, applied mechanics, vegetable anatomy and physiology, and steam. To obtain the elementary grade, or "workman's," certificate, the candidate will be required to "pass" in practical geometry and the elements of mechanics: he may then count marks in any of the other subjects above mentioned. For the advanced or "foreman's" certificate the candidate will be required to have obtained at least a "first-class" in the elementary stage of practical geometry, machine construction and drawing, elementary mathematics, and applied mechanics or steam, and when he has qualified in these he will be allowed to count marks in any of the other subjects. For "honours" the candidate must evince a higher knowledge of the various "necessary" subjects, and will then be allowed to count marks in the others. The "technological" portion of the examination requires a knowledge of the nature and properties of the raw materials, of the methods of preparing them, and of the machines by which the various operations of the manufacture are performed. A knowledge of the "stiffening and weighting" processes will also be required, as well as of the numerous articles or kinds of woven cotton fabrics. These particulars will give a fair notion of what may be expected to be required for the different technical examinations, although the "paper" examination will, judging from the report of the committee, require a knowledge of a greater variety of subjects than the "cotton."

We can only hope that the requirements of the examiners will be supplied by the candidates; and with the nine hours' movement spreading gradually there is just a minimum chance that workmen will find the requisite time to devote to study. We are, of course, presuming that what is termed "obtaining a first-class," really means a sound and thorough knowledge of the various subjects constituting the elementary stage; but we do not know at what point the standard will be fixed. If placed too high working men will be discouraged; if too low the object of the society will not be served so well as it might be if the "happy medium" should be chosen. We observe that in the special competition for prizes the candidate must "come up" in all the subjects in which he wishes to count marks; but for the certificates he will be allowed to take the subjects in successive years—the latter a very necessary regulation, for it is useless to suppose that a workman could acquire a knowledge of all the subjects in the limited time at his disposal, and until the primary education of the masses is lifted above its present level the numbers who will go in for the "exam." will not come up to the expectations of the founders of the scheme. The Society of Arts' certificates, we have reason to believe, are highly valued by both employers and employed, and Mr. Lawton said at the conference that applicants for situations in the cotton mills and warehouses of Lancashire who could produce one of these certificates, generally obtained the preference. Similar results would doubtless follow the establishment of "technical" examinations in manufactures, and in course of time employers would look upon these certificates of proficiency as a guarantee of the ability of the applicant to perform the work he desired to obtain. If the proposals of the committee are carried out, and the programme adhered to, the advanced or "foreman's" certificate will be evidence that its holder is an educated man; for the "foreman" of a paper-mill will have a "first-class" knowledge of practical geometry, machine construction and drawing, pure mathematics, mechanics, steam, acoustics, light and heat, and inorganic chemistry or vegetable physiology, besides an acquaintance more or less extensive with magnetism and electricity, organic chemistry, and systematic and economic botany. In other words he will be, as the phrase goes, a "well educated" man, possessed of more solid information than many of his predecessors in office ever dreamt of. We shall probably return to this subject at a future time. The scheme should not be allowed to fail, now it is once formulated, and be the results much or little, if properly worked it cannot fail to improve the rising generations of artisans, who, as children, it is to be hoped, will soon be taught the rudiments of science at school just as they are now taught the A B C. Till, however, primary education is immensely improved it is useless to hope that a sufficient number of workmen will "qualify" to leaven the whole mass and elevate technology to the high position it ought to occupy in a manufacturing country like Great Britain. In the mean time we cannot but regret that the Society has determined to discontinue the ordinary examinations, which for seventeen years have been tolerably successful. We hope the new "technological" examinations will meet with a greater measure of success.

PERSPECTIVE.*

THIS simple, excellent, and most intelligible little work appears *a propos* with regard to a discussion which has for a good many weeks been carried on in our own columns; and we would refer the disputants, with some considerable amount of confidence, to it, for a perspicuous solution of the leading points of difficulty mooted in the course of the debate.

There is one observation of our author's, the simplicity of which impresses us with an idea that it must be trite; but the truth of which may be well laid to heart by all who aspire to sketch correctly. It is this: "The most frequent cause of failure in attempts both in drawing and colouring is — not knowing how." We are only doing Mr. Collins bare justice when we say that a careful perusal of his book must certainly remove this particular deficiency, so far as the knowledge of perspective is concerned; inasmuch as, beginning at the very beginning, he enunciates and explains its leading principles with a degree of lucidity which must render them apprehensible by any one who will follow his explanations with the most ordinary care. Moreover, essentially mathematical as the whole subject is in its fundamentals, there is a marked absence, in the work under notice, of anything in the shape of mathematics which cannot be easily followed by any one who can use a pencil and ruler, and knows what an angle is.

Beginning with plain definitions of the few technical terms to be afterwards employed, the author goes on to explain the nature of sight, and to tell us what the "projection" of a picture means. He then proceeds to exhibit the difference between perspective and orthographic projection, and to exemplify the nature of isometric and stereographic drawing. All this is done in a way which a child might comprehend, by very moderate application. Then the subject of perspective is treated in full detail, and a typical and somewhat elaborate view of the interior of an old hall is taken, and instructions given, step by step, for drawing every item in it. As the particular example selected presents several points of difficulty, it is scarcely too much to say that the student who will follow the author's teaching, pencil and sketch-book in hand, and reproduce his frontispiece by the aid of the principles which he so clearly enunciates, ought, hereafter, to meet with no difficulty whatever in delineating any object which ordinarily occupies the amateur, in correct perspective.

The work concludes with notices of "false pictures," the hanging of pictures, the reflection of the moon in water, complementary colours, the colour of the sky, and the effect of mixed pigments; subjects all more or less cognate with the main one of the book, that of "the art of drawing what one sees."

Thirty-eight carefully-executed woodcuts (in addition to the frontispiece) illustrate the work, one of them (Fig. 19) dealing expressly with the point concerning which the concluding part of a sustained argument appears in letters on our 489th and 599th pages.

Briefly, then, we would commend this little book to all such of our readers as may sketch from nature; and counsel them to include it with their drawing materials, when packing up their travelling bags this summer.

* "Perspective, or the Art of Drawing what One Sees," &c. By Lieut. W. H. COLLINS, R.E., F.R.A.S. London: Longmans.

THE "FALLACIES" OF DARWINISM.*

PROBABLY the name of no writer on scientific subjects is better known throughout the world at the present time than that of the author of the "Origin of Species" and the "Descent of Man." Not merely because his books deal mainly with the animals which are joint inhabitants with ourselves of the earth, and are replete with entertaining anecdote and narrative, but also because they contain an hypothesis which is calculated to disturb in no slight degree the self-satisfied and complacent frame of mind with which we regard the inferior or brute creation, conscious of the superiority which, for all we *know* to the contrary, is our birthright. It might be expected that any one who should publish a statement that man's immediate ancestor was in all probability an ape—and what is worse show incontestably that he had some grounds for the opinion—would meet with a storm of opposition from the great mass of humanity, and even from a very large number of those specialists who from their acquirements and intelligence were best capable of weighing the evidence placed before them. As a matter of course, when Darwin published his hypothesis the outraged feelings of the community found vent in an avalanche of wordy pamphlets containing much of the *odium theologicum*, little argument, and no facts. But against the storm Mr. Darwin showed a bold front, and now numbers a very large following. It is only natural that it should be so; for Mr. Darwin brings great scientific attainments, laborious collection of facts, and undoubted honesty of purpose to bear upon the statements he has to advance on the side of his theory. One by one his opponents, if not completely defeated, have at least failed to demolish his hypothesis, and a similar fate would appear to be in store for Dr. Bree, who considers the time "opportune for a review of the whole subject, and in venturing upon the task, proposes to treat it in a spirit of pure scientific investigation." But so far from being a "pure scientific" examination of the Darwinian hypothesis, Dr. Bree's exposition of its "fallacies" covers a far wider field, and argues "the subject in reference to an issue ten times more important than the knowledge of man's biological history." Perhaps it is impossible to dispute the propositions of Mr. Darwin in their full bearing without bringing Revelation into the controversy; and a writer who does this well and does it fairly will be sure to obtain a wide circle of readers for his book. Whether this will be the case with the volume issued by Dr. Bree remains to be seen; but in venturing to doubt it we can offer reasons which are furnished by the book itself. On the very first page we find it stated that Dr. Hooker, in the well-known address to the British Association at Norwich in 1868, asserted that "so far from 'natural selection' being a thing of the past, it is an accepted doctrine with every philosophical naturalist." This statement Dr. Bree characterises as a "sweeping assertion," and proceeds to point out its inaccuracy. Now it is in the highest degree necessary that any attempted "exposition" of Darwin's fallacies should be based on facts; but so far from this being the case with Dr. Bree's work we find at the very outset a "misquotation," and several pages devoted to the correction of an error which only exists in the imagination of the author. Most persons would have thought that before occupying several pages in refuting a statement made by Dr. Hooker, Dr. Bree would have at least taken the pains to see that he had not made a mistake, even if he could not generously credit Dr. Hooker with truthfulness. So far from saying "every philosophical naturalist," according to the authorised report Dr. Hooker said "almost every philosophical naturalist"—a qualification which brings the assertion of the ex-president within the confines of fact, and renders worse than useless the pages Dr. Bree devotes to the correction of the supposed error; for even in these he misquotes or misunderstands Mr. St. George Mivart, making the talented author of the "Genesis of Species" say the direct contrary of what he really did say. Blunders of so stupid a nature as these inevitably create a suspicion in the minds of unbiased readers, and lead them to look upon the arguments of the author with distrust.

Dr. Bree divides his subject under the different heads of the "physical," the "physico-psychical," and the "variation and natural selection" arguments, and though possibly, standing on the ground he occupies, he has the advantage of Mr. Darwin, he has certainly not used his advantage in the best or most conclusive manner. He furnishes us with a frontispiece showing in an illustrative form the "Descent of man after Darwin's theory," in which we find the protozoa of the unknown past as derived from "inferential protoplasm," or from the meteoric "mass" of Sir William Thomson, which he brackets as "very inferential." From this protozoa the diagram takes us to the ascidian-like larva which is Darwin's starting point (an inferred organism) and then the "Descent" goes from the Amphioxus or Lancelet, the first "so-called vertebrate," through the Sturgeon to the Lepidosiren—or amphibious reptile. We then come to the first break, for here we have to "infer" a line of reptiles ending in another "inferred organism"—an early implacental mammal which carries on the "descent" to the Ornithorynchus and the Kangaroo; but here two organisms are wanting—the "implacental progenitor of the first placental mammal, and "man's ancient ancestor, with cocked ears and tail, prehensile feet, both sexes bearded and hirsute, males with great canine teeth." Surely "man's ancestor" is out of place here; for the descent continues through the lemur, the Simiadæ and the old-world monkeys to the "so-called man-like ape." Here the great break occurs which separates the lowest type of man from the highest animal—a link in the chain, which has to be supplied by an "ape-like man" before Mr. Darwin's theory can connect man with the apes. On this point Dr. Bree says, "It must be obvious to the most superficial observer what an enormous amount of mere guessing is made use of in such a pedigree. Still more clear is the fact that, even supposing the present state of science justified apparent plausibility in the indicated line, the science of to-morrow may send such guesses into a totally different direction. [It may also prove the correctness of Darwin's hypothesis.] Mr. Darwin starts with guess No. 1; he then jumps over almost the whole class of vertebrate animals, to arrive at what he calls the first vertebrate animal—a form which has very little in common with the sub-kingdom it is placed in, but naturalists do not, in fact, know what to do with it. He then passes through cartilaginous fishes to guesses Nos. 2 and 3, as regards the amphibia and reptiles. Then an animal new to science, the early progenitor of implacental mammals, forms guess 4. He cannot keep the platypus nor the kangaroo in the direct line, but he makes them minister to guess 5, in being the lines to the implacental forefather of lemurs, leaving out the great class of birds. He then jumps to the Lemuridæ at a bound, leaving all the principal families of mammals out of the line altogether. Here he makes enormous guess No. 6, about man's early progenitor, who had cocked ears, a tail, prehensile feet, both sexes covered with hair and wearing beards. From the lemurs he passes to the Simiadæ, and follows the Catarrhine (or old world) group of monkeys, and has to make another huge guess (No. 7) in order to get into the line an imaginary creature he calls an 'ape-like man,' who leads him to the summit of existence—man. Nothing displays more the real ignorance of science, or the extreme baldness and improbabilities of Mr. Darwin's hypothesis, than a table like this." Dr. Bree has not omitted any of the defects of the theory, and it is very probable that "intelligent thinkers and men of education and high mental culture" will shake their heads and become disbelievers in natural science founded upon such a basis. "The chance of [the remains of] some of these variations being found in the different gravels or fresh-water formations above the tertiaries must be very great. And yet not one single variation, not one single specimen of a being between a monkey and a man has ever been found. Neither in the gravel, nor the drift-clay, nor the fresh-water beds, nor in the tertiaries

* An Exposition of the Fallacies in the Hypothesis of Mr. Darwin, by C. R. BREE, M.D., F.Z.S. London: Longmans.

below them, has there ever been discovered the remains of any member of the missing families between the monkey and the man, as *assumed* to have existed by Mr. Darwin. . . . The celebrated Neanderthal skull belongs confessedly to this remote period (the bronze and stone ages), and yet presents, although it may have been the skull of an idiot, immense differences from the highest known anthropomorphous ape." These intermediate forms, too, must have been in great numbers, and the changes which the ape's skull must have undergone would alone have taken a vast time; it is strange, therefore, if the Darwinian hypothesis has any foundation in fact, that remains of these intermediate forms have not been discovered. Dr. Bree also examines the various points in the hypothesis, and step by step refutes them, as he considers; but it is, of course, on the main point referred to above that his position is strongest. He quotes largely from the numerous articles published against the hypothesis, and devotes a chapter to the principle of "least action" as propounded by Dr. Haughton in lectures which will be found in Vol. XIII. It is needless to say that he makes use of every fact that bears in any way against the hypothesis, but into even a few of these fragments of his argument we cannot here follow him. And yet this is not the book to counteract the Darwinian tendencies of the majority of scientific men, nor a safe and trustworthy guide or exponent of the "fallacies" of "natural selection" suited to the requirements of the general public. If Dr. Bree had confined himself to the main points and defects of the theory, his work might have been accepted as a popular exposition of some of the so-called "fallacies," but even then it would have been necessary to avoid misquotation and misconception. As it is, his book teems with errors. Speaking of Mr. Mivart's doctrine of evolution we are told that it is offered "as a means of reconciling scientific and religious thought, and of bringing together the two lines which, Mr. Spencer remarks, *are running parallel and gradually approaching each other*." This extraordinary statement is illustrated by a diagram—two lines nearer at one end than the other, but certainly not parallel. Speaking of the vivid colours of birds, Dr. Bree says they are produced by striæ of pigments which "decompose the light and enable the feathers to *absorb* the most brilliant rays" and so commingle them as to yield the most beautiful tints. In an appendix Dr. Bree reproduces a large portion of M. Flourens's criticism of Darwin's "Origin of Species," but appears to have forgotten the replies to it—notably Professor Huxley's in the *Naturalists' Magazine*.

Many minds have been unsettled by the hypothesis of Darwin, and the acceptance it has met with in scientific circles in different countries, but we cannot think that Dr. Bree's book will do much to quiet those who have been disturbed by the "suggestion" that their reason and their intellect have been derived from a monkey—however far back in time it may be when the gap which now separates man from the ape was bridged over. They are already aware of the great defects in the hypothesis, but the minor points and details upon which Mr. Darwin has built are not to be set aside so easily, and if the connecting links should ever be discovered, few, indeed, would be his opponents, and weaker still their arguments. In the mean time, Mr. Darwin has been refused admission to the French Academy as a foreign correspondent, because, according to a correspondent of *Les Mondes*, "the science of those of his books which have made his chief title to fame—the 'Origin of Species,' and still more the 'Descent of Man'—is not science, but a mass of assertions and absolutely gratuitous hypotheses, often evidently fallacious. This kind of publication and these theories are a bad example, which a body which respects itself cannot encourage."

IMPROVED TURNING TOOLS.

An improved form of cutter or die for turning shafting and similar articles has been recently patented by Mr. J. Fensom, of Toronto, in Canada, and in conjunction therewith he constructs the bed of the lathe in a peculiar manner, when employed for turning such articles. The improvement in the cutter or die consists, according to the inventor, in making the front cutting edge like a chaser or screw-cutter, the thread of which gradually diminishes in depth until it runs completely out, leaving the back portion a broad cutting edge, which is in the same plane as the innermost part of the first thread. In this manner the thread, which is commenced by the first cutting edge, is utilised or caused to operate as a feeder for the cutter, but is gradually cut away as the threads in the cutter become less deep, and is completely removed by the back cutting edge. The effect produced by a cutter of this kind is that of distributing the cutting points, and thereby reducing the friction upon them, while at the same time the cutter is self-feeding.

The improvement in the bed of the lathe consists in making it of the shape of a trough, without the ordinary heads, the spindles fitting

FIG. 1

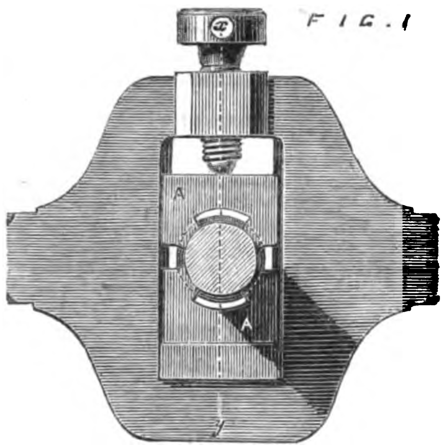

FIG. 2 FIG. 3

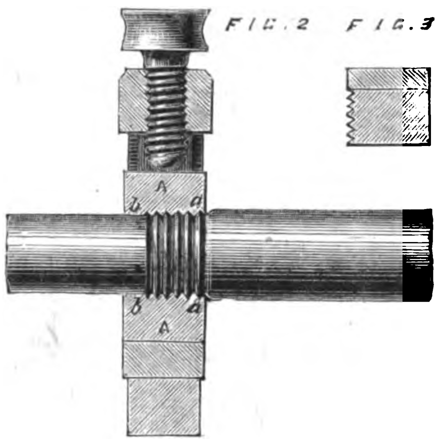

FIG. 4

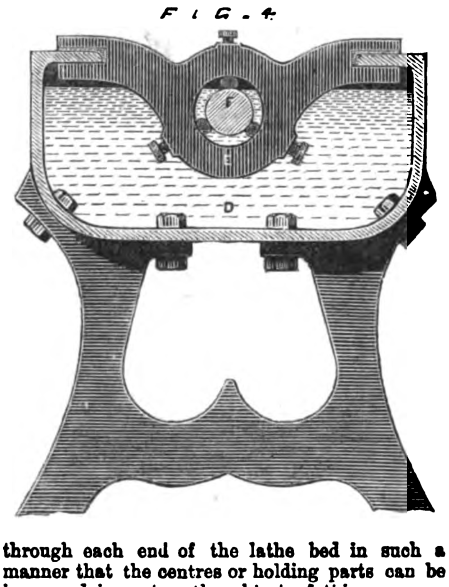


through each end of the lathe bed in such a manner that the centres or holding parts can be immersed in water, the object of this arrangement being to keep the iron well lubricated and cool while under the operation of turning.

In the engravings, Fig. 1 is a front view of an ordinary blacksmith's stock holding a pair of the cutters or dies, and Fig. 2 is a transverse vertical section of the same on the line x y. A shows the cutters or dies, which in Fig. 2 are represented as performing the operation of turning a piece of shafting. It will be seen that the front part a of the cutter A commences with a full thread, which gradually becomes less deep until it runs completely out, and leaves the back part b a broad cutting edge, which entirely removes the thread produced by the front part a, and leaves the shafting plain and smooth, and reduced in diameter, as shown at C. Blacksmiths and others who do not usually possess machinery for turning can with these dies or cutters utilise the ordinary stock for that purpose. The cutters may be applied in various ways, either singly or in any number, to common or bolt-cutting lathes, either with or without the usual feeding gear as may be required. Fig. 3 shows an ordinary screw cutting die connected to a cutter, which will answer in a rough way the purpose of the cutter or die A.

Fig. 4 is a transverse vertical section, showing the improvement in the bed of the lathe mentioned above. It will be understood that the revolving spindle passes through the end of the bed D, which is, of course, fitted with proper journal boxes and requisite bearings. The tool-rest E must also be shaped so as to admit of the shafting or other iron under operation being held in the position shown at F, that is, immersed in the water contained in the trough-shaped bed D. Both the bed D and the tool-rest E may, of course, be varied in form.

IRRADIATION.

If two circles of equal diameter, one white on a black ground, the other black on a white ground, are looked at together, the white one appears larger than the black. This is the phenomenon called irradiation. The apparent magnitude of the stars when we look at them is doubtless affected by it; and its influence is very well observed in the appearance of the moon when only a few days old, the bright crescent apparently extending beyond the darker portion of the disc, and holding it in its grasp.

Plateau has assigned a physiological cause to irradiation, saying that the impression produced on the retina extends beyond the outline of the image. Welcker and others assert the cause is a physical one—viz., the dispersion of light. In support of the latter view it is urged that irradiation increases with faulty accommodation in the eye, and that by the use of proper glasses it may be removed. It is not only light objects on a dark ground that irradiate, the opposite also occurs. A simple way of proving this is to draw on fine white paper two equal thin dark lines, meeting at an angle of 1° to 2°. Look at these and note the point at which the breadth of the lines seems to be equal to the distance between them. Check this next by careful measurement, and it is found that at the point fixed upon the distance between the lines is considerably greater than their breadth, showing that the dark lines had appeared to broaden at the expense of the white space. This is only perceived, however, when the dark objects are very small.

Dr. Volkmann, of Halle, has experimented carefully on irradiation. He used an instrument which he called a macroscope. This is no other than a telescope tube with only the object-glass left in it. He looked through it at broad parallel bands (of black or white), which thus gave a diminished image. If the breadth of the lines did not appear equal to the distance between them their distance from the lens was altered till this took place. The following are some of the results that were arrived at:—The amount of irradiation varies with the size of the image on the retina: the smaller the image the greater the irradiation. Two parallel white lines 1mm. broad, and which could be made to approach each other, were placed at eight different distances, successively, from the lens, giving eight different images. It was observed in each case at what distance from each other they had to be placed in order that their breadth should be equal to their apparent distance, and the above result was obtained.

White lines on a black ground irradiate more strongly than black lines on a white ground. The surface of a board was half covered with white paper, and half with black. Two black parallel lines were drawn on the white half, and two white on the black. They were each 2mm. thick, and each pair 6mm. from each other. The distance from the lens at which each pair had to be put in order to their distance from each other being equal to their breadth was noted. This was much greater for the one pair of lines than for the other.

The amount of irradiation is dependent on the difference in light intensity between the object and its ground. An experiment was made with white objects on a black ground, the source of light being placed at various distances successively, and the result was that the irradiation was greater in proportion as the light was further removed—that is, as the light contrast between object and ground was less. Another mode of experiment, however, gives a somewhat different result (which the law must be made to include.) If we have four equal discs, one white and and one gray on a black ground, one black and one gray on a white ground—then the white looks larger than the gray on the black ground, and the black looks smaller than the gray on the dark ground.

The amount of irradiation further varies with the dispersion of light; it varies in different individuals; it is increased through the slightest fatigue of the eyes; and the reflection of light trom the field of vision external to object and ground has also an influence on it. A. B. M.

THE WATCH, AND HOW TO REPAIR IT.

By "Seconds' Practical Watchmaker."

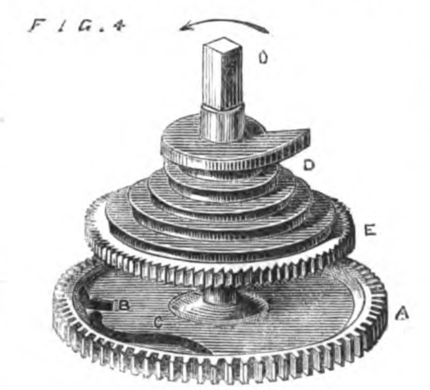
(Continued from page 503.)

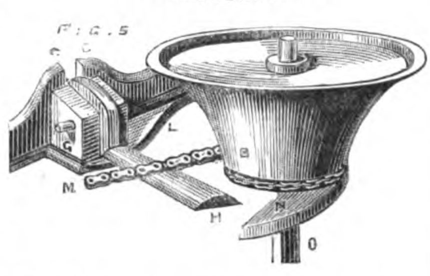
The Adjustment of the Mainspring.

To commence. Place the barrel A and the fusee B in the frame, and secure the upper plate by pins, which pass through the four pillars; place the hook of the chain (1) into the hole at the top of barrel, and then wind the chain on it; fix the hook (4) into the notch of fusee, and then wind on the barrel by the endless screw, or by the click and ratchet method—both these terms are familiar to the amateur as well as to the workman—say half a turn. Fix on the fusee-square the adjusting-rod, which had better be described before proceeding further. This rod (or tool) is formed of a piece of moderate sized round steel wire, nearly 12in. long. At one end it has a very small screw-vice attached, and by unscrewing a small thumb-screw belonging to it it can be secured to any size of watch fusee-square. Upon the wire of this rod there are two brass weights which pass up and down freely, and by their screws may be made secure at any part of it. Supposing that the rod is firmly fixed to the fusee-square, and the frame held in the left hand with its edge upward, the right will be at liberty, and thus the rod may be turned to wind the chain from the barrel, and thereby fill the grooves of the fusee. When fully wound up, the adjustment can be tested, and then so arrange the frame by the hand holding it that the rod can be easily turned. The movable weights on the rod will be on it below the fusee-square, and be very similar to the ordinary steel-yard. Allow the weighted end of rod to rise, and so place the weights that it will only just rise. Allow it to turn: observe the next turn whether the weights go over with the same or less power than the first one; continue till all the turns-over of the rod are accomplished. Generally the adjusting-rod will scarcely rise at the last-but-one turn, and at the last there is no force apparently left. In such a case set the spring up more—that is, turn the ratchet and click, or endless screw, another quarter of a turn more, making, with the half-turn first started with, three-quarters of a turn, then try again in the same way. Should the result be an improvement, proceed two or three clicks more, and repeat the trial. If the rod passes over equally except the last turn, hesitate whether any further alteration should be made for this reason. The whole turn of the fusee may correspond in value of time only five hours, and then by removing the adjusting-rod and fixing just on the opposite side of the fusee-square, the power by which the rod is lifted may be judged by the value of from two to three hours; therefore, it can with safety be so left, because no watch is supposed to continue going till quite down. Again, should the rod turn over more freely toward, and at the last turn, the mainspring is set up too much. But if the greatest force is evident at or about the middle of fusee's motion, it is evident that that fusee is too large thereabout; and if the watch under trial be of superior quality, remove the mainspring, apply another, and repeat the trial. It is customary with manufacturers and examiners of superior work to have the cutting of the fusee tested before it is delivered from their place of business, and therefore rather doubt the quality of the mainspring than the form of the fusee.

Having left the power equalised by which the train of wheel-work is kept in motion, we have to consider, in the next place, in what way the watch is made to tick. Below the fusee D is a wheel A—in old watches similar to that represented in Fig. 4, generally having fifty-five or sixty teeth cut thereon. The wheel A has to remain stationary during the time of winding up the watch; we will therefore describe in what manner this is effected. This wheel A represents the first wheel of the train, and detached from the fusee D in order to illustrate more fully the consequent action when both fusee and its wheel are connected. This wheel A is represented lower than the fusee, to show that at the lowest part of the fusee saw-like teeth are formed, E, termed "ratchet-teeth," and also that the centre portion of the wheel is hollowed to allow the ratchet portion of the fusee's base to lie within it so as to come in connection with the click B, it being a small hook and movable. The piece marked C is a piece of brass so secured to the inner part of the great wheel that it forms a spring so as to press the click B toward the centre of the wheel, and when the ratchet-teeth part of the fusee E lies within the wheel A, a click-and-ratchet action is formed. The watch-key being placed on the squared arbor of fusee O, and turned, will wind the chain from the barrel on to the fusee until the grooves are filled; then an arrangement gets into action, and prevents the over-winding of the watch. (See Fig. 5.)

By inspecting Fig. 4 it will be readily seen that the key must be turned in the direction of the arrow, and that the saw-like teeth at the bottom of the fusee will raise the click C, which, when it has arrived at the highest point of the ratchet-





tooth, falls from it, and is pressed to the base of the succeeding one, and by the flat face of the preceding tooth being presented to the point of the click, prevents the fusee being turned in the opposite direction. This click rising and falling causes the clicking noise heard when winding the watch. Thus, both fusee and its wheel are carried together, and caused to follow the inclination of the mainspring's force, the result of which is that the chain is uncoiled, and when all the chain has left the fusee the watch is then down, and must be rewound before it will again tick.

Having thus far become acquainted with the office of the mainspring, barrel, fusee, and great wheel, our attention must now be directed to another diagram, Fig. 5, in order that we may understand the simple but effective means employed to prevent the watch being over-wound. In Fig. 1 we see that the stop-stud G is the fixture in which the stop is placed, also that a small spring L, which is secured at one end by a screw, passes underneath that stop. The office of this spring L is to press the stop upward, in order that when the watch has been fully wound up an automatic action shall follow in connection with this stop, as the chain uncoils from the fusee.

By inspecting Fig. 5, B, we may readily recognise the fusee, as in Figs. 2 and 4, although the grooves are not represented, one turn of the chain being sufficient for our present purpose; and the mind's eye may be assisted in following the means whereby the stop acts at the termination of winding up the watch, and also in what manner the parts forming the stop-work get out of action again, and so allow the fusee to continue its motion without obstruction. This stop-stud G is a piece of brass securely riveted into the upper-plate, and across which a notch is made with a thin saw; into this notch the thin blade of the stop is placed, and therein secured by a small pin passing through the stud and stop, which are so arranged that the stop moves freely in the stud notch as well as on the pin. Underneath the stop, close to the stud, the spring L passes, and is so bent that it forces the stop upward, and thus remains until the winding-up of the watch.

We will now consider in what way the stop becomes useful. When the winding key is applied to the fusee-square O, for the purpose of winding up the watch, it is quite clear that the chain is wound from the barrel on to the fusee. It therefore happens that when the last turn of the key is about to be completed the chain has to fill the last groove of the fusee, and as the chain passes across the stop H, in the direction M (toward the barrel), it presses it toward the upper-plate; therefore, when the point N of the fusee-cap has advanced to its completion of winding, the flat end of the stop H is presented to it, and the key cannot be turned further. This, then, is the stopping of the winding, because the key cannot then be turned beyond that point. This simple arrangement is termed by watchmakers the stop-work. When the fusee has made one revolution after the watch has been fully wound up, by being moved in the opposite direction, the point N of the fusee-cap has passed under the stop H, which is brought about by the spring L pressing upward this stop, thus allowing freedom for the passing of the cap of fusee, and thus the chain is again transferred from the fusee to the barrel.

Our next consideration is that of the train, or wheels constituting the watch. Every watch is made up of four portions or divisions, that is to say, the barrel, fusee, and stop-work are termed "the great work," the three wheels following are known by the term "the small wheels," the last wheel, with the rest of the parts constituting the escapement, is recognised as the "escapement," and the two wheels and one pinion under the face is known as "the motion-work." Each section or portion will be referred to separately, and therefore we proceed to consider that portion of the watch which immediately follows, from the fusee-wheel including, which is termed the train.

We can, then, understand that the term train has for its signification those wheels and pinions forming that part of the watch until they become connected with the escapement. When the term wheel is made use of it refers to circular pieces of metal, usually brass, with teeth formed on their circumference. When the term pinion is made use of we refer to the small steel wheels into which the leading and succeeding wheels act. The five wheels of a watch are fixed on steel spindles (or arbors which terminate in two small ends) or pivots, and turn in holes made in the frame. When we refer to the teeth of wheels we understand by that term the notches formed on their circumference; but when we refer to those teeth which form the pinion we term them leaves; therefore, as the two terms will be frequently employed, it has been thought advisable to mention the distinction.

As the fusee continues its action by the mainspring's force, the train of wheels are put in motion, and, as we have stated, would have moved so rapidly that in a very short time would have ceased to move were it not for the arrangement just referred to as the third portion of the watch, termed the escapement, the object of which is that the wheels shall be permitted to perform their revolutions in such periods of duration as may be assigned to them by the medium of its intervention, and by which the mainspring is permitted slowly to uncoil after it has been coiled up in its box by the process of winding up the watch. Thus the term escapement at once suggests to the mind that means by which the power, after it has been concentrated in the barrel, is permitted to escape; and hence it will be seen that at each tick of the watch a portion of the mainspring's force has been disposed of.

SUNSTROKE.

Dr. Horatio C. Wood, jun., has recently published in America an excellent paper on the subject of sunstroke, founded upon some observations and experiments undertaken by him with the view of elucidating the phenomena. After showing that in cases of sunstroke the blood undergoes no primary changes in its physiological or chemical properties, Dr. Wood's next step was to ascertain why the heart and muscles are found so rigid after death from sunstroke, and what it is that really kills in this affection. By subjecting myosine to different temperatures, he found that this substance coagulated with great rapidity from 108° to 115° Fahr., and the temperature of the body in cases of sunstroke often reaches 110° Fahr. at the time of death. But the heart is found to continue to beat in animals dead of sunstroke—at any rate, dead in the sense that they had ceased to respire. The rigidity of the cardiac muscles, then, is a post- and not an ante mortem phenomenon. As some experiments by Dr. Wood proved that heat applied to a nerve trunk would not destroy its conducting power, his further investigation was directed to the action of heat on the nerve centres. By some ingenious appliances, hot water was made to circulate over the surface of an animal's head, and it was found that sudden insensibility, and ultimately death from asphyxia, could always be induced at certain temperatures. A brain temperature of from 112° to 114° was fatal to a cat, and one of 114° to 117° to a rabbit. Owing to the possession of a more highly organised brain, it is probable that in man a less degree of heat would produce the same set of symptoms. The mechanism of an attack of sunstroke then, according to Dr. Wood, is that "under the influence of external heat the temperature of the body rises until at last a point is reached at which the heat paralyses, by over-stimulation, the controlling centre regulating animal heat; then a sudden additional rise of temperature, with a corresponding increase in the severity of the symptoms, occurs." Of course cold is the remedy, and cold water the readiest way of applying it. It is a great mistake, says the *Lancet*, to suppose that these cases are commonly due to the action of the direct rays of the sun, for in India, as in America, attacks are very frequent at night. One of the main things to be attended to is, as we have said before, the function of the skin by the daily use of the bath.

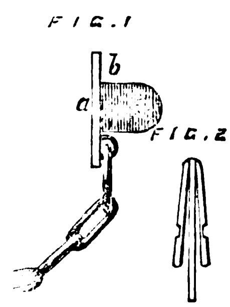
TEA, COFFEE, COCOA, AND ALCOHOL.

THE remarks of Dr. Arlidge, which we printed on p. 269, appear to have led to further investigations of the properties of tea and other beverages, and we extract from the *British Medical Journal* the conclusions of a French physician who has been experimenting in this direction:—

Apropos of the recent grave discussions concerning the abandoned class of persons stigmatised by learned writers as "tea-drunkards," it may be interesting to state the conclusions of an elaborate research by Dr. Angel Marvaud, which has recently attracted much attention in France, on the physiological and therapeutical effects of coffee, tea, coca, maté or guaraná (Paraguay tea), and alcohol, which he classes together as aliments of economy, or anti-waste foods. He considers their influence on nutrition from two points of view: as stimulants to the nervous system; as anti-waste foods, or anti-assimilators. Alcohol acts directly on the sensory apparatus of the spinal cord, and indirectly on the motor apparatus. Coca acts directly on the motor apparatus, which it excites in the same manner as strychnine. Coffee, tea, and maté act principally on the brain. Alcohol and coca excite the exercise of the muscles; coffee, tea, and maté, the exercise of thought. Further, by lessening the waste of the tissues, counteracting organic oxidation, and diminishing loss by means of the secretions, they all act as aliments of economy. In this way is explained their action in stimulating to work in the evening, in partly supplying the want of solid food, and in moderating vital combustion. Hence arises their increasing consumption, and their more general use as articles of daily régime; hence, too, their utility in alimentation, and their important place in hygiene. The abuse of these aliments has, it is true, two principal inconveniences. In the first place, the excitement of the nervous system which they cause is liable to be followed by fatigue, weakness, and even inertia. In the second place, by their interference with and reduction of the processes—indispensably necessary to life—of combination, transmutation, and decomposition, they may cause arrest, suspension, or even complete suppression of the nutritive changes in the cellular elements, and may produce as results, torpor, atony, fatty degeneration, and necrobiosis of the tissues. Thus are explained alcoholism, coffeeism, theinism, and cocoaism. The therapeutic properties of these substances result from their physiological effects. Medicine is capable of deriving great power from them as stimulants of the nervous system, as anti-calorifics, and as retarders of waste. They ought to find a place in materia medica among the medicaments that excite the function of the nerves of relative life, and depress those of organic life. The second of these properties may be regarded as a consequence of the first, if the mode of action of the nervous system be considered. Those centres which preside over nutrition and its principal phenomena (assimilation and decomposition) act with less energy in proportion as the centres which regulate the intellectual, sensory, and motor powers are subjected to a more lively and lasting stimulation.

FASTENINGS FOR WATCH-CHAINS.

A METHOD of securing watch-chains to the waistcoat in a reliable, and at the same time ornamental, manner, has been patented by a Mr. Dolby, of London. The device is applicable to Albert and Victoria chains or guards, which are generally secured to the waistcoat by means of a bar on the end of the chain, which bar is passed through one of the button-holes of the waistcoat. This mode of attachment, while giving little or no scope for ornament, is very inconvenient on account of the difficulty in getting the bar through the hole, and in afterwards passing the button through the same hole. Victoria chains worn by ladies are generally attached at their upper end to a hook on a brooch or on the dress itself, an insecure mode of attachment. To obviate these inconveniences, and provide a reliable fastening, the inventor employs a plate, key, shield, or ornament of any kind, provided at the back with a shank to pass through a button-hole or through a small hole made for the purpose, the shank being secured inside the waistcoat or dress by a spring bolt. The chain is attached to the plate, key, shield, or other ornament, or to the shank, and remains entirely outside the waistcoat or dress, together with the plate or other ornament. The general idea will be readily understood from the engravings, which represent one form of the "invention," which is, of course, capable of great modification. Fig. 1 shows the plate *a*, which may be ornamented to any desired extent; and *b* the shank which is passed through the hole in the waistcoat, and secured by means of the bolt shown in Fig. 2.



COAL AND DOMESTIC ECONOMY.

A FRIEND of Sir William Bodkin's has offered to the Society of Arts the sum of £500 to be awarded in prizes "or otherwise" for the invention of stoves, adapted for ordinary sitting-rooms and kitchens, which shall as far as possible consume the smoke and insure "the most perfect and judicious use of the coal to be consumed." This is, indeed, a timely offer, and the Society has thankfully accepted it, and appointed a committee to report on the best manner of taking action in the matter.

THE MANCHESTER STEAM USERS' ASSOCIATION.

THE last ordinary monthly meeting of the executive committee of this association was held at the offices, 41, Corporation-street, Manchester, on Tuesday, July 30th, 1872, Sir William Fairbairn, Bart., C.E., F.R.S., LL.D., &c., president, in the chair, when it appeared from the report of Mr. L. G. Fletcher, chief engineer, that during the past month 673 visits of inspection had been made, and 679 boilers examined, 406 externally, 6 internally, 6 in the flues, and 261 entirely, while, in addition, 6 new boilers were tested by hydraulic pressure, as well as specially examined both as regards their construction and complement of fittings, before leaving the maker's yard. The following defects had been met with:—Furnaces out of shape, 1; fractures, 12; blistered plates, 4; internal corrosion, 12 (1 dangerous); external ditto, 8; internal grooving, 5; external ditto, 13; water gauges out of order, 4 (2 dangerous); safety valves ditto, 4 (2 dangerous); pressure gauges ditto, 6: total, 69 defects (5 dangerous).

During the month two explosions had arisen from boilers not under the inspection of the association, injuring eight persons, though fortunately not fatally. The cause of one of these explosions, which had been investigated by an officer of the association, was found to be the same as that so frequently met with on previous occasions—viz., the use of an old worn-out boiler, the plates along the bottom, where resting on the brickwork, having been reduced by external corrosion till they had become as thin as a sheet of paper. This corrosion was greatly accelerated by the fact that the boiler was not set upon suitable seating blocks, but let down on to the solid brickwork with wide seatings, which harboured moisture, and thus promoted the corrosion. The entire boiler had been thrown from its seat, and a considerable portion of it hurled across a deep ravine to a distance of 120 yards. The roof of the boiler house had been blown up and the slates scattered in all directions. It was a wonder that no loss of life resulted. Competent inspection would have prevented this explosion.

ATMOSPHERIC GEOLOGY.

A PAPER was recently read by Professor J. Wise before the meteorological section of the Franklin Institute, under the somewhat fanciful title of the "Geology of the Atmosphere."* We are assured, however, that this is no fancy misnomer, but is as much a matter of scientific fact as is the geology of our planet's crust. Indeed, while the geology of the earth's crust confines our positive observation within the limits of one or two thousand feet beneath its surface, that of the atmosphere allows us a practical scope of examination of 30,000ft. above its surface, and of that portion of it most interesting to our welfare and study. Now, whatever the condition of terra firma may be beyond the point of certain examination in regard to its crust and internal structure, whether solid to its centre, or hollow like a geode, or whether filled with plutonic lava as some physicists maintain, we do know that the geology of the atmosphere proves itself to be a stratified elastic substantive shell to the distance of as many miles outward as you choose to count it under the law of geometrical diminution of density, which brings it so near to a nonentity at forty-five or fifty miles above the earth's surface that the atmosphere philosophers have placed its ultimatum at about that limit, but they forget to tell us what begins where the atmosphere ends, leaving us in a sort of philosophical quandary, and so we may as well come down into the shell of our subject, for shell it is, as certain as is the shell on the embryotic egg of the animal.

True it is that we shall not find it nearly so difficult of penetration through its strata as the granitic layers of its correlative basement, or even the liquid shelves of hot and cold brine on which it mainly rests, but we shall nevertheless find it possessed with counterparts as interesting to contemplate as are the old red sandstones and primitive serpentines of the nether geology.

Viewed from afar off, as we might see it from a standpoint on Mars or Venus, we should in all reasonable probability find the semi-transparent geology of our atmosphere to present us with a field of view similar to the belted Jupiter or striated Mars, since we have such well-defined lands in the torrid, the temperate, and the frigid zones that must of necessity give aspects in accordance to their temperatures, their reflections, their underlaid water bases, liquid and frozen, and its persistent equatorial cloud-belt that shifts itself in accordance with the earth's declination to the plane of its orbit.

While the gravity of our earth, by which all the other planets are weighed, at best is hypothetical, the weight of its atmosphere can hardly be questioned, as demonstrated by the Torricellian balance. That instrument tells us that our atmosphere is equal in weight to a shell of water 34ft. thick, encompassing the whole world; so you see we have a positive data of its weight, and have a good foundation to start on in the investigation of its geology. Now, as it may safely be alleged that the general stratification of the atmosphere is constantly liable to slides, and heaves, and avalanches, and shiftings, as compared to the geology of the more solid crust of the earth, the difference is only as to time. While the one is liable to changes in short periods of time, the other is just as liable to changes in long periods of time; and in the one case, as in the other, the relation they bear to that infinite eternity is all the same as regards the computation of time and change.

That the atmosphere has its fixed geological strata is manifest in various indisputable conditions of constant recurrence, well known to the seafaring and airfaring man, and he knows them as well in their courses as does the engineering landsman know the valleys of the Mississippi and the Amazon, or the ranges of the Cordilleras. The trade winds were for a long time only studied and understood as related to ship sailing voyages, as the squirrel understands and practices the art of crossing rivers, as a failure of the nut-crop makes it a necessity to migrate from one side to the other. Now, since we are a little more advanced from the ancestry which Darwin gives us, we are prone to look a little higher, and that, in accordance with the law of progress, leads us to study the higher strata of the atmosphere, with a view, if not to make ourselves wings to fly with, at all events floats to sail with, that bring us face to face with aërial highways, mountains and valleys, streams and counter streams, tides and storms, layers of clouds, warm and cold, just as we find stratifications, tides and gulf streams, in the more crude form here below; and thus we behold that unity of force and law in nature that moves and vitalises all things with its providential life and motion recognisable in the multifarious forms of matter springing out of it. You will not object to the term highway, as applied to this upper ocean, when I tell you that great processions of the thistle-seed, with its tiny silken chariot carrying it along, may be seen high above the second stratum of clouds, as is seen the gulf-grass moving with the current of the nether ocean. So with the pollen, the impregnating principle of the vegetable king-

* We are indebted to an unknown correspondent for a copy of the paper from which these lines have been extracted.

dom, which may be seen in these moving strata in the form of faintly outlined nebulous clouds, in their mission of destiny fulfilling the works of nature.

That great centrifugal furnace — our equator, with its seething band of heated and volatilised vapour, that is pumped up, as it were, by a tremendous irrigating engine, as if made expressly to send heat and moisture to the uttermost parts of the earth, is of itself a grand and interesting study, before which the heaving fires of Vesuvius are comparatively tame. That is the stratum which has not yet received its full share of consideration in the cosmogony of our planet, but rather neglected and left to the unimaginative sailor, who conjures it up into "calm belts" and "horse latitudes," and into "doldrums" and "crossings of the line," &c.

Owing to the configuration of the globe in its continents in connection with the motion of the earth, and the gulf streams that are projected from this huge steam generator, the mariner tracks out his roads and byeways as definitely as does the civil engineer his glades and valleys in his surveys. And while this great engine is moving the waters of the sea it is just as diligently at work in moving the great ocean of vapour over our heads above, presenting the grand conjunction of the trade winds rushing into this equatorial vortex from the northward and the southward, only to be raised and conducted outward, freighted with its life-giving materials, to be distributed over the land in the mechanism of its ways, as constantly as is the blood of the animal in its peculiar economy.

Old "Probabilities" — I mean the original one, Joseph Henry—gave me a lesson in this weather prediction fifteen years ago. With his weather map before him, and a telegram from S. Louis describing a storm then and there in action, he began to trace it by sticking pins into the map. As we had been discussing the nature of storms and the upper trade winds the evening before, I remarked, "You ought to be able to tell when that storm will reach the meridian of Washington," and he did predict it truthfully! He further remarked, "You know the snowstorms always commence in the west, and whenever I get a telegram from S. Louis of a snowstorm raging there, I can tell about what time it will reach the Atlantic seaboard." It is only when the east wind of winter forms a conjunction, and an atmospheric node with the west wind, that a deposition of snow takes place; and this winter node of snow, rain, or sleet, always travels eastward. Our weather signal service is mainly indebted to the early experiments of Henry; for as soon as a general system of telegraphy was established, the western predictions were an accomplished science, and he pressed the matter as a necessary and economical action of the Government for the benefit of seamen and agriculturists.

Such is the use of the study of the geology of the atmosphere, and while it would be too prolix for an evening essay to attempt the details of arrears of high and low barometer, and the exact tracing of isobarometric lines indicative of the course of the storm, it is in order to say that high and low barometer is only an effect of the storm motion—that is to say, the condensation of the atmosphere, caused by its pushing forward, makes the mercury rise, while its dilation, following in the wake, causes the mercury to fall.

The heat and force that actuates all our storms comes from the intertropical belt of our planet, and they ever take their rise from the vapour that is pumped up by the great centrifugal engine of the equator, and from thence sent north and south in the form of cyclones, and from the offshoots of these come our more northern gusts and storms, never so great and grand in the temperate zone as in the tropical. It does not belong to the solid earth alone to develop the stratification of horizontal and inclined layers, since we find the atmosphere presenting a similar condition. We often see the stratum of clouds with their feather-edged outlines as clearly defined as any stratification in the solid crust of the earth, and when the setting sun throws her golden sheen over them their forms and figures require no vivid imagination to trace the geology of the atmosphere. We also find an expressive counterpart of the upheaving earthquake and lava-projecting volcano in the downheaving waterspout and fire-projecting thunderbolt.

The great balance of nature is vibrating all the time with exact rhythmical motion—the earthquakes, cyclones, and volcanos are but bars and semiquavers in the harmony of the universe, and we, short-sighted creatures, often look upon them as catastrophes, and, with the uneducated, as the visitations of an offended Deity.

The shell of atmosphere that enfolds the solid earth is full of life and full of uses. One of its uses is yet to come. When man shall have studied more fully its matter and its condition; its highways and its byeways; its mountains and its valleys; its tide of flux and reflux; its capacity to float ships of copper or iron (a balloon made of copper plate, weighing a pound per square foot, and of 100ft. diameter, will float in the air), then shall we also appropriate the knowledge of the atmosphere's geology to our use as a means of devising fleet and pleasant travel.

The individual who nowadays neglects to look at "Probability's" enunciation in the morning papers—especially when he says are a of low barometer will pass over you to-day—and determines to leave out his hay for the morrow, or goes out on the day's excursion without his umbrella, deserves to have his hat sopped with rain, and his garments soaked with an admonitory moisture.

A more advanced theory of the geology of the atmosphere will teach us to predict earthquakes, as it is already more than surmised that the elastic shell of the atmosphere pumps up a bubble in the shell of the earth, and then lets it sink again, as does the indiarubber ball the water when we press the ball, and then suffer it suddenly to expand.

COAL-CUTTING BY COMPRESSED AIR.

At the recent meeting of the Institution of Mechanical Engineers, a description of a machine for getting coal was read by Mr. Winstanley, and as the subject has more than usual importance at the present time we reproduce it almost in extenso. Mr. Winstanley said that at no time in the history of the coal trade had a greater want been felt than at the present for the substitution of machinery for manual labour in the working of coal, and never, since the year 1761, when Michael Menzies made one of the earliest attempts on record to construct coal-cutting machines, had the difficulties experienced by coal proprietors been greater than now—a time when it is almost impossible to make production keep pace with the demand, and when the difficulty is further increased by the lessened output or production which accompanies a high rate of wages. Any improvement, therefore, in the working of coal mines which would increase the quantity of coal got and diminish the cost of production, and at the same time relieve the miner of the most laborious and dangerous part of his work, must be a benefit, not only to those immediately interested in the work, but also to the consumer generally. The object of the paper was to describe a machine which had been worked daily or nightly for the last two years at the Platt-lane Colliery of the Wigan and Whiston Coal Company, in a seam of coal known by the name of the "Pemberton Little Coal." The coal is about 2ft. 4in. in thickness, and is notoriously hard, so much so, that it was with the utmost difficulty men were obtained to work it, and at one time the seam stood idle for some time, because colliers could not be got to work in it, whilst the proprietors had always to pay a higher rate for getting it than for any other seam coal they work. The cutter, which is the invention of the writer and Mr. Barker, is, like most others, driven by compressed air, which is conveyed down the shaft and along the main roads in iron pipes, and from the end of the drawing-road to the machine in indiarubber hose pipe, 2in. in diameter. The coal is cut by a spur wheel fitted with teeth, this wheel being 3ft. 6in. in diameter. The wheel cuts its way into the coal without any previous "holing," and the depth of the "holing" made by the wheel can be varied at will. The machine is drawn along the face of the coal as it "holes" or cuts its way, throwing out the small coal or slack between the tram rails upon which the machine runs. The chief advantages of the machine are the following: 1. What may be called the "swivel movement," by which means the cutter "holes" its own way into the coal, cutting, in fact, from nothing up to 3ft., and for bringing the cutter back underneath the framework of the machine when not at work, and in this position the machine can be taken through any narrow roads or portions of the mine without the necessity of removing the wheel from the machine. Another advantage is that of applying the power to drive the cutting-wheel directly on the periphery of the wheel; whilst the mode of gearing also allows the small pieces of coal or slack to fall through to the bottom, so as not to lock or clog the teeth of the machine. The average rate of holing by the machine is from 25 to 30 yards per hour, according to the material the machine is holing in; but this, the writer said, was, after all, a matter of no great importance, as the great points to be considered were the amount of work the machine would do, and how it would do it. The machine in question had frequently cut the whole length of the face of 120 yards in a night, or between 7 p.m. and 4 a.m. This, however, included all stoppages, such as meal times, changing cutters, &c. In the same mine five yards per day is much above the average work for one man with the pick; and under ordinary circumstances it is considered the work done by the machine would be equal to that of forty men. The machine works in the night time, the coal being removed by ordinary manual labour in the day. No powder is used, the coal falling by its own weight after it is holed by the machine. For over six months the machine had had little or no repairs, and the practical advantages found in its workings are, the writer said—first, that without the cutter they could not get men to hole this particular coal on account of its thickness: second, that when the seam was worked by manual labour the proportion of coals and slack was as three of coal to one of slack, and with the machine it is eight of coal to one of slack; third, that work is done independently of the men, who could not be got to work regularly, and consequently the production is more certain with the machine. The actual cost of getting the coal by the machine and by hand labour had been found, from the payments made during a period of six weeks at the Platt-lane Colliery, to be as follows:—Hand labour, 3s. 6½d. per ton; machine labour, 3s. 1½d. per ton, showing a saving of 5d. per ton by the machine. This profit however, was considered to be absorbed by the expense of compressing the air for the machine, and by interest on outlay, and wear and tear. The increased value of the produce, in consequence of less slack being made by the machine than by hand labour, was estimated as follows:—By hand labour, 3 tons of coal at 11s. per ton, and 1 ton of slack at 7s. 3d. per ton = 40s. 3d., or an average value of 10s. 0¾d. per ton; by the machine, 8 tons of coal at 11s. per ton, and 1 ton of slack at 7s. 3d. = 95s. 3d., or an average value of 10s. 7d. per ton, being an increase of 6¼d. per ton in the value of the coal when worked by the machine. In a seam of coal a few inches thicker than that of the Platt-lane Colliery, and under more favourable circumstances, it was considered there would be a saving over manual labour of from 25 to 30 per cent. The cost of getting the coal by the machine, given at 3s. 1½d. per ton, could not, however, be taken as a correct representation of the cost, the one at the Platt-lane Colliery being the first that was put to work, and, as a commencement, a liberal rate of pay was given to the man attending it, as an inducement to give it a fair trial. The same man has now been working the machine on contract for the last fourteen or fifteen months, and now earns more than three times as much per day with the machine as he previously did with the pick.

The President (Mr. Siemens) said:—According to the paper, there is an economy in working by the machine; and another advantage which every one will appreciate is, that the machine, I presume, does not strike, and that men, to superintend its working, will be more readily got than men picking at the coal itself.

Mr. Fidler, who has the machine at work, said it now had had a fair trial, and, he thought, must make its way. The machine in question, however, had not sufficient ground to work upon, or they could by its use effect a greater saving than 5d. per ton in getting the coal.

Mr. Lawrence said it was not the all-important point to compare the cost of the machine with the wages paid to the miner, because, if it worked in a seam of coal which could not be worked economically by men, he thought it would prove of sufficient value without any comparison as to the cost of manual labour. It seemed to him, however, that there were some classes of coal in which the machine would not work well, and that with soft coal it would very soon jam itself up. He would like to know what depth of coal was left below the holing, and whether the wheel was not likely to be jammed by the coal coming down.

Mr. Winstanley said the depth of the coal below the holing was about 7in. in this instance. As to the question in respect to the coal falling, the man who worked the machine had wooden wedges which he inserted behind the machine to prevent the coal coming down. In this seam the coal was very firm indeed; and it very seldom happened that it came down and jammed the wheel. They had not had any experience yet in a very soft coal, but he thought cutting machines would not be required where the coal was soft, because it could be cut easily enough by hand.

Mr. Fidler, in reply to a question, said they did not take any coal out before they started the machine, as it worked its way in itself. In reply to another question, he said the machine was not stopped once a month in consequence of the teeth of the cutter getting out of order.

Mr. Menelaus said he had paid much attention to the question of cutting coal by machinery, but for their purposes in their district he had never seen a machine which he thought could possibly compete with colliers' labour, and he was very sorry for it. He found that the holing was about one-tenth of the whole labour of the collier, and in his district there was really very little of it, owing to the soft nature of the coal; so that the whole economy they could get was a saving upon 10 per cent. of the labour of the collier. What the increased price of and difficulty in managing, labour, might yet bring them to he did not know, but he confessed he had given up as hopeless the introduction of coal-cutting by a machine of that kind in his district. He had seen and paid attention to every machine, and he could say that if Mr. Winstanley's was not the best, it was one of the best; and if any machine would succeed in effecting its object this one was as likely as any he had seen. He could easily understand that for thin veins and hard coal it might be introduced with very great economy, but for soft coals and thick veins it was not likely to be of much use. He was hopeful that it might be introduced, and if they had seams in the Dowlais district which he thought it would work he should be very glad to give it a trial.

The President, in proposing a vote of thanks to Mr. Winstanley for his paper, said he was certainly disappointed to hear a man of so large an experience as Mr. Menelaus speak in faint praise of the machine. He was quite sure, however, he would be the first man to change his opinion, if the inventor could prove there was an advantage to be obtained even in soft coal; but, in regard to hard coal, all seemed to agree that considerable advantage might be derived from the use of this machine.

CUT-NAIL WORKS AT MIDDLESBROUGH.

MESSRS. JONES, BROTHERS, & CO., of the Ayrton Rolling Mills, have inaugurated a new branch of industry in Middlesbrough. On about an acre of ground adjoining their mills they have erected thirty nail-cutting machines, three shears for cross-cutting, a number of grindstones, lathes, and drilling-machines, requisite for making tools and keeping them in order. The cut nail trade is a special branch of a number of trades included in the term nail-making. The nails are made out of sheets or strips of Cleveland iron, and the thickness of the sheet varies according to the length of the nail required. The sheets are cut into strips transversely, the width of the strip being identical with the length of the nail. A youth "feeds" the machine with strip, which is seized by a "clamm," and turned over at each cut, the nails being produced at the rate of from two to three per second. The machines are constructed by the firm of Messrs. J. Rice and Co., of Birmingham, and embrace the latest improvements in nail-cutting machines. The machines are driven by a horizontal engine, the steam power being derived from two horizontal boilers, which are fixed outside of the building. Foundations are put in for another engine, to be coupled to the one already erected, when additional machines are laid down. Provision is also made for the erection of half a dozen "washer" machines. The sheets from which the nails are made are manufactured in the adjoining mill belonging to the firm, and an interesting system of three-high sheet rolling has been introduced for the purpose of turning out those sheets more rapidly, and with a better surface than is done by the old process. Generally, cut nails are made in Birmingham, Leeds, Manchester, and Gateshead. At present, the price of cut nails, from 3in. to 6in., is £22 per ton. There is no place in the United Kingdom where cut nails can be manufactured cheaper than at Middlesbrough. The town is also favourably situated for the London and Scotch markets. The works are producing rose, clasp, and clout nails, joiner's sprigs, ceiling brads, floor brads, lath nails, colliery plate nails, and any other class of cut nail not less than 1in. in length. The machinery is capable of making about forty tons per week, but the works are laid out for ultimately turning out about 100 tons of cut nails per week. The building is erected with the view of giving as much light as possible to the interior, and for this purpose a good portion of the roof is constructed of glass.

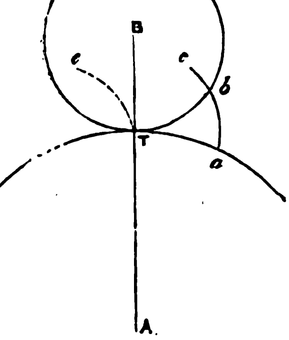
MECHANISM.*

(Continued from p. 507.)

THERE are four recognised modes in which a near approach may be made to a faithful reproduction of rolling contact by a process of sliding.

In Fig. 13, suppose that A and B are the centres of two shafts, then A B will be the line of which we have so frequently spoken as that in which is the pathway for the communication of motion from one wheel to the other. If the point T, at which that motion is communicated from one to the other is invariable, then the relations between the velocities of the two shafts will also be invariable.

FIG. 13

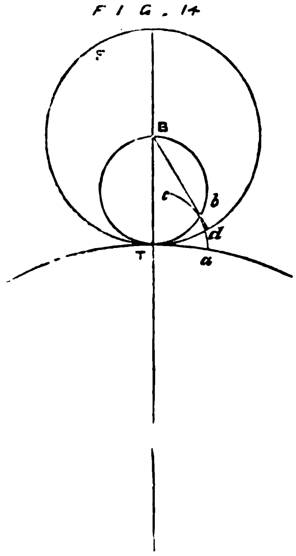


Suppose the circle and portions of circle to be the wheels keyed on the shafts, then one mode of determining the form of a contrivance for conveying motion from A to B by sliding, similar to that conveyed by rolling, is thus: Let there be at b, in the rim of the circle round B, a pencil-point, and suppose a sheet of paper to be gummed on the back of the wheel round A. Then, with the pencil-point at b resting on the paper, and b being at a, and the circle round B be rolled freely like a wheel up the hill from (a) to T, then the pencil-point will trace the line $a\ b\ c$. Now, suppose a piece of wood to be shaped like $a\ b\ c$, and to be attached by an arm to move round A, and suppose an arm to be fastened to move round B, and to have a pin in it where the pencil b was. If, now, the arm with the curve ($a\ b\ c$) be placed so that a is at T, and if the arm with the pin b be placed so that b is also at T, then if the arm with ($a\ b\ c$) be moved, pressing forward the pin b, it will be found that the pin will so slide up the curve $a\ b\ c$, as to reach "by sliding" the exact point b, which it would have reached, had the circular wheels "rolled" truly upon each other.

If, now, we increase the number of these curved arms and pins, or if we remove the rolling circles and put on others, which, not touching, carry curved arms and pins, then the one will be a wheel with the requisite number of teeth, each curved as ($a\ b\ c$) and the other will be a pin or lantern wheel, such as has been previously referred to. These pins are well and good for producing motion, but they are very much like a steam-engine which looks very well and very pretty so long as it has no work to do, but as soon as you put it to work there is a breakdown. If you put work upon these pins on wheels they will very soon break down. Prior, however, to a rejection of a scheme of teeth and pins, which has some very commendable features, the mechanic endeavours to avail himself of the labours of the mathematician, by strengthening the pins by means of end framings. Thus the pin-wheel becomes a "lantern" or "trundle" wheel. (See Fig. 6.) It is, however, desirable to try if we can find some substitute for the pin, or some other contrivance. Hence the mechanic has again to apply to the mathematician. The mechanic says, "I want something stronger than a pin;" and the mathematician says, "then you must put a line there." He adopts a process which Fig. 14 may serve to illustrate as a second stage of development.

Assuming the explanation which has been given with the former figure, instead of the circle round B rolling as a wheel on that round A, let a circle whose diameter, T B, is the same as the radius of the former circle, B, roll up a T, the curve traced on the paper will be the one ($a\ b\ c$). Putting the curve ($a\ b\ c$), as before, to an arm moveable about A, the mathematician could easily show that if this arm has to produce the same effect on the circle, F, as in the former case was produced upon the circle round B, it will be requisite to do away with the point or pin, and instead thereof to put a straight arm (B b d). With such an arrangement the mathematician informs us that the sliding of the curve along or touching the straight arm (B b d), in the passage of the wheel on A from T to a, will communicate the same motion to the shaft, B, as though the two wheels on A and B, in Fig. 14, had rolled perfectly on each other.

FIG. 14

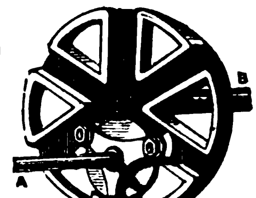


Here (referring to a model) are two wheels constructed upon this principle, and it is easy to see that what are usually called teeth are, in the one wheel, radial straight lines, and in the other, the curve of which we have been speaking, the motion is free and satisfactory, and it possesses a peculiar property in reference to the numbers of arms and teeth, as this model illustrates.

Recognising, as all must do who consider a general audience, that mathematical demonstrations, however divested of technicalities and complexities, appear "dull, stale, flat, and unprofitable," no apology is needful for interrupting the sequence of reasoning on which the true forms of teeth on wheels have been developed. Let us do so to turn to this interesting model possessing peculiarities which these demonstrations explain.

The wheel on the shaft B, Fig. 15, has on its face six radial grooves; on the shaft A is a smooth-faced pulley, having three pins at equal circumferential distances on a circle whose diameter is equal to the radius of the grooved pulley on B. On each of these pins is a small roller, fitting or nearly fitting the grooves. If now the shaft A be rotated, you may notice that each roller slides backwards and forwards in its diametrical pathway, and it is interesting to watch how equable is the motion and how neatly it is transferred to the grooved wheel and shaft B A, from roller after roller.

FIG. 15



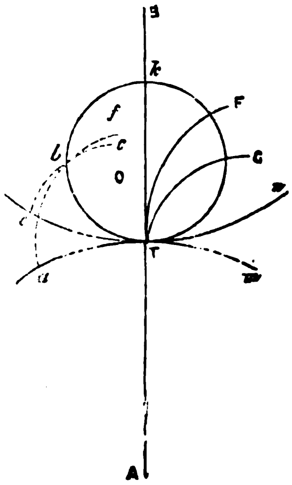
The velocity ratios are such that A makes two revolutions whilst B makes one. Four radial grooves and two pins produce the same velocity ratios.

Two applications of this motion may be named. One is to compel a polished bead placed on the top of one of the pins to describe a straight line. This bead thus moving causes a reflected light, as that from a candle, to appear as a straight line. Thus from two or more lights are formed two or more straight lines. Hence the intensities of the lights can be compared, and the instrument becomes a photometer. Another use of this motion is to obtain what, by a misnomer, must be called "a parallel motion;" the end of a piston being attached to one of the pins will, of course, be guided in a rectilineal path.

It will be observed that the two methods already suggested for making available the principle of sliding to accomplish the results of pure rolling, are applicable only to wheels of the sizes for which the calculations have been made, and working in one direction only. It is very desirable that rotation in either direction may be communicated, and that either one wheel or the other may be the driver, and that they may run freely when geared with different sizes. If, then, the mathematician cannot provide for the mechanician and the mechanic some principle of more varied application, and enable him to use wheels with teeth made so that of an extended set any two may be put in working gear—if this cannot be done, the complexities of wheel-work would almost be a bar to the use of it.

These considerations led to a generalising of the principle hitherto described. In Fig. 16 (T b k) the circle which rolls upon (a T m) is taken of a diameter smaller than the radius T B. Let it roll on (a T m) from T to m, and describe the curve T C. Instead now, of taking either a pin or a radial line, let the same circle (T b k), roll in the inside of (n T e), then will the point, T, describe the curve T F. If, now, these curves be the shapes attached respectively to the shafts, A and B, they will (mathematicians tell us) communicate the required motions, even though the sizes of the wheels on A and B be variable. This gives that extensive generality to the construction which enables mechanics to keep wheel patterns and wheels within a moderate number.

FIG. 16



The previous explanation of the principle upon which the most accurate system of teeth for a specific purpose can be formed, admits of only a slight deviation from perfect workmanship. There is another plan very generally adopted, which proceeds upon a different view of the relations between the driving and the driven wheel. Fig. 17 is intended to explain this method. The dotted circles touching at T represent what would be the circles if perfection of rolling were practicable. D H and E F represent other smaller circles or wheels. Through T draw E T D a common tangent to D H and E F. Let us suppose T D to be a piece of string having a pencil at T, and we proceed to wrap T D round the rim of D H, the pencil would trace the curve, K T H. Transfer the pencil to the end, T, of E T, and wrap round the rim of E F, then will the curve F T G be traced. Teeth formed with these curves, and placed upon wheels fixed to the axles A and B, would cause these axles to move as though moved by the one dotted circle rolling on the other. Wheels formed upon the curve named in the first two methods (Figs. 13, 14) are said to have epicyclic teeth; those in the third method (Fig. 16) are called epicyclic and hypocyclic teeth; and those upon the last method (Fig. 17) are called involute teeth.

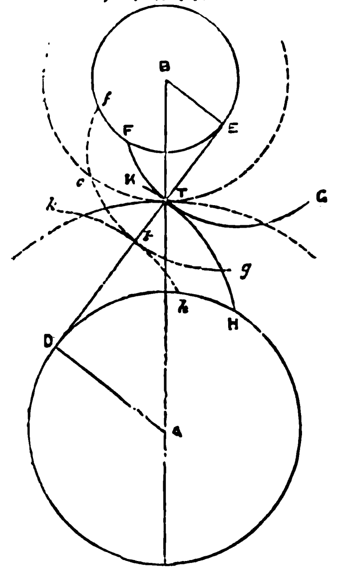
The explanation now given will to many appear deficient. For example, it is wanting in any attempt

* By the Rev. ARTHUR RIGG, M.A., being the Cantor Lectures delivered before the Society of Arts.

to show that the line in which these sliding surfaces transmit the motion is a line which always passes through the point T. To show this involves a property of the curves used, and, as mechanicians or mechanics only, we must accept the mathematician's statement that it does so. Should any one present desire to follow out the inquiry, he may refer to Professor Willis's "Principles of Mechanism," or to Professor Goodeve's "Elements of Mechanism," both published by Messrs. Longmans.

One difference between teeth formed upon the epicyclic and involute principles may, however, be stated. The action of epicyclic teeth when crossing the line of centres A B, and therefore when in the act of transferring motion, is always, at T, perpendicular to this line of centres, A B, whereas the action of involute teeth is always in the direction of the common tangent, as D T E, Fig. 17. Hence,

FIG. 17



owing to the great strain this oblique pressure puts upon the shafts to which the wheels are keyed, the latter (viz., involute teeth) are not adapted for the transmission of pressure or the communication of power. For modifying motion, or the simple communication of velocity, involute teeth are valuable. They have, too, this further advantage, the tooth of one wheel may be made to touch both back and front of the other. Suppose two wheels thus perfectly made, then, by a very slight increase of distance of the centres, there will be a sufficient space and clearance, and so that which is sometimes wrongly called "backlash," will be reduced to a minimum. Hence, too, with involute teeth, what the microscopist calls "loss of time," is not a serious inconvenience to these workers in a field of science where "time" is so valuable that none can be spared for the tolerance of what the mechanic generally considers to be necessary, safe, and inconsiderable.

Such being the principles which govern the formation of teeth in general use, and as wheels are employed in all extremes of varying velocity, an inquiry naturally arose at a very early date—what is the size of the smallest wheels in any system which shall insure that a second tooth is coming into position before the acting or driving tooth has quit contact, and thus that jarring or shaking be obviated which occurs when there is a sudden transfer of the source of motion? Such, in fact, as may be illustrated by the periodic brightening of a gas-flame when the mechanism of a gas-meter is not well arranged and balanced. The mathematician answers the inquiry thus:—

The least numbers which can be safely employed

Of involute teeth are	25
Of epicyclic teeth	12
Of cylindric teeth, or pins	6

Pin-wheels, as deduced in Fig. 13, ought always to be followers and never drivers. The reason is very simple, and may be illustrated in this way. If you take a stick and draw it backwards, with the end resting on the ground, you can do so easily, but if you attempt to push the stick in front of you it is continually being shaken or stopped. In other words, if the stick be drawn towards the side on which it makes an acute angle, the following is smooth and easy. If the motion is towards the obtuse angle, such is not the case. It is the same with a pin in a wheel.

In Fig. 13, suppose B is driving A, then the pin would come in contact with the tooth (*c b a*), and in order to turn the wheel, A, it would have, as it were, to rise up the hill, from *b* to *a*, of this tooth. It would have to do with the tooth, practically, what you have to do with the stick when you push it forward over the rough ground, and the resistance so met would produce a constant jarring; whereas, if the pin slides down the tooth, as when A drives B, there is that sliding motion which is characteristic of toothed wheels, enabling the engineer to attain to perfection of rolling contact.

So much for the teeth of wheels. Those teeth slide on each other, and we have therefore a motion communicated by sliding only.

ON MEASURING TEMPERATURES BY ELECTRICITY.*

THE truth revealed to us by one of the younger branches of physical science, which has been cultivated and expounded nowhere more effectually than within these walls, has divested heat and electricity of their mysterious character, and has taught us to regard them simply as "modes of motion." Light also has been shown to be identical in its nature with heat, and the only remaining physical agency, "chemical affinity," has been recognised as a force differing only in "quality of action" from the others. According to these views, force, in whichever type of action it presents itself, is as indestructible as matter itself, and is, therefore, capable of being stored up and measured with the same certainty of result. We have a unit of force or the foot-pound, and a unit of heat, or the heat necessary to raise the temperature of 1lb. of water through 1 degree Fahr., and it has been already proved that 772 units of force are the equivalent value of one unit of heat. Again, the chemical force residing in 1lb. pure coal is equal to about 14,000 heat units, or 14,000 × 772 = 10,808,000 foot-pounds = 4,825 tons lifted 1ft. high.

Questions regarding the quantitative effects of heat present themselves, however, much less frequently for our consideration than questions regarding its intensity, upon which depends the nature of the phenomena surrounding us at every step, both in science and in ordinary life. The instrument at our command for determining moderate intensities or temperatures, the mercury thermometer, leaves little to be desired for ordinary use; but when we ascend in the scale of intensity, we soon approach a point when mercury boils, and from that point upward we are left without a reliable guide. The result is that we find in scientific books on chemical processes statements to the effect that such or such reaction takes place at a dull red heat, such another at a bright red, a cherry red, a blood red, or a white heat—expressions which remind one rather of the days of alchemy than of chemical science of the present day. There are pyrometers, it is true, but these are either of a complex nature, or little reliance can be placed on them.

FIG. 2 FIG. 1

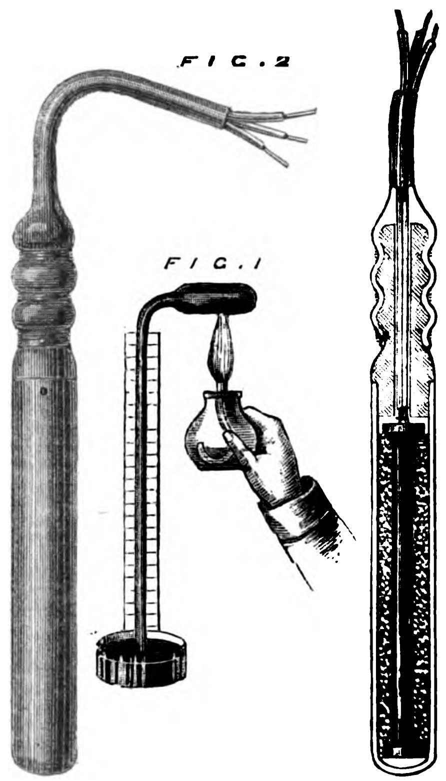


FIG. 3

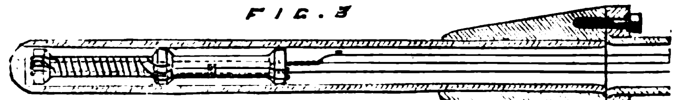


It is my purpose this evening to place before you an instrument by which I hope to fill up to some extent the existing gap. It is the result of occasional experimental research, spread over several years, and it aims at the accomplishment of a double purpose, that of measuring high temperatures, and of measuring with accuracy the temperatures of inaccessible or distant places.

But before entering upon the details of my subject, I propose to place before you an instrument which fulfils, in principle, all the conditions essentially necessary in thermometry, and is at the same time the very first instrument that was ever proposed for measuring temperatures. I speak of the air thermometer by Galileo! It can be shown on theoretical grounds that the expansion of a permanent gas at constant pressure is the most perfect index of temperature. It is, in fact, the degree of energy of the atomical motion in an elastic fluid which determines its volume, and which constitutes at the same time its temperature.

The air thermometer consists simply of a bulb of glass with a long tubular stem, open to the atmosphere at its extremity. If I heat the bulb (by dipping it, for instance, into boiling water), and put it into a holder, with the hollow stem reaching downward into a cup of mercury, the air within the bulb will no longer communicate directly with the atmosphere, because the mercury is interposed. If now I cool the air within the bulb, by the external application or iced water, its heat motion will diminish, and its volume would be reduced proportionally, if the external atmosphere could enter freely to fill up the vacancy thus created. But inasmuch as the external air cannot enter, a reduction of pressure will take place, which, according to the law of elasticity by Boyle, must be proportionate to the reduction of volume at constant pressure. The difference of pressure thus created between the bulb and the external atmosphere will be balanced by the column of mercury rising up into the tube, and the elevation to which the mercury attains is a true index of the temperature to which the air in the bulb had been previously heated. This is true with regard to all temperatures, from the lowest to the highest, and the instrument may be termed a universal thermometer. If the bulb could be cooled down to 273° Cent. below the zero point it would follow by the law of Charles that the elastic pressure of air would be reduced to nothing, that is to say, the motion of the particles of air, which we call heat, would have ceased, and we should have reached the point of absolute zero, a point which has been theoretically established also by other means.

Practically, such an instrument would be most inconvenient; its indications would have to be corrected by calculation for barometrical variations; the capacity of the descending tube, which contains air not subjected to variation of temperature, would have to be taken into account, and no reliable observations could be arrived at without taking special precautions, such as are only within reach of the experimental physicist.

[The other known methods of measuring ordinary and furnace temperatures were here passed in review, and the limits of their application pointed out. They were classified into:—Thermometers, by expansion of liquids; thermometers, by the expansion of solids; pyrometers, by chemical decomposition of solids, comprising Wedgwood's and Deville's pyrometers; pyrometers, by observing the melting point of metals; pyrometers, by thermo-electricity; pyrometers, by exposing a copper or platinum ball of known heat capacity to the heat to be ascertained, and of quenching it in a measured quantity of water.]

The instrument which forms the subject matter of my discourse presents many points of analogy with the air thermometer, if we substitute "electrical resistance in conductors" for "expansion of gases." Both these effects are functions of temperature, increasing with the temperature according to progressive laws, which in the case of the gases we call the law of Charles, and in the case of conductors the law of "increase of electrical resistance with temperature." The latter law, which is of recent origin, had already been partially developed by Arndsen, Swanberg, Lenz, and Werner Siemens, when my attention was directed, in 1860, towards an application of the same to the measurement of temperatures at places inaccessible to the ordinary thermometer. By means of the contrivance which I shall describe presently, I was enabled to tell, in the testing cabin of a cable ship, the increasing temperature of the interior of the mass cable in the hold, and to prove the necessity of transhipment of the same into a vessel fitted with water-tight tanks, which have been resorted to ever since, to avoid the danger of softening the guttapercha covering.

* Read at the Royal Institution, by Mr. C. W. Siemens, F.R.S.

I have arranged an apparatus for proving to you, in the first instance, that the conductivity of a wire of platinum or other metal is greatly influenced by its temperature; for this purpose I direct the current of a galvanic battery at will through two branches of equal resistance, each branch comprising a free spiral wire of platinum, and one of the coils of a differential galvanometer. By throwing the powerful light of an electric lamp upon the face of the differential galvanometer, and by throwing the image by means of a mirror and lens upon the screen, the audience will see any movement of the needle to the right or the left that may take place when I complete the battery connection. The resistance of both branch circuits being the same, no deflection of the needle is observable on depressing the key, but when I pass the flame of the spirit lamp under the one platinum coil the needle is thrown immediately over to the right, because the electrical resistance of the heated wire is increased, and consequently a larger proportion of the current is passing through the cooler circuit, exercising a preponderating influence upon the galvanic needle. When I withdraw the spirit flame from the wire the needle rapidly returns to its zero position, but in passing it under the other spiral wire the needle immediately deflects in the opposite direction.

If instead of using the open spirals I were to wind thin insulated wire of any pure metal upon two small cylindrical pieces of wood, and were to inclose the tiny spirals in small silver casings, as shown in view and in section by Fig. 2, taking care that the extremities of the spiral wires were soldered to thicker insulated wires leading respectively to the battery and differential galvanometer before mentioned, it follows that no deflection of the needle ensues when both the protected and equal spirals are dropped into a jar containing iced water. But if I take one of the spirals from the water and place it, for instance, by his kind permission, into the hand of our president without disconnecting the same from its leading wires, the balance of resistance will no longer take place, and a deflection of the needle to the right actually takes place. I will now endeavour, however, to re-establish the equilibrium by adding warm water to the iced water surrounding the comparison coil near me until no deflection of the needle is observable. This result being obtained, it follows that the temperature of the water surrounding the one coil must be identical with the temperature of our president's hand, and the delicate mercury thermometer which I have placed in my solution must give me the temperature of the distant place which I intended to measure. The temperature here observed is 89·5° Fahr., which is at this moment that of Sir Henry Holland's hands. This result is independent of the ratio in which the electrical resistance increases with temperature in the similar coils, and considering that the silver casings containing the coils are not larger than small pencil-cases, this method might be advantageously employed in physiological research. The one coil would only have to be placed within the cavity to be measured to enable the observer to read the temperature from time to time, without disturbing the patient, with the accuracy of which the mercury or spirit of wine thermometer employed is capable. But the same method is applicable for measuring the temperatures of distant or inaccessible places, such as the interior of stores or cargoes of materials liable to spontaneous combustion; of points elevated above the surface of the ground, or of great depths below for meteorological purposes, or for measuring the temperature of the sea continuously in attaching such a coil to the mariner's sounding lead. An error would in such cases arise, however, through the uncertainty of the resistance of long leading wires, if a complete remedy of error from such a course had not suggested itself. This consists in uniting three separate insulated leading wires into a cable by which the distant coil is connected with the measuring instrument. One galvanic circuit passes from the battery through one of the leading wires, through the distant spiral and back again through the second leading wire to the differential galvanometer and the battery, and the second passes from the same battery through the near coil, and through the third leading wire up to the distant coil without traversing the same, and back again through the second leading wire to the galvanometer and battery. Thus both galvanic circuits comprise the leading wires up to the distant coil, and all variations of resistance by temperature to which the leading wires may be subjected affect both sides of the balance equally. In constructing coils for measuring deep sea temperatures a large quantity of insulated copper or iron wire is wound upon a metallic tube open at both ends to admit the sea-water freely in order to impart its temperature to the innermost layers of the insulated wire. The coil of wire is protected externally by drawing a tube of vulcanised indiarubber over it, which in its turn is bound round by a close spiral layer of copper wire, whereby the sea-water is effectually excluded from the sensitive coil. By these arrangements the temperature of distant or otherwise inaccessible places can be accurately ascertained; but the method is limited to the range of temperature which can be obtained and measured in the comparison bath. In order to realise a pyrometer by electrical resistance, it is necessary to rely upon the absolute measurement of the electrical resistance of a coil of wire which must be made to resist intense heats without deteriorating through fusion or oxidation. Platinum is the only suitable metal for such an application, but even platinum wire deteriorates if exposed to the direct action of the flame of a furnace, and requires an external protection. The platinum wire used has, moreover, to be insulated and supported by a material which is not fused or rendered conductive at intense heats, and the disturbing influence of leading wires had in this case also to be neutralised. These various conditions are very fully realised by the arrangement represented on the following diagram, Fig. 3.

Thin platinum wire is coiled upon a cylinder of hard-baked porcelain, upon the surface of which a double-threaded helical groove is formed for its reception, so as to prevent contact between the coils of wire. The porcelain cylinder is pierced twice longitudinally for the passage of two thick platinum leading wires, which are connected to the thin spiral wire at the end. In the upper portion of the porcelain cylinder the two spiral wires are formed into a longitudinal loop, and are connected crossways by means of a platinum binding-screw, which admits of being moved up or down for the purpose of adjustment of the electrical resistance at the zero of Centigrade scale. The porcelain cylinder is provided with projecting rims, which separate the spiral wire from the surrounding protecting tube of platinum, which is joined to a longer tube of wrought iron, serving the purpose of a handle for moving the instrument. If the temperatures to be measured do not exceed a moderate white heat, or say, 1,300° Cent. = 2,372° Fahr., it suffices to make the lower protecting tube also of wrought iron, to save expense. This lower portion only, up to the conical enlargement or boss of iron, is exposed to the heat to be measured. Three leading wires of insulated copper united into a light cable connect the pyrometer with the measuring instrument, which may be at a distance of some hundred yards from the same. They are connected by means of binding-screws at the end of the tube to three thick platinum wires passing down the tube to the spiral of thin platinum wire. Here two of the leading wires are united, whereas the third traverses the spiral, and joins itself likewise to one of the two former, which forms the return wire for two electrical circuits, the one comprising the spiral of thin wire, and the other returning immediately in front of the same, but traversing in its stead a comparison coil of constant resistance. The measuring instrument may consist of a differential galvanometer as before, if to the constant resistance a variable resistance is added. If the pyrometer coil were to be put into a vessel containing snow and water, the balance of resistance between the two battery circuits would be obtained without adding variable resistance to the coil of constant resistance, and the needle of the differential galvanometer would remain at zero when the current is established. But on exposing the pyrometer to an elevated temperature the resistance of its platinum coil would be increased, and resistance to the same amount would have to be added to the constant resistance of the measuring instrument, in order to re-establish the electrical balance. This additional resistance would be the measure of the increase of temperature, if only the ratio in which platinum wire increases in electrical resistance with temperature is once for all established. This is a question which I shall revert to after having completed the description of the pyrometric instrument.

(To be concluded.)

THE PROPERTIES OF CAST IRON.*

THERE are few things more interesting to one who is accustomed to watch the onward movements of natural and physical science than to observe the evidence of progression which has marked every process in the treatment and manipulation of cast iron. New efforts at improvement and economy are seen and heard of on every hand. Ingenious contrivances completed, or on trial, to diminish the cost of its production, or improve its quality, are strikingly manifested in the growing number of inventions under the stimulus of increasing competition. The progress of knowledge forbids us to cling pertinaciously to old opinions or old processes, or to pronounce improvements to be impossible, because we cannot at once discover the right mode of making them. The application of scientific principles to new mechanical contrivances, and a stricter attention to the properties of this material, may redeem us from reproach, and enable us to anticipate a time, and be destined to witness greater results and improvements than the most sanguine of us has ever dreamed of or ever hoped to see realised. To emulate and excel is a maxim and creed so excellent and useful that we should be the last to sneer at any exhibition of earnestness. I shall not attempt to foreshadow the results of the many attempts, chemical and otherwise, which have been made from time to time to improve the quality or increase the tensile strength of cast iron by rendering its fibres more dense, and its composition more uniform in texture. Whether this may be accomplished by chemical agency in the separation and absorption of impure and foreign substance, or by the union or mixture of other metals or substances, one of your members (Mr. Galloway) has made some efforts to explain. He has brought out and placed before you a proposal to combine lead with iron, so as to increase its homogeneity and strength. Although, as I believe, Mr. Galloway was somewhat cavalierly treated in discussion, I by no means join in the opposition to his suggestions and efforts. It is well known to chemists, and is, indeed, one of the deductions of the atomic theory, that metals and other elementary substances combine with each other by ordinary chemical affinity, and it has been accurately demonstrated by analysis that their combinations invariably take place in certain definite proportions, in fact, in simple multiples of those proportions. The numbers which represent those simple proportions represent also the relative weight of the atoms to each other. Definite chemical action and union can only exist when these conditions are present, and exist in the combination of two or more metals when joined by a state of fusion. For example, our mixtures of two metals, composed of copper and tin, or copper and zinc, known as gun-metal and brass, are not composed of the two metals in their atomic weights and equivalents. No chemical combination exists between them, but the simple condition of a state of mechanical suspension of their particles in contact with each other, without any definite or existing chemical union. Hence, the trouble and inconvenience so well known and often experienced by our brass founders, arising from the permeating action of copper and its constant tendency to separate itself from the tin by reason of its greater specific gravity, and the higher temperature at which it is fusible.

I do not know in what proportions Mr. Galloway proposes to mix the two ingredients, iron or lead, or for what special purposes he anticipates the compound metal will be best adapted; but, for a mixture to produce chemical combination, and insure the conditions I have just referred to, the relative atomic weights of the two metals would be, for the iron 28·0, lead 103·7. Specular metal, one of the hardest and most dense mixtures, although extremely fragile and brittle, is composed of copper and tin, in the proportions of about two of tin to one of copper. The atomic proportions begin nearly in those of the atomic weights, or for tin 59·0, copper 31·7; but, since this metal was known and in use before the discovery of the atomic theory, its discovery must have been the result of chance or experiment. As, however, a great deal of valuable information may yet be acquired respecting the properties of metals in combination with each other, by a careful study of the atomic theory in its relation to metals and their compounds, I recommend it to your consideration in its more exact and extended aspect and form.

Time will not permit that I should further pursue the investigation of this part of my subject, and I shall proceed to direct your attention to that which has high claims on our consideration at the present time, and is forced on our notice by the advocates of high engineering in their importunate demands for extreme pressures and great expansions. The advantages or disadvantages of extreme pressures with great expansions are eminently controversial points, but as the use of high pressed steam involves a high temperature, it is a vital question as to how far cast iron is capable of sustaining those pressures for any great length of time, under such conditions as those we have referred to. By way of illustration, let me refer to the case of a cylinder of the moderate dimensions of 30in., filled with steam, say of 200lb., a pressure which is said to be actually in use, and giving good results both as regards economy and performance. The area of such a cylinder would contain about 706in., which, multiplied by 200, would equal a pressure inside it of about 141,200lb. acting against the two ends and around its internal circumference, in a line parallel to its axis, and tending to produce rupture in a tangential direction. To contend against this force, we have the resisting power of some 94in. contained in its circumference, assuming our metal to be 1in. thick. Now, if we divide 141,200 by 94, we shall have a quotient of 1,396, equal to three-quarters of a ton of strain per square inch. The mean of many experiments shows that the average tensile strength of cast iron is nearly 7 tons to the square inch of section. Therefore, we may assume the force exerted by the steam on the inside surface of the cylinder would be about one-tenth of its breaking or bursting strain. We may consider this a very safe and moderate margin on the right side of security. I am by no means insensible to the modification this extreme strain would undergo from the accomplishment of motion by the performance of work, but this favourable condition would be considerably diminished from the constant and repeated blows from the steam entering the cylinder, and its repellant and expand-

* Abstract of a paper read by Mr. Laird at a recent meeting of the Association of Foremen Engineers.

ing action on the piston and the ends of the cylinder. But steam of 200lb. pressure has a temperature of 387° Fahr., and we must now introduce and deal with the irresistible forces produced by the high temperature of such extreme pressures. For, although the experiences of our workshop practice show that the results of cold inducing straining from compression, are oftentimes far more destructive in its effects on cast iron than heat causing expansion, it is found that increments of heat, by extending and stretching the particles of cast iron, always causes a diminution of strength.

According to the experiments of Professor Daniel the elongation of a bar of cast iron due to 75° is ·000416. Now, 75° is contained in 387° five times, therefore five times ·00046 = ·00233, about 1/500 of its length. The compressibility of cast iron is greater than that of wrought iron, and a ton per square inch is capable of compressing through 1/6000 of its length, and as the above expansion was nearly 1/3000, the power exerted must be nearly 2½ tons per square inch. Now, although danger might not perhaps be apprehended from simple pressure, yet, when these pressures are accompanied by motion, and that of an intermittent kind, there might be some risk of a strain being produced by accumulation, far greater in amount, and being sometimes forward and sometimes backward, far more destructive in its effects than simple pressure. From these considerations, it becomes a question of some importance, and one requiring attention, as to how far or to what extent the elasticity of cast iron is capable of sustaining expansion when it is subjected to high temperature, and when the expansion is very considerable from that cause. It is to be regretted that the limits of this paper will not permit us to enter into the experimental details and subsidiary inquiries connected with this extensive and laborious investigation, the details of which are always ingenious and instructive; this consideration will amply repay the minute study of the mechanical student and workman. It is principally by the collection of facts and accurately recorded statistics that we can gather data for the solution of such questions. Perhaps, at the present time, no mechanical question has more claims on our attention than that which relates to the numerous instances of failure amongst the cylinders of the marine engines in the British Navy. The causes of these are mostly of a preventible nature, but there is so much confusion prevailing over the whole subject that the disposition to attribute such results to metal, to contraction, or some other equally indefinite cause, points to a want of a clear apprehension of the exact points wherein those cylinders fail. If we separate the forces of expansion into two groups, which shall include the strains produced both by the agency of steam itself, and likewise that which is due to expansion of the metal arising from the temperature of the steam. The interior surface of the cylinder will be understood to be exposed to two strains, each one acting at right angles to the other; and now, if fracture occur, it will certainly be in the line of those forces. In some cylinders, however, from a want of judgment on the part of their designers, or from oversight at the proper moment, those forces are entirely ignored, and disaster follows inevitably.

The remedy for all this unsatisfactory designing and practice lies in the investigation and adoption of the principles upon which endurance depends. In other words, we must wisely follow, as our guide, those groups of forces in all their radial and longitudinal directions, and observe the various appendages that are cast on and surround the tubes of cylinders in a practical light.

Nearly allied to this section of our subject, there is yet to be dealt with what constitutes the gigantic and imperial question as to the suitableness of cast iron as a material for ordnance. This is a point of most intense interest and importance, for, although we are warned that cast iron, from its low tensile resistance and strength, is totally unsuited and unsafe for the requirements of ordnance of large calibre and power, we yet believe there is a successful future in store for the advocates of its use. With the example and practice of the Americans before us, with their manner of casting, and then of cooling their guns by means of a hollow, spiral tube, and streams of water flowing through it until the casting is in a condition for the lathe, we ought to grow wiser. Cast iron treated in this manner has thrice its previous strength. The astonishing superiority of such guns has been proved to be due, in a great measure, to the effectual manner in which the cooling is thus made to take place. In fact, rapidity in cooling a casting improves the quality and strength of the iron, by imparting to it closeness and density.

We have long believed, and recent circumstances have added to the strength of our conviction, that better results would be obtained in casting our heavy ordnance, if external longitudinal ribs, intersected by rings, were made to surround the circumference, the principal bands covering the seat of the cartridge and of the shot or shell behind the trunnions, the ribs gradually tapering off towards the chase and muzzle of the gun.

As the bursting energy and power of gunpowder is said to be 33 tons per square inch, or some five times greater than the tensile strength of ordinary cast iron, we are enabled to suggest and determine upon a section of sufficient, but yet moderate area, which would secure a given resistance to the explosive force of the powder, whilst insuring a margin of safety. This may be done without having recourse to those ponderous yet graceful forms so familiar to all of us in the Dahlgren, Parrot, and Rodman ordnance of the Americans, which, however, do not add to their strength, but which make them look heavy and unwieldy. Without wishing to annihilate your patience by the recital of what is speculative and uncertain, I cannot but avail myself of this opportunity of reminding you, that although cast iron from its low tensile strength seems inferior to malleable iron or steel, yet that its cheap and easy construction, and the quick and ready manner in which cast ordnance can be produced, will at all times entitle this material to consideration. The history of scientific discovery teems with proofs that it is very unsafe to predicate that no progress will be made in a direction which we may think to be a wrong one. Transatlantic steam navigation was pronounced by a very distinguished savant to be an impossibility—how many voyages are now made to prove that prediction a false one? When, therefore, we hear any one assert that cast iron is unsuitable for the purpose of producing trustworthy ordnance, and pronounce its doom as certain, if not already accomplished, and that no improvement is to be effected, and no progress is to be made in this direction, such remarks are not without their value, and they will not assuredly shake our faith in the ultimate triumph of cast iron over its detractors.

We now propose to glance for a moment at the indirect claims of our subject—to use a popular and political phrase of the day—and to notice the products of the modern school of engineering design and construction.

Those ponderous mechanical incongruities which we sometimes observe, and which are designated as steam-engines, suggest, in the exuberance of their malformation, notions of specimens of the extinct species of the pre-adamite world. But even as contemporaneous man dwelt then in tents of skins, with curtains hung round about them, and his descendants build palaces of alabaster, so may the descendants of the present race of engineers and machinists produce eventually works that shall combine strength with graceful outline and form—the utility of the modern, with the philosophic grandeur and beauty of the ancient style. It is to be deplored that with the exception of a few of the leading firms of this country, as certain agricultural implement-makers and small machinists, for example, no efforts seem to be made to introduce expression into the construction of engines, or to combine the maximum of strength with the minimum quantity of material. Our prodigality of material, indeed, seems only to be equalled by that of our fuel. There really exists, as a general rule, but little connection or affinity between the proportion and strength of a structure and the mass of material of which it is composed, or in the general outline and disposition of its parts. It is common to specify for an unnecessary margin of strength, apparently only with a view to meet the chances of mistake on the part of the designer. But why allow the incompetency of the designer, or the fancy of the overseer, to supersede mathematical precision or the cause of good taste and order? The ancient Greeks owed their superiority in architecture and sculpture to this characteristic. Thus, in columns, for instance, the details of mouldings and parts were multiples of diameters, whilst in figures they copied and reproduced everything with just scientific proportion and accuracy. Why should the details and parts of a steam-engine not be made conformable to some such plan? Upon what principles of mechanical science should unreasonable variations be allowed to exist? We find in the practice of wheel work wide differences in the arrangements of several firms and individuals. The proportion of the length of teeth to the pitch ranges from seven-eighths to five eighths of the latter.

Why should not something like uniformity of design, regularity of proportion, and ratio of material, be conditions subsisting between all the parts of an engine or piece of mechanism? That it is not so arises primarily from the want of purpose and of uniformity in technical education and scientific culture. Were it otherwise, economy of material would be secured and safety enhanced. Notwithstanding the importance of this subject, it is rarely mastered by the ordinary race of draughtsmen and mechanics in a way to influence their practice beneficially.

In the discussion which followed, Mr. Stabler said, as regarded the systems of ordnance, which from time to time had been started, he remembered the elaborate experiments and explanations given on the subject by Mr. Keyte, at the Woolwich Arsenal, about ten years ago. The endurance of cast-iron guns, hooped on Sir William Armstrong's principle, was at that time a vexed question, and Mr. Keyte had had much experience on the subject. It was then that the tensile strength of the several pieces of ordnance underwent severe testing, and the cast-iron gun with its cumbersome fittings sustained, nevertheless, a considerable explosive force. As to the best mode of casting cylinders there was much variety of opinion on the subject. As the author of the paper had pointed out, our incapacity of designing proportions that shall render the castings at once ornamental and safe was undoubted; but it might be shown, on the contrary, that the outline of a casting had really little to do with its intrinsic value. Mr. Laird had touched upon the chemical affinity which existed between certain constituents; it had even been shown that the influence of the earth's magnetism could not be disregarded with impunity, and the entire question had received and deserved great consideration at the hands of engineers, but the problem of good castings was far from being solved, although often the most palpable mistakes were made from sheer ignorance of first principles. The complex form of cannons had given way to a more simple pattern; sharp angles and corners which are perfectly useless, if not dangerous, have in many instances been abolished. It is the perfection of the gun, as an instrument, that must be aimed at; and, however plain it may look—to the really educated eye—such a piece of ordnance will ever command the greatest consideration. In the casting of large cylinders the most elaborate precautions had often failed to insure the desired success. Disintegration of the component parts is mainly caused by unequal and unsatisfactory cooling. However, a great deal might be done in bringing about more satisfactory results. Mr. Stabler then described a plan according to which the metal is more equally divided, and better disposed for the purpose of cooling. In the absence of a diagram the explanation was difficult to understand, but the casting is, as it were, honeycombed, cups at regular intervals being inserted, thus creating an almost uniform thickness of material all through. He went on to speak of the merits of steam-jackets, high pressure steam cylinders, and the employment of steel in casting cylinders. The substance in that case might be considerably reduced in thickness, but to all intents and purposes it was his opinion that for engine cylinders cast iron would hold its ground against all other materials.

Mr. Briggs briefly reviewed what had been advanced on the subjects of tensile and compressive strength, power to resist impact or shock, modulus of elasticity or stiffness, but he regretted that internal strains had hitherto received but little attention. He proposed to those who were able to take the matter up to construct cylinders of 2, 3, 4, 5, &c., inches substance, to burst them experimentally, and thus to ascertain a ratio which might be approximately correct.

Attention being drawn to the effect of rings placed outside of the cylinders, Mr. Bragg, who was understood in the main to corroborate Mr. Briggs, thought that there was one point which must not be lost sight of in accounting for the bursting of cylinders—viz., that there is more elasticity outside than inside. He demonstrated the fact simply and clearly by assuming that two beams, one 18in. long, and another 3ft. long, were stretched at the same time. He need not say what the result would be, but that clearly established the relation between the inside and the outside of a cylinder. He further said that as a matter of experience if a cylinder split lengthwise, the bottom remaining intact (which, by the bye, it did in one case out of a hundred), the line of fracture passed through the vent hole.

Mr. Jordan, who spoke from practical experience in the matter of hydraulic cylinders, thought that that was not difficult to account for. By drilling into the body of the cylinder a wedge is actually made for its splitting. There could, however, be no difficulty in avoiding these consequences. The drilling should not touch the body of a cylinder at all, it should be kept outside, and that was done by having a boss at the proper place.

Mr. Briggs replied that the boss itself would hardly offer a guarantee against fracture, that might take place right through boss and all.

Mr. Jordan thought that would undoubtedly occur where the engineer neglected his duty, and that was to see that the metal was properly mixed, and the moulders were prevented from having it all their own way. As to the question of rings, he had no doubt whatever upon the matter. Practically, they were of the greatest use in insuring the strength of the cylinder, but they were additions which people simply declined paying for. There could further be no question as to the possibility of fusing cast with wrought iron.

The Panama Canal.—According to the latest intelligence from the Isthmus of Panama new hopes are entertained about making a ship canal across that obstruction. After failing to discover a promising line for the excavation in the narrower portions of the neck, the American surveyors have gone back to Nicaragua, and now report a favourable place towards the north of the Isthmus, where they believe the enterprise can and should be accomplished. It cannot be doubted, however, that much greater difficulties stand in the way of this canal than in the case of that of Suez.

LETTERS TO THE EDITOR.

[We do not hold ourselves responsible for the opinions of our correspondents. The Editor respectfully requests that all communications should be drawn up as briefly as possible.]

All communications should be addressed to the Editor of the ENGLISH MECHANIC, 31, *Tavistock-street, Covent Garden, W.C.*

All Cheques and Post Office Orders to be made payable to J. PASSMORE EDWARDS.

"I would have every one write what he knows, and as much as he knows, but no more; and that not in this only, but in all other subjects: For such a person may have some particular knowledge and experience of the nature of such a person or such a fountain, that as to other things, knows no more than what everybody does, and yet to keep a clutter with this little pittance of his, will undertake to write the whole body of physicks: a vice from whence great inconveniences derive their original."—*Montaigne's Essays.*

**** In order to facilitate reference, Correspondents when speaking of any Letter previously inserted, will oblige by mentioning the number of the Letter, as well as the page on which it appears.*

263 P. XVIII. AQUILÆ—EYEPIECES—CENTRIFUGAL "FORCE"—PARALLELOGRAM OF FORCES — COMET — FIELD-GLASSES — SUNRISE AND SUNSET—AND THE HARVEST MOON.

[4653.]—IN compliance with the request preferred by "Epsilon" (let. 4588, p. 485), I have looked at the star 263 P. XVIII. Aquilæ, but confess that I should not have recognised it from his description. Webb's directions for finding this object are perfectly correct; and if "Epsilon" will get his namesake in Aquila at the bottom, or north, of the field of an eyepiece of the magnifying power he specifies, or perhaps of a rather lower one, he will see the star he seeks almost south of it, and on the other side of the centre of the field—in fact, after ε, it is the most conspicuous object in it. Now, however, comes the curious part of the matter, 263 P. *is*, I see, triple—*i.e.*, it has a second faint, and considerably more distant companion than the one whose position angle and distance Webb gives (from Smyth). Unquestionably, however, the position angle of—what we may call—the original companion is almost precisely 289°, while that of the more remote one is much nearer 20° than 110°, at which latter angle no star whatever is visible in my instrument. Moreover, the comes now under discussion is a good deal farther off than 14" from its primary. It is too faint to bear the illumination necessary to measure its position angle and distance micrometrically; but, at all events, the whole asterism by no means corresponds with "Epsilon's" description of the object he picked up, and which I have quite failed to identify. Should my querist be the possessor of an equatoreal, in proper adjustment, he ought, by taking the R.A. of 263 P. XVIII. Aquilæ as 18h. 54m. 9s., and its north declination as 14° 44·2', and setting his circles accordingly, to get it almost centrally in his field of view.

There is a tacit assumption contained on the letter (4634) of "Betsy Summercity" on p. 513, which it is necessary in the outset to correct. It is this, that the image formed by a properly-constructed achromatic object-glass is less perfect than one produced by a parabolic mirror. Now, disregarding the small and scarcely appreciable secondary spectrum, I assert, quite confidently, that one of Dallmeyer's object-glasses transmits an image in every way as optically perfect as the finest mirror ever ground, and that the Huyghenian eyepiece produces no more effect upon the one than it does upon the other. If we construct one of these eyepieces with two lenses of the same material, so placed that the distance between them is an arithmetical mean between their focal lengths, the combination is *ex necessitate* achromatic—*i.e.*, it magnifies the rays of all colours precisely alike, and shows a white image white, a green image green, and so on. A properly made Huyghenian would, in no shape or way, give "the necessary correction" to an "imperfectly corrected" object-glass; on the contrary, were the latter under-corrected, we should have the ultimate transmitted image fringed with red and yellow; and were it, on the other hand, over-corrected, such image would be edged with deep blue. As for curing spherical aberration, the Huygenian eyepiece would not do that either, because the kind of distortion which takes place in it merely produces the result of rendering equal angular intervals in different parts of the field non-correspondent with equal divisions of a micrometer covering it. Any object in a definite part (say the middle) of such field is sensibly free from distortion. Besides, Sir George Airy's formula enables the optician to eliminate the greater part even of this defect of aplanicity. I rather fancy, from internal evidence, that "Betsy" has been reading the description of the Huyghenian eyepiece as applied to the microscope, written originally by the late Andrew Ross in the "Penny Cyclopædia," and reproduced by Quekett in his work on the "Microscope," p. 167, *et seq.* I was quite aware that "B. S.'s" notion of employing a microscope as an eyepiece was not new. Our greatest living spectroscopist, Dr. Huggins, F.R.S., &c., used his Ross binocular in this way as far back as the year 1861, in order to obtain *quasi*-stereoscopic images of celestial objects. Nothing, however, ever came of it. Reverting for a moment, before concluding, to the subject of the secondary spectrum, I may reiterate, what I have before mentioned in these columns, that I saw last autumn an object-glass by Wray in which this was for all practical purposes cured, in fact, which was sensibly aplanatic. It had an aperture of 3·75 inches only, but exhibited the colours of Jupiter's belts marvellously; in fact, I question exceedingly whether any 6in. mirror could or would have shown this phenomenon much better.

I would join "C. H. W. B." (let. 4646, p. 514) in deprecation of such a term as "centrifugal *force*," the centrifugal tendency merely has its origin in the first law of motion.

It is something fresh for me to learn from "Marine Engineer" (let. 4649, p. 515) that ". . . to produce a double velocity requires the expenditure of a fourfold force;" because I have always hitherto been taught, and have believed, that a double force applied to the same body produces a double velocity in a unit of time, a triple force a triple velocity, a sextuple force a sextuple velocity . . . and so on to *n* terms. For example, let us conceive an iron ball to be dropped from a height, then at the end of one second, it will have acquired a velocity of 32ft. 2in.; but, having started with a velocity of O, will have fallen through 16·1ft. Let us now, though, further imagine that a magnet placed underneath our supposed ball begins to act upon it at the same instant as gravity does, and with exactly the same force, then, as that alone would impart a velocity to it at the end of the first second of 32ft. 2in., the combination of the two forces will induce one of 32ft. 2in. + 32ft. 2in., or 64ft. 4in.; and, inasmuch as the ball started from a state of rest, at the expiration of the second it will have fallen just 32ft. 2in., or exactly twice as far as it would have done if acted upon by either of the two equal forces alone. How "Marine Engineer" has mixed up "the theory of projectiles," with the simple and obvious law which I have attempted to illustrate it is not for me even to attempt to guess.

I can only say in reply to Mr. Grayson Golcar's query (12545, p. 521) that I don't know. I may perhaps add that I think it probable that this reply will be echoed by the rest of "our astronomical contributors."

It is practically impossible to answer such a question as that put by "Lambda" (query 12549, p. 521) without seeing the glasses of which he complains; but I should say that the appearance which he describes almost certainly has its origin at the eye-end of his field-glasses, and *may* possibly be a diffraction phenomenon, having its seat in the stops bounding the field of view. It might even be a spectral appearance, arising from fatigued retinæ; but, as I have implied before, it is idle to theorise in the absence of the offending instrument.

I trust that the following formula and example will enable "Delta" (query 12570, p. 522) to calculate the time of sunrise and sunset for himself. It is abundantly accurate for all ordinary purposes. Let us call the co-latitude of his place of observation ψ, the zenith distance of the sun z, and his North Polar distance d, and let us call $z + d + \psi$, 2 S, and the hour-angle from the meridian when the sun is on the horizon H. Then—

$$\text{Sin.}\ \tfrac{1}{2}\,\text{H} = \sqrt{\frac{\sin.\ (\text{S} - \psi)\ \sin.\ (\text{S} - d)}{\sin.\ \psi\ \sin.\ d.}}$$

By the aid of an example, we will put this into figures. At what hour will the sun rise and set, in lat. 51° 30', on August 10, 1872?

Here we have—

Co-lat. ψ	38° 30'
Sun's N.P.D. d	74° 35'
Sun's Z.D. z	90° 50'
2	203° 55'
S	101° 57'
S − ψ	63° 27'
S − d	27° 22'

Sin. (S − ψ)	63° 27' =	9·9516020
Sin. (S − d)	27° 22' =	9·6624586
Co-sec. ψ	38° 30' =	0·2058504
Co-sec. d	74° 35' =	0·0159148
	2)	19·8358258
Sin. ½ H =	55° 52' 15"	9·9179129
	2	

H = 111° 44' 30", and this in
Time = 7h. 26m. 58s.

Now the sun is on the meridian on the 10th at 0h. 5m. 8s., and if from this we take 7h. 26m. 58s. we get 4h. 38m. 5s. for the time of his rising, and adding the same quantity, 7h. 32m. 1s. for that of his setting. It must, however, be borne in mind that this is not rigidly accurate, since at his rising his north polar distance will be less, and at his setting greater, than the quantity we have assumed. This change in declination, which in the case of the moon is very rapid, added, moreover, to her perceptible parallax, renders the accurate calculation of moon rise, &c., a very complicated matter indeed, and one, the explanation of which would demand very much more space and many more figures than I feel at all disposed to ask you to grant me, or to print. May I advise "Delta" to compute a table of semidiurnal arcs for his own latitude? He will find the simple formula, and an example worked out, on page 461 of your thirteenth volume. (I must, by-the-way, ask him to correct the misprint of "T" for D on lines 12 and 23.) Such a table would be very useful to him on many occasions.

I will, after the Scottish fashion, answer the question (12591) of "A. S.," on page 552, by another. *Does* the harvest moon appear larger than at other times? I see that another of your correspondents, "M. A." (let. 4622, p. 509), appears to labour under the same hallucination as "A. S.," and to imagine that she does. I suspect the fact to be that people hear that the harvest moon rises, about the full, nearly at the same hour for some nights, and so look out for her on the horizon. Were they to watch her rising at other times, they would see that she would appear just of the same diameter as she does at that particular one. The question of the apparent increase of size of bodies as they approach the horizon is a very curious one, though. It is very marked in the case of a descending balloon; albeit, it may actually be travelling away from the spectator. This question has been mooted in "our" columns before, but I have no time just now to wade through the indices.

A FELLOW OF THE ROYAL ASTRONOMICAL SOCIETY.

PERSPECTIVE.

[4654.]—IN my first endeavour to introduce a glimmer through the wondrous Chinese sun-screen of M. Paris on this matter, some three months ago, I had sketched, but did not think of asking you to engrave, the diagram now given in Mr. Proctor's letter (4621, p. 509). I could not conceive any one requiring a figure to realise my simple remark that the top and bottom of the tower's picture were at distances from the eye just as different as those of the tower itself. Now, referring to the diagram, does M. Paris mean to deny that *ab* is "optically less" than *cd* in the exact ratio that AB is less than CD? It is marvellous that others, as "Bobo" (let. 4605, p. 489), will repeat that the reason "artists draw all vertical objects" without convergence because the upward convergence is "slight." It is neither slighter nor anywise less sensible than horizontal convergence in a street. It is simply that the pictured lines *must* be parallel *in order to converge rightly* in the eye. Similarly the "figures in a market-place" of M. Paris's last letter (p. 510), if standing in a rank parallel with the picture plane, must all be drawn of equal height, *in order that* the lateral ones may (in the eye) be duly diminished; and M. Paris, by making the latter shorter in his picture, would simply falsify the *drawing*, which branch of art (apart from *painting*) is matter of rigorous science, no more admitting of "compromises" than geodesy or arithmetic admits of compromises. It is true, as I have pointed out, there are a few trifling details wherein a picture to ornament a wall, and so to be viewed from various directions, away from the point of sight, should differ from a "cosmorama," *i.e.*, peep-show or stereoscope slide. These, however, only apply to artificially regular objects, as architecture and furniture; and the chief is, that the scene should not embrace above 40° or 50° of the horizon, though it may have far more range vertically for the reason I explained. The next, and perhaps only farther modification is that horizontal circles, as the caps and bases of columns or turrets, however near the sides of picture, should have the major axis of their ellipse horizontal, instead of rising toward the side, as rigorous drawing requires it. Again, the sun, moon, or a full fronting clock-face, however far from the picture's centre, should be circular, not elliptical, as strict perspective (or photography) would make them; but indeed the ellipticity would hardly be sensible except at greater distances from the point of sight than any picture is likely to place them.

These might be called "*gallery* compromises," *i.e.*, between the strict truth of a projection for one defined point of view, and one whose spectators are supposed to move. But none such will apply at all to a cosmorama, nor to a book illustration, or anything having a supposed single definite place for the eye; and any difference *of line* in "pictorial perspective" as distinct from "linear" in the phrase of "M. A.," p. 509, I must beg utterly to deny as sanctioned in any place or time pretending to real art. The sun's or moon's diameter in a picture must bear that relation to its architectural vanishing points that 32' or 34' bears to their real angular distances on the horizon. In no case can it be magnified without mere barbarism. One of Robert's views of the Pyramids grossly exaggerates the rising sun, to many degrees diameter. To make it true, the whole picture would have to represent the field of a telescope many miles from the objects; and in that case, of course the architectural vanishing-points would be perhaps as many yards out of the picture as they are inches. If any peculiarity of light or colour is held to convey to any eye an impression of greater size, let the painter so imitate the light or colour as to convey the same impression (or "illusion" if you will), but to falsify the size itself—to falsify *line*—is sheer blundering puerility; and there is no case of "compromise" in form yet described by "M. A." or M. Paris that is anything else, or that even Chinese would now (since the spread of photography) tolerate. As for the impressions given by a mountain slope in front view, and the picture of it, the latter, being vertical, cannot well avoid (except in a stereoscope) appearing the steeper of the two. I presume it would puzzle even M. Paris to give (p. 510) the "real slope" rather than "the apparent." If he means, however, that any one over-estimates the slope of outlines seen in profile, the same mind (not "eye") will equally over-estimate that of a *truly drawn* representation. The artist's business is to give the spectator the same means or *linear material* for judgment that Nature gives, and leave him to judge or misjudge accordingly. There are artifices in colour, or what "M. A." calls "pictorial perspective" (more properly "aërial perspective"), but the whole *form* or line system, and *every line* in a picture, is either true or false, just as each number in an almanac or a bank account-book is true or false; and cooked outlines are just as much or as little needed or tolerable in any world, artistic, "æsthetic," or what you will, as cooked accounts.

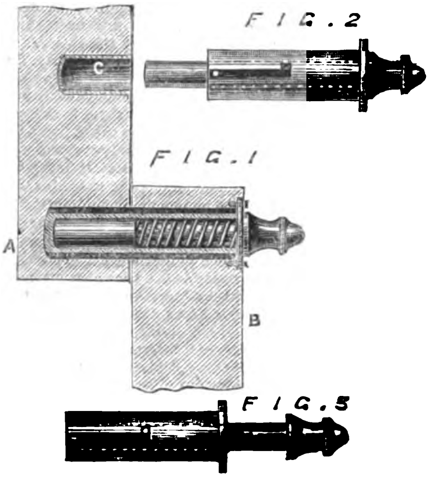
What Sir David Brewster cited a rectangular tower to illustrate was probably the straightness (as well as parallelism) that the eye, however near, attributes to the sides, though their images on the retina are decidedly curved, more so than the *entasis* of any column. If M. Paris would obtain for his stereoscope the Salisbury spire view that I long ago referred to, and which I find is marked "Sedgfield's English Scenery," No. 377, it would greatly enlighten him. It is perspective with *no* parallel lines, and with *three* vanishing points, the upper one or zenith probably the nearest of the three. It is a view, but not a picture, because the latter word implies a view projected on a *vertical* plane. A photograph of a tower, however near, taken on a vertical plane (as I have repeatedly told him), *cannot* have *any* upward convergence. Neither can a plummet, near or distant, detect any leaning in lines that do not really lean.

The optical corrections (so-called) in the Parthenon and other Greek buildings, are a wonderful evidence of refined art, but have really nothing to do with these perspective rudiments. It is quite certain those who contrived them would never have tolerated any outline-cooking such as M. Paris defends, in the representation of them or of anything else. Moreover, I doubt if many of them were "optical" in their object, so much as mechanical, or directed to high philosophic ideas of perfection. Thus the convergence of the axes of all the columns tended evidently to firmness, duration, and resistance to earthquakes. Their entasis was almost necessary if the workman (as Ruskin first remarked, I think) was on no account to cut *within* the straight line, any invasion within it being truly intolerable. Then the hyperbolic curves of the long courses must make them, from some central point, exactly fit the cone of rays from the sea horizon, evincing that they observed its dip, that Minerva's architects were no Hampdens of a poor nineteenth century, but were building on a globe of definite size, and knew it!

E. L. G.

NEW SASH FASTENERS.

[4655.]—THESE drawings almost speak for themselves. Fig. 1 shows the section of window closed; to open it to admit air you draw out the knob and throw



up the window, which will fasten itself at any height you may require. Figs. 2 and 3 show the bolt fastened and withdrawn. This is a perfect and simple fastener, and I am told does not readily get out of order. A and B in Fig. 1 represent the sashes, C hole made in them to admit bolt, which can be made at any height you require the window to open. J. W. RICHFORD.

ECONOMY IN USING COAL.

[4656.]—W. BROWNE (let. 4556, p. 468) very wisely suggests the use of fire-balls, made of coal slack and clay, as a substitute for coal, that has become and is becoming so very dear. These are used very successfully in South Wales, where they are made of culm (the small of anthracite coal) and wet clay, beaten together, and formed into larger or smaller balls, as a slower or quicker fire is desired. They make a very pleasant and economical fire for any weather, but more especially for warm weather, when a gentle fire for cooking only is needed. Some months ago you inserted the description of a mode for making these fire-balls impervious to wet, which I have tried to refer to without success. I think it was by dipping them into melted paraffin, but am not sure. The Welsh fire-balls being made of culm, containing little bitumen, burn with very little smoke or flame, the latter being chiefly that of carbonic oxide. Most of the heat produced by the flame is absorbed by the clay, and given off as radiant heat, less than usual being either conducted away by the grate or carried up the chimney—the way most of the heat of a common fire goes. Ordinary slack is not, I am told, so suitable for making fire-balls as culm is, but perhaps would be if some gas coke were added. Count Rumford recommended fire-balls to be made of equal parts of coal, charcoal in powder, and wet clay. He suggested that straw chaff or sawdust might be tried; also that balls, if to be used for lighting fires, might be dipped into a solution of nitre to make them burn easily. The clay in the fire-balls makes the ashes more dusty, but that is a slight inconvenience to set against the great economy. PHILO.

THE GULF STREAM.

[4657.]—I HAVE been much interested in perusing the article by R. A. Proctor on "Oceanic Circulation." I quite agree with him in retaining the term Gulf Stream, although I have long held the opinion that it does not all traverse the Gulf of Mexico; but what I wish more particularly to draw attention to is a method by which its presence may be traced which is not yet recognised by the scientific world. My idea is that it impinges on our west coasts at an angle much more nearly to a right angle than it is laid down in the chart which accompanies the article. I trace its effects on the coasts reaching from Brest to the North Cape, wherever they are exposed to the direct action of the Atlantic Ocean. A glance at the map will show a peculiar ruggedness of outline in contrast to the sandy shore of the Bay of Biscay. This characteristic marks the coast in the neighbourhood of Brest, the south-west coasts of Devonshire and Cornwall, the Bristol Channel to the Bay of Carnarvon, south-west and west coasts of Ireland, west coasts of Scotland, north of the latitude of Ireland, the Orkney, Shetland, and Faroe Islands, Iceland, and the coast of Norway to the north of the latitude of Scotland and the Orkneys. Whence this ruggedness of outline? It results from the absence of the protection of a sea-beach. If you observe a sloping sandy beach after an on-shore gale of wind, you will find that there has been a movement in a seaward direction, and probably the sand has moved seaward and left the gravel. This phenomenon admits of an easy explanation: an on-shore gale must necessarily raise the surface of the water in-shore. This, of course, creates a counter current in an opposite direction, and although this current may not have the power to move the sand when in a quiescent state, yet when the breaking wave stirs it up it will remove it in a seaward direction. A little reflection must convince us that the Gulf Stream must have a similar action on the shore as an on-shore gale, with this difference, that this action will be constant, not alternating with the change of wind from an on-shore to an off-shore breeze, as in the latter case there is nothing to counteract the natural action of the wave, which, taken *per se*, is always accumulative. I consider that the Gulf Stream is forced into its present position by the polar counter current which hugs the coast of America, but it must be evident that this was not always the case, as previous to the elevation of the Scandinavian peninsula, we have many proofs that this counter current came down the White Sea and along the Baltic, bringing the polar icebergs to this country, and when the land became too much elevated to allow of the icebergs drifting in our direction, we should still have the cold current and the thinner ice, keeping down the temperature of these islands so that glaciers would form on the hills. As to the geological period to which this change may be referred, I may remark that A. Geikie, in his "Scenery Geology of Scotland," p. 320, mentions a raised beach, about 40ft. above high-water mark, which contains Arctic shells, and thinks this elevation dates from the later part of the glacial period, which coincides with my view as being on the coast of Argyleshire and Inverness, consequently facing the Atlantic. If the Gulf Stream then ran in its present direction it would have removed this beach. He also mentions another beach about 20ft. to 25ft. above high water; but this only exists to the southward (page 323), where it is sheltered from the action of the Gulf Stream by Ireland. It is evident that the Glacial Period had passed at the time of this last elevation, as human implements have been found in it, showing that the climate was milder, and the island was inhabited—its absence to the north shows that the Gulf Stream had then changed its direction. I attribute the traditions we hear of the wasting away of the land on the south-west coast of England, in the neighbourhood of the Channel Islands, &c., to be a consequence of this change. J. WILSON.

AURORA.

[4658.]—AN aurora was seen here on Saturday last, the 27th July. At ten p.m. a bright diffused homogeneous light was visible over the northern horizon, from which at midnight shot up bright white streamers, which were well visible even in bright moonlight. This display seems to have been the conclusion of the hot and stormy period commencing on the 20th July. It is worthy of remark that the stormy period during January last was succeeded by the great auroræ of February 3 and 4, 1872. HERBERT INGALL.

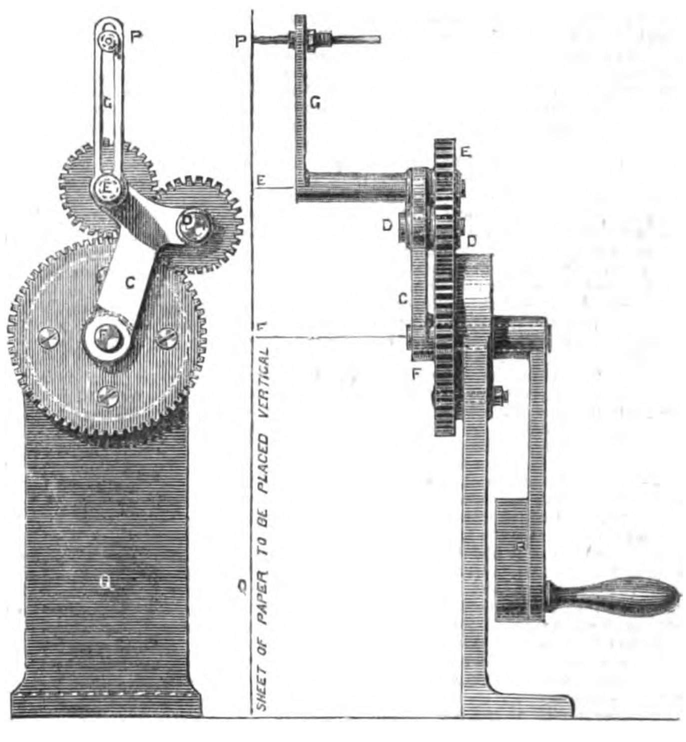
Champion-hill, S.E., August 1.

CHANGING RECIPROCATING INTO ROTARY MOTION (p. 484).

[4659.]—THIS appears to be a modification of a plan which I saw working a small steam-engine to turn a lathe, in the town of Lincoln, some years ago, and which made a very objectionable clatter in revolving, but was simpler than this, although neither are applicable to large engines, more especially sea-going ones, as the backlash of the cogs would be something awful to contemplate. In the engine to which I allude there was a cog-wheel with the teeth on the inside rim, which was attached to the standard H in the position of the dotted circle shown in diagram, the pinion revolved in end of arm C, and was fast to arm G, thus doing away with the intermediate wheel. Verdict: Cog-wheels not a practical arrangement for large engine cranks.

A., Liverpool.

[4660.]—THE so-called "new method of changing reciprocating into rotary motion" (described in letter 4578, p. 484) is fifty years old, and would have been employed had it been of any value. I send you a sketch of the apparatus we used in the drawing-office about 1848 for describing ellipses, &c., which is perhaps its best application. If any of your readers will take the trouble to make one it will afford them a month's amusement, as they can describe figures of marvellous extent and beauty, particularly if the proportions of the wheels E and F be slightly altered, the paper made to rotate, or motion endways communicated to it, &c. The intermediate wheel D should have two teeth less in number than the wheel E. The diameter of the wheel E is one-sixth, and the diameter of the wheel F is one-third, of the length of stroke required. The levers



C and G being of equal length, a pencil placed at the end of the lever G will describe a straight line equal to the length of stroke required. By moving the pencil inwards elliptical or oval figures are then produced. Wheels E and F are placed as near as possible to each other without being actually in gear.

REFERENCES.

P Q = length of stroke required.
E P = E F = one-fourth of ditto.
Diameter of wheel E = one-sixth of ditto.
Diameter of wheel F = one-third of ditto.
R balance-weight for levers C and G and wheels D and E.

JOHN H. KIDD.

WATCH REPAIRING.

[4661.]—I QUITE agree with an "Aberdeen Watch Jobber" that the method adopted by "Seconds' Practical Watchmaker" for bumping Geneva escape-wheels is far from being a safe one. I also think that of "A. W. J." defective, for if you allow a hammer (unless it be a brass one) to strike the crosses, it leaves a mark; besides, there is a risk of the pane of your hammer coming in contact with the teeth. My plan is as follows: I lay the wheel upon a leaden stake having a hole in its centre, to free the pinion, then with a punch (made of peg-wood) and hammer strike the cross required to be raised. The lead readily gives to the slightest blow of the hammer. I hope that "S. P. W." will give us jobbers some valuable wrinkles in his papers, taking care to avoid any of those connected with the "soft Tommy" argument.

JOHN MCKAY.

HINTS ON THE CONSTRUCTION OF GREENHOUSES.

[4662.]—I have for some time had an idea that if your horticultural readers were, figuratively speaking, to put their heads together, they might conjointly hit upon a design for a modest greenhouse which would suit the pocket of the average English mechanic, and yet be all that he could require. As the season is fast approaching when the greenhouse is in requisition, I hasten to lay before those whom it may concern a few notions on the subject, which, though doubtless crude, and maybe impracticable, will possibly load some of your readers of a more mechanical turn of mind than myself to lend their assistance in furtherance of the object. I need not say that a greenhouse affords healthful and pleasant amusement or recreation, as well as profitable occupation, and though at times requiring great and unremitting attention, there is ample reward even when the plants are not turned into money. The cost of a greenhouse, it is true, is considerable (comparatively speaking), but I scarcely think that is the only cause tending to prevent it becoming a more common appendage to a garden than it is. Few working men can consider themselves as permanently settled in any house in the suburbs of large towns, and unless the amateur floriculturist is a freeholder or leaseholder he is naturally chary of erecting a structure which he may be compelled to leave for the benefit of some one else. The difficulty of removing a greenhouse has something to do with this, and so has the law of fixtures; but the latter is obviated by erecting the house on a foundation of brick, when all that the law requires is that the bricks should be left, because they are "in the ground" and have become part of the "estate." That in a rough way is the law of fixtures as applied to greenhouses, and several manufacturers have taken advantage of it, and now supply houses which to all intents and purposes are "tenants' fixtures." But the cost of even these structures is rather heavy, the cheapest advertised being about £37 10s. for a span roof 20ft. by 12ft. This includes fixing and everything but the brickwork, the staging, and the heating apparatus. The framing and sashes are of red deal, the latter 2in. thick, glazed with 16oz. glass, with four coats of paint; the guttering, locks, and the requisite gearing for opening the ventilators being also supplied. It is obvious, however, that one-half of the sum stated is the price of the labour, and that if we estimate the cost without charging for our own handiwork, the amount will be considerably reduced, even allowing for the facilities of manufacture possessed by the seller, and for the lower cost to him of the materials. But as a matter of fact, few of the floriculturists contemplated by this letter would require a house of the dimensions specified; for besides being larger than most working men could spare time to attend to, it is naturally more expensive than a lean-to. The ideal house, therefore, with which I propose to start the subject, would be (say) 12ft. long, by 6ft. wide, and 8ft. high at the back, and about 5ft. or 5½ft. at the front. The brickwork would thus be, allowing a door 2ft. wide, 22ft. long by 3ft. high, so that 1,000 bricks laid half-brick thick would be ample for the wall and the fireplace, and enable piers a full brick thick to be built at intervals of a yard. The first two courses, full brick, might be laid *in* the ground, so that the front of the house above the ground level would be about 2½ft. brick and about 2½ft. wood and glass. Any tolerably sound old bricks would answer the purpose, and they would probably not cost more than 10s., including carting. Before starting with what may be called the foundation, it is highly necessary to settle the method of heating to be adopted, and also whether the floor of the house is to be on the ground-level or sunk about 2ft., more or less. Several advantages are claimed for a house thus sunk, and where lamps or gas are to afford the heat there can be no objection, but if hot water or the ordinary flue is intended to be used, my advice is emphatically build on the ground level, for with a fireplace it is absolutely necessary that the grate should be some distance below the level of the flue, and a similar arrangement will be necessary with a boiler, though in a greenhouse of the proposed dimensions hot water is scarcely a desirable or even economical heating medium. This part of the question, however, I will leave to another letter. Personally, I incline to the old-fashioned flue, and therefore proceed with my ideal house on the ground level; but independently of all considerations of heating arrangements I think a house far more convenient and pleasant when *on* the ground.

Before laying the bricks, then, it will be necessary to choose a site and mark out the plan on the ground. The best possible position for a greenhouse, then, is one in which the greatest surface of glass is presented to the south-east, for it is in or about this quarter of the heavens that the sun rises during those months of the year when his assistance is of the greatest importance to the inhabitants of the greenhouse, for the morning sun is the most beneficial to vegetation—why, I know not, but every one who has lived in walled town gardens running north and south has had ocular evidence of this fact. For obvious reasons, too, the greenhouse should be as near the dwelling-house as possible. The site being chosen, then, take out the soil to a depth of 6in. all over, and well ram along the line the bricks are to follow, except where you have determined to build the fireplace. In laying the bricks, when the course about 2½ft. high is reached, leave out one at intervals of a yard: these apertures are to be afterwards closed with wooden flaps which will act as ventilators when required. For the corner posts, 3in. quartering will be required, and these are to be connected by beams 2in. by 3in. with tenon and mortice joint, cramped together with bedscrews, dowel holes being cut in the 3in. posts, and dowels made to hide the screw heads when all is painted up. I propose that all the framing should be jointed in this way, which will present no insuperable difficulty and will enable us to take up our greenhouses and walk as easily as we do our bedsteads. In the 12ft. length three or four posts will be required to support the front beam, according to the sizes of the front sashes, and here I am slightly in a quandary as to the proposed dimensions, for my idea is to purchase second-hand or the machine-made sashes, but I do not know the sizes. However, these posts, be they three or four, will be stepped in the wall-plate of 3in. stuff bevelled off on the outside edge, and each sash should be hung by hinges at the top and fit fairly close against filleting nailed on the sides and bottom of the frame-work. The ends to be filled in with sashbar stuff (sold at 5s. the 100ft.), and the glass fitted in between each bar in one piece if possible. At the end at which the door is made, a post of 2in. stuff is to run up from the step to the sloping beam, and at a suitable height a cross beam will secure it firmly to the end post, while an iron rod will connect the door post to the front corner post, a similar rod being used to tie the other end together. I do not propose sashes for the roof, but fixed sashbars, let into the back and front beams and fixed by screws, so that the glass may lap over the front and be carried up to within 2in. of the back beam. The fillet or tongue of the sashbars is to be cleared off for the top 3in. to enable a board hinged to another screwed down to the back beam to fall close on the glass. This is to act as a ventilator, and would possibly be better in two or even three pieces, being made to open by small pulleys and strings from the inside. An iron rod, screwed at each end, should pass from one end beam to the other close under, and indeed, pressing against the rafter sashbars, being secured by a nut at either end. The glazing of the roof is a matter of some moment, and I unhesitatingly advise that the glass be in pieces, of uniform size, for convenience and economy of repairing, as well as to prevent scalding or scorching, which is very apt to occur under a hot sun when the glass is in single pieces for each pane. As to the best kind of glass—16oz. or 21oz.—I don't know what to say. It would seem natural that 21oz. is better able to resist hailstones than 16oz., the weight usually given by the makers for the lower priced houses, but a friend of mine assures me that 16oz. resists a hailstorm better than 21oz. as it "bends" and yields to the stones. If this is so the difference in price will settle the matter. With regard to fixing the glass, I think I should putty in all the vertical panes and fasten those in the roof with tacks or pins; but *chacun à son goût*. The whole of the framing should be exposed to the sun before painting, and when thoroughly dry four coats should be given, over and in all joints as well, for it can be rubbed off with sandpaper to make a fit afterwards, or the joints may be well dressed with raw oil. Now to the main point; I think all this may be done for about £5, according to locality, and a very cheap and serviceable house it will be; for, given a wall of the requisite height (if this is not to be had the difference must be made up with inch boards, which will keep out "cold" as well as 4½in. brick), shelves may be fitted all along, while ample height on the stage will be found for camellias and choice evergreens. The brickwork of the fireplace would, of course, be built in the house, with the ashpit and door in a hole outside, for by this means a very handy means of raising tender seeds is provided. It will be observed that I have confined myself to what is really a wooden house, for few amateurs understand working in iron, whereas many do in wood. I notice, however, that houses 30ft. by 12ft. span roof in metal are to be had for £35, but despite all that has been said to the contrary, I doubt whether they are more durable than wood, when it is *properly* worked. One well-known firm in the county of Essex supply galvanised structures at the following rate, 6ft. 4½in. long, 6ft. 3½in. wide, 7ft. 7½in. high at ridge, 4ft. 6in. at eaves, for £4 4s. 8d. This includes two glass ends and one door; the glass is cut up and a priming coat of paint on the wood. It will be understood that they are only made to certain sizes, so that the cost of the nearest approach to my ideal house would be £8 8s. 6d. without fixing, wall-plate, or brickwork. I should be glad if some one will correct my estimate. I make it somewhere as follows:

	£	s.	d.
Glass at 3d. foot	1	16	0
Two planks at 3s. 6d. 12ft. × 11in. × 3in.		7	0
200ft. sashbar at 5s.		10	0
Bricks, mortar, &c.	1	0	0
Wall-plate, a 3in. plank, cut longways		3	6
Front sashes, iron rods, screws, &c.	1	3	6
	£5	0	0

It will be seen that I have omitted to mention the paint, but I have allowed liberally for the other items, and at all events the cost is sufficiently near to be put at £5, at which price a greenhouse ought to pay for itself in a couple of years. But I have said enough at present, and shall be pleased to have the plan criticised.

Saul Rymea.

BLINKERS REMOVABLE.

[4663.]—I bought a five-year-old mare for gig and light work. She was blinkered, but I removed them safely and permanently. In a return journey, when the mare had expended her superfluous spirits, I took off her blinkers. This quickened her speed for a time. When she was fresh I put her blinkers on. This practice I continued for a few weeks; now she runs easily and freely without them. I have seen other instances of like character.

H. Clark.

ON COVERED STRINGS IN PIANOS; ALSO, WHERE AND HOW TO COMMENCE USING THEM.

[4664.]—In most of the best modern upright pianofortes not exceeding 4ft. 8in. high, it is usual to commence using covered strings at or about tenor C, in those 6in. shorter at D, and to make the first covered strings from one-sixth to one-eighth shorter than double the length of the uncovered strings which sound the octave above, according to the proportion the thickness of the steel under wire bears to that of the covering wire which is coiled around it; but, notwithstanding these comparatively large deductions from what would—were they uncovered—be their proper lengths, these strings are usually too tight to vibrate as freely as could be wished.

A very common defect is employing steel wire for the first covered strings many sizes smaller than that used for the lowest uncovered strings. Supposing the thickness of the copper covering wire to remain the same, it is obvious the thinner the steel under wire is, the more heavily it must be loaded in proportion to its tensile strength by coiling the same copper wire (say No. 1) around it; although (the length of each coil required to inclose a thinner steel wire necessarily being somewhat less than that needed for one of larger diameter) this evil is not quite so rapidly developed in practice as it would be if the same total weight of the coils on (say) No. 16 steel wire was equal to that on No. 20. The proportion of load to strength being, however, considerably greater in the instance of the thinner (No. 16) wire, we are compelled, to avoid the risk of breaking it, to make it shorter when employed to produce as sound of given pitch (say tenor C) than it need be, if covering wire of the same thickness were coiled on No. 20 steel.

As all pianoforte-makers well know that any great difference in the lengths of the last uncovered and the first covered strings causes a very sensible difference, not only in the loudness, but also in the timbre or quality of the sounds we obtain from them, they ordinarily make the first covered strings somewhat too long, thinking that they may thereby render less obvious that disagreeable "break" in the tone commonly induced by the substitution of covered for uncovered strings; but it is questionable if their second Devil is not worse than their first; for by making the first covered strings too long for the proportions of their covering and steel under wires, they are necessarily compelled to put too great a strain on the latter. In tuners' language, they don't "come up" readily, and when, by persistent pulling, they are compelled to come up, or rather are "dragged up," they are apt to be very stiff in their manners, in a word, too rigid to vibrate properly, not to mention that they then often fail to do good service for any long period, and they "crack up," and "go under," from which I infer that it is best to treat tenderly our slaves; and that "the merciful man who is merciful to his beast—even if that "beast" be his wife—will obtain by far the most profitable service.

It is a great mistake to suppose every increase of tension improves the tone of a pianoforte, at least below middle C. It is quite as possible for the base string of a pianoforte to be too "tight" as it is for its tuner to become so; and I can aver from experience, this is a condition of "things" which don't anyhow improve the voices of either of those "things;" certainly not the voice of the human "thing," for when "too tight," his voice is rather apt to be less clear than it normally is; and want of "clearness," both of thought and vocal utterance, is not so vary uncommon that we need hardly employ "tightness" to increase a natural imperfection, which is so remarkably common to many of us.

In many cottage pianos which have come under my observation, the last uncovered strings have been of Nos. 20 to 22 wire, and the steel under wires of the first covered strings only Nos. 16 to 18—a difference of from four to six sizes in two successive semitones; need we wonder a difference of length equal to about one-sixth was found necessary, or that the difference of timbre was most offensive, and the "break" so obvious, that I was tempted to "break" the covered strings which caused it. *Cæteris paribus*, the more nearly the lengths and thicknesses of the first covered approximate to those of the last uncovered ones—or rather to those of uncovered strings which are of the proper thickness and length for the sound one semitone below it—the less will the timbre of the sounds they produce differ from those of the lowest uncovered strings, because among other things the nearer will the bridge, which supports these strings on the soundboard, be to that which supports the former, consequently, I am far from being confident there ought to be any difference at all (certainly not more than one size, if any) between their thicknesses. Not having tried the effect of making them both of the same thickness when they were supported on different bridges, I cannot positively say they ought to be equally thick. Often, however, have I asked "ye practical men" why they use strings whose thicknesses differ; but the most "satisfactory" reply I have yet obtained is, "because it always has been done," which, no doubt, is quite conclusive if "whatever is, is right." Of course, a mere unpractical blacksmith (even if unable to swallow our poetical Pope's dogma) must be quite put out of court by such a reply as this, and if he (privately) presumes to think "whatever is is (occasionally) wrong," he had better—like all wicked heretics—keep his convictions to himself, lest he be further convicted of that mortal (original) sin ignorance, common to all; but he believes this word is also very commonly employed to designate incapacity to perceive the existence of alleged facts, which others think they know to be truths. Of course, such "incapacity" must be morally wrong; in fact, the very greatest of wickedness, quite deserving that everlasting "condemnation," which affords such great comfort to the piously benevolent.

However unpractical they may deem him, the "Blacksmith" probably has had, in this matter, rather more practical experience than some of "ye practical men" themselves, who afforded him the above very satisfactory reason for the faith that was in them which induced their employment of thin under wires for covered strings. In the course of some experiments carried out under his direction by the late "W. T.," it was found that when a No. 19 steel wire covered with No. 1 copper was substituted for the original No. 17 wire carrying the same covering, it not only "came up" much more readily than the latter did, but it vibrated very much more freely, and produced a sound of somewhat greater loudness, whose timbre differed much less from that of the sounds of the uncovered C♯ strings of No. 21 wire than those uttered by No. 17 wire did, C♯ being 45in., and the covered C strings 40in. long. On trying some further experiments on the monochord—not on the piano—we found No. 20 steel, covered with No. 0 copper, came up to tenor C, and vibrated pretty freely; its length was 44in., only 1in. shorter than the aforesaid C♯, but its tone was hardly so good as that yielded by No. 21 wire with the same covering, and both were surpassed by No. 21 when it was covered with only No. 00 copper, and its length made the same as that of the C♯ strings—*i.e.*, 45in., which is about 1/9th part shorter than double the length of middle C in that scale. Its vibrations were very free, the tone firm and powerful; and with such wire as is now produced, I have no doubt its pitch might have been raised at least four semitones without the least danger of its becoming broken for many years. After this, am I not justified in asking why use two bridges which are, unless firmly connected, *à la* Broadwood, almost certain to increase the "break" in the quality of the tone.

What is true of pianos 4ft. 8in. high, is no less true of those 4ft. 2in., or shorter. It is also equally true of those which are longer, yea, even of 8ft. 6in., and would be of concert grands 10ft. or 12ft. long, such as the late Robert Mott longed to construct for me—probably he thought this unusual longitudinal extension might match the ears of the writer, who, he doubtless believed possessed "more money than brains," which might have been very true without his possessing much of the former; but, happily, he did possess enough of the latter to avoid paying about £100 for some three additional feet of case, belly, and strings; the latter of which were even then quite long enough (in an instrument of the usual length) to produce sounds whose loudness well nigh drowned those of its treble strings. Years after I had a little experience of the "delights" (and expenses) of (amateur designed) grand pianoforte-making, and felt little or no temptation—after the experiments above detailed—to make even one or two covered notes any shorter than the lowest uncovered strings. On the contrary, I preferred stringing three more notes with uncovered wire, the first two *one* and the last one *two* sizes larger, which I found quite prevented the ear from detecting any want of firmness in the timbre of the sounds they produced. The long bridge and the short bass bridge were united by halving them together at about 8in. from the extreme end of the latter, which was tapered down to about ¼in. thick at its end; and that portion of the bass bridge which extended about 7in. to the right of the long bridge—*i.e.*, towards the bent side—was also tapered to about the same thickness at its end, which reached within a few inches of the rebate which supported the belly. I copied this method of connecting the two bridges from what I observed Messrs. Broadwoods had done in cottage pianofortes, perhaps nearly twenty years ago, and its advantages are, of course, not confined to pianos in which the first covered strings are as long as the last uncovered ones; for it is obvious the bass bridge may cross the long bridge—*i.e.*, be halved under it—at any distance desired up from its extreme end.

I have been told by "practical" men that it is objectionable to put two (unconnected) bridges on the same soundboard near each other, because when so posited, unless connected *à la* Broadwood, they mutually mute each other. If it be true that they do this objection can hardly apply to the bridges of my design for an improved upright grand cottage piano figured in No. 235 of the English Mechanic, for in that—and some other instruments of similar design which have been imported from America—the two bridges are quite far enough apart to be out of each others way. I have not a very strong faith in the mutual uniting power of contiguous bridges, but I do believe it conduces to the durability of the instrument to connect them *à la* Broadwood, for this is practically distributing the downward pressure of the strings over a larger proportion of the surface of the soundboard. If not an absolute necessity, it seems at least an error on the safe side.

When stringing my grand, had I been what an old workman of mine was accustomed to call me, to wit, "nasty nice," I might have shaded off the differences of the tensions of the last uncovered and the first covered strings by yet further reducing the weight of the load of covering wire coiled round the latter. Two methods of doing this are possible—using thinner wire or substituting some metallic material less heavy than copper or brass. Iron has been used, perhaps to advantage, and in this respect steel would be preferable to iron, for not only is its specific gravity less than that of copper or its alloys, but its tenacity is far greater. It follows as a matter of course that it can be used when thinner than copper, and yet be coiled tight enough on the steel under wire to adhere to its slightly roughened surface. Thus, the load of the under wire may be rendered less without much risk of breaking the covering wire by subjecting it to more tension than it can safely bear while it is being wrapped round the former. A really good method of doing this I greatly desiderate—*i.e.*, coiling very thick round comparatively thin steel wire (say) No. 40 or 42 copper or brass wire round No. 26 to 30 steel, without any risk of twisting the latter. I have been told such machines are made, but kept as trade secrets, indeed, I designed one myself, which I may contribute to "our" journal if its editor thinks it worth engraving, in which the under wire is securely held by clips only one-tenth of an inch apart, while the covering wire is being coiled around it, and consequently it is not subjected to any appreciable force tending to twist it, but the great practical difficulty seems to be communicating sufficient tensile force to the covering wire, when the latter is extremely thick, and consequently inconveniently rigid, to insure that it shall be coiled tightly enough on the thin under wire to prevent the string from becoming "false."

Besides using steel covering wire, which is said to deteriorate the quality of the tone produced by a covered string, I might have employed for the strings of a note only one semitone lower than the sounds of the last uncovered string, an open coil. What, in the—alas, long past!—days of my youth were termed "open" covered strings were common enough, in fact, few others were used. Now, it must be "obvious to the meanest capacity," that if the covering wire be wrapped round the under wire in the form of open coils (like a corkscrew or a bell spring extended) each of which are perhaps five times as wide apart as the diameter of the wire of which they are formed, only one-fifth as much covering wire will be coiled round the under wire as there would be if the coils were close to, or touched each other, as they usually do. At present I see no objection—excepting perhaps, prejudice, and the look of the thing, both of which have wonderful power over poor humanity—to the employment of open covered strings for the first two or three covered notes if it be possible to wrap the wire tight enough to prevent them from becoming "false." It is for ye string coverers—rather a prejudiced and therefore "conservative" race—to say if this is a difficulty. Query, might not the ends of the covering wire be soft soldered to the steel under wire if the latter be previously tinned, and the customer willing to find the "tin." I, for one, have great faith in the efficacy of "soft sawder," intelligently applied, for prolonging human and other "attachments," because it can be employed without sufficient "heat" to spoil, or even try the "temper" either of steel wire, or what are far less tender than that not very "soft" material, "married couples."

The Harmonious Blacksmith.

IN WHAT DIRECTIONS ARE SOUNDBOARDS MOVED BY THEIR STRINGS?

[4665.]—Mr. Schucht says the string of a piano moves its soundboard in the same direction that it would be moved by a lever, inserted vertically in its bridge, if that lever was pulled to and fro, alternately, in the direction of the string's length. How the string can move the bridge thus to any appreciable extent in that portion of the piano's compass which is near to and below tenor C (in which, from the longitudinal direction of the bridge forming a very acute angle with the string its resistance to motion in that direction must be enormous) I can hardly conceive, although I can very easily suppose it to do this to some small extent in the lower bass, where the bridge is nearly at a right angle with the strings. Were the string—instead of being extended beyond the bridge to the plate, as it usually is—attached to the bridge, its vibrations must rock the bridge to and fro just like the vibrations of a harp string alternately lifts its soundboard and—when the string again becomes straight—allows it to descend to its normal position.

From the fact that violin bridges are not in contact with the breast throughout their lengths, but have two legs, I infer the impulses communicated to them in reverse directions by the strings alternately depress each half of the soundboard, allowing each half to rise again before the string commences to move in the contrary direction, and depress the reverse side of the soundboard, just as the harp string allows its soundboard to descend when it becomes straight. The strings of a piano being struck in a direction vertical to its soundboard, naturally are at first compelled to vibrate in the same direction as that of their impelling force, at least, their earliest vibrations must be vertical to the plane of the soundboard, whatever directions they may afterwards assume during their continuance hence I infer that when the string descends or is driven backwards by the force of a blow delivered from above or in front of it, it carries the soundboard with it, and in the instance of a horizontal piano, whose hammers strike its strings from below upward, that the strings as they rise lift the soundboard.

That a harp string does lift its soundboard was demonstrated by Dr. Tyndall when lecturing on sound. He stretched a thick and long steel wire, one end of which was attached to what he termed the bottom of a wooden tray, but which was, however, for all practical purposes, a true soundboard or *table de harmonic*. On vibrating this string a very loud sound resulted, and he said that sound was a convincing proof that the direction of motion had been changed—*i.e.*, that the vibrating string pulled the bottom of the said wooden tray—which performed the function of a soundboard to it—every time it vibrated, and thereby compelled this wooden surface to vibrate synchronously with itself. "The Harmonious Blacksmith's" new violin, figured on p. 254, No. 374, is an exact copy of Dr. Tyndall's experiment, excepting that he prefers employing many connected soundboards to a single one, but this does not alter the principle of the contrivance one jot, neither "The Harmonious Blacksmith's" violin nor Dr. Tyndall's wooden tray bottom can be said to possess anything which can act the part of the bridge in stringed musical instruments, nor has the harp. Perhaps Mr. Schucht, "Fiddler," and other readers who are better versed in acoustics than the writer, and have experimentally investigated the action of soundboards, will enlighten, on this subject,

One who Desires to be Instructed.

A NEW MATERIAL IN ORGAN-BUILDING.

[4666.]—I do not know of any objection to the use of paper for organ pipes, as proposed by "Sucram," provided one is satisfied with the tone produced, but for one I should not be satisfied. Organs and organ pipes have been made of almost every conceivable material, from brass to paper. Most of us have heard of the celebrated organ erected in Winchester Cathedral in the early part of the tenth century, which had four hundred pipes of brass and ten keys, with a wind power produced by the united exertions of seventy men; and some have heard of an organ made by a French Abbé at the close of last century out of a pack of playing cards, which is said to have produced agreeable tones, although one would suppose not quite so powerful as the Winchester instrument. Twenty years ago I made some pipes of paper, with metal lips, and a wooden block or languid; but could not get any clear tone, and the smaller pipes seemed to be born with a violent attack of asthma, which was quite incurable by me. I would not, however, attempt to discourage others who would like to make the experiment, for it is not a costly one; but, for my own part, I should prefer to make a set of wooden pipes, as far as time and trouble are concerned, to the plan proposed by "Sucram;" the tone, also, would be greatly superior, and if a Scudamore arrangement of pipes is desired, let them be stained, say, the smaller pipes a very light shade and the large pipes in the back row a dark shade, then well varnished, and they will look quite as well as any wall-paper pipes. J. D.

[4667.]—Paper, or rather "papier mâché," has been used with great success in the construction of pipes by F. Besson, of the Euston-road, who, I feel confident, would willingly communicate the results of his experiments. S. Bottone.

[4668.]—I beg to inform "Sucram" (let. 4579, p. 481) that I have practically tested the adaptability of paper for circular organ pipes. I took the following plan:—An ordinary paper ruler of 7in. long, and fully ⅛in. in diameter, round which I wrapped four pieces of paper gummed, each 7in. by 9in.; I then formed a cone in the same manner, the block used being a piece of clay, shaped accordingly, but rather longer than necessary, so as to allow the insertion of the top piece. I then punched out a circular piece of card for the languid, cutting off a small piece so as to make it correspond with the top of the cone, which is a little flattened at one side, and nicked it as fine as possible. When perfectly dry they were taken off the blocks and glued together, having previously inserted the languid and cut out the necessary portions of the pipe. You may imagine my surprise when I blew into it. The sound came out quite clear. It is perfectly in unison with G in alto of stopped diapason. I am much pleased with its tone, being nice and soft. Perhaps I may not have been explicit enough with some parts of it, but will be glad to answer any questions on the subject. Opaline.

MUSICAL EDUCATION.

[4669.]—What "Fiddler" says in his letter about the scarcity of amateur players who consider music as a science is perfectly true, and it exactly confirms what I said in my last. It is because so many people, not naturally musical, learn to play that we have so many performers and so few musicians. Every young lady is expected to play, the consequence is that those who learn because it is a fashionable accomplishment do so merely for the sake of display, and the music which is easiest to rattle off, producing the greatest amount of noise and so-called "brilliancy" of effect, with the least expenditure of trouble, is what they prefer to all other. The first requirement is that a piece shall be easy, the rest is of but little moment. Ask these too common drawing-room musicians, as "Fiddler" says, to play one of Haydn's or Mozart's sonatas, and they will not—not always because they cannot, but because they are absolutely incapable of understanding its beauty. And all this strengthens what I said before about musical education, and the mistaken ideas of it entertained by most English parents. They will not see that music is not a matter of mere teaching, like the alphabet or the multiplication-table—that it cannot be driven into all alike, by so many lessons from Herr So-and-so, and so many hours' daily pounding upon the pianoforte. And so long as this is so, and one sex is taught indiscriminately, and the other left alone, without regard to the tastes and talents of each individual, which are the gifts of God (not by any means to be imparted by man), so long shall we see music at home in its present degraded condition—so long shall the music-sellers' shelves be loaded with stale dance-pieces and new, though far from original, "morceaux de salon"—so long shall the divine compositions of the great masters be neglected for the reams of spoiled paper which the publishers turn out, week by week, for the benefit of the amateurs of society.

Vertumnus.

ON CO-OPERATIVE STORES AND COINS.—To "E.L.G." AND OTHERS.

[4670.]—"E. L. G." (let. 4630) says coins were invented for "facilitating the payment of taxes." Whether for that purpose or not, there can be no doubt —as Bob Lowe could testify—the possession of abundance of coin does greatly facilitate that first duty of Britons. May be "coin is a badge of conquest," not necessarily in this case of oppression, for my small experience compels me to believe it is the means of liberty—*i.e.*, liberty to purchase what you desire. No doubt the shekel was a weight; but what, in the name of commen sense, is a coin but a certified given weight of gold or silver?—the fact that it is certified to be of given weight and fineness by legal authority saving us the trouble of weighing and assaying it, and thereby much oftener facilitating purchase than tax paying.

The utility of coin may be "a superstition," but it seems rather a well-founded one. I have found this "superstition" extremely convenient when I wanted to buy anything. No doubt the precious metals are not the only possible "medium of exchange." Iron in Sparta, leather—there is nothing like leather—in China, and paper promises to pay in Europe, from bank notes to assignats, Yankee greenbacks and shinplasters, have all served our turn. Indeed paper, which is issued under conditions preventing its value in exchange becoming depreciated—*i.e.*, convertible paper, not necessarily convertible into the precious metals—will in all probability become the common currency of the future in civilised countries. N.B.—One kind of "convertibility" I have stated at some length in No. 1 of the *British and Foreign Mechanic*—one of the many journals since absorbed by "our" "Aaron's serpent."

"E. L. G." says the trader is not, as such, a product of Providence. Possibly not; but I find it hard to conceive to what other productive energy we owe his existence. To me it seems he must be just as much the product of the "all Father" as his customers, be they kings, labourers, or the mighty middle class. Such questions as these I prefer not to discuss, because, as Matthew Arnold would say, it "ain't edifying," besides which, divine Providence not having condescended to reveal all things unto me, I am compelled humbly to acknowledge myself "ignoramus." Not having the honour of being personally acquainted with certain and sundry "live and dead Satans," I am also ignoramus in relation thereto, always assuming the aforesaid Satans really have any personal existence, and are not one of the many melancholy mental "crazes" of our clever correspondent "E. L. G."

A word in season on co-operative stores, so-called. How, in the name of the "thingummy"—who is, I suppose, nearly related to the Satans above mentioned —could co-operative stores (or, for that matter, any other machinery for distribution in any society in which community of property does not exist) work if we had no medium of exchange, not necessarily stamped, and thereby certified, gold and silver. Perhaps some modification of Robert Owen's "labour notes" might serve, or yet better, an undepreciable national paper currency, which would command rather more general confidence than either R. Owen's labour notes or any other merely local issue. Certes, it could not much facilitate exchanges if all purchasers were compelled to exchange one form of wealth—which especial form might not be in local demand—for another they needed. Sure-*ly* bank notes are better than barter, and it must be easier to carry a check on your banker in your waistcoat pocket than to carry your own (iron, leaden, or porcine) pigs to market.

THE HARMONIOUS BLACKSMITH.

SELENOGRAPHICAL.—GASSENDI.

[4671.]—IN answer to Mr. Birt's question (let. 4528, p. 487), I may say that the formation marked *a* in my sketch does appear very like an outpouring from the crater that, for some reason or other, with which elegance or descriptiveness has little to do, has been called "the spoon." Its outwardly curved outline seems to be such as a flow of molten matter would assume when arrested in its progress by cooling, and the re-entering angles that divide the outline into several curves would show where the discharge was held back by obstacles on the surface over which it moved. It is far otherwise with the formation *b*, which seems to overlie the former, and to have intruded on the spoon, dislocating and pressing inwards its southern rampart—that is, the spoon's rampart.

Mr. Brown (let. 4585, p. 485) discusses certain apparent evidences of recent change in the central hills of Gassendi, and compares Professor Phillips's sketch on the one hand with the sketches by M. Gaudibert and me on the other. It is seen, however, that although in our sketches we differ entirely from Professor Phillips, we agree with the old observer, Schröter; and it is not likely that the central hills, after suffering a complete transformation, would be restored just to their original state by subsequent disturbing forces. If we could believe that the view given by the Professor is not an inverted one like the others, the apparent discrepancy would be explained away at once.

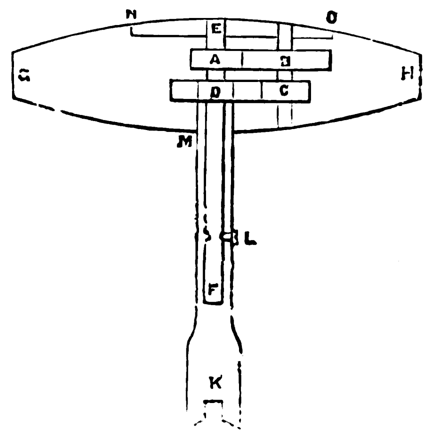
Among the several observers cited by Mr. Brown M. Gaudibert alone has correctly shown the curved figure of the east central mountain. He is also more correct than I in the southern boundary of Gassendi, which appears too much flattened in my sketch. I may say for myself, however, that I attempted no very general accuracy, as my purpose was principally to direct attention to the formations *a* and *b*.

J. BIRMINGHAM.

PIANOFORTE TUNING KEY.

[4672.]—IN response to the invitation of your talented correspondent "The Harmonious Blacksmith" (let. 4561, p. 463), I forward a rough sketch of a tuning-key I designed many years ago, but for want of appliances could not carry out. I trust it will answer its purpose.

The spindle E F, made with a square top at E, fitted into a square hole in the handle G H, to insure their turning together. On this spindle is fixed the pinion A. The wheel B and pinion C to be fixed on the same axle, and they turn together. The wheel D fixed on a square at the head of the key K, and they turn together. Through the centre of the wheel D is a round hole for the spindle E F to pass freely, and the head of the key K passes freely through a round hole in the handle at M. The screw L keeps the spindle E F in its place. If the pinions A and C have half the number of teeth as the wheels B and D, the handle



would turn round four times to the key once. If the wheels and pinions are made of steel and the handle of brass, the tool would bear the strain in tuning a piano. The above sketch shows the principle. In constructing it the wheels and pinions ought to be placed nearer in contact, that is, A and B nearer to D and C, to give room for the wheels in the handle. A movable cover N O, to take the form of the handle, would admit of the introduction of the works.

The expense of such a tool would be great, but few amateurs would object to this, considering the advantages it offers. The writer would be but too glad to purchase one if made.

BEDCA.

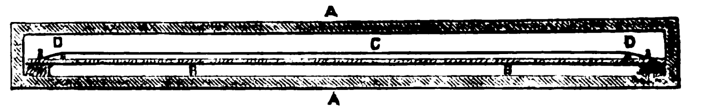
CHEAP SUPER FOR COTTAGE HIVES.

[4673.]—"PHILO" is evidently no beekeeper, or he would not write what he has done on p. 462, in the number for July 19. If the queen should go into the super, which is a very rare occurrence, she will certainly leave it before the drones are destroyed, and never should you take a super until the drones are annihilated, which will occur, to show that with them at least the swarming season is over. A diameter not over 2in. will keep the queen out after the drones are dead. Bees will certainly not eat putty; they like pudding better. Nevertheless, either paint or putty will destroy the hive. A friend of mine once painted his hive ridiculously, and the bees were all dead in three days.

H. B. E.

IMPROVED ÆOLIAN HARP.

[4674.]—SOME of "our" correspondents are showing the mistake which is so often made in musical instruments—*i.e.*, inclosing the soundboard so that the tone becomes necessarily choked and coffined. I send a drawing of an Æolian harp, which I have constructed; the usual mistake is rectified, and there undoubtedly is far more sweetness in the tones than I have ever heard expressed by the ordinary box-shaped instrument.



This improved harp consists of a strong rectangular box of oak with the sides open; the timber is about an inch thick, the sounding-board is placed about three-quarters of an inch above the bottom board of this box, and at a few inches on either side (which position should be practically determined) are placed the bridges (half an inch high), on which the strings, eight in number, rest. The tuning-pins are turned by inserting a suitable key through holes in the upper board or top of the box. On either side of the box, extending as far as the bridge, pieces of wood are placed, which give strength to the instrument, and cause the breeze to flow only over the strings. The tone and power of this contrivance might be further increased by improving the form and material of the soundboard; probably it would be a material benefit to cut it away in the centre.

REFERENCES.—AAAA, a rectangular box open at the sides; B, soundboard of thin pine; C, strings; DD tuning-pins.

E. B. FENNESSY.

HYDROPHOBIA.

[4675.]—SOME interesting information respecting this terrible disease appeared in "our" MECHANIC some time since in response to a letter from me which you inserted. Do any of your correspondents who then wrote know anything of the following remedies, an account of which I have met with in a Salopian paper?

M. Marochetti, an Italian surgeon of the hospital at Moscow, being in the Ukraine, was requested to give assistance to fifteen persons who had received the bite of a mad dog. Knowing the worthlessness of the professional treatment of this disease, he administered help to the unfortunate persons through a peasant, who, during several years, had acquired great reputation in curing hydrophobia, the peasant administering to fourteen of the persons confided to him in a peculiar way, while the fifteenth, a young girl of 15, was treated by M. Marochetti in the ordinary manner, for the purpose of proving the effect of both modes of treatment. To each of the fourteen the peasant gave daily one pound and a half of the decoction of the buds of yellow broom flowers, and he examined twice a day under the tongue the place where, according to his statement, little swellings were formed containing the virus of madness. These swellings rose on the third or ninth day, and were seen by M. Marochetti. Very soon after they appeared they were touched with a red hot needle, after which the patient gargled the part with the decoction of broom. The result of this treatment was that the fourteen patients were cured in six weeks, whilst the young girl, treated differently, died on the seventh day in the convulsions of madness. The same physician, a few years later, at Padolia, had a new opportunity of confirming this interesting discovery, curing twenty-six persons who had all been bitten by a rabid dog.

The other cure for this disease is given by Don Victores Aguilar, who has seen the medicine administered in the last paroxysms of the disease, in which it was never known to fail. It is as follows: Soak a rennet in a little more than half a tumbler of water for about five minutes. When this has been done, add of pulverised sevadilla—(*Hordeum causticum*), a species of veratrum—as much as may be taken up by the thumb and three finger; mix it thoroughly, and give it to the patient—that is, force it down his throat in an interval between the paroxysms. The patient is then to be put into the sun if possible, or placed near the fire, and well warmed. If the first dose tranquillise him after a short interval, no more is to be given; but if he continue furious, another dose must be administered, which will infallibly quiet him. A profound sleep, or rather a total loss of all power over the bodily and mental faculties, with a death-like stupor, without any symptom of animation, will succeed, which will last twenty-four or forty-eight hours, according to the strength of the patient's constitution, at the expiration of which time the effects of the mixture will arouse the patient, and its violent operation, as emetic and cathartic, will last ten or fifteen minutes (the attack lasting till the poison be entirely ejected), the fluid discharged from the stomach being black as charcoal, and offensive to the smell. He will then be restored to his senses, ask for food, and be perfectly cured, feeling nothing but the debility produced by the combined effects of the disease and the medicine.

KAPPA.

DISPERSION OF SEEDS BY THE WINDS.

[4676.]—IN *Nature* of June 27, there appears an article on "The Dispersion of Seeds by the Wind," over the signature "A. W. B.," in which the writer doubts the wind performing this important duty. In 1852, I made a balloon voyage from Zanesville, Ohio, and when I reached the heights above the first layer of clouds I found myriads of the thistle seed, with its tiny parachute, sailing along in the upper current, and these little air-floating vegetables had the seed with them. I have frequently noticed nebulæ of pollen floating along in the same way. In a paper read before the Franklin Institute on "Balloon Meteorology" several years ago, these facts were also mentioned. I mention this matter of fact for the benefit of science, believing that it is useful in the establishment of a great physiological question not yet thoroughly understood. The migration of certain portions of the vegetable kingdom is not more curious than the migration of certain portions of the animal kingdom. Motion is the prime law of nature, and when the seed-bearing float takes to the wind it does so from the force of circumstances, just as we do ourselves when we are moved to emigrate, and in this our migration we are after all as subservient to the universal law of motion as is the seed and the pollen, although we may stultify ourselves in the vain conceit that we may do, or may not do, the things that are done.

JOHN WISE.

Hall of the Franklin Institute, Philadelphia.

IS THE MOON SPHERICAL?

[4677.]—I SHALL be glad to see M. Rabache's proof. See let. 4683, No. 384, p. 518.

W. R. BIRT.

THE ORGAN BUILT.—VIII.

[4678.]—Having got the framework of the organ put together, it will be better to make the pedal soundboards. Get a set of cardboards the size of the Bourdon pipes, and divide them into two lots, taking every alternate one to form each lot—viz., CCC, DDD, EEE, FFF♯, &c., for one lot, and the alternate cards—viz., CCC♯ DDD♯, FFF, &c., to form the other lot, there will thus be thirteen in one lot and twelve in the other. Now lay the thirteen side by side, leaving a quarter of an inch between each, and get out a piece of inch pine 8in. wide, and the length of the row of cards; mark on the board the centre of each card, taking care that the largest card is on the end of the board that goes to the back of the organ. Now bore the holes for the wind; the hole for the CCC should be 2in. by 1in., and for the C ⅞in. in diameter. The channel for the largest pipe must be 1½in. wide and ⅞in. for the smallest; the depth of the channels to be 2in. Make the channels with bars, as previously described, only that each channel being exactly under its pipe, there will be a space like a wide channel between each real channel. Let the wind-chest be 4½in. deep and 6in. from the treble end; in each wind-chest cut a hole in the back 3½in. square for the wind-trunk to enter. No slides or stockboards are necessary for these, as the draw-stop acts upon a valve in the wind-trunk instead of the ordinary plan of slides; the pallets in these wind-chests are to be the full length of the channels. Over each hole in the soundboard a block of 1½in. pine is to be firmly glued, having a round hole bored in it, to receive the foot of the pipe; the hole for the largest should be 3in. in diameter, and for the smallest 1in. (See Fig 1.)

Before describing how to make the movement for the organ, it will be as well to explain a simple plan for preventing the noise often caused by wires working in holes in wood. Every hole in a piece of wood in which a wire works should be lined with cloth, and although apparently a very difficult job, it is in reality very easy. Bore a smooth hole in the wood ½in. in diameter, get a strip of cloth ⅜in. broad, and cut it into lengths of 1½in.; cut one end to a point, rub a little glue into the hole, and draw the cloth through the hole until the pointed part of the cloth is pulled through.

FIG. 1

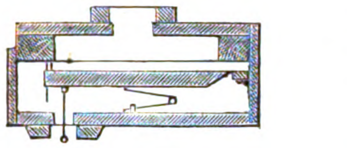


FIG. 2

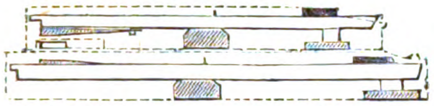
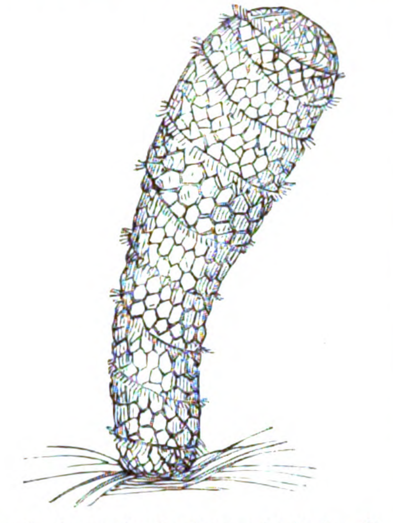
FIG. 3



Cut the cloth off close to the wood on each side, and push a small bradawl through the centre of the cloth to force it nicely round the hole; the holes which require bushing, as this lining is termed, are those in which the roller ends work, and the centre holes of backfalls and squares. Now get out the rails in which the backfalls are to work; two will require to be 4ft. long—viz., for great and swell organs—and one 2ft. 8in. long—for the coupler great to pedal, the width of each to be 3½in.; the rails are made of a thickness of mahogany and one of pine glued together, the mahogany 1in. and the pine 1½in. thick; while these rails are drying make the "coupler" swell to great; it is a rail of mahogany or oak 2½in. by 1¼in. The exact length between the ends of the keyboards to be left the full thickness, and a tenon 2in. long and ⅜in thick to be left at each end. (Fig 2.) The tenons slide in a groove cut in the frame of the swell keyboard; the rail is to slide 3in. backwards and forwards in this groove. In the rail bore a quarter-inch hole exactly over the centre of each key; great care must be taken to make these holes vertical. After making all the holes line them carefully with cloth, and afterwards get out a sufficient quantity of mahogany rod, round and smooth, of a size to slip easily through the holes after they are lined. The length required will be about ten feet. Next fix small wedge-shaped pieces of wood on the great organ keys, as shown in Fig. 3; they are to be 3in. long and the width of the key. Make similar pieces for the swell keys, but 5in. long, and fix them to the underside of the keys by a screw only at the thin edge of the wedge; at the other end of the wedge put a wire screw through the key, so as to adjust the wedge to the top of the coupler sticker, and then cut the mahogany rod into lengths to fit between the wedge-pieces on the keys. After getting the stickers the right length, blacklead them well to make them work easily. The dotted lines show the key frames and the groove for the coupler to work in; the coupler is shown in position when in action; to throw it out it merely requires to be drawn forward. It is advisable to cover the wedge-pieces with a piece of leather to prevent any noise; the smooth side of the leather to be outside and well coated with blacklead. J. D.

EUPLECTELLA.

[4679.]—Some time ago a query appeared in our paper respecting the *Euplectella spinosa*. No answer has been forthcoming, and as I have learned something about this creature since the date of the query, I feel



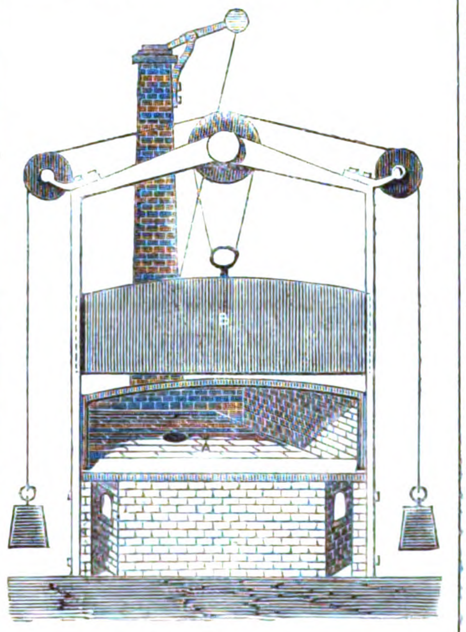
it incumbent on me to give the querist the benefit of that acquired knowledge. In the first place, the name given is not correct; it ought to have been *Euplectella speciosa*, "the beautiful euplectella," and not "spinosa," the thorny. The creature itself is a kind of sponge, which fixes itself by means of a lovely silky base to the sea bed. Until very lately it was thought to be extremely rare, and good specimens fetched from thirteen to fourteen guineas. Lately, however, its habitats have been discovered, and by means of a peculiar kind of drag, resembling a small but long-headed rake, considerable quantities have been raised, so that the price has fallen to 30s. for good specimens, and 12s. for those of commoner aspect. The peculiar shape, silky white lustre, and delicate texture of this remarkable sponge, will ever cause it to be a favourite with the lovers of the beautiful in nature. I inclose a rough sketch, which may serve to call attention to this "wonder of the deep." S. Bottone.

FENUGREEK.

[4680.]—Fenugreek powder as a cattle condiment. A friend told me a day or two since that he has in very many cases used this as a cattle restorative with very good effects. It has been tried recently on a donkey of mine that was going off his feed with equally good results, a small quantity only (about 1oz.) being daily mixed with a feed of chopped mangold and bran mash. Can any one state whether "Thorley's Condiment" is partly or chiefly composed of this substance, and if it is known to have any similar restorative effects on the human subject? Animals' Friend.

FURNACE FOR HEATING WHEEL TIRES, &c.

[4681.]—A new furnace for heating cart-wheel hoops, engine-wheel tires, spring plates, or any kind of article to nearly white heat. Black spot A is chimney-hole on



flat floor, where articles lie to be heated, B door to cover mouth of furnace fire holes at each side below floor; they run all the length on each side inside. Can be got to any heat quickly, from cold to melting point. Damper at top of chimney to regulate heat. Furnace door B should be li[ned] inside with fire-bricks. The furnace appears to ha[ve] one corner short, but all can be seen that is required.

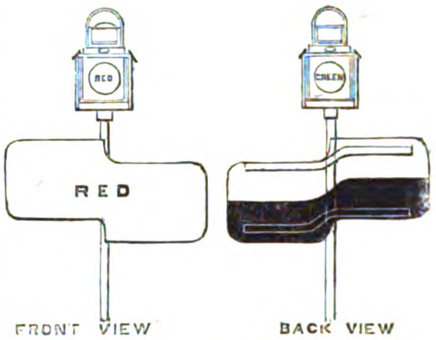
Outgenious Whitesmith.

FALL OF A BULLET.

[4682.]—With reference to the paragraph quoted by "Puzzled" (query 12377, p. 444) from Mr. Proctor's letter (4411, p. 381), I cannot see how it is "perfectly true that gravity draws down the most swiftly travelling bullet—fired horizontally—so that it reaches the ground as quickly as a ball dropped from rest from the same height," for would not a ball, if propelled swift enough, continue to revolve round and round the earth, yea, and even recede from it every revolution and part of a revolution, until at last the earth's gravitation would lose all control over it? And can we not conceive of a ball being propelled horizontally with such force as would make it revolve round the centre of the earth, but becoming nearer and nearer each revolution, until at last—after a period, we may say, of a century—it would reach the centre? And would not a ball dropped from rest from the same height have reached the centre long ago? What I hold is that this theory is not perfectly true, but nearly, and even then only on comparatively short distances. Francis Lewis.

ALTERATION OF DISTANT SIGNALS ON THE MIDLAND RAILWAY.

[4683.]—The distant signals on this line consist of an oblong board; when turned facing a train they are "on," when turned edgeways so as not to be seen they are "off." Great difficulty arose then to distinguish at a distance whether a signal was facing the train or whether it was simply the back of a signal belonging to the other set of rails. To remove this difficulty the right hand sides of the boards are to be lower than the other, so that at sight it will be seen to which line it applies. Some of the signals have already been altered to this pattern, and have been found to answer well. All new distant signals will be made of this pattern, and it will also be applied to the old signals as soon as possible. I think the "directions" will interest your readers.



With a view to increase the efficiency of the distant signal in use on the Midland Railway, by enabling drivers, on sighting a distant signal, to distinguish by the shape of the signal, as well as by the colour of it, whether it is applicable to the line on which they are running, or whether it is simply the back of the signal which is presented to them, it has been arranged that the form of the disc shall be altered, and shaped as shown below:—

It will be observed that the disc consists of a high side and a low one, and the signal will be so arranged that, when turned on against an approaching train, the high side will always show on the left-hand side of the post as drivers approach it, and the low side on the right-hand side of the post. Drivers will easily recollect that, as all semaphore signals are shown on the left-hand side of the post, so the elevated side of a distant signal shown on the left-hand side of the post indicates that the signal applies to the line on which they are running, whilst the low part of the signal appearing on the left-hand side of the post indicates that the back of the signal is towards them, and that it applies to the other line, and not to the one on which they are running.

When the signal is at "all right," the board is turned edgeways so as not to be seen, and the lamp shows a white light. C. E. S.

SEPARATE RAILWAYS FOR GOODS TRAFFIC.

[4684.]—Some twelve or eighteen months since a letter was published in one of the weekly professional journals pointing out the advantages of, and the necessity for, the making of entirely distinct lines of railway to be used for goods traffic solely. I do not know whether any action is being taken upon his suggestions, but I think it is an idea which ought not to be lost sight of, especially as some of the companies are now doubling their existing main lines in order to accommodate the increasing goods traffic thrown upon them. If this example be followed by the other companies, as it certainly will be to a considerable extent unless better means are provided, the result will be that when Government takes possession of the railways (which I think only a question of a few years' time), it will find a badly-arranged system—one made not for the general interest, but for that of each particular company—duplicate and even triplicate lines where one would have sufficed, and almost as much danger from accidents as at present, as the additional goods lines would have to cross on the level the numerous branches running into the main lines.

The existing canals might be utilised so as to form portions of main goods lines, and the position of the many large works erected on their banks being a fertile source of traffic ready to hand, would be a great argument for converting them; but unfortunately their courses are often so devious and winding that the distance would be greatly increased. I anticipate, however, that before many years have passed away they will, under Government control, be shortened by cutting off the windings. But this cannot be expected at present, and in the mean time the doubling process will go on. The writer above alluded to recommended a new railway to be made which would accommodate by one main line the midland counties, the potteries' district, and the whole of the north of England. Commencing at London by connections with the goods termini of the northern lines, it would run to about the neighbourhood of Leicester, where it would divide into two forks, the one passing up the Erewash Valley, near Sheffield and Barnsley, to the West Riding towns, whence it would be continued through the Durham coal-field to Newcastle: the other through the potteries to Liverpool and Manchester, with connections to all the Lancashire towns. To this might be added a branch from the neighbourhood of Market Harborough to Birmingham and South Staffordshire. Short junction lines should be made to each existing line, crossed in order to throw as much traffic as possible on the goods railway. There are several existing lines, which, being scarcely used except for goods traffic, might be utilised as portions of these lines, among which are the Chesterfield and Masborough branch of the Midland Railway, the Biddulph and Sandbach branches of the North Staffordshire Railway, and perhaps others.

I am aware of one great objection which will be urged against such a scheme as this. None of the existing companies would of themselves offer to make the line, because of the opposition they would be sure to receive at the hands of the companies whose territory they proposed to invade. But I think the difficulty would soon disappear were they all to unite together for the purpose, each contributing capital in the proportions to which they are interested in the traffic, or as nearly so as can be computed; pay interest on this capital at 5 per cent. (or a lower rate as might be arranged), and divide the surplus profits among the companies in the proportion to the amount of traffic conveyed, and which would in the ordinary course have been taken by each of them. Thus each company would receive the profit of its own traffic, and the only extra expense would be the interest on the capital employed in the construction of the line; against which should be set off the increased safety of the passenger lines and the consequent diminution of the large annual charge for compensation, in addition to the far greater scope given for developing the passenger traffic on lines almost altogether free from goods.

There is another point. On lines employed exclusively for goods traffic there would grow up in time a natural desire on the part of the residents in the districts through which it passed to avail themselves of it for passenger traffic. This would, of course, be a departure from the principle of separate goods lines; but in case of a sufficient amount of traffic from that source being likely, a third line might be laid down running by the side of the others until the nearest junction with a passenger line was reached, where the passengers would be handed over to the other company, who might indeed work such traffic themselves at a percentage of the gross receipts.

I am convinced that if this or a similar scheme were carried out it would reduce the chances of accident to a minimum, simplify the management, and eventually prove a great saving, not only to the companies but to the nation on whom the cost of all unnecessary works will ultimately fall.

Manchester. W. H.

WARMING RAILWAY CARRIAGES.

[4685.]—Having some time back in "our" Mechanic seen several letters on the warming of railway carriages, and having lately travelled in differeng parts of Germany, I found in operation four different systems of warming. Three have been described by several of my brother readers; but the best, in my opinion, is on the Berlin-Potsdam Railway. The carriages need little or no alteration. You take two pieces of chemically prepared charcoal the size of a brick, put them in a wire box similar to a rat-trap, set fire to it, and you have the carriage warm for eighteen to twenty hours without further attendance. I was lucky enough to obtain several pieces of Herr Ober, engineer's turner, in Potsdam. One piece I laid on the window-sill in a strong breeze: it gave no spark whatever. Another piece I lighted and put in a dish in the middle of a very small room, door and window shut, so as to exclude all ventilation for five hours. I was in the room working all the time, and I am still alive and kicking. What a boon for an infirm lady or gentleman, and many others who are obliged to travel in the rough, cold winter time to sit in a warm carriage. The coal is very cheap, about the London price of the best Welsh coals, which must induce the Railway Companies to adopt the system.

H. Menz,

Factor to the Westfälische Marmor-Werke, in Allagen by Soest.

A GIANT PLANET.

[4686.]—If "Hyrab Sen" will make his calculations as to the temperature of Jupiter's satellites in Centigrade instead of Fahrenheit degrees he will find that he will arrive at a temperature for them about seventeen times as great (according to his method of computation) as the one he gives. This alone ought to show him that there is some fatal fallacy in his reasoning, and that he has been counting his degrees Fahrenheit like a schoolboy counts marbles, as Mr. Proctor suggested he must have done before he demonstrated it by his last letter. T. H.

[4687.]—In "Hyrab Sen's" letter (4573) there are several grave mistakes. He supposes, in the first place, that 1200° Fahr. divided by 600 are equal to 2° Fahr. They are nothing of the kind, for let him work it out, using the Centigrade scale, for instance, and see what he will arrive at. 1200° Fahr. are equal to $648\frac{8}{9}$° Centigrade; this, divided by 600, equals, according to "Hyrab Sen's" method, $1\frac{11}{135}$°, which, if "Hyrab Sen's" method is correct, ought to equal 2° Fahr. But this is not the case, as it equals 1·96° Fahr., the reason why there is so small a discrepancy being that the zeros of the two scales are not far removed. Again, "Hyrab Sen's" method of finding how much the temperature of Jupiter's satellites would be influenced is incorrect—that depends solely upon the apparent diameter of the planet as seen from its satellites, and from its own surface. In the case of the furthest satellite, Jupiter has an apparent diameter of 21°–44′, while at the surface of the planet itself of course its apparent diameter is 180°. Leaving out the question of Jupiter's ellipticity, the amount of heat received from the planet at the furthest satellite bears the same proportion to the heat at the surface of the planet as the squares of the above quantities do to each other—viz., as ·0146 : 1·000; that is, the planet's temperature, if obtained solely from Jupiter, would be equal to ·0146 of that of the planet. Finally, "Hyrab Sen" asserts his belief in the theory that distance *per se* diminishes the brilliance of an object, and in support of his supposition he asks why the earth-lit surface of the moon should not look equally brilliant with the moon-lit surface of the earth. Just for the same reason that a lighted candle will appear black when held before the sun's disc, the intenser brilliancy of the sun-lit portion of the moon eclipsing the more feeble light from the remaining portion. Besides, if what he supposes were correct—viz., that distance diminishes brilliance—he will see that that would give a considerable advantage to Mr. Proctor's theory, as in order to shine as brightly as he does, Jupiter must be immensely more brilliant than he appears to us, and must therefore shine with considerably more than three or four times the brilliance that he would if merely reflecting the sun's light. G. F. H.

DOUBLE STARS.

[4688.]—The following double stars, found since the 20th July, 1872, are not in "Celestial Objects," &c., nor in Mr. Proctor's smaller atlas.

Ophiuchus.—12° N. of β, and 85′ preceding. Magnitudes 6, 8. P. 20°, D. 35″.

Ophiuchus.—A wide double, about 3° N. of β, and 20′ preceding. Magnitude of primary about 8. Prevented taking position of companion.

Ophiuchus.—A wide double, about 15′ N. of β, and 25′ preceding. P. 360°, D. 25″.

Ophiuchus.—A rather close double, 8′ N. of 73, same right ascension. Magnitude 8, 9. P. 140°, D. 1·2″. As this double is in the same field as 73, I dare say it has been noticed before.

In my letter 4589, Ophiuchus 2° 30′ N. of E, read N. of ϵ (epsilon).

Jumet-Hainaut. C. Gaudibert.

THE AUGUST METEORS, 1872.

[4689.]—I am desirous of directing the attention of your scientific readers to the meteoric display which may be expected to occur on the evenings of the 9th, 10th, and 11th inst., and would recommend all those who have the leisure and inclination to maintain a careful watch of the sky on the evenings I have mentioned, so that the details of the appearances, numbers, &c., of the meteors may be placed on record. By a reference to letter 2528 (Vol. XIII., p. 619), it will be seen that during the interval from August 9 to 11 last year I observed no less than 260 shooting-stars, and in a similar period, in 1869, 159 came under observation. In the latter year it was estimated that, on August 10, meteors appeared at the rate of 38 per hour, while on the following evening the number was 40 per hour. In 1871 there was a particularly grand display of the August meteors. Mr. W. Davenport, of Lancaster (see Vol. XIII., p. 644), in company with three friends, observed 42 meteors on August 10, between 11h. 30m. and 11h. 45m. Other observers have also published the results they obtained, and it would appear that meteors were very numerous in August of that year, particularly so on the 10th and 11th. On the former date three observers at York counted no less than 120 from 9h. 45m. to 12h. 0m., and on the following evening they saw no less than 47 in the two hours preceding midnight. From the observations made at various places, Professor A. S. Herschel was enabled to compute the heights of 20 shooting-stars. See *Quarterly Journal of the Meteorological Society* for November 15, 1871. He found that, at the first appearance, the average height, in British statute miles, was 86·1, while at disappearance the average elevation was 53·5; their velocity per second was 51·6, and the length of their paths 42·4. The average heights of some of the meteors, which had been previously seen, were as follow:—Of 16 meteors doubly observed in 1869 = 74·1 British statute miles at first appearance, 47·6 at disappearance; of 10 meteors seen in 1870 = 71·7, 54·4; of 20 meteors observed in August, 1863 = 81·6, 57·7. The above figures are given in the last "Report" of the British Association Committee on Luminous Meteors, which also contains particulars of all the large meteors that came under observation during the preceding year, and refers in detail to the progress made throughout the year in meteoric astronomy. Observers cannot, therefore, do better than send to one of the members of the committee the results they may obtain during the forthcoming display of meteors. The observations can then be compared and discussed, and in cases where the same shooting-star has been observed at two different stations, its height, length of path, and other particulars may be determined. Observers must, of course, be as accurate as possible in describing the paths of the meteors, and should also be careful to note their dimensions, times of appearance, radiant points, duration, and the like. If this were invariably done, our stock of knowledge in this department of astronomical science would soon be considerably augmented. William F. Denning.

Hollywood Lodge, Cotham Park, Bristol.

SPINNING TOPS AND GYROSCOPES.

[4690.]—An answer to the last question in "Gy's" letter (4581, p. 484) virtually answers all his questions. "Taking out of account friction and the resistance of the air," the velocity of the top or gyroscope would remain undiminished, the axis would maintain the same inclination to the vertical, and the speeds, both of rotation and of gyration, would remain unaltered.

I think "Sigma's" remark (let. 4592, p. 486) about the ball moving in a tangent to the earth's surface unnecessarily complicates the question. It would be tedious, although quite easy, to take the feature referred to into consideration; but the simpler plan is to restrict the conditions of the case first proposed by "A.," by assuming that the ball starts in a direction parallel to a horizontal plane, that gravity acts at right angles to that plane, and that the resistance of the air is absent.

"A.'s" letter (4594, p. 486) shows curious contradictions. He appears to see that it is the lever action which makes the centrifugal force act partly in raising the governor-balls, when he refers to J. M. Taylor's theory. When speaking, however, of the weight and cord, he says, "The cord has nothing to do with holding it up"! The fact is that the cord has everything to do with holding up the weight, for it acts precisely like the lever or link of the governor.

Glasgow, July 27. E. H.

[4691.]—Any one who reads "Sigma's" letter (4593) will see that he fully confirms my position instead of confuting it. That opinion is, that if a body be discharged or propelled with sufficient velocity—and mind you that this propelling power be kept up continuously—that said body would maintain a straight course in spite of gravitation. I suppose that no one will deny that if a cannon were pointed upwards and a ball fired from it with a continuous propelling apparatus attached thereto, that said shot would never return to poor gravity any more; and if this be true vertically, why not equally so horizontally? I never disputed the fact that a cannon-ball yields to the force of gravity as its velocity decreases, but do maintain that it cannot fall in the same time as the ball left to fall freely, and invite "Sigma" to controvert the following proposition: Take a light globe tied to a string, and run swiftly; it will follow in what is commonly termed a horizontal line as long as the speed is maintained. It is evident that the same would take place if it were a cannon-ball if sufficient speed was attained. Now, it cannot be said that the cord holds it up, as it only drags it along. I maintain that propelling it would have precisely the same effect as the cord has; and allow me to ask, oh where and oh where are poor gravity and the parallelogram of forces in this case?

A., Liverpool.

MONOLITHIC BUILDING.

[4692.]—In reply to "Epsilon" (let. 4576), I trust he will forgive me when I criticise his criticism. Were I or any other man—adopting our friend "The Harmonious Blacksmith's" word, monolithic, as distinctive of a concrete form of structure—to admit the presence of joints properly so-called, we should at once plead guilty to having employed a word the significance of which we did not understand or knowingly misapplied. "Epsilon" is perfectly right as to his theory of cementing surfaces, but wanders away into a consideration of the cementing process in ordinary brickwork. Now, I will not admit that any comparison can be made between a good concrete wall and a brick one; the first is a solid mass of matter, every particle of which is possessed of greater tenacity and resistance than brick itself, to say nothing of ½in. joints of mortar, in many cases not better than so much mud. Only fancy a brick wall put up in such weather as we are now experiencing, when the workman can hardly spread his mortar to get the brick in position. To talk of tenacity in such work is to insult the understanding of any reflecting mind. My comparison was drawn between stone and concrete, and in any discussion on the relative merits of building material I should decline to enter were brickwork, the only and sole merit of which is facility of construction, permitted to take a place. I certainly committed a slight *lapsus* when in my former letter I compared the joints of stonework and concrete as in the latter. The addition of a layer of material cannot be said to constitute a joint any more than the addition of a load of hay to a rick can be said to do so. Did "Epsilon" ever see a large work executed in plaster? and if so would he say that there were joints in it? I venture to say that if the work was well executed, not only would it be impossible to find any, but that absolute fracture would fail to show where the additions of material had been made; and so it should be with concrete—the frames should be raised and the work progress in such a manner that the surface is never permitted to bake, when, due care having been observed in proportioning and mixing the materials, a truly monolithic structure would result. We are as yet in the infancy of this matter. True, the ancients knew and practised the system, but the light brought to bear by science in the preparation of cements has rendered its application at once simple and effective, so that those who will take the trouble to inquire for themselves may look forward with confidence to the day when it will be generally adopted. That failures have happened, and will occur again, is only in the natural course of events, but so surely as truth ever overcomes prejudice, so surely will concrete building, whether truly monolithic or not, supersede brickwork. In the same number of "ours" as the letter of "Epsilon" I find a selected article from the *Aberdeen Journal* on concrete, but from the description there given of the process it is not properly named. It is a system of cement puddle or grout construction, and could never be depended upon as compared with true concrete, though doubtless for cottages as described it answers every purpose. M. G. C.

INEXPENSIVE AND SIMPLE STEAM ROAD-CRUSHER.

[4693.]—A CRUEL means of coercive restraint the bearing rein is, doubtless, most truly stated to be, and "Old Ploughman" (let. 4434, p. 384), deserves much credit for drawing attention to the evil. But there is yet another form of barbarity to which all our horses alike are subjected even against the will of their owners—namely, the custom of leaving the sharp macadam of a newly-repaired road to be gradually worked down in the course of public traffic by the horses' feet. This practice, although it has been much denounced and condemned, is yet everywhere prevalent, and the costly and cumbersome steam road crusher is, owing to its limited local application, not likely to find much general favour. A cheaper and more handy appliance is very much needed. Now, while recently looking over an illustrated description of a steam plough, in a magazine, the thought occurred to me that such a contrivance might be utilised on a common road by merely substituting a heavy stone or iron roller for the plough, all the other apparatus being retained without alteration. Movable barriers might be set up at (say) 200ft. or 300ft. apart, half across the section of road under the operation, the other half, as is usual, being retained for traffic. The roller might then be run by a stationary engine to and fro over the metal till crushed in. A small roller might trundle immediately behind the large one to act as a pawl to check recoil in case the rope should give way, which would be more particularly needful in ascending inclines. This simple apparatus might be promptly set up, and as easily removed in almost any locality (except on very steep inclines) at a small cost when compared to the ponderous machine which is occasionally and exceptionally brought out to do similar duty. I send the above suggestion for what it may be worth, and shall be very pleased if it may be found practically available to lessen needless animal suffering. ANIMALS' FRIEND.

"VERITAS" AND THE PENDULUM.

[4694.]—I CANNOT understand what "Veritas" is attempting or doing in letter 4606, page 489. Why does he multiply the seconds in a month by the seconds in a day? And why divide this by the number 330, and then the square root of the quotient by π, and by the n° to log. 0·00072332? What is the latter quantity, and what is he going to find?

The polar diameter is not 7900·18 miles. Neither is the mean diameter a geometrical mean between the equatorial and polar. It is twice as near to the former as to the latter, because the larger diameter applies to two dimensions, and the smaller to only one. Coming to his second letter (4645, page 514), he is wrong in placing the earth's mean diameter at latitude 45°. It is at 35° 16′, and is the mean of *three* extreme ones, the polar and *two* equatorial diameters, instead of one of each. The mean diameter is that which the earth would have if moulded into a sphere without change of bulk. It is not the mean between *only two*, the largest and smallest. He is right in placing *this* at 45°, but wrong in calling it "the mean diameter."

The strangest thing, however, is whence he has got his false data of the feet fallen in a second. These are half the velocity acquired in a second, and the latter is π^2 × the length of second's pendulum at the same place. Nothing has been more accurately measured than the pendulum at various latitudes. It is (according to Airy's work, referred to in his first letter, page 489) 39·01677 inches + ·20377 sin.² *lat.* This is for the sea-level, and shows that the longest pendulum possible, namely at the polar sea-level, would be 39·21704 inches; and the shortest possible at any sea level—namely, at the equator—is 39·01677 inches. Now, the latter multiplied by π^2 exceeds 32 feet. It gives 385·08 inches, or 32·09 feet. So that there is no latitude where the fall of bodies in a second, at the sea level, is so small as 16 feet. "Veritas" contradicts himself by saying—first, it is 16·03 feet, at a latitude within four miles of 45°, and afterwards that "somewhere" it is 16 feet, "and that point is 45° latitude." The real fall at 45° is 16·086, and at the equator 16·045. To get to a place where it is as little as 16 feet, we must either descend below any mine or ascend above any mountain yet climbed—namely, more than five miles, even at the equator. I lately remarked, on the metrical question, that if we were ever to adopt Sir J. Herschel's proposition of augmenting our inch and foot by one-thousandth, so that a cubic foot of water might be 1,000 ounces instead of 997, and his "module" of 50 new inches (or 50·05 present ones) be a decimal fraction of the polar axis; then the new foot would represent the quarter-second fall of bodies *somewhere*, at some accessible height on the Quito Andes; but it would still be a little short of the fall at any place inhabited. E. L. G.

P. S.—"Veritas" cannot deduce the mean fall here on earth from the moon's fall per second, as if the latter were known by some independent measure! Of course her distance (and hence her velocity) are only measured by her parallax and our measures of degrees on the earth, and the former can hardly be known to four figures; even the latter are uncertain beyond the fifth figure, while pendulum lengths are pretty certain to the seventh. The nearest miles to the earth's equatorial diameter are 7,926, but to the polar 7,899, and to the mean 7,917, instead of those he has found.

PROPOSAL FOR UNIVERSAL STANDARD MICROMETER EYEPIECE FOR MICROSCOPES, &c.

[4695.]—SOME of your readers may be interested in learning that I have calculated and completed a compound micrometer eyepiece which I think might be used as a standard one. I have had it in use for some months. It is not mere theory. I give a few reasons for considering it a standard:—

1. It magnifies just ten times of itself, which is an easy multiplier, and is not like any I can hear of.
2. It shows the magnifying power of any objective (simple or compound) at sight, by measuring the size of the image formed by the objective of a stage micrometer ruled to 100ths and 1000ths of an inch.
3. It shows the magnifying power of the combined objectives and eyepieces by multiplying the magnifying power of the objective by 10, its own power. If the objective be 10 ×, and the eyepiece (or ocular) be 10 ×: then 10 × 10 gives 100 = the magnifying power of the whole combination.
4. It will show the real size of the original object.
5. It will enable us to calculate easily the magnifying power of any other eyepiece used with the objective.
6. In the telescope it will show the real size of the image formed in the focus of the telescopic object lens or reflector.
7. It will measure the breadth of the pencil of light emergent through the eyepiece of a telescope, and show its magnifying power.
8. In the spectroscope: It shows at once the distance of the Fraunhofer lines in the spectrum formed in my (Browning's) spectroscope.
9. It will show the relative dispersive power of the prisms by the distance between the Fraunhofer lines.
10. It will give a rough measure of angular magnitude.
11. It makes the focus of any object for parallel rays easily calculable.
12. It verifies its own utterances as to magnifying, for any one can see it magnify by 10.

GEO. FINDLEY.

RADIUS OF SURFACE OF OBJECT-GLASS.

[4696.]—IN reply to Mr. Oldfield and Mr. Vivian, I would take any amount of trouble to get my object-glass better corrected, if Mr. Oldfield will give the kind assistance proferred in his letter (4483, p. 412). The actual clear aperture of the object-glass as mounted in a plain screw-down brass cell, is 4 $^{8}/_{10}$in., the real diameter is 4$^{9}/_{10}$in. If Mr. Oldfield thinks 70in. long enough by his proportion for the above diameter, it would save some of my present work. There is one thing I am yet in doubt of. Is it possible that my flint lens is too thick in proportion to the crown? I will state the measurements in decimals of an inch, and perhaps matters may be improved in this respect. Crown in centre ·35, on edge ·13, flint in centre ·26, on edge ·35. With regard to the quality of the glass, I cannot see any veins or striæ, only a very small seed or air bubble, one in each lens, and in both cases close to the edge. In examining photographic lenses I have often seen these veins by holding the lens between the eye and a bright cloud or a lamp. As a certain distance is reached, they show very plainly. This test to my lens, with even the crown taken separately, did not reveal any.

I must now plead guilty to having given some wrong specific gravities of the glass. The fragments do not vary to the extent I gave in my letter (4389) on page 355. Perhaps it would be better to say nothing about a bad workman quarreling with his tools as an excuse, but I found that one of the knife edges of the balance was broken. Before going to work, according to Mr. Oldfield's directions to get an accurate specific gravity, I got the weights most carefully adjusted, and also the balance put in first-rate order. The water used was distilled, the temperature kept to 60° Fahr. A mean of one dozen results on the lenses and fragments included gave 2·5529 for the crown, and 3·6452 for the flint. A still more careful test of the object-glass itself last week gave, to my great satisfaction, exactly the same result even to the fourth figure, which I have no doubt is the real thing. I shall be very glad if Mr. Oldfield will set me to work with some new curves. Does the above agree with my refractive index given some time since—viz., ·638 for the flint, and ·529 for the crown, both of which I took some trouble over? W. H. CASH.

COMPARING ELECTROMOTIVE FORCES.

[4697.]—REFERRING to letter 4610, p. 490, I beg to assure "Pi" that the three equations contained in my letter (4475, p. 411), are quite correct. The term *gi* should, however, be preceded by the sign + in the second, and by − in the third equation, or *vice versâ*. Bearing this in mind, these equations hold generally, and not merely when the current in the galvanometer is *nil*. I derived them from the following consideration, that "the sum of all the products of the separate intensities and resistances in any closed circuit equals the sum of all the electromotive forces in the same circuit." This is a natural consequence of Ohm's law, by which the product of the intensity and resistance in any part of a circuit equals the fall of tension in that part.

The truth of these equations may be shown in another way. By considering E_1 alone to act, find the current it would cause in the galvanometer. Do the same with E_2, and the difference of these expressions must represent the actual current. It is:

$$i_3 = \frac{E_1(r+y) - E_2(R+x)}{(R+x)(r+y) + g(R+x+r+y)}.$$

Now, by eliminating i_1 and i_2 from my second and third equations, with the assistance of the first, the above expression is also arrived at, thus showing the accuracy of the equations. O.

BOAT BUILDING.

[4698.]—WOULD some practical boat-building correspondent kindly give me information on the following points—viz.: Wherein consists the superiority of diagonally-built boats over clincher-built ones? Are they more difficult to build? Are they lighter, with the same degree of strength? Are timbers required? Is the planking at and about the midships continued from gunwale to gunwale round the keel, or fixed to the keel as in ordinary clincher building?

I have frequently built small craft clincher fashion, and am thinking of building a small lifeboat to coast in, 14ft. long × 4ft. beam, with air-chambers, &c., and decked over, canoe fashion, and think it best to build it diagonally, time being no great object. I would therefore be glad of the above information, or any other ideas in connection with the matter. I should mention I am intending to build it of two ¼in. skins of white spruce or yellow pine, and would also wish to know if the timber would be suitable, and of sufficient strength. CANOEIST.

USEFUL AND SCIENTIFIC NOTES.

Whitworth Scholarships.—The following were the successful candidates in the competition for the Whitworth Scholarships, at the Science and Art Department of the Committee of Council on Education, South Kensington:—Robert H. Smith, aged 20, mechanical engineer, Edinburgh; Albert E. Seaton, 23, draughtsman, Hull; George W. Sutcliffe, 23, joiner, Bacup; John C. Jefferson, 21, mechanic, Leeds; Henry G. Willis, 24, student, Trimley, near Ipswich; Frederick H. Millington, 21, millwright, Worsley, near Manchester; Edwin G. Field, 20, engineer's apprentice, Wolverton; Robert Coey, 20, student, Belfast; John C. Fell, 20, mechanical engineer, London; William Firkin, 21, analytical chemist, Crewe.

Maine Power.—The State of Maine is in one sense the most powerful State in the world, although it contains only 30,000 square miles. It has about 1,800 lakes covering nearly 3,000 miles, nearly all of which lie at the head of rivers running to the sea, and their great altitude gives to the descending water an immense power. Rangely Lake is 1,500ft., and Lakes Umbagog and Moosehead are each over 1,000ft. above the level of the sea, and the whole surface of the State is, on an average, 600ft. in elevation, so that the waters of all the lakes and rivers must fall that distance. It is estimated that the total water-power of the State is equal to the combined working energy of 4,000,000 horses or 34,000,000 men labouring day and night all the year around, or, counting only that available, exceeds the actual working power of all the men in the United States, England, France, and Germany.

Submarine Photography. — According to the correspondence of the *New York Herald*, an ingenious plan has been adopted by Prof. Agassiz's expedition for determining how far the submarine regions are pervious to light. A plate prepared for photographic purposes is inclosed in a case so contrived as to be covered by a revolving lid in the space of forty minutes. The apparatus is sunk to the required depth, and at the expiration of the period stated is drawn up and developed in the ordinary way. It is said that evidence has thus been obtained of the operation of the actinic rays at much greater depths than hitherto supposed possible.

REPLIES TO QUERIES.

*** *In their answers, Correspondents are respectfully requested to mention, in each instance, the title and number of the query asked.*

HINTS TO CORRESPONDENTS.

1. Write on one side of the paper only, and put drawings for illustration on separate pieces of paper. 2. Put titles to queries, and when answering queries put the numbers as well as the titles of the queries to which the replies refer. 3. No charge is made for inserting letters, queries, or replies. 4. Commercial letters, or queries, or replies, are not inserted. 5. No question asking for educational or scientific information is answered through the post. 6. Letters sent to correspondents, under cover to the Editor, are not forwarded; and the names of correspondents are not given to inquirers.

[11589.]—**Dry Steam.**—Will "E. L. G." kindly refer to experimental proof that 30lb. steam suddenly relieved of half the confining pressure will at once expand to not only double but to nearly four times its volume. I do not remember to have seen this stated before, but that is no reason for denying its correctness, nor does it seem to be improbable, but I should like to see it proved. If it be so, the sudden expansion of compressed steam will cause more of the apparent loss of heat than I supposed to be caused by its expansion alone. "A., Liverpool," is mistaken in supposing that I attributed the increased pressure of superheated steam to the increased quantity of water in it. Its elasticity may be increased just as that of any gas may be, by increase of temperature alone; but when steam is heated in contact with water, its increased tension is caused chiefly, not exclusively, by the increased quantity of water in the form of vapour, and the increase of its tension is very great in proportion to its sensible increase of temperature. As before stated, I do not think the increased tension of dry steam is the chief reason of its advantage, but that the excess of heat allows some of it to be transmuted into power, without any steam being condensed into water. I do not know that this opinion is generally accepted, but it is, I believe, correct, or nearly so.—Philo.

[12103.]—**Staining Glass.**—"Clinchey's" reply (p. 491) confounds three perfectly distinct things, the making of coloured glass—(*i.e.*, tinging its ingredients in the manufacture), painting on panes of glass with vitrifiable enamels, and the staining the same yellow or orange, for these are the only two stains yet discovered. The "very fine red" he first copies is merely red enamel for porcelain, or such as we see on the old German glass beakers. Being "fine" only as an opaque paint or by reflection, it would, in a window merely adorn the outside, and have no more effect within than so much sealing-wax. The same applies to all the other recipes with which he favours the querist. The yellow stain he describes indeed, but with no hint how it is applied; and doubtless a green of some sort has sometimes been produced by this "yellow on one side and a blue on the other," but he describes no blue! Oxide of chrome has *not* "been employed to *stain* glass green," but only to make green glass—*i.e.*, to tinge it in the melting-pot, which copper, however, does more richly. The chrome green is used only for trinkets in which also gold and uranium are employed to tinge glass, but not that of windows. The other tinging metals in use for window glass, besides copper (which gives both the finest red and finest green) are only cobalt for blue, manganese for violet, antimony for orange, and silver for yellow. Of all these, the only colorant known to *stain* glass already made is silver, either alone or alloyed with antimony. The silver, to stain yellow, may be either metallic or in the form of Chloride, and being levigated with a cream of clay or ochre (merely as an inert diluting vehicle) is spread and dried on the glass, being afterwards scraped off any parts that are to be left unstained; and when it has been exposed to a red heat, the layer being scraped or washed off, can be used again. The parts covered by it are found to be as transparent as before, but tinged yellow to a depth of a fortieth or even twentieth of an inch. With the antimonial silver, a similar stain, but of a dull orange or sherry colour, far less valuable artistically, is produced, and even one miscalled "red." Antimony alone, or in excess, has no effect; nor have means of staining in any other colour been found, though these have been practised for at least five centuries. Panes thus stained yellow have even superseded, for use in windows, all glass manufactured of that colour in fusion. It is to be noted that when, as in the Munich style of glass painting, the same pane is to receive both enamel colours and either of these stains, the painting and stain must be on opposite sides, or they would run together in the burning, and spoil each other. In the golden age of this art, till the end of the thirteenth century, neither these stains nor any painting in colour was yet known, (the only enamel applied being shadow-colour) nor was even any glass that we should call white, producible! Those who made the glorious windows of the Cathedrals of Chartres, Bourges, the Sainte Chapelle, or the Trinity Chapel, Canterbury—works of art as impossible for modern man ever to replace as to build a new Parthenon, or paint a new Vatican—had no glass that we should deem good or colourless enough for the rudest penny drinking vessel or toy, or any outhouse window.—E. L. G.

[12140.]—**Chemical (U. Q.).**—In answer to Mr. J. S. Hoyles, it is my opinion that Professor Dolbear's method for making potassium is not dangerous. The explosive compound, which is formed in the ordinary process of manufacture, is a compound of potassium with carbon monoxide. Now, carbon dioxide is not present in Dolbear's method of manufacture, and from the ingredients used, I think it is impossible for an explosive combination to be formed. It remains now to be seen whether the process is commercially useful. Certainly the separation of the metal from the paraffin oil will be no hindrance to its introduction, it needs only to be poured away or filtered, for potassium is not soluble in that menstruum.—George E. Davis.

[12153.]—**Ant Hill Earth (U. Q.).**—I know nothing of the above, but if "Proven" will sift his Bath-brick fine, add one-third whiting, and wet with brine of common salt, not too strong, he may burn his moulds and blow them out clean with a bellows; but you must guard against exposing your moulds to the action of the atmosphere as they absorb it very rapidly, and in drying again are apt to explode; therefore, when once dried and burnt keep in stove or oven until wanted. The same material can be crushed, sifted, and used over and over again. These can be fired very hard and clean, making good sharp work. Paraffin I have found as good; in fact, to my fancy, better than wax.—Jack of All Trades.

[12167.]—**Dry Soap (U. Q.).**—I don't know much about it, but I started to repair some machinery at a dry soap works; they caught me looking at them, so they sent me off before I had got all particulars. They had a pair of rollers like those that grind clay in a pan, by means of which they ground soda, tallow, and some sort of whiting or clay—lots of soda, lots of clay, and little tallow. The heavy rollers are to well mix it. When they had well ground it they shovelled it out into low boxes about 4ft. square and 6in. deep. There they let it lay till it dried a little (it won't stand drying with steam or fire, it melts the tallow). Then they put it into a mill, something like a coffee mill, and knocked it about, and it ran out underneath, dry soap. There is a firm not quite a thousand miles from Bradford, in Yorkshire, where they make lard out of soap-suds, which they get from washing machines at factories; the residue makes tallow for dry soap.—Outgenious Whitesmith.

[12167.]—**Dry Soap (U. Q.).**—"An Old Weston Subscriber" has not, I see, obtained an answer to his query, so I will now do my best to help him. Dry soaps may be made in many ways. I know several manufacturers of them, and they all use different processes. This is one process: Boil 9 parts of soda-ash (containing from 8 to 12 per cent. of caustic) in 10 parts of water, and add 10 parts of fat of any kind; keep constantly stirred, and add 80 parts of soda-crystals; keep hot and well stirred until all the crystals have melted or dissolved in their water of crystallisation, then run out into shallow iron trays, and keep constantly raked about, with a very fine-toothed rake, until cold. The dry soap will then be in a powdery state, and ready for doing up into packets. Another process is to melt 80 parts of soda-crystals in their water of crystallisation, and add 15 parts of hard white soap until dissolved; it is then run out as before, raked into coarse lumps, and afterwards ground in a mill. A third process may let my readers into a practical exposition of the saying, "one-half of the world doesn't know how the other half lives." A dry soap is made by this process by a "a dry-soap maker" in one of the northern counties. A soap is made by the first process, but with only 20 parts of soda crystals instead of 80, and this is afterwards ground up with not a very definite quantity Glauber's salts. The following are analyses I made some time since of the first and last specimens:—

	First.	Second.
Fatty acids	10·000 ...	8·774
Sodium chloride	1·228 ...	1·046
Soda crystals	79·440 ...	14·936
Soda ash at 50 per cent.	8·510 ...	2·244
Glycerine and sodium sulphate	·822 ...	73·000
	100·000 ...	100·000

—George E. Davis.

[12170.]—**Dyeing (U. Q.).**—I know of no association for the chemistry of the above, but you might apply to Lockwood and Co.; I believe they publish a good work upon dyes in general.—Jack of All Trades.

[12172.]—**Constipation.**—I beg to inform "Saxum" I have used the enema daily, and still continue; as regards its continued use, that must depend upon circumstances. Mine was a bad case. I may explain: At two years of age had a fall, which resulted in a determination of blood to the head; at four years my parents were informed that by the age of fourteen I should be a confirmed idiot; at fourteen a capital head-piece, but very weak constitution; put to hard work and long hours; at twenty-one very costive and head-ache; twenty-three, a continuation, with great mental anxiety, piles, rheumatism, sickness after each meal, and considered physically broken down, and mental powers weakened; at twenty-nine gave up my doctors, took to scientific pursuits (as a recreation to divert the mind), with excellent results; had a great deal of out-door exercise, but bodily ailments still continued; at thirty-two cured myself of rheumatism with egg liniment (try it); at thirty-three operated on at S. Mark's for piles (a good cure, but in my case not permanent: given up as incurable); took to the enema at thirty-four, and in three months my old friends forsook me; at thirty-seven I have not taken a dose of medicine, nor needed one, for three years. A debility of the system to a slight degree is left, the effect of so severe a drilling. My experience shows me that I require a daily use of the enema, but in some cases every other day would do, where the lower gut has not been so much weakened. From a pint to a quart of plain tepid water can be used in winter, or quite cold in summer; the cold is useful when the vessels require constricting, or where actual piles are present. I should not use it without. As regards medicated water, that would only be used in urgent cases of illness, such as a soapy lather would act as an irritant, and the starch as a counter-irritant. The best form of instrument is an indiarubber one, which can be bought for not more than 6s. 6d. at any indiarubber shop. It is a hollow bulb, with about 18in. of tubing at each end. With such a one any quantity of water can be pumped; to any one a stranger to its use I would privately send instructions. Most good doctors know the value of it, but very few have experience of a continued use, because patients, as a rule, do not like any trouble; it is a good thing for medical men they do not. Even if a strict course of diet was ordered to a half-dead patient, it would be considered very hard to be obliged to restrict oneself, and for a doctor to act strictly conscientious means poverty to one struggling for a living. An old woman doctor (12172) recommends cabbages, turnips, carrots, &c., which are quite right for a person in good health, and digestive organs sound, but awfully flatulent for weak stomachs, and I now know numbers of costive persons who dare not eat them, in consequence of not being able to digest them: the remedy in that case is worse than the disease, and I know it to my cost. It appears to me from a long experience that the proper course is to eat food which easily and quickly digests; take no medicine to further weaken and irritate the mucous membrane, but empty the bowels by means of the enema, and in course of time the system will strengthen and allow you to eat green stuff as much as you like. That is precisely what has taken place with myself. I eat anything now, but continue the enema, through the lower gut, being still my weak part, although I have no piles.—J. W.

[12172.]—**Constipation.**—I fully indorse the views of "A Physician" on the above subject, as to the constant use of white bread aggravating, if not being the main cause in many cases, of confirmed constipation, though at the same time whole wheat or brown bread are not always suitable means of relieving it, as many weak stomachs and bowels cannot bear the irritating effects of such. Vegetables and fruit are much more suitable in such cases, with daily ablutions. Dr. E. Johnson's theory is "that nervous excitement is the cause of constipation—that is, the cause of the arrest of the alvine secretion. The cause of constipation, therefore, does not reside in the bowels themselves, but in the nervous system, and can only be cured by a remedy which has the power of allaying excitement, and strengthening the great nervous centres." He regards the hydropathic treatment as a great means of cure, as drugs of any kind only relieve for a time, leaving the system weak and more susceptible to a future attack. He also regards it a most unnatural practice when the bowels are sluggish to have recourse to the constant use of medicine, as in almost all cases the fæces has not been secreted, and the effect of the purgative is simply to force and expel that from the bowels that nature intended should be retained some time longer. He also holds that the entire of the food is taken up into the blood, except indigestible substances, which pass without undergoing any change, and that no part of it is expelled in stool or fæces till secreted from the blood into the bowels. Among other reasons, he gives the case of a patient kept alive by the daily injection of mutton broth, and the yolks of eggs, his bowels being regularly relieved every three or four days of a well formed and healthy stool, possessing all the properties of an ordinary ejection. Another instance: you daily administer medicine, and daily the bowels are opened, though no food is taken. Surely if the common-received notions were true that the stools are the residuum of the food it would be a matter of great wonder, since out of nothing assuredly nothing can come. There are thousands of individuals who are constitutionally relieved only once a week, and sometimes once a fortnight (of a spare habit of body, with good appetite), whereas others again are daily relieved. If the old medical theory is correct, what becomes of all the refuse accumulating in such individuals, the retention of which gives them no trouble whatever. I recommend the perusal of Dr. Johnson's pamphlet on constipation and indigestion to those of your readers suffering from such ailments. I could write much more on the subject, but fear I have already trespassed too much on your space; but the subject is one of such importance, no doubt, to many of your readers, more especially to those who are brain-workers, and those following sedentary occupations (the great sufferers from constipation), as the man labouring by the sweat of his brow, and whose sleep is sweet, seldom suffers.—T. L. V.

[12173.]—**Coloured Inks.**—The fault of many who make coloured inks from the aniline colours is, that they make them too strong. I have for a long time written with magenta crystals dissolved in water; for a red ink it is very brilliant, and I have never needed that it should be thickened with gum. I have never used sugar either; it might certainly increase the brilliancy, but my inks have always been as brilliant as I have cared to see them.—George E. Davis.

[12245.]—**Chemical (U. Q.).**—Mr. R. Terret does not say whether he wishes for a method for separating the illuminants from coal gas, on the analytical, or on the large scale. Presuming that he wishes to do it on the large scale, he has only to pass the coal gas through a small column filled with flints, down which highly concentrated oil of vitriol is poured in a continuous stream. The olefines will be absorbed, while the vitriol will only take up traces of the marsh gas.

If a eudiometrical analysis is required of the gas, the olefines must be absorbed by a ball of coke saturated with a solution of sulphur trioxide in hydrogen sulphate, and when the absorption is complete, to remove the acid fumes with a potash ball.—GEORGE E. DAVIS.

[12269.]—**Staining Leather.**—A solution of salt of tartar or common soda will stain leather brown. The gloss is put on by rubbing with a piece of hard wood.—E. M.

[12272.]—**Electrotyping.**—To W. H. H. C.—The objects I am trying to electrotype are wood engravings, the electrotype to be used to print from, instead of printing from the engraving. When I have obtained the thin shell of copper by the deposit, it is quite evident I must have something to mount it upon before being able to print from it; those used in the printing trade are upon type metal, how is this type metal made to stick to the copper? I have dusted the copper over with powdered rosin, and poured melted metal on, but it would not answer at all. I have seen some electros with very thin coatings of copper indeed, and which appeared to me as if the copper had been deposited upon the metal stereotype, instead of being deposited on a mould and filled up with metal at back; perhaps this is the right process after all in this department of electrotyping. Up to now all my moulds have been of guttapercha: I could not make wax moulds take a deposit anyhow. I see another correspondent (qy. 12485) is inquiring for information respecting electrotyping, for the same purpose—viz., electrotype blocks for printers.—ZOO ANDRA.

[12276.]—**Boiling under Pressure.**—"W. W." does not say at what temperature he wishes to boil his liquid. A Papin's digestor is the best thing to use, but any vessel strong enough in which the "lid" could be kept down would do.—E. M.

[12277.]—**Aniline Black.**—A. Muller gives the following formula for an aniline black which can be used for printing:—20 parts chlorate of potash, 40 parts sulphate of copper, 16 parts of chloride of ammonium, and 40 parts of aniline salt, are dissolved in 500 parts of water, and warmed to about 140° Fahr., then removed from the water bath upon which it has been heated. If black enough, it is to be exposed to the air for a day or two; if not, heat again before exposing. After being well washed the powder or paste is fit for use. There are other formulæ in use, but I think this will suit "W. W."—GEO. E. DAVIS.

[12278.]—**Mercury.**—The symptoms of mercurial poisoning are said to be unmistakable. A coppery taste in the mouth, loose teeth, and spongy gums, and so on. The remedies are the dilute sulphuric acid of the Pharmacopœia, lime or lemon juice, and saline aperients. For the throat, use a very weak gargle of chloride of lime. Don't follow this advice unless you *know* it is mercurial poisoning from which you are suffering; although you can't do any harm by using the remedies, you may be neglecting the "beginnings" of something else.—SAUL RYMEA.

[12280.]—**Winter's Machine.**—The "wire passing through the wooden ring" may be of brass—preferably so, in fact. I suppose it increases the length of spark by collecting more electricity.—E. M.

[12282.]—**Holes in Valve-Board of Harmonium.**—These are made long for convenience. You may make them round if you like, but you won't get them tighter then. It is not the shape of the holes that is at fault.—K. T. L.

[12288.]—**Radius of Object-Glass.**—I send "Amateur" a set of curves for the discs named. The flint glass must be ground to the following radii, or on the following tools:—Convex side of flint lens must be ground to the radius of 102in. and the concave side to 17in., ditto that of the crown must be ground to 17⁸/₁₀in. by 26in., both convex.—W. OLDFIELD.

[12302.]—**Stains in Oak Plank.**—Try oxalic acid and water, or weak muriatic acid and water. The first removes all ordinary stains from most woods.—E. M.

[12304.]—**Phrenology (and Electric Sparks.)**—I am quite sorry for "Sigma." I had no intention of hitting him so hard as from the tone of his letter at p. 492 it is evident I have done. This he will of course deny, but nothing short of extreme irritation can explain or excuse his ill-mannered reply, of which, however, I make no complaint, as bad language injures those only who use it. "Sigma," as is natural with a man of his temper, thinks that I, who doubt his infallibility, cannot know what I write about, but the proof he gives is in this instance a queer one, for he abandons the opinion he gave at p. 418, to adopt that I gave at p. 468, which is that all but universally held by all great writers on the subject. At p. 492 he asserts, as if he thought it was denied, that children from their birth have very different powers and dispositions; but allows that they know nothing they have not learned, which is exactly what the great writers taught, who, he says, were never more mistaken. He does not tell us what writers he did refer to, and says he does not know or much care whether John Locke held the opinion or no. If "Sigma" neither knows nor cares what opinions great writers do hold or do not hold, would it not be as well for him to hold his peace on the subject until he does know? Electric sparks seem to be a sore subject with "Sigma," so I will say no more about that; except to refer those who wish to see whether it was I or he that was dogmatic, to the letters, and that they may do so with little trouble, I have looked out the pages in which they appear—namely, 615 and 667 of Vol. XIV., and 42, 62, 119, and 256 of Vol. XV. I gave no opinion of my own at all, but merely stated a fact which I had been told and believed, which "Sigma" very rudely denied, but which turned out to be quite correct. "Sigma" says I am incapable of understanding what I either read or write, and proceeds to misrepresent what I did write by saying I appear to grumble when people laugh at me. If he will look again at p. 472 he will see that I said I would rather be laughed at than have no laughing at all, though I prefer laughing at others, especially at those who cannot bear the most gentle correction without their dignity being insulted.—PHILO.

[12308.]—**Iron Vats Leaking with One Liquid and Not with Another.**—If "R. J." would screw his vats together with sheet indiarubber between the flanges, instead of wood, I think that would stop, or reduce to a minimum, the leakage of which he complains. The reason the mixture leaks, and not the nitre (potash nitre), is that nitrate of potash is not deliquescent, whilst muriate of potash and also the nitrate of soda both are, and it is always found when operating upon the large scale that if there is any tendency to leaking that it always happens first with deliquescent compounds.—GEORGE E. DAVIS.

[12321.]—**Chess Player.**—"Zoo Andra," p. 492, thinks Kempelen's own neglect of this toy for so long after it had answered its end of amusing the Empress, was a "presumption in favour of the pretensions of this contrivance to be a masterpiece of mere mechanism." Without regarding it as any way remarkable for mechanism, I cannot but think his conduct very natural. The object was to outvie some magnetic "experiments" or paradoxes that had excited the Court's admiration. The mystery of the so-called "automaton" is not in a concealed player working the figure so as to make moves of the pieces, which any one must have known was easy by mechanical transmission; but in this unseen and unseeing director knowing what moves his antagonist has made. He is placed, I am told, under the board, which is thin, and has 64 little pendents of iron hung under the centres of the squares, each with a little play up and down. The antagonist's pieces each contain a magnet, and when the concealed director sees a pendent that is sticking to the board drop, and another that was hanging down jump up to the board, he knows that the piece which was over the former pendent has been moved and placed over the latter. Having a little pocket-book board and men in his hand, he accordingly registers this move of his opponent, then considers and registers his own, and then proceeds to execute it publicly by the mechanism. As most players, on first attacking the "automaton," tried the experiment how he could treat a false move, they gave him the opportunity of thumping the table, replacing their piece (or turning it off the board, I forget which), and proceeding to a fresh move of his own; no small advantage. The inventor evidently saw nothing to be proud of in the mere mechanism. The magnetic indication of the moves was the gist of the puzzle. After its revival, however, in 1781, the popular idea seems to have been that a real automatic player, *i.e.*, a self-directed chess-playing *machine*, was either made or pretended to be made. The exhibition travelled to every town in Europe, and in the beginning of this century, I believe, to every part of Asia and both Americas; the main question raised everywhere being whether its moves were or were not directed by a human mind! But the climax of the joke was that even when this had been settled, as probably all civilised men soon did settle it, (for mind applied to each move, not mind that had made a playing-machine once for all), the decision was on false grounds; and probably 99 in 100 of us even now fancy the bare idea of a chess-playing machine is absurd, or would involve creation of something. It involves nothing of the sort. It is not more certain that an engine can be made to count sovereigns, and sort them into two boxes, the light and heavy, without further interference of mind after it is once set going, than that machinery *might* be made, were there time for its study and execution, to play, and either win or draw the game with every human chess-player infallibly. The late Mr. Babbage is the only writer on the subject, I have heard of, who maintained this view; which being laughed at, he once, I believe, proposed to clear up the befogged vulgar mind upon it, by constructing an actual automatic player of "*naughts and crosses*," a child's game on nine squares, probably the simplest of the class to which draughts and chess belong. The fact is that all such games are a mere trial of who will make fewest mistakes; and a machine might therefore play them, and making *no* mistakes, must always either win or draw. Between two machines (or perfect players) there must always be a draw.—E. L. G.

[12344.]—**Disappearance of Art.**—The débris of iron "bridges, cranes, and girders," waning when unpainted, into "that indestructible material" rust, will not, I fear, after the "many thousand years" of Mr. "LXXXVIII." (p. 518) yield quite so much evidence of mechanical (to say nothing of "fine") arts as the sculptured alabaster, delicate bronzes, and pottery of Assyria; and stupendous masonry, surrounded by endless broken glass, pottery, and bricks, of Egypt, each alike truly "indestructible" materials; and in the latter climate even papyri and mummies nearly as much so. The chances, or rather certainty, in all present appearance, promise those old lands very decided monumental survival yet, after the "disappearance" of the arts of "girder" riveting and all pertaining thereto. Mechanical arts and manufactures must surely be displaced, superseded and vanish; that of papyrus-making for instance, which employed half Egypt's population, and now it is far more than 1000 years since a sheet has been made, or a plant grown. (Isa. XIX. 7). There is small mystery in such changes. As for "fine arts," they seem a blossoming into which no race or tribe blooms more than once, in a real genuine manner. Ornament and architecture have been slowest declining in India. After many centuries of steady fall, they seem even now no lower than ours under the Tudors, or even equal to the French of that date in all but its statuary. As the Mahommedan horror of idolatry has always at least equalled the very earliest Christian, these late Hindoo and the earlier Arab decorative arts abundantly disprove *that* theory. Besides, the decline of classic European arts began as early as Alexander, was far gone even before Christianity *appeared*, and was pretty well at its bottom by the time Constantine acknowledged the new religion, when alone it could begin to affect art generally.—E. L. G.

[12348.] — **Spanish Pronunciation.**—Thanks for Mr. Wray's very full particulars. Is he sure any other than *Blanco* is legitimate? Another point in which the grammars seem to differ from what I have heard spoken, is in defining the *j* as simply equivalent to a *g* preceding *e* or *i*. Are not *ja, jo, ju*, really equivalent to *gia, gio, giu*, the *j* being a double letter, sounding as *gi*, the German *ch* (or rather what Orientalists now express by *hh*) followed by short *i*? *Hijo, bajo*, = echhio, bachhio; *not* echho, bachho. I agree with him that the Spaniards, by their sensible philosophic reform of their spelling, have made their tongue, in this century, the most regular and easy in grammar, probably, in Europe. It is also, I think, the finest in sound; at least, excelling the Italian on that score, *longo intervallo*. Besides having due shares of all the vowels, or more of *o*, and less of the thin *e* and *i*, there is freedom from the doubled consonants, and indeed from all syllables ending in other consonants than the six best terminals *d, l, n, r, s*, and *theta*. (These, by the way, would be our only abundant word-closers in English, if we had not the wretched *k* and *t* as often.) Though Italian boasts of almost entire absence of consonants ending words, it perpetually ends a syllable with one, and even repeats it to begin the next, a defect as bad as any in our barbarous north. Spanish has not only, thus, more vowels to its consonants, but a rare subordination of the acute or harsh mutes, *p, t, k, f*, to the grave or soft, *b, d, g, v*. They make *acuto* into *agudo*. I think that admirable; a due proportion of such letters barely appearing in French, while in Italian, English, and above all German, they are swamped by the harsh mutes. Germans, who have not learnt some foreign language young, can hardly sound words like *hand, rub, dog*, without making the final letter acute. Both southern tongues happily lack our corrupt short dull northern vowels, and have hardly more variety of sounded than of written vowels, all distinct and full. But Italian, besides fewer vowel, has fewer consonant sounds (and hence fewer letters) than, I think, any other alphabet; whereas Spanish is singularly rich in choice of consonants. It keeps at once our *ch* and the German *ch*, French "*ll* mouillé," Italian *gn*, and the ð and θ that none others but we and the Greeks have. True, it singularly lacks both our *j* and the French *j*, and *b* and *v*, having only their intermediate, the Greek β and probably Latin B. Our *w*, the Latin V, they can express by *hu* or *gu*, according to its aspiration. Doubtless theirs is the tongue most like the Classics. Then, apart from sound, its grammar is most rational. It alone has the four distinct auxiliary verbs that we elsewhere smash up into two. A Spaniard must see that it is a barbarous defect our having only "to be" for *ser* and *estar*, and only "to have" for *haber* and *tener*. We are all as much behind Spain in this as the ancients were behind us in not having two articles, the Romans none; or as the French are in their odious use of *femme*. How absurd, again, that none of us out of Spain, writing a question, will distinguish it by the ? where most needed, to mark the beginning, but only the end!—E. L. G.

[12350.]—**Sulphuric Acid.**—I cannot say exactly how Dr. Ure compiled his percentage scale, but it may be done by taking a known weight of acid at a known density, precipitating with barium chloride, and calculating the acid from the sulphate collected. As to calculating the quantity of vitriol from the cubic feet, the following ready method is followed by some manufacturers:—It is taken that 1in. of vitriol at 120° Tw. (1·75 specific gravity) weighs 10lb. Then, if we have 40 cubic feet at 1720 specific gravity (144° Tw.) and x = the weight required

$$x = \frac{144 \times 12 \times 10 \times 40}{150} = 4608\text{lb.}$$

Now this method is incorrect, for in the first place an inch over a cubic foot does not weigh 10lb., and the quantity of the di-hydrated sulphuric acid ($H_2SO_4H_2O$) does not increase in proportion to the degree on Twaddle's hydrometer. Now, taking a cubic foot of water to weigh 1000oz., we shall get the weight of a cubic foot of vitriol from its specific gravity, thus a cubic foot at 1720 will weigh 172·0oz., and at 1750 it will weigh 175·0oz. 40 cubic feet of vitriol at 1720 will weigh 4300lb., and as vitriol at 1·720 specific gravity contains about 79 per cent of H_2SO_4, and at 1·750 contains 81·5 per cent., the following equation will give us the weight of vitriol at 1·750 which 40 cubic feet at 1·720 is equal to:—

$$x = \frac{4300 \times 79}{81 \cdot 5} = 4167\text{lb.}$$

Difference, error in first method 441lb. Now, the first method, which is so simple, requiring so few figures, may be brought very near the truth by taking the weight of an inch over a square foot to be 9·1lb., this brings—

$$x = \frac{144 \times 12 \times 9 \cdot 1 \times 40}{150} = 4193\text{lb.}$$

—GEORGE E. DAVIS.

[12358.]—**To "The Harmonious Blacksmith."**—On referring to my contribution to the early history of pianofortes printed on p. 435 of No. 381 you will find your question relating to the combination of organ pipes with pianoforte strings substantially answered. I have little to add to what I there wrote, but may just remark that if the same rank of keys be employed for both, the pianoforte "touch" must be utterly spoiled so far as capability of expression on that instrument is concerned, just as it is in some modern combinations of free or harmonium reeds with the piano. You are quite correct in supposing the main difficulty is preventing variation of the relative pitches of strings and pipes, which, although unisonous at the same temperature at which they were tuned, become dissonant by any increase or diminution of heat. I fear nothing but maintaining the temperature at which they were tuned can entirely prevent this evil, although something may be done by mechanical contrivances which vary the pitches of many reeds at once, or by the late General Perronet Thompson's contrivance, which he designated a (pitch) regulator, which was a system of adjustable shades. Some two years ago I got so "awfully" wigged for suggesting to blow the same pipe with varying pressures of wind that my, perhaps, rather long ears have hardly ceased smarting yet, for even donkeys can feel, although pachydermatous. Nevertheless, this so-called impossible thing was done long ago by S. Erard, with what results I can find no record. My other old suggestion to put each pipe of a solo rank into a separate swell box to be opened gradually by the further depression of the manual for the purpose of obtaining expression *à la main* in organs seems but a still-born child. Long ago, I requested our late able "Adept's" opinion of this crotchet, but he has made no sign since he promised to reply to this and some other queries. Considering his writings in "our" journal long ago proved him to be "hevery hinch a gentleman," I greatly fear his long continued silence is the consequence of serious sickness, if not something yet worse. Surely all us "crotchetty" correspondents cannot but regret the cessation of his most able, instructive, and practical papers on the organ.—THE HARMONIOUS BLACKSMITH.

[12371.]—**Truss.**—Have the metal work plated or covered with vulcanite as done by the instrument makers to some surgical instruments, and have the pads to unship. One of the ordinary kind for the land and one filled with horsehair only, and covered with macintosh for the water, and the same with padding for the springs. Highly dangerous to bathe without one.—D.

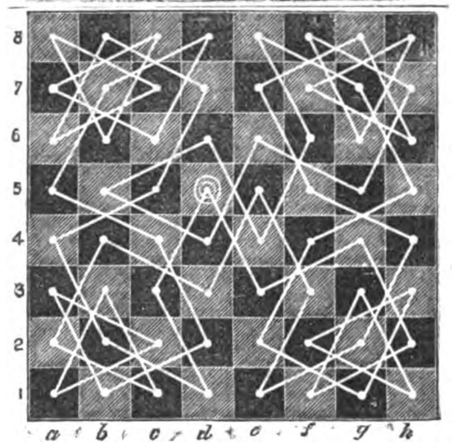
[12386.] — **The Prevention of Incrustation in Steam Boilers.**—Probably, "J. D. K.," with many other users of steam, has found by experience how little good accrues from the use of mineral compositions for boilers. Fuller's earth was once eagerly used until it was found to rapidly silt up the boilers. Tannic acid or tannate of soda is now having a good trial. Nearly any easily decomposed organic substance makes a good composition, the mineral matter becomes surrounded by the organic, which gets charred, when it forms a scale and allows the water to creep behind it. Bones form a good anti-incrustator.—GEORGE E. DAVIS.

[12387.] — **Amateur Organ Building.**—The sizes given are sufficient. If the bellows are to be worked by mechanical power or by hand double feeders will be better, but if occasionally by the foot of the performer a single feeder will be most useful. There is not any extra difficulty in making them of the dimensions proposed. The scale of the Bourdon is amply sufficient, viz., 6 × 5¼in. I very much prefer a moderate-sized pipe made to speak up well than a large pipe which is reduced so much. A small organ should be a minature church organ in tone.—J. D.

[12399.]—**Organ Building.**—The Viol d'Amour is a very small scale pipe of 8ft. pitch, it is half the diameter of the Dulciana, the mouth is one fifth of the circumference and as high as it is wide; the pipe has a sweet clear reedy tone, beautifully delicate and soft. There is no difference in shape between a Wald flute and Claribel flute, but the Wald has a higher mouth and is more reedy in tone. I would recommend the Bourdon to be mitred or elbowed and keep the pipes vertical.—J.D.

[12430.]—**Automaton Chess Player.**—1. For the article in German, with engraving, apply to Veit and Co., Leipzig, Germany, and order *Schachzeitung* of May, 1869, pp. 141 to 144. 2. For the article in Dutch, write to Dr. W. J. L. Verbeck, to Wijk bij Duurstede, Holland, and order *Sissa* of January, 1870, pp. 5 to 7. 3. For the article in English, with game and diagrams, write to Mr. Harrison, Merton House, Salisbury-Court, Fleet-street, London, and order *Gentleman's Journal*, supplement for March, 1870, pp. 105 and 106. 4. For a German notice in a Portuguese paper, apply to Mr. W. Spaythe, 66, Ludgate-hill, London, and order *Echo Americano* of October 27, 1871, p. 198. 5. For an English article on the *old* Automaton, apply to Trübner and Co., 60, Paternoster-row, London, and order *Chess World*, April and May, 1868, pp. 1 to 4 and 41 to 45. 6. See Professor C. Tomlinson's valuable work, "Amusements in Chess," pp. 87 to 113 (with 11 engravings and 4 games): London, J. W. Parker, West Strand, 1845. H. Meyer corresponds with Mr. Hooper, inventor of the figure at the Crystal Palace, and is willing to give further information.—H. MEYER, Sydenham.

[12438.]—**Chess.**—The following Knight's tour has no ends, therefore you can commence it on any of the 64 squares. There are several solutions to your question:—*d* 5, *e* 3, *g* 4, *h* 2, *f* 1, *g* 3, *h* 1, *f* 2, *h* 3, *g* 1, *e* 2 *f* 4, *h* 5, *g* 7, *e* 8, *f* 6, *e* 4, *d* 6, *b* 5, *d* 4, *e* 6, *g* 5, *h* 7, *f* 8 *g* 6, *h* 8, *f* 7, *h* 6, *g* 8, *e* 7, *f* 5, *h* 4, *g* 2, *e* 1, *f* 3, *e* 5, *d* 3,



b 4, *a* 2, *c* 1, *b* 3, *a* 1, *c* 2, *a* 3, *b* 1, *d* 2, *c* 4, *a* 5, *b* 7, *d* 8, *c* 5, *a* 7, *c* 8, *b* 6, *a* 8, *c* 7, *a* 6, *b* 8, *d* 7, *c* 5, *a* 4, *b* 2, *d* 1, *c* 3.—H. MEYER, Sydenham.

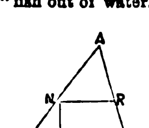
[F. Lewis and C. N. Abbott have also answered this query.—ED.]

[12439.] — **Working Plane Surfaces.** — Mr. Roberts, I think, may be able to grind plane surfaces if he gets two plane grinding tools, either planed flats or turned perfectly flat, and grind them together till all turning marks are removed with fine emery, and finish off with pounded pumice stone; after they are ground true together work the articles on either of them in the usual way of grinding and polishing true surfaces. This should answer for ordinary purposes, but if required in large pieces then Mr. Roberts will have to apply machinery, which Mr. Tydeman, I have no doubt, will explain according to promise.—WM. OLDFIELD.

[12444.]—**Day and Night Telescope.**—The day and night telescope is made with very large field of view, abundance of light, and only a moderate power, much less than that of other telescopes, which enables the seaman to see an object on a dark or dull night, when other telescopes would be useless on account of their higher powers.—W. O.

[12447.]—**Employment for a Retired Tradesman.**—Let a retired tradesman fit up a small printing-office; I warrant he will find plenty of amusement and interest in that; I shall be glad to give any information through the medium of the MECHANIC.—ZOO ANDRA.

[12447.]—**Employment for a Retired Tradesman.**—Being myself a "retired tradesman"—well, a retired manufacturer of remarkably "retiring" habits—I can fully appreciate my fellow correspondent's necessity, for he and most of his class (which has but few resources) are generally sadly in want of something useful to do, hence, nearly all retired tradesman, however pecuniarily rich, must of necessity be like "fish out of water."—THE HARMONIOUS BLACKSMITH.



[12457.]—**Geometry.**—Let A B C be the given triangle, and S the given given point. Draw S N parallel to A C (Euc. I.), and N R to B C. Then because N S is parallel to R C and N R to S C, ∴ N S C R is a rhombus inscribed in the triangle A B C.—P. W. H. J.

[12463.]—**Vision.**—"H. Science" puts two queries, the principal of which, I presume, is "How does the eye see an object erect when an inverted image is depicted on the retina?" I fear he will get little other explanation from scientific sources than he has himself indicated. The education theory seems to me to be a mere assumption. I hold to the common opinion, that the eye sees the outward object and not the inverted image. The proof is in the fact that objects appear in their natural position. Perhaps some of your able correspondents can tell us what amount of proof attaches to any scientific theory on the subject.—COMMON SENSE.

[12464.] —**Aquarium.**—From reading Mr. E. Fowler's query I am reminded of a young lady who kept some small trout in a glass globe. Mr. Fowler says "One day the water is nearly white; the next day, &c., to the end of the chapter where the tragedy occurs." Just what Mr. Fowler graphically depicts happened to the trout, from the young damsel fancying that one globe of water would do her much-prized fish for an indefinite time, but they were all "with the majority" next morning. Perhaps some spiritualist, who did not disdain such trifles, cast a spell over the imprisoned fry and sent them swimming through the narrow ocean of his fancy. At all events, the young lady's fish wandered round the globe no more, like some puny, discontented individuals, but lay "contented and still." She was then advised, if she wished to keep fish for the future, for their health and vivacity, to keep them supplied with a constant stream of fresh water. This was accomplished by forming a communication with a water-barrel outside by means of a small pipe and tap to regulate the supply. A small fountain was afterwards made to play through the glass globe by making some small holes in the top, and it formed a beautiful ornament with the lively fish inside. The water was carried away in an overflow pipe and conveyed to another barrel standing beside, but lower than the other.—RAT-TAT.

[12465.]—**Compound Eyepieces.**—In reply to "C. B.," the following is a good rule which will answer his purpose for the Huyghenian eyepiece with the proportion as 1 to 3; divide twice the product of the focal lengths of the field and eye-glass by their sum. Thus, if the focal lengths of the field and eye lens be 3 and 1, that of the equivalent lens is equal to $\frac{2 \times 3 \times 1}{4} = 1\frac{1}{2}$ or 1·5. The positive or Ramsden's is as follows:—The lens equivalent to an eyepiece of this description is found by dividing the products of the focal lengths of the lenses composing it, by their sum less the distance between the lenses; hence, if the focal length of each lens be 1·5, and the distance between them 1in., it will be as follows:— $\frac{1\cdot5 \times 1\cdot5}{3 - 1} = \frac{2\cdot25}{2} = 1\cdot125$ or nearly 1⅛in. focus; this method will, I have no doubt, suit "C. B.'s" requirements.—WM. OLDFIELD.

[12466.]—**The Harp.**—Although "The Blacksmith" is not the especial "Man at the Wheel," our "East-end Mechanic" asks his question "at," as Di Vernon expresses it, perhaps he will permit "The Harmonious Blacksmith" to inform him he can see some specimens of Irish harps at the present loan exhibition of ancient musical instruments in South Kensington Museum. Also—with the attendant policeman's permission (N.B.—Bobby is a very civil fellow whose temper is much tried by the genteel mob who will not keep their hands off what they don't know how to touch without great risk of injuring)—of measuring their strings. One of these harps, numbered 226 in catalogue, is strung with rather thick wire, but it looks very slack, I "rather guess" it 'aint "up to much," and certainly not "up to pitch." Another (No. 227) bears the date 1621, and yet another A.D. 1671, quite a juvenile. (N.B.—This "baby" in years is lent by a lord, consequently it is something to interest, and to be almost worshipped by such folks as blacksmiths and "East-end Mechanics.") Besides our ancient Hibernian friends, while "harping" on this subject, I may mention there are sundry Welsh harps, also one English ditto, said to have belonged to our most religious and moral King Charles II., of pious memory, to whose reign we are indebted for the Lord's-day Act, which don't shut up the publics in the East, but, by way of compensation, does shut up the Bethnal-green and many other museums on Sundays. (See the "Too Great Contrast" in *Punch*, of July 17.) Considering the "pious" memory of its royal owner, the harp must yet have an odour of sanctity far too powerful to be smelled on Sunday, at least by the "common people," although "King Cole" has occasionally admitted his "religious"—who are also "rich"—friends within the sacred precincts of science on that day. Of course, I need hardly add—for it is quite self-evident—that this would be so very dangerous to morality in so poor a locality as Bethnal-green that it could not be tolerated, so the police had orders to deprive of their tickets the wicked aristocratic visitors who "desecrated" the Sabbath by visiting our "East-end Mechanic's" local museum last Sunday. (See Mr. Goschen's statement in "the House.") There are also some French harps of the period of "Louis Carthorse," and later, but, to my humble judgment, not one of them is fit to hold the candle to a good performance on a modern double action Erard. This collection well repays the cost of a visit, for it is, perhaps, the most extensive collection of "ancyent instrvmentys of mvsick" ever brought together, and (as the little girl expressed the interesting fact) it may be seen "all for nothink" three days per week, and for "the ridiculously small sum" of sixpence you may get a "stuffed cat," I mean a catalogue "stuffed" with very interesting matter.—THE HARMONIOUS BLACKSMITH.

[12469.]—**Bees.**—F. J. Gooden will be lucky if his bees continue to hang out without swarming the second hive, for second swarms are always a mistake, much so when late in the season. I should recommend him to put a glass over the swarm and he will have a good take of honey next year. The plan he refers to, to turn up the stock hive and place another over it, I do not like. Will C. N. Abbott kindly forward his opinion and oblige —H. B. E.

[12473.]—**Printers' Rollers.**—Small rollers can be cast in an ordinary tin canister if it is perfectly round, care to be taken to let the composition set before drawing the roller out; the inside of the canister should be oiled to prevent its sticking. The best thing to clean a roller with is benzoline, the same as burnt in lamps; never wash a roller with lye (potash) as it ruins them; when out of use take as much ink off with paper as possible, and slightly oil with a little neatsfoot oil, and keep in a well ventilated cupboard or box. To make the roller take ink after being oiled go over it with a damp rag or piece of waste. By following the above directions a roller will be as good and tacky at the end of a twelve month as it was when first cast.—ZOO ANDRA.

[12474.] — **Machine for Making Aerated Drinks.**—I believe the gas and water is pumped into the condenser by means of a pump. The cost of the excellent machine producing from 30 to 700 siphons or from 700 to 1,500 bottles per day, is cheap mounted for use: £44 700 bottles, £69 1,500 bottles. I forgot to mention that the gas remaining in the machine after an operation can be used for the next, and will make an economy of about a third in the acid and whiting. I do not know if it could be worked by steam, but will endeavour to ascertain for "E. L. P. G."—H. B. E.

[12476.]—**Bee-Keeping.**—Perhaps some of the plans suggested by Mr. Abbott from time to time would be practicable in "B. H. J.'s" case, or he might try the methods recommended by me to "Willie Scarer" and "W. T. L." The bees seem to have formed a very desirable amalgamation, though very singular from the fact that after driving or fumigation bees are more inclined to rob the neighbouring hives. However, the order of procedure, as members of the law say, may have been reversed in "B. H. J.'s" case from some unexplained reason or circumstance. Perhaps two or three hives were fumigated the same day, which may account for the bees being bewildered and not knowing their own hives. "B. H. J." says that his bees have built the combs in his "Nyborg cabinet" diagonally, instead of straight with the frames. To prevent them building in any but the right direction, and in the right compartment, a few bits of comb from the old hive should be attached; by heating a little, along the tops of the bars, the bits of comb may be about two inches long, half an inch deep and the width of the frames.—RAT-TAT.

[12477.]—**Water-Glass.**—A simple form of water-glass may be made by cementing a circular piece of glass to one end of a wooden tube, the tube may be 6ft. long, and about 4in. in diameter; to use it the glass end is dipped some depth in the water, and the other end closely applied to the side of the face. It has, of course, no magnifying power. A similar one is used in Norway; if lenses were used the focus would be very much longer for water than for air, on account of the refractive index of water being considerable.—PHILANTHROPIST.

[12478.]—**Sour Ale.**—Rack it off, and put some bi-carbonate of soda and some hops, and bung up again for a week or two.—JACK OF ALL TRADES.

[12480.]—**Silk Working.**—No remedy but to be filed out and burnished again.—JACK OF ALL TRADES.

[12480.]—**Silk Working.**—Touch the males with hydrochloric acid, and the rust will soften and drop out with the working of the silk.—RAT-TAT.

[12481.]—**Wax Moth.**—Treat them while in the hive, or in a covered vessel, with tobacco smoke, or carbolic acid gas. If moths are about cover the entrance holes at night, and stand a shallow vessel containing a mixture of impure honey and iodide of potassium on the top of the hive, or on the stand. The moths and other insects will be attracted by the odour, and fall an easy prey.—RAT-TAT.

[12482.]—**Integral and Differential Calculus.**—This branch of mathematics is used in the higher branches of mathematics. In astronomical calculations, optical investigations, in calculating strength of materials, &c., it is the foundation of the higher mathematics. If a person knew Euclid and algebra, he could begin the calculus, but it is usual to study trigonometry also. There are some excellent rudimentary treatises in Weale's Series. Todhunter's Differential and Todhunter's Integral Calculus are read at Cambridge. They are expensive, 10s. 6d. each.—PHILANTHROPIST.

[12483.]—**Rewiring Old Piano.**—I rewired an old one about 12 years ago with as near the same size wires as I could judge, and it answered well. If you put stouter, the pins will not bear the strain required to tune it. I put all plain wire; you can get it in hanks from 1oz. If you want to know where, and will advertise address, I will send to you.—WEBB.

[12484.]—**Inorganic Chemistry.**—The "Science and Art Syllabus" mentions the following works for the advanced stage:—Chemistry, Inorganic and Organic, Bloxham; Manual of Elementary Chemistry, Fownes; Elements of Inorganic Chemistry, Miller; Chemistry for Students, Williamson; Chemistry for Schools, Houghton Gill; Qualitative Analysis, Galloway. Besides these works, the following are recommended for reading and working for honours:—Second Step in Chemistry, R. Galloway; Chemical Physics, W. A. Miller; Dictionary of Chemistry (4 Vols.), H. Watts; Elementary Treatise on Heat, Balfour Stewart; Heat as a Mode of Motion, Tyndall; Quantitative Analysis, Vacher's Fresenius. "Science and Art" wishes to know what "honours" consist of. This is asked by many, but having passed them myself, I can say that you have the honour of seeing your name printed upon a piece of paper called the results of the examinations. I think the Government should give something, even if it is only a printed card, as a mark for having passed through such a stiff examination as it usually is.—GEO. E. DAVIS.

[12485.] — **Electrotype Casting.**—Moulds for these are best made of either marine glue or gutta-percha, keeping the model in close contact by means of a weight until cold. Treat the face to a polish with a very soft brush and plumbago until it has a good metallic lustre. Use two small batteries and a decomposing trough.—JACK OF ALL TRADES.

[12486.]—**Machine for Cleaning Boots.**—I have somewhere seen a drawing of a machine brush, similar to those used in modern hairdressers' establishments, worked by the foot in the same way as a lathe or sewing machine. Why should there not be shops in London or elsewhere where you might go in and have your boots cleaned on your feet by an attendant with a revolving brush in his hands? Let some of your hair-dressing readers introduce this practice into their establishments. A few extra brushes and a longer band are all that are needed.—C. P. E.

[12486.]—**Machine for Cleaning Boots.**—If "S. J. R." will refer to reply 6739, p. 597, Vol. XII. of the ENGLISH MECHANIC, he will there find a sketch of a boot cleaning machine "driven by power or hand," which, "with only three brushes, cleans from 230 to 250 per morning."—THOMAS HUTTON.

[12486.]—**Machine for Cleaning Boots.** — Merely a machine like a scissors-grinder's barrow, substituting brushes for stones.—JACK OF ALL TRADES.

[12487.]—**Annealing Spring Steel.**—This is a new "kick" entirely, annealing steel for welding—at least to me. To anneal iron or steel, take small chalk, old mortar, or whiting will do, inclose it in that in a piece of tin or ball of clay, and make it red-hot. It will make it beautifully soft and free from pins, and if the operation is continued with care, cast iron or steel may be made so soft that you may cut it with an ordinary pen-knife like lead, and no detriment to the steel.—JACK OF ALL TRADES.

[12487.]—**Annealing Spring Steel.**—I don't know but to weld a spring plate as well as it can be done is to weld a piece of iron to it, then the other piece of steel to it same as cast steel. To temper any kind of springs, make red-hot all over, cool in soft water, then hold over bright fire, get a lump of tallow, grease all over, hold it till it blazes all over, let it cool out itself.—OUTGENIOUS WHITESMITH.

[12488.]—**Zinc for Hot-water Tanks.**—It must be very stout to be of any service, as it contracts and expands so much that it cracks at angles and joints, and soon becomes useless. Try galvanised tinned iron.—JACK OF ALL TRADES.

[12489.]—**Lacquering Brasswork.**—Yes, it is sometimes done, or attempted; it is not always that they succeed in making a job of it. The best way is to dip it quick.—JACK OF ALL TRADES.

[12489.] — **Lacquering Brasswork.** — Brass-finishers often give brasswork two or three coats of lacquer, and re-heat for each coat given.—W. O.

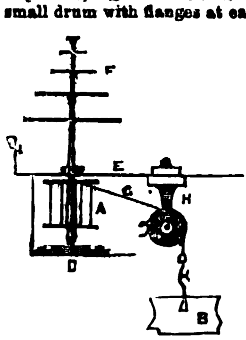
[12490.]—**Grape Culture.**—"Horatio" will find abundant information in a work composed by Thomas Mawe and John Abercrombie.—CLINCHEY.

[12490.]—**Grape Culture.** — "Hoare on the Vine" is an exhaustive treatise on the subject.—OLD BOOTS.

[12491.]—**Overgraining.**—Discard the beer. It should only be used for dead colours and show-boards. Use turps instead.—RAT-TAT.

[12491.]—**Overgraining.**—Use vinegar; when beer or size is used it has a habit of crawling and pealing off; by using the above you will get over the difficulty.—JACK OF ALL TRADES.

[12492.]—**Show Stand.**—To drive show stand, a small drum with flanges at each end, four straight pins for rope G to lap on to, riveted into flanges, H double eye with collar and nut to hold to floor boards for pulley C to work in, rope G works over attached to lump of stone B. I is shop front, F show stand, lowest end as a centre working on a piece of iron with a centre in it. E is supposed bottom of shop-front window. The reason for having a large stone or a bundle of bricks is that you can speed it yourself by knocking a lump off or putting a lump on. When you want to wind it up you catch hold of bottom wing of stand, and twine it the other way till weight comes close to pulley C. The drum A must be a small one.—OUTGENIOUS WHITESMITH.



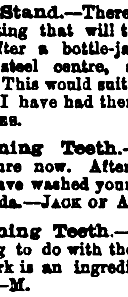
[12492.]—**Show Stand.**—There is a maker of a jack for meat roasting that will turn from 100lb. to 150lb., something after a bottle-jack. The foot of frame rests in a steel centre, and the affair is regulated by a fan. This would suit you. The maker's name I know not. I have had them under repairs.—JACK OF ALL TRADES.

[12494.]—**Hardening Teeth.**—It is the effect of the acid. No cure now. After taking the compound you should have washed your mouth and teeth with carbonate of soda.—JACK OF ALL TRADES.

[12494.]—**Hardening Teeth.**—I do not think quinine has anything to do with the breakage of the teeth. Cinchona bark is an ingredient of one of the best tooth powders.—M.

[12496.]—**Stained Scarlet Tunic.**—Well wash, and after rinse in salt and water, after in pure water.—JACK OF ALL TRADES.

[12499.]—**Trigonometrical.**—Draw DE perpendicular to AC.



$$\text{Tan. ACD} = \frac{\text{DE}}{\text{EC}} = \frac{\text{DE}}{\text{AE}} \cdot \frac{\text{AE}}{\text{EC}} = \frac{\text{BC}}{\text{AC}} \cdot \frac{\text{AD}}{\text{DB}} = \frac{a^2}{b^2}.$$

$$\text{Again, } \because \frac{\text{AE}}{\text{EC}} = \frac{\text{AD}}{\text{DB}} = \frac{a}{b}, \therefore \frac{\text{AE}}{\text{AE} + \text{EC}} = \frac{a}{a+b}.$$

$$\therefore \text{AE} = \frac{ab}{a+b}.$$

$$\text{Also CD} = \sqrt{\text{DE}^2 + \text{EC}^2} = \text{AE}\sqrt{\frac{\text{DE}^2}{\text{AE}^2} + \frac{\text{EC}^2}{\text{AE}^2}}$$

$$= \frac{ab}{a+b}\sqrt{\frac{a^2}{b^2} + \frac{b^2}{a^2}} = \frac{ab}{a+b} \cdot \frac{\sqrt{a^4 + b^4}}{ab} = \sqrt{\frac{a^4 + b^4}{a+b}}.$$

Q. E. D. Many solutions.—ALEPH.

[T. Hucklebridge and "Xenophon" have also answered this query.—ED.]

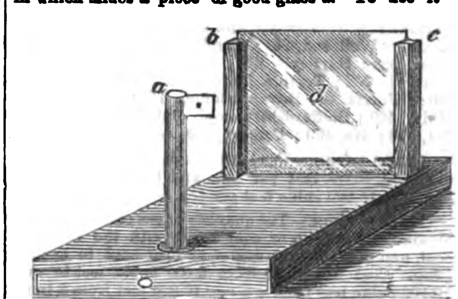
[12500.]—**Land Surveying.** — A land surveyor should be able to survey an estate and make a map of it; he should have also an elementary knowledge of civil engineering, and be able to make a road, &c.; he should be acquainted with drainage and irrigation. As to studies, a fair knowledge of elementary mathematics, such as Euclid, algebra, and trigonometry is necessary. Surveying should be studied theoretically and practically; drawing and mapping are very important. A practical acquaintance with the instruments used by the civil engineer should be attained; many moderate surveys have been made with the chain alone, as it saves the trouble of carrying other instruments, it is necessary, however, to understand the use of the theodolite, the level, the box sextant, prismatic compass, &c. I do not know the technical requirements demanded of the surveyor.—PHILANTHROPIST.

[12501.]—**A Cheap Gas.**—Your correspondent will find some valuable information in a book published by the late Mr. Weale. The following is the title:—"A Treatise on Gas-works and the practice of Manufacturing and Distributing Coal Gas." By Samuel Hughes, C.E. The nominal price of the book is 3s. Too much of your space would be occupied by giving extracts.—W. AIREY.

[12501.]—**A Cheap Gas.**—"A., Liverpool," does not say the quantity he wishes to make at once, nor the purpose he wishes to apply it to, but after stating that it need not be inflammable, we may suppose he does not wish to burn it. Coal gas costs more for making in some places than others. I know a place where cannel gas only costs 2s. 6d. per 1000ft. for making, and another where coal gas costs 3s. 2d. per 1000ft., so it depends upon the locality for one thing, which would have to be taken into consideration before a price was given. If "A." wishes to make it at Liverpool it would cost him about 2s. 10d.—GEORGE E. DAVIS.

[12503.] — **Testing Tartaric Acid.** — Make a clear solution in pure water, drop into it a little solution of chloride of barium, and a dense white precipitate will form; pour off the liquid, suspend the precipitate in a little water, and add nitric or hydrochloric acid; if any remain undissolved, there is, probably, a sulphate mixed with the tartaric acid, perhaps alum.—PHILO.

[12504.]—**Sketching from Nature.**—Let T. King get a piece of well seasoned wood, about 16in. by 10in., or even larger. At one end insert an upright centrally (*a*), in which is fixed a small piece of tin, card, or other material with a small neatly punched hole about the size of the letter "o" in the type with which this is printed; two more uprights *b* and *c* with grooves, in which slides a piece of good glass *d*. To use it—



wash over the glass a very thin solution of gum arabic and white sugar-candy, twenty parts of former to one of latter, let it dry; now set it up; look through the small hole to get the object or landscape subtended by the glass, and with a soft Paris Conté crayon outline the subject on the prepared surface; remove the glass and lay it over your sketch; if you require the outline you should have a second plate of glass, and trace over it the reverse way with charcoal, then lay your paper on, and a little gentle rubbing will transfer the outline. By adding a drawer to your board and screw holes for your uprights you may carry the apparatus about with ease.—OLD BOOTS.

[12504.]—**Sketching from Nature.**—Make a square or oblong frame of strips of wood 1in. wide by ½in. thick (6in. by 8in. would be a convenient size), stretch fine string or wire across each way to form about 1in. squares; suspend this in front of you and look through it at the object you want to sketch.—WEBB.

[12504.]—**Sketching from Nature.** — Let T. King provide himself with a frame of light wood of such dimensions as he would be satisfied to carry; let him divide this into a series of squares or oblongs by strings or wires stretched across the length and breadth of it. Let him rule the paper on which he means to sketch into a set of proportional divisions, by lightly marked dots or lines in pencil. Let him carry a walking-stick with a taper ferrule at one end, and a T top, each end of the top to have a screw-hole for attaching it to the frame; the double attachment will keep the frame from swinging. Having selected his view, he is to attach the stick to the frame and fix it upright in the ground, then taking up a suitable position behind it proceed to sketch the most marked objects in the centre division of the frame exactly in the same relative positions in the centre division of the paper. It would be well to have one or two test objects in the corners, or on the actual intersections, for during the progress of the drawing he will be sure to shift the position of his eye, and by bringing these test objects into their original place he will get right again. It is better to jot down the principal objects first, and afterwards fill in the connecting parts. The inconvenience of wires is their getting bent; of strings, their becoming slack; but most people know how to tighten a string. A plate of glass might be used in the frame on which the lines could not vary; but this would add to the weight, and glass is very sure to come to grief.—T. S. G.

[12506.]—**Power of Engine.**—The effective horse-power of Hecla engine, if it is high pressure, would be about 74, but as for nominal he can give it any name he likes.—H. T. P.

[12506.]—**Power of Engine.**—The nominal and effective horse-power of engine of the following dimensions:—Cylinder 20in. diameter, 18in. stroke, and 100 revolutions per minute (which is equal to 300ft. per minute; steam 40lb. pressure, and cut off at two-thirds of stroke (which is equal to 26·666lb. mean elastic force throughout the whole stroke). First I will find the nominal horse-power, which is merely a term in the buying and selling of engines, independent of locomotives. Rule, find the piston's area in square inches, multiply by its velocity in feet per minute and × by 7lb., which is always taken as a constant number; divide the product by 33,000, and the quotient is the expressed effect in nominal horse-power, which is 19·99.

$$20^2 = 400 \times \cdot 7854 = 314\cdot 16 \times 300 = 94248\cdot 00 \times 7 = \frac{659696}{33000} = 19\cdot 99 \text{ horse-power nominal.}$$

Or can be found by dividing the square of the diameter of piston in inches by 20, which answer is not far out of former one.

$$20^2 = 400 \div 20 = 20 \text{ horse-power, nominal.}$$

The effective force or working power of the same engine is—Rule, multiply the piston's area, in square inches, by the mean pressure or elastic force of steam per square inch, then by number of feet piston travels per minute, and divide product by 33,000, the quotient = the effective horse-power, which is 80·7.

$$20^2 = 400 \times \cdot 7854 = 314\cdot 16 \times 26\cdot 666 = 8377\cdot 39 \times 300 = \frac{2663217}{33000} = 80\cdot 7 \text{ effective horse-power.}$$

—G. Valentine.

[12511.]—**Gas.**—The following is the average quantity of gas obtained from one ton of Lancashire Cannel, 11,600 cubic feet; Wallsend, 10,300; Newcastle (Hartley's), 9,600; Temple Main, 8,100; Staffordshire (best), 6,400; Primrose Main, 6,200; Pembry, 4,200. The following is a table, showing the comparative qualities of coal, Scotch coal being estimated at 1,000:—Scotch Cannel, 1,0 0; Lancashire, 986; Yorkshire. 949; Bewicke and Craister's Wallsend, 875; Russell's Wallsend, 861; Tanfield Moor, 850; Heaton Moor, 822; Hartley's, 810; Killingworth Main, 792; Pontops, 762; Temple Main, 690; Manor Wallsend, 650; Forest of Dean Middle, Delf, 612; Eden Main, 562; Staffordshire coal, 1st, 546; 2nd, 514; 3rd, 492; 4th, 490; Pembry, 354.—William H. Hey.

[12511.]—**Gas.**—Newcastle coal yields from 9,500 to 10,000 cubic feet per ton, and Cannel yields from 11,500 to 15,000 cubic feet per ton.—W. Airey.

[12511.]—**Gas.**—The quantity of gas capable of being obtained from a ton of coal varies with the variety of coal, and also with the degree of heat used in carbonising. Coal will yield from 6,000 cubic feet to even 10,000 cubic feet from a ton. 10,000 feet from a ton of coal is a rarity, but it has been done. From 8,000 to 11,000ft. may be got from a ton of cannel coal, but if 10,000ft. are obtained from either Wigan or Bridgwater Cannel, it is not bad carbonising.—George E. Davis.

[12511.]—**Gas.**—Newcastle coal will give from 8,000 to 11,600 cubic feet of gas per ton. Cannel from 9,350ft. to 15,000ft.—Excelsior.

[12512.]—**Spotted Kid Gloves.**—Touch the spots with benzine collas.—Rat-Tat.

[14514.]—**Elder Flower Water.**—Take of fresh elder flowers 10lb. (or an equivalent quantity of the flowers preserved while fresh with common salt); water two gallons. Distil one gallon. This is according to British Pharmacopœia. For lavender water take of essence of lemon, essence of bergamotte, and essence of cedral, of each half an ounce; oil of cloves and oil of citronelle, of each half a drachm; otto of roses, three drops; and oil of lavender, half an ounce; spirits of wine, one pint; a few grains of musk may be added. It improves with age.—Opaline.

[12515.]—**Mowing Machine.**—There are various causes which will account for the frequent breakage of the knives of "A Countryman's" machine—viz., they may have been repaired with inferior iron, or are too long or too short, in either case breakage will occur. The finger beam and fingers may require setting and adjusting, this is a frequent cause of breakage. I don't think a short connecting-rod has much to do with it, although I decidedly prefer a machine with a long rod. I repaired a machine last week troubled with the same complaint as "C.'s"; in this case I found the crank shaft was crooked. But the best advice I can give him is never to allow any one but a thoroughly competent machinist to have anything to do with repairing his machine, he will find out what is wrong and remedy defects.—Toyo.

[12515.]—**Mowing Machine.**—I had a machine made by the same makers which worked very well until the third season, cutting about 100 acres each year, when several knives were broken before I found out the cause, which was from the pin and pinhole of crank having become worn; mine worked with a long rod, in consequence of this part having play the knife-bar is struck instead of being pushed. Any long iron bar will drop in two pieces if struck repeatedly on one place, with a small hammer.—Old Ploughman.

[12516.]—**Mathematical.**—To show that

$$\cdot\dot{1} = \frac{1}{9}$$

$$\begin{aligned} \cdot\dot{1} &= \cdot 1111 \ldots \text{ \&c. multiply by 10} \\ &= 1\cdot 1111 \ldots \text{ \&c. subtract } \cdot\dot{1} \\ &= \cdot 1111 \ldots \text{ \&c.} \\ \hline 1 &= 9 \text{ times } \cdot\dot{1} \\ \text{therefore } \cdot\dot{1} &= \frac{1}{9} \end{aligned}$$

See also Munn's "Theory of Arithmetic," p. 134.—C. H. W.

[12537.]—**Compressing Air.**—"Mechanical Equivalent" has miscalculated the pressures his air will have when confined to the 5in., 4in., or 3in. Instead of 3, 4 and 5 atmospheres at these three volumes, it will be 2·4, 3, and 4, inversely as the volumes themselves. The halving or doubling, Dalton found to raise or lower the temperature, if no heat were to escape, about 50° Fahr.; and for other ratios of compression or expansion, the heat being as the work exerted, and this being as the hyperbolic logarithm of the ratio of change of bulk, the rise or fall of temperature, if the act could be perfectly sudden, would be to 50° as the common logarithm of the ratio is to ·30103. Hence we have—

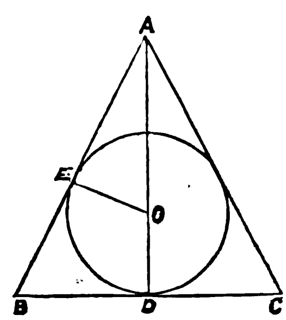
Log.	2	=	0·301030	∝	50	Fahr. temperature.
"	2·4	=	0·380211	∝	63·4	"
"	3	=	0·477121	∝	79·5	"
"	4	=	0·602060	∝	100	"
"	6	=	0·778151	∝	129·7	"
"	12	=	1·079181	∝	180	"

These would be the rise of temperature at the compressions into 6, 5, 4, 3, 2, and 1in.; and at expansion to 2ft. the fall would be 50°; to 4ft. 100°; to 8ft. 150°; to 16ft., 200°; to 32ft., 250°; to 64ft. 300°; to 128ft., 350°; to 256ft., 400°; and to 512ft. (if that is what the last figure means) 450°. As for "raising the piston to an infinite height," it is certain that, without receiving more heat, the air would not expand beyond a certain height, where it would become, in fact, a liquid, with an inelastic surface, as it must at the top of the atmosphere, at a temperature (as is supposed) of − 58°. At lower temperatures, it would not expand so far, and the absolute zero, where all fluids would lose elasticity, is probably about −490° Fhr. The work expended will be about 14·3 foot-pounds (or 183 5 times the air's weight) for each degree. To heat a pound of air 1 degree without change of volume requires 130 5 foot-pounds. To heat and also expand it, without change of pressure, requires 183·5 foot-pounds, the difference, or 53 foot-pounds, being the power exerted in expanding. It is questionable whether a heating of the whole upper half of the atmosphere to boiling or even red heat, so as to expand to several times its present height, would be perceptible to us otherwise than by slightly altering astronomical refraction, and very slightly lowering the barometer, by the gravity lost through increased distance of the upper layers from the earth's centre. All this heat would probably radiate into space before a very sensible portion could creep down to us here, four miles below, by conduction. The question has much bearing on the diluvial comet-fall.—E. L. G.

[12559.]—**Cleaning Oil Painting.**—I cannot give "Semper Paratus" a "trustworthy recipe which has been proved," or rather I could give him some half-dozen such, but, alas! not any single one which is the "universal medicine" or menstruum he requires, simply because different varnishes are used for pictures, and the solvent of mastic will not dissolve copal. Picture cleaning is an art not to be learned in one day, and before the operator can be safely trusted to go to work on any picture whose varnish has become discoloured by age, he must have had considerable experience. In its absence, no doubt you may "clean" a picture very effectively, so much so that it is often so thoroughly "cleaned" that it becomes so difficult to determine what the subject was that it is almost a necessity to make a copy beforehand to enable you to "restore" by repainting it all over. I am sorry to add many of the valuable productions of the old masters have been "restored" after this fashion by men who are neither old nor new masters—in a word, who have exhibited no "mastery" of the brush at all. I think I have replied to similar questions more than once before. See No. 293, p. 135 of our journal.—The Harmonious Blacksmith.

[12572.]—**Piano Construction.**—1. The engraving of action Fig. 3 is half the size of my drawing, consequently the hammer-shanks and other parts are double the dimensions shown therein. 2. A double brass rail may be employed if desired, but personally I greatly prefer being able to remove each hammer singly, consequently I most decidedly recommend a separate fork, or—if the butt be forked—a separate prong for each. 3. In my drawing only the round parts were shaded, consequently the positions of the dowels were very distinct. Probably my mere outline drawing was not sufficiently "artistic" for the wood chopper—I beg pardon, I mean engraver—so he (or rather, perhaps, the draughtsman) shaded all the parts "pretty considerable I guess," hence the positions of the two horizontal dowels in the hopper are difficult to see—they are but just visible when the dotted lines are carefully looked for. In my model the width of the hopper for the upper 1¼in. of its length is 7/16in. where the inclined part is glued on, and it is reduced to ⅜in. below when it is in the forked guiding socket. If "Pianette" prefers making the head of the hopper no wider than ⅜in., he must use thinner dowels, say ⅛in. or 1/10in. diameter. I believe the latter, if made of good English oak or hornbeam, would be strong enough; brass or copper wire rivets might be preferable. 4. For preventing the hopper from sliding sideways, probably the cheapest thing is a forked socket just like those used for the jacks or hoppers of ordinary grand pianofortes. In his patent, Mr. Molineux specifies a clothed mortice in the hopper, which is guided by an oval key-pin inserted in the rail behind it. This has the great advantage of enabling the side shake to be reduced to a minimum by partially turning the oval pin, just as we prevent the rattling of keys which have clothed front mortices and oval pins—a luxury well worth its trifling extra cost. The "rattle" of loose keys is to me a very unpleasant "plaything." 5. The set-off screw is in the hopper, which is reinforced—or left thicker—where it is screwed through it. This screw has a slot for the screw-driver at its front end. By the way, the front surface of the tail of the hammer-butt is erroneously represented "out of the square" with the inner end of this screw. Of course it should be parallel to the screw's hinder surface. 6. In all actions in which the dampers are attached to the hammer-butt, it is customary to take the dampers away from the strings by moving the action frame forward. If wire bridges be made only long enough to receive the strings of one note, unless secured by other means than the downward pressure of the strings on them, there is some risk of their falling out when the strings are taken off. In some respects I prefer studs to wire bridges. See article on improving the trebles of cottage pianos in No. 381. But I yet believe the tone is purer when the wire bridge is employed, especially if the lowest inch of the space between the strings and the wrestplank be well stuffed with felt or cloth, so as to prevent any audible vibration above the wire bridge.—The Harmonious Blacksmith.

[12574.]—**Calculus.**—Let ABC represent the required triangle. Join A with O (the centre), and produce AO to meet BC in the touching-point D. Join EO. Let angle BAD = α. Then AO = 50 co-sec. α, ∴ AD = 50 (co-sec. α + 1), and BD = 50 tan. α (co-sec. α + 1). If w = area of triangle, w = AD. BD = 2500 tan. α (co-sec. α + 1)². Differentiating and equating right member to zero $\frac{1}{\cos.^2 \alpha}\left(\frac{1}{\sin. \alpha} + 1\right)^2 -$



$\frac{2 \sin. \alpha}{\cos. \alpha}\left(\frac{1}{\sin. \alpha} + 1\right)\frac{\cos. \alpha}{\sin.^2 \alpha} = 0$. That is, $\left(\frac{1}{\sin. \alpha} + 1\right)$ $(1 + \sin. \alpha - 2 \cos.^2 \alpha) = 0$. From first factor, sin. α = − 1. From second factor, 1 + sin. α − 2 + 2 sin.² α = 0; ∴ sin. α = ½ or − 1; ∴ when w is a minimum, sin. α = ½; ∴ α = 30°; ∴ angle BAC = 60°; ∴ the required triangle is the equilateral circumscribing triangle. The side of this is easily found to be 100 $\sqrt{3}$.—Aleph.

UNANSWERED QUERIES.

The numbers and titles of queries which remain unanswered for five weeks are inserted in this list. We trust our readers will look over the list, and send what information they can for the benefit of their fellow contributors.

Since our last George E. Davis has answered 1214, 12167, 12245; "Jack of All Trades," 12153, 12170; "Ingenious Whitesmith," 12167.

12303	Small Castings, 393

QUERIES.

[12592.]—**Silk Solvents.**—Many months ago I inquired concerning this matter, and "Sigma" kindly suggested that instead of dissolving my better half's old silk dresses and trying to make them into new ones which did not seem to be a very promising scheme), that I should—no doubt he assumed I am or was a cockney—send her "ex cathedra" (I mean outside our metropolitan cathedral—*i.e.*, to S. Paul's Churchyard), and having presented her with a blank cheque, allow her to select as many new silk dresses (at a cost not exceeding the moderate rate of 15s. per lineal yard) as her æsthetic taste dictated. At the time I felt duly thankful for this "good advice," for which "small thanks is yet the market price;" but notwithstanding this powerful dose of the "cold water cure," I again beg to say I have a very distinct remembrance of reading that a French chemist had not only succeeded in making a solution of silk, but also in recovering it from the semi-fluid state in the form of cords, which, if I am not mistaken, he formed by forcing it through suitably-formed apertures (just as we make peppermint pipe or draining tiles), the aforesaid cords resembling the so-called "silkworm gut" of the angler. I opine such solid silk cords would not only form fishing lines without knots, but would make excellent first fiddle strings. They might also be at once far cheaper and preferable—inasmuch as we may expect them to be stronger, torsion considerably diminishing the effective strength of any rope—than the twisted silk lines made in France for deep sea soundings. Will any of our scientific correspondents let the light in on this matter?—The Harmonious Blacksmith.

[12593.]—**Lightning and Thunder.**—Will you kindly inform me whether lightning ever occurs without its being accompanied with thunder? And if so, the cause?—Paterfamilias.

[12594.]—**Varnish Cells.**—Will any reader inform me of the best substance for making varnish cells? Gold size and Brunswick black make good cells for dry mounting, but on the application of heat for balsam mounting, the varnish runs into the balsam, and so spoils the object. I want a varnish that will resist the heat when mounting in balsam.—Alf.

[12595.]—**Boats.**—I wish to construct a small pleasure boat about 14ft. long. Could "A., Liverpool," inform me of any book, and its price, that gives practical directions for building boats? I should also like to have lee-boards and sliding keels explained, and how the water is prevented from getting into the boat where they enter the water. In reply to query 12397, "A., Liverpool" says that it would take more room than the editor would allow to describe fully the art of boat-building. I think this subject is as worthy of attention as many others which appear weekly in the pages of "our" Mechanic. I am sure that articles on it would be warmly received by a number of subscribers, as I see from recent queries that many others like myself seek information in this branch.—J. E. D.

[We would manage to find space for a series of articles or letters on boatbuilding.]—Ed.

[12596.]—**Canoe.**—As there are doubtless many practised canoeists amongst your contributors, may I ask of them a few hints as regards the following:—I intend to take my holiday in the autumn, and to proceed down the Trent and Humber to Hull, then, if practicable, to go by sea to Filey or Scarborough. Is the canoe safe enough to do this in, or would it be better to go by rail from Hull. What is the best size for such a one, so as to enable me to feel perfectly at ease. I am practised with the paddle, but have not tried a sail. Would the use of one be safe without any practical instructions as to its management on such a trip?—Paddler.

[12597.]—**Waterwheel Floats.**—I wish to learn the most approved form and directions of the floats for an undershot waterwheel, for which little water will be available and economy very desirable.—D. J.

[12598.]—**Age of Trees.**—Would you oblige me by asking through your columns for authentic records of the extreme age of trees growing in Australia, Africa, and California?—Lignum Vitæ.

[12599.]—**Dimensions of Mail Boats.**—Can any of your readers give the chief dimensions of one of the Dublin Steam Packet Company's boats (and engines) carrying the Irish mails between Holyhead and Kingstown?—C. E. S.

[12600.]—**Hydraulic Explosion.**—I was making hydrogen gas by decomposing water with sodium the other day. I took a rather large (in fact too large) piece of sodium and held it under water by a gauze spoon. There was a violent (if I may use the term) decomposition at once, and I held a glass jar, which would hold about a quart, in the usual way to receive it, but alas! before the jar was half filled, there was a violent explosion, the jar and sundry bottles, &c., near, were smashed to atoms, and the pneumatic trough (tin) was knocked into a cocked hat. Now, would any correspondent of "ours" kindly explain, if he can, the cause of the explosion? I was once performing the same experiment, and with the same result, but used then a little flask with a narrow neck in which I forced the sodium wrapped in paper, and so held it under water, and I always thought the capacity of the flask was too small for the amount of sodium used; but this time the jar was not half filled when the explosion took place. I have thought that the hydrogen must by the great heat evolved have taken fire, but by this means I could not account for such a violent explosion. I have also wondered whether it was possible or not, there being such a rapid decomposition of the water, for the oxygen to be liberated as well, and the heat evolved to have recombined them. If this could be so, of course I could then understand the explosion.—Dabbler.

[12601.]—**Tuning Æolian Harp.**—I have one of these instruments strung with 14 strings. Will some of your musical correspondents tell me how to tune it? Is it tuned like a piano, or how?—Opaline.

[12602.]—**Extinction of Fires.**—Many gases are far more soluble in water than carbonic acid is. Would Mr. Bottone kindly inform me if a solution of some of the other gases, such as chlorine, &c., would not be more efficacious in extinguishing fires? Some are supporters of combustion, as sulphuretted hydrogen, &c., and others, perhaps, are too expensive; but could not some sort of salt be dissolved in the water which would generate gas by the action of heat when the water evaporated, the gas generated to be such as would extinguish fire. Of course, much less water is to be used in these engines than in ordinary ones.—Philanthropist.

[12603.]—**Acoustics.**—Can any of your correspondents inform me what is the amount of the absolute motion of each particle of the air, or other medium, in a sound wave? I do not know whether this has been or can be determined by experiment, but if it has been determined, I should like to know by what means. I suppose the amount will vary with the loudness of the sound. If this is so, what is its amount for the lowest sound we can hear?—Gy.

[12604.]—**Quill Pen Making.**—Will some one who is an adept at making quill pens by hand, kindly tell me how to insure a straight and clean "split"?—W.

[12605.]—**Organ.**—For some time back, I have been studying the various letters that have appeared in the Mechanic, with a view of commencing the building of a small organ, of one manual, and four stops. I can understand in theory, the making of the bellows, soundboard, and pipes, according to the instructions given; but I cannot as yet comprehend the mechanism of the key acting on the pallet. An illustration of an action to push down the pallet appears in Vol. XII., p. 187; and an illustration in Vol. XIV., p. 665, giving me some idea of the square action; but I cannot learn from it the position or use of the rollers and backfalls. The engraving seems to show the action as consisting of squares, trackers, and pull-downs. There is, I believe, an action called fan frame, said to be the most simple. Would some of your correspondents furnish diagrams, on a large scale, showing both actions, merely tracing the mechanism from the key to the pallet; also show how to connect the bass keys by cross action with the bass pipes, which may be placed at the treble end of the soundboard? I should also feel obliged if the length of middle C, 8ft. pitch clarabella, 1¼in. × 1⅝in., and the breadth, depth, and length of a CC dulciana (wood) could be given, to enable me to form a scale. The latter, I believe, being a narrower and longer pipe than the same note in diapason. As my acquaintance with the Mechanic commenced with Vol. XI., I am unable to refer farther back; and but for the valuable instructions lately given by the various contributors, my case would have been hopeless.—E. J. D.

[12606.]—**Submerged Forests.**—I should feel obliged if some one would inform me whether there is any cheap and special work on submerged forests. If not, where should I be most likely to see and learn something on the subject?—J. G. W. R.

[12607.]—**Watch Repairing.**—In a reply to "Second's Practical Watchmaker," by "Aberdeen Watch Jobber," let. 4609, is given a method of flattening a Geneva escape-wheel, which I do not think altogether safe, especially for young hands. I have done them in the manner described, but I think that one runs a great risk in thus flattening them. The way in which I have done them is by taking a strip of common soft solder, making a hole in the centre of it so as to admit the pinion and no more. As the wheels are generally all hard, and as a rule in treating anything hard—say, for instance, a pinion—you would strike the article to be made straight on the low side, so as to raise it, so in flattening the escape-wheel, I rested the wheel on the solder, striking the cross which wanted to be raised on the low side gently; the cross resting perfectly solid on the solder runs no risk of breaking, as might occur in the method which our Aberdeen friend gives us, but perhaps some of our brother pivots would kindly give us more information on the subject, and explain the reason why steel when hard requires to be struck on the low side to bring it up, and when soft, to be struck on the side that is bent.—A Midlothian Pivot.

[12608.]—**Bookbinder's Press.**—Wanted to know the best method for lapping the holes for the screws to work in bookbinder's press, the diameter of screw ⅞in. I have no way but the ordinary screw box and its corresponding lap, and to send it through 5½in. dry hard beech is more than two men can accomplish. Any instructions or notice of any apparatus to save so much labour would be gladly received by—Dublin Subscriber.

[12609.]—**Packing Grapes.**—What is the best plan to pack grapes to travel by rail without knocking the bloom off them?—A. B.

[12610.]—**Lighting Gas by Electricity.**—Can any reader of "ours" oblige a brother by giving practical details of the method employed to light the gas at the Royal Albert Hall. All the various burners are lighted at same instant by electricity, but is it accomplished by an induction coil? and if so, how are the wires insulated? and do the points from which the spark passes remain constantly in the gas flames, or is any method used to remove them when the gas has been lighted?—A. Bosquet.

[12611.]—**Moth in Pianoforte.**—What is the best thing to destroy moths which have attacked the dampers, &c., in a pianoforte?—Graham Young.

[12612.]—**Action of Oil on Waves.**—In an account given of a shipwreck which occurred recently, the crew took to the pinnace (the ship's cargo consisted chiefly of colza oil), on board which they took a large quantity of colza oil. The waves being very boisterous, and being in momentary danger of being swamped, they poured the above on the waves, which quite calmed them. In fact, had it not been for the action of the oil on the water they must have gone to the bottom. The above is quite an old story, but I never yet heard the scientific reason why.—Graham Young.

[12613.]—**Drying by Steam.**—I have fitted up some steam pipes for drying purposes, with indiarubber washers between the flanges, but cannot get heat enough. Will any of my fellow readers tell me if superheated steam will destroy the rubber?—T. King.

[12614.]—**Corpulence.**—Will some one kindly inform me on the following points: How can a thin fellow acquire bulk (fat or flesh)? Is it to be done by diet, inactivity, or what? Some say sugar, milk, cocoa, &c., are good for producing the desired effect. Any information on this subject will oblige.—Anti-Banting.

[12615.]—**Tide Waiters.**—What are the qualifications of a tide waiter in the Customs (not clerkship), and what are the examinations necessary to undergo?—A Subscriber from the Beginning.

[12616.]—**Hemlock.**—The mention of hemlock once or twice lately as a poison reminds me of a paragraph I read a year or two ago in the *Graphic*, in which it was stated that some professor had been experimenting and had found it *not* a poison. Does any botanical correspondent remember this statement, and is it false? In the same number were mentioned the researches of a Swiss savant, which showed that the far-famed William Tell must be considered a rather mythical person.—A. C. G.

[12617.]—**Tennessee.**—Can any of "our" readers furnish any reliable information as to the prospects in Tennessee, or the adjoining States, for a settler with a few hundred pounds? Are farms cheap? What prices does produce fetch, and is there a ready sale?—Emigrant.

[12618.]—**Excessive Perspiration.**—I should feel much obliged if one or more of your readers would tell me of a remedy for excessive perspiration. It is a great source of annoyance to myself and others, this hot weather especially.—A.

[12619.]—**Bad Water.**—I think that there is something very deleterious in my pump water. If new potatoes be scraped and washed in it the water becomes at once quite of an inky colour. And if a little of the water be put into a goblet and two teaspoonsful of white brandy be added it immediately turns to a dark brown. Can any of your numerous readers account for these occurrences?—Inquirer, Rugeley.

[12620.]—**Suspended Tramways.**—Will some subscriber inform me which of the two suspended tramways is the most simply constructed, and require least labour to push the load along? It is for conveying grain in baskets, which we now run on the floor by means of wheels fixed to bottom of baskets, but find the wheels crush and damage a large quantity of the grain.—H. B.

[12621.]—**Black Dye for Leather.**—Will any one inform me what is the best dye for staining leather a good black?—R. M.

[12622.]—**Labour Saving Machines.**—A cabinet manufacturer, employing some 16 to 20 hands, wishes to be informed by some of your practical correspondents of the most useful labour saving machines for the workshop where steam is not practicable. He is informed that in many of the workshops in Scotland very useful machines are employed, more especially for veneering, &c.—S. V., Dublin.

[12623.]—**Lampblack.**—Can any reader describe or give a sketch of the arrangements that are necessary for the manufacture of lampblack on a commercial scale from tar, pitch, &c.? What weight of pitch is required for one ton of lampblack?—Fr. Scot.

[12624.]—**Stuffing Reptiles.**—Will some brother reader kindly tell me how to stuff a boa constrictor's and shark's skin? They are both dried. Also how to make a varnish for the same?—W. C. C.

[12625.]—**Heat Bumps.**—Would some one inform me of a good recipe for heat bumps? I have tried two good doctors and every thing I could think of, and all to no effect. The child is three years old, and sometimes there appears twenty of these bumps in a night, and some as large as a threepenny piece, very unsightly and irritable; we are frequently disturbed four or five hours in a night.—D. C.

[12626.]—**Indiarubber Models.**—Will any reader of the Mechanic kindly give information on the following subject. I want to make an indiarubber model which shall retain its elasticity when made. Something, *e.g.*, like a flexible doll's face. 1. How can I dissolve the indiarubber? 2. How liquid must it be? 3. Must anything be mixed with it? 4. What substance and in what proportion? 5. Of what must the moulds be made, will plaster of Paris do or must it be some metal, and if so of what kind? 6. By what process must the model be set? 7. If by heat, what degree and how procured? 8. If excess above or deficiency from the prescribed degree, what would be the effect?—Claudio.

[12627.]—**Carbolic Acid as a Hair Dye.**—Will "Outgenious Whitesmith," (Qy. 12001), please say how often he applied the carbolic acid, and if he washed his face in the same water. Does it darken the skin or injure the hair, and does he continue to wash in the water with carbolic acid after his hair has turned colour, and does he use it every time he washes.—A. J.

[12628.]—**Rusty Iron Castings.**—I have 10 or 12 hundredweight of small castings, such as pinions, bearings, &c., deeply rusted, can I clean them with acid so as to get them painted?—Paddy.

[12629.]—**Skeleton Flowers.**—Will any reader of "ours" kindly tell me how to prepare "skeleton flowers and leaves," and the best time of year for doing so?—J. B.

[12630.]—**Magnetism.**—I have a strong electro-magnetic machine of the usual horse-shoe form with revolving cylinders or coils of wire. I used it for rheumatism. Can I use it for any other purpose, useful or ornamental, and if so, how?—D.

[12631.]—**Fixing the Bloom of Scarlet Runners.**—How can I prevent the bloom falling off? I have some stalks on which there have been as many as thirty blooms, all of which have fallen off instead of coming to beans.—Disappointed.

[12632.]—**Photochrome.**—What is the nature and composition of photochrome, which is used for darkening the hair?—Disappointed.

[12633.]—**Dried Yeast.**—Will any of your chemical correspondents inform me what ingredient is necessary to be added to compressed yeast to insure its keeping for some days? I press mine with one of Needham and Kite's presses, but find it will not keep often more than a few hours before it becomes moist. Many brewers sell an article which keeps as well as the German yeast. There is no doubt some chemical is added to insure this.—H. W. T.

[12634.]—**Photography.**—Can "Photo.-Bristolienis," or other fellow-reader, tell me how to produce a photograph on porcelain or opal glass, and the best known vehicle or medium for an artist to work them up in watercolour with?—Art-Photo.

[12635.]—**Transferring Pencil Drawing on Paper to other Paper.**—Will John Hopkins or some one else, give me instructions how to transfer a pencil drawing on paper to other paper, and the sort of paper used. Also how to take an impression of a printed impression or engraving on paper on to other paper?—T. H.

[12636.]—**Enlarging Photographs.**—I shall be most happy to hear "Photo-Bristoliensis'" suggestions with regard to the above, assuring him that daylight will answer my purpose equally as well as the magnesium, and at the same time I am anxious to go to work as cheaply as possible.—Industrious Will.

[12637.]—**Optics.**—Can any of your numerous mathematicians or students of optics kindly inform me how to work the following:—At what distance from a mark ¼in. square shall I stand so that it may appear of the same size as a mark 8in. square at the distance of 200 yards?—Optics.

[12638.]—**Fleas in Dogs.**—Will any brother reader inform me if one teaspoonful of sulphurous acid mixed with a quart of water sponged over a dog would be injurious to his skin or hair, as I find that acid so diluted will kill fleas almost instantly?—Countryman.

[12639.]—**Worms in Pony.**—What is the best thing to give a pony that is troubled with worms? All the food he eats seems to do him but little good. Could I give him anything with his food to destroy them? They appear to be about 2in. long.—Countryman.

[12640.]—**Ice.**—Can any of "ours" give a recipe for a cheap freezing powder, and cost for making a gallon of water into ice?—W. R.

[12641.]—**Sticklebacks.**—Can any one kindly inform me the bestway to destroy sticklebacks without destroying the other fish?—Boatman.

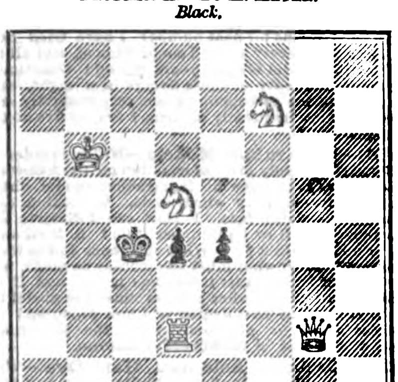
CHESS.

All communications intended for this department to be addressed to J. W. Abbott, 7, Claremont-place, Loughborough-road, Brixton, S.W.

A match is being arranged between Steinitz and Zukertort, the prizes being £20 for the winner and £10 for the loser. The winner of the first seven games to be the victor, drawn games not counting. The struggle between these two athletes in the recent tourney which resulted in a game for each, and three drawn games, imparts additional speculation to the present contest, and the result will be watched with interest by chess players in all parts of the world.

Problem X.—By H. Meyer.

Black.



White.

White to play and mate in two moves.

*** In future the solutions to our problems will be withheld for a fortnight.

T. A. Hind.—Thanks for the "Knight's Tour," but we have no space for the same; moreover, such productions are only interesting to a few.

R. S. and A. Cunnington.—The Black King has two moves at his disposal—if to Q 5 Kt takes P, mate; if to Q 3 Kt to K B 7 mate. Surely this is plain enough.

W. Airey.—You are not the only correspondent who has failed to solve Problem VIII. The defence to the line of play that you and others suggest is—

$$(1)\ \frac{\text{R to Q B 6}}{\text{P takes R}}\quad (2)\ \frac{\text{B to K B 5}}{\text{Q to Kt sq.}}$$

How do you propose to mate next move?

A. L. (Lincoln).—You shall be informed of the result.

G. Haywood.—A very neat little problem; it shall appear in its turn.

Sea-Serpents.—According to *Nature*, the South African Museum, Cape Town, recently received a specimen of the Ribbon fish (*Gymnoterus*) fifteen feet long without the tail. It appears that this fish is known to distant inland fishermen as being forty feet long, and from its slender shape and snake-like movement is probably the "sea-serpent" of late years so minutely described by navigators. From its head there is erected a plume of flexible rose-coloured spines, and from head to tail along its back there is a conspicuous mane-like fin. Its general colour is like burnished silver. The eye is large and silvery, and the profile of the head comports well with that of the horse. The specimen could not be preserved, but there are two smaller specimens in the Museum.

ANSWERS TO CORRESPONDENTS.

*** *All communications should be addressed to the* Editor *of the* English Mechanic, 31, *Tavistock-street, Covent Garden, W.C.*

The following are the initials, &c., of letters to hand up to Tuesday morning, August 6, and unacknowledged elsewhere:—

W. L. Breare.—Rev. G. M. M'Cord.—E. C. Phillips.—J. Dresser.—Thomas Baker.—Alfred W. Knight.—P. Frank.—James Puttick.—E. Woodward.—J. Sharpe.—George Jarmain.—Henry Northcote.—W. Crisp.—L. E. N.—J. Taylor.—Taylor and Bodley.—H. H.—J. K. P.—Thomas Fletcher.—Wm. Pakeman.—James Pulman.—P. and L.—J. H. R.—E. B. W.—Chip of the Old Block.—Jack of All Trades.—A Berlin Subscriber.—T. J. M.—Columbia.—Hy. Clarke.—James Simpson.—F. Perks.—Rev. F. Gilbert White.—Edward Mould.—A. Chesterton.—James Malins.—E. Jones.—C. H. Wingfield.—Webb and Son.—J. M. Gilbert.—P. A. Calais.—Thomas Fletcher.—J. J. H.—E. P. Hart.—C. B. A.—J. B. Waring.—E. Sutcliffe.—James Hazard.—J. F. Coulson.—James Ward.—C. H. P.—Rev. James Henry.—World Wide.—Clock Maker.—Sun Spots.—J. T. M.—J. T.—Outre Mer.—St. Crispin.—James Daw.—The Harmonious Blacksmith.—W. J. Hodgson.—Soda.—George Knott.—Epilepsy.—The Suffolk Amateur.—A Subscriber.—J. B. Sharpey.—Wm. Cruickshank.—R. Mellor.—J. Griffith.—Herbert Jackson.—Aquarium-Maker.—T. J. W.—Tyro.—J. Johnson.—Excelsior.—Wm. Tryer.—J. M. G.—Horatio.—Surveyor.—J. G. Matthews.—Paste.—Aqua.—Amateur.—J. G. N.—W. H. K.—H. Bastow.—W. H. H. C.—Wm. Hoyle.—W. George.—J. H. Gilbert.—X.—Rat-Tat.—E. O. Simmonds.—Vandyke.—W. Hatfield.—R. A. Proctor.—C. Norris.—E. L. G.—Odgen and Gibbs.—Fiddler.—Sting.—L. H. O.—Simplex.—James Martyn.—S. Canning.—Inquirer.—J. W. Rhodes.—Alfred A. Allen.—W. Pike.—Rev. H. R. Bayley.—Artillery Captain.—Mil.—L. W. D.—F. R.—J. W. Fennell.—R. Henry.—Reckoner.—Busy B.—C. N. Abbott.—A Mental Sufferer.—Thom.—A. B. W.—W. S. B.—Salmon Sons and Ritchie.—A Bookkeeper.—R. A. H.—Aries.—Commoder.—E. T. Grays.—Tawse.—A. C. L.—Coach-painter.—Padlock.—R. Stephenson.—A Lecturer.—Bobo.—Artillery Gunner.—Beekeeper.—V. B.—A. L. G.—M. Paris.—Collen.—Balcairn.—N. Y. R.—Gypsum. T. E.—T. Hucklebridge.—J. K. P.—James Hicks.—Jack of All Trades.—W. H. H. C.

Veritas, W. F. Dawson, Canary, and Gold Leaf, are requested to consult back numbers.

Landscape House.—Your inquiry about the earth being recently in the tail of a comet would possibly lead to an idle controversy. If you wish to excite discussion why not suggest something more practical and of every-day utility.

H. A. G.—Your query is an advertisement.

J. Williams.—You will find information on the Whitworth scholarships on p. 258 of Vol. XIV., No. 348; but all the particulars are to be obtained from the Science and Art Department, South Kensington. The examination papers of the Science and Art Department are to be obtained from the same source, by addressing a letter to the secretary.

Erratum.—In letter 4579, p. 484, "Sucram" intended to say that *no* glue should be put on for the first time of placing the paper round in making organ pipes.

Communications which can only appear as advertisements to hand from W. Karslake, Young Telegraphist, Musical Subscriber, A. W. H., A. M. Z., A. Douse.

Chime.—It is not lawful.

C. C. C., T. M. P., E. O. S. Z., E. Gardner, and Tinker, are referred to indices to back volumes.

J. Baxter.—No. Of course if you vary the invention the matter is different. We have no more room for replies to the query answered by you.

Birmingham Subscriber.—Apply to the chief of the department in the town in which you reside.

B. B.—Advertise your coins if you wish to know their selling value.

C. Townley.—The furnace described in this number by "Outgenious Whitesmith" will perhaps meet your requirements.

H. Menz.—Yearly subscription, including postage to Prussia, 17s. 4d. A reduction is made on such a series of advertisements as you mention. Prussian paper money may be sent.

"T. A.," in a letter, says he "cannot comply with 'E. L. G.'s' request of fixing the time of change in reckoning in the genealogy of Shem and the lives of Abraham, Isaac, and Jacob, because he has not the Septuagint, and our version being so notoriously incorrect." If "T. A." had the Septuagint, and was able to satisfy "E. L. G.," "ours" would not be the fittest columns for the controversy.

Tinman.—We have given the process of galvanising iron in several places in back numbers. The articles to be galvanised are cleansed by dipping into a bath of diluted sulphuric acid, scoured with sand, and immersed in melted zinc, which should have a tolerably thick covering of sal ammoniac. It would seem that you have not had sufficient sal ammoniac, or the heat has not been high enough to prevent the article chilling the zinc when immersed. Try again, and if you fail, write.

Nathaniel Waterall.—The lengths of the Atlantic cables are as follows:—The 1865 cable contains 1,896 knots; the 1866, 1,852 knots. The French cable contains from Brest to S. Pierre, 2,584 knots; and from S. Pierre to Duxburg, 749. 100 knots are equivalent to 115·2840 miles.

Samuel Smither.—Next week.

R. A. Proctor.—Next week. On account of what is called the Bank Holiday we had to prepare for press ast Saturday.

C. E., James Leeward, Tomatoes.—Your queries are advertisements. See "Notes to Correspondents."

Hy. Clark.—Let there be no subterfuge. Will you or any professional phrenologist accept the challenge such as it was? The merits of the inquiry in no way affect the statements in your rejected letter.

E. H. Thomas.—The best way is to write on white paper with black ink. Red ink on white paper is not so good, neither is black ink on blue paper.

W. G.—We can bind your volumes in cloth at half-a-crown per volume.

Terms of Subscription,

PAYABLE IN ADVANCE.

5s. 6d. for Six Months and 11s. for Twelve Months, Post Free to any part of the United Kingdom.

Volumes V., VI., VII., VIII., IX., X., XI., XII., XIII., and XIV. bound in cloth, 7s. each.

Indexes for each half-yearly volume, up to Vol. X. (except Vols. II., V., and X.) inclusive, 2d.; Post Free, 2½d. Cases for Binding, 1s. 6d. each.

*** Subscribers are requested to order Cases and Vols through their booksellers, and not to send direct. The new regulations of the Post-office prevent their transmission through the Post.

To American and Belgian Subscribers.

☞ American and Belgian Subscribers, *especially when renewing their subscriptions*, are *particularly requested* to advise the Publisher of the transmission of the Post-office Order, and the exact amount for which it is made payable.

Subscribers in the United States and Belgium can be supplied with the ENGLISH MECHANIC post free from this Office, for the sum of 18s. (3dols. 25c. gold, or 15fr. 60c.) per annum, payable in advance.

The remittance should be made by International Post-office Order. Back numbers cannot be sent by the ordinary newspaper post, but must be remitted for at the rate of 5d. each to cover extra postage.

Notice to Subscribers.

Subscribers receiving their copies direct from the office, are requested to observe that the last number of the term for which their Subscription is paid, will be forwarded to them in a *coloured wrapper*, as an intimation that a fresh remittance is necessary, if it be desired to continue the Subscription.

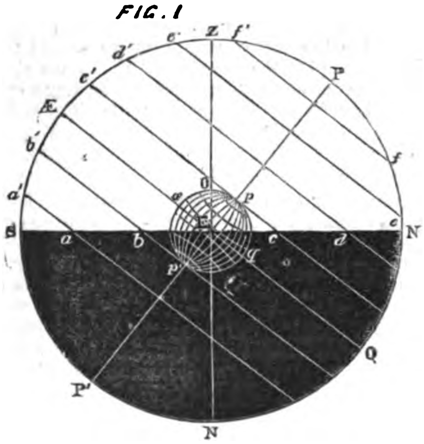
ARTICLES.

THE EQUATOREAL—ITS USE AND ADJUSTMENTS.

By a Fellow of the Royal Astronomical Society.

SOONER or later (and, as a rule, sooner rather than later) every possessor of a telescope who employs it for the purpose of celestial observation finds out the discomfort, annoyance, and impracticability of a mounting which, like the ordinary tripod stand, admits only of motions in a vertical and a horizontal direction. Such a mounting in effect limits him to the employment of low powers, prevents him from recognising a star or other heavenly body from a catalogue, and absolutely precludes him from any form of micrometrical measurement, or from even the approximate determination of the place of any unknown body in the heavens; so that he ultimately discovers that, for anything like systematic work, an equatoreal, in some shape, is absolutely indispensable. Moreover, this is true concerning every description of telescope (reflecting or refracting) in use; the kind of mounting of which we are speaking being alike applicable to, and necessary for, the efficiency of instruments of the Galilean,

FIG. 1



Achromatic, Newtonian, Herschelian, Gregorian, and Cassegrainian forms. In the interest, then, of those who are not already familiar with the nature of an equatorial mounting, we propose to explain, in the first place, the principles on which its action depends, and we shall then go on, in the next, to describe one of the most usual forms in which it is constructed, and to give such detailed instructions for its adjustment and use as shall enable the possessors of telescopes thus mounted (who may yet not be sufficiently familiar with the theory of astronomical instruments to adjust them with facility) to regulate and employ them in the most efficient manner. Here, as in our preliminary explanation, we shall endeavour to employ the most simple language at our command, and systematically sacrifice any mere grace of diction to our leading object of making ourselves apprehensible to those, whose acquaintance with the subject has yet, in effect, to be made.

For the purpose, then, of the exposition which we have proposed to offer, it will be necessary to begin at the very beginning, and to recall some of the most rudimentary astronomical facts to the recollection of the student. Let us, therefore, conceive ourselves to be placed upon a very small island in the midst of the sea, in some northern latitude; let us further imagine the evening to be sufficiently far advanced for stars to be visible, and let us try to realise the spectacle which will be presented to us.

At the first glance we shall notice that the sea and sky do not, as it were, shade off into each other, but form all round a hard, sharp, well-defined line, in point of fact a circle, of which the eye of the observer forms the centre. This circle, pretty evidently, cuts the heavens into two equal hemispheres, one of which above us, is visible; while the other, beneath our feet, cannot be seen. We will suppose, too, that we know the point of the horizon above which the sun is situated at apparent noon. This will, of course, be the south. (Further on we shall reiterate directions, already given in these columns, for finding this south point with some considerable degree of accuracy, but at present we will imagine it to be

FIG. 2

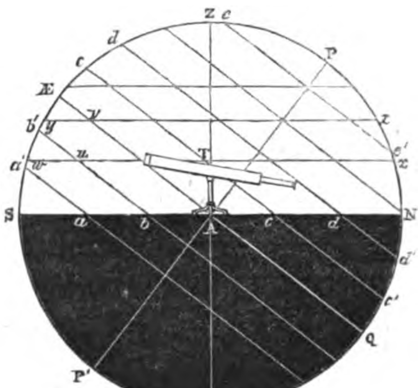


FIG. 3

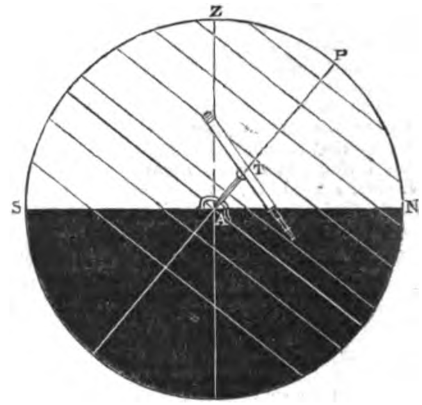

FIG. 4

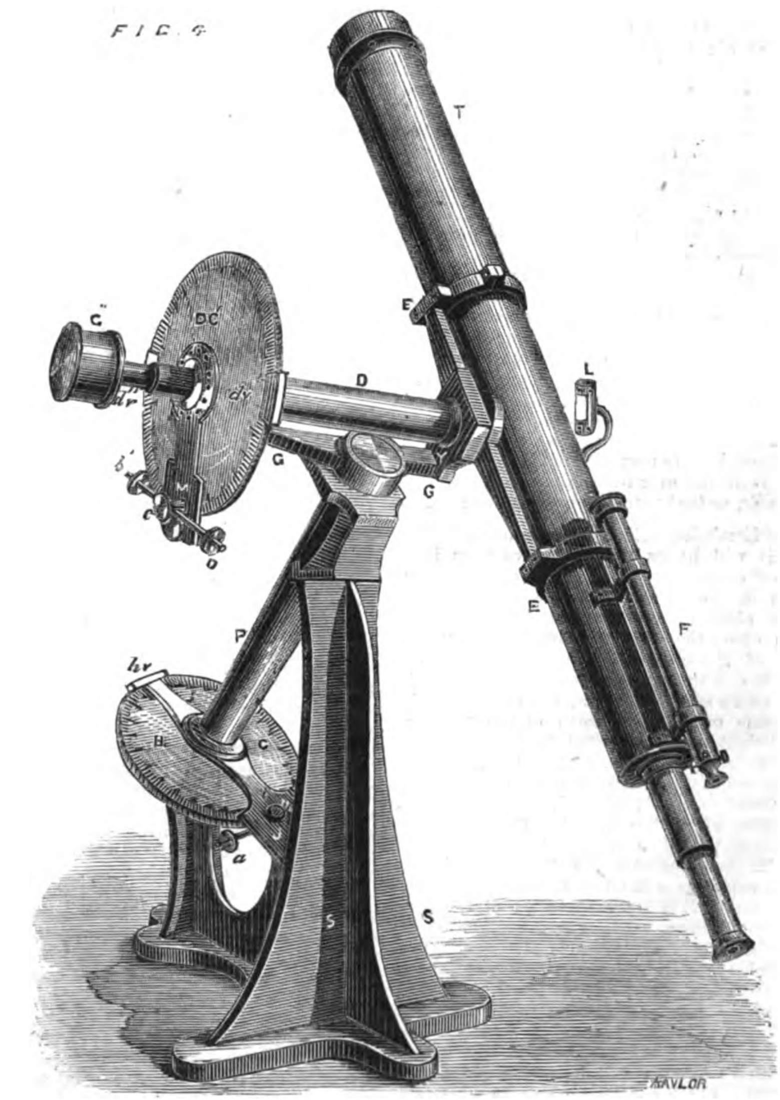

known.) Facing, now, towards the south, we shall notice stars in the western part of the celestial concave, gradually disappearing beneath the horizon, while others previously invisible will rise in the east. Furthermore, if we can watch through any considerable interval of time it will be seen that every star seems to describe more or less of a circle in the sky; but that these circles are not all of the same size, those stars, for example, which rise very little to the east of south describing a very small segment of a circle of certain size, and remaining a very short time above the horizon; those which rise further toward the east, a larger segment of a larger circle, and remaining longer visible; and so on, until we come to stars which rise due east, which will be found to travel over a semicircle, and set exactly in the west just 12 hours after the time of their rising. If, now, we consider those which rise to the north of east, we shall observe that they describe the larger part of their diurnal paths above the horizon, and remain visible for more than 12 hours (the circles themselves, however, growing smaller, inasmuch as the greatest of all are those described by stars which rise precisely in the east), and so on, until we shall find some which never disappear below our horizon at all, but describe their entire diurnal circular path above it, round one common point which is called the pole of the heavens. There is no visible star exactly on this point, but there is one sufficiently near it in our northern heavens to justify its appellation of the Pole Star. Its position may be recognised by reference to the map on p. 25 of our tenth volume. Moreover, we shall notice that the stars do not change their relative positions in the sky, but revolve as though they were attached to the internal surface of a vast sphere, which itself rotates on an axis passing through the pole just spoken of and an opposite and, of course, invisible one, beneath the horizon. Furthermore, a little attention will show us that there is a point in the sky at which each star ceases to ascend and begins to descend, and it will not be very difficult to discover that a semicircle drawn perpendicular to the horizon, and passing through its north and south points, will be that upon which stars will, one and all, reach their highest points, or, as it is technically called, culminate. This line is called the Meridian (from the Latin word *meridies*, mid-day, because at noon the sun is upon it). It is further self-evident that it must pass through the poles and also through the point immediately over the observer's head, or, as it is called, the zenith. Its determination, as we shall hereafter see, is a matter of the highest importance.

Before proceeding any farther, it will, perhaps, be as well if we endeavour to realise the description and definitions which we have just given by the aid of a figure.

In our first figure, then, O represents our imaginary observer and S E N his horizon, of which S is the south point, E the east, and N the north point (the west point being obviously *behind* E, as seen in our sketch). Then $a\ a'$ will represent the path of a star in the southern part of the sky from its rising, at a, to its culmination, or transit, at a'; after passing which it will, of course, begin to descend and set as far from S on the *other* side of a' as it rose on this. b represents a star rising nearer to the east, and so on to E, which shows one which rises precisely in the east, reaches Æ (or arrives at the meridian) 6 hours afterwards, and sets, at the expiration of another 6 hours, exactly in the west point of the horizon. As we proceed northwards, d, d', e, e'', and f, f'', may stand for the apparent diurnal circles described in the sky, by stars nearer and nearer to the pole. The visible pole, or end of the axis, about which the celestial sphere seems to rotate, is seen at P; the other extremity of such axis P' being, of course, invisible; and if we imagine a huge sheet of metal to pass through the earth's equator, $æ\ q$, and to be produced outwardly, until it cuts the heavens, it will trace out the great circle, Æ, E, Q, distant, of course, at all points 90°, or the quarter of a circle, from the points P and P'. We may add that Z is the zenith, or point vertically over the observer's head, and N the nadir, or that precisely beneath his feet.

Before dismissing this figure from our consideration, it will be as well to prove from it a theorem of capital importance in the consideration of the principle of the equatoreal. We mean that the elevation of the visible pole of the heavens above the horizon is always equal to the latitude of the place of observation. For, let $æ$, q, be the earth's equator, and O the observer's position on its surface, then $æ$, E, O is obviously his latitude or distance north of the equator. Now, all right angles are equal (a fact of which the veriest tyro may assure himself by placing a pencil square to the surface of a slate, and viewing it from various positions), and, therefore, in our figure Æ, E, P = Z E N. Take away the part common to both Z E P, and the remainder Æ E Z = the remainder P E N. But Æ E Z (which is evidently $æ$ E O) is the latitude of the observer, and P E N is the elevation of the pole P above the horizon. Therefore the elevation of the pole at any given place is always equal to the latitude. Q E D. Assuming the student, then, to have thoroughly familiarised himself with the nature of the apparent diurnal motion of the celestial vault, let us proceed to examine the condition of any one with respect to it, who is provided with a telescope mounted on a pillar and claw stand. Fig. 2 has been drawn to illustrate this.

A very brief study of it will suffice to show that, while the apparent paths of the stars a, a'; b, b', &c., are inclined to the horizon at a definite angle (that of the co-latitude, or 90°—latitude), and the axis of rotation of the sphere P P' has the inclination P N to it; the telescope rotates round the vertical axis T, A, and cuts out the circles $w\ x$, $y\ z$, &c., in the heavens, parallel to the horizon, intersecting those of the stars' paths at two points only (such as u or v, and their corresponding ones on the other side of the meridian). Hence it will be seen that (save at the time of its culmination) a star must always be travelling *obliquely* through the field of an instrument thus mounted; so that, in order to follow it, *two* simultaneous motions are required, vertical and horizontal; or, as they are technically called, in altitude and azimuth. Annoying as this is with low powers, and in the observation of large objects like the Sun or Moon, it becomes almost insufferable and intolerable when we are examining faint stars with a high power; while, as we have previously intimated at the beginning of this essay, it practically precludes the observer from the identification of a star from a catalogue; or from any form of micrometrical measurement.

The remedy, however, will readily suggest itself to any one who has considered our last figure with the smallest attention. It is indicated in our sketch below; in which it will be at once seen that all we have done is to make the principal axis of rotation of the telescope T A *coincide with the axis of rotation of the heavens*; so that, if we now set it upon any given star, by turning the telescope round such axis, we can, by a single motion, follow that star from its rising to its setting. (We here ignore the effect of refraction as immaterial to our present purpose.) In fact, we have converted our telescope into a rude form of Equatoreal.

We have, however, gained but one solitary advantage attendant on an equatorial mounting, that of following certain stars by a single motion of the telescope. We have said *certain* stars advisedly, because it must at once strike the most careless observer of our third figure that it would be absolutely impossible, in the position of the telescope there delineated, to turn it upon any object at all near the pole. Preserving then, the vital principle of the coincidence of the principal axis of rotation of our instrument with that of the heavens, let us see how our primitive mounting can be modified so as to enable us to reach every part of the visible hemisphere; and, incidentally, to set it, by the aid of certain co-ordinates, upon any object contained in a list or catalogue.

Now, the object of these papers being wholly practical, we shall not occupy needless space by the delineation and description of the various shapes which the equatoreal has assumed, but shall, at once, proceed to describe the German or Fraunhöfer form of it. We select this, since it is the one most commonly employed to carry all telescopes, such as are ordinarily found in the possession of amateurs; and as, moreover, our explanation of its construction and detailed instructions for its adjustment and use, will, if once fairly mastered, enable the student to deal satisfactorily with any kind of equatorial mounting which may come under his notice. It is shown in Fig. 4.

Here we see the telescope T supported by a cradle E E', and thus immovably fixed to the end of the declination axis D, to the other extremity of which the declination circle D C' is also attached. As this axis terminates in cylindrical pivots which rotate in two Y's (one of which is shown at Y, and the other is hidden behind the declination circle in our drawing), it will be seen that the telescope and circle must move together. The Y's, as inspection of the figure will show, are carried by or form part of the framework G G, which is itself attached at right angles to the polar axis P; the principal axis of rotation of the instrument, the extremities of which of course must point to the poles of the heavens. Means for adjusting the declination axis to a small extent are provided at l Y; those for the adjustment of the polar axis are covered by the hour circle—H C in our figure. This hour circle, which is divided right round to XXIV. hours, is read by the aid of the vernier $h\ v$; the vernier being adjustable by the arrangement shown at $i\ j$. It should, of course, read either XII. or XXIV. hours, when the telescope is accurately in the meridian, according as it is placed to the west or east of the polar axis. In our sketch it will be noticed that we have shown the telescope to the west of that axis, and the declination circle, of course, to the east of it. The declination circle D C'—is almost always divided into 4 quadrants of 90° each, starting from the equator as their initial points; so that when the optical axis of the telescope is directed to the equator, the verniers $d\ v$ and $d'\ v'$ read 0°. The verniers referred to are supported by, and adjustable on, a framework, which the declination itself covers in the figure. S S is the cast-iron stand supporting the working parts of the equatoreal; this is generally cemented or screwed down on to a pillar, according as the latter is formed of brick or stone, or of iron. The rest of the mounting is almost invariably constructed of gun-metal. The edges of the circles D C and H C are racked with a screw tool, and into the worm-wheels thus generated work endless screws $a\ j$, $b\ c\ b'$ by which slow motions are given in right ascension and declination, respectively. These screws are thrown in and out of gear by a simple arrangement at c and m, which it is scarcely necessary here to describe. C'' is a counterpoise, which is shifted when a micrometer or analagous apparatus is attached to the telescope. F is, of course, the finder, and L a little lamp swinging in gimbals. This reflects light through a hole cut in the side of a telescope on to a perforated mirror, placed diagonally in it, which itself casts the light down the tube, and so illuminates the wires of the micrometer or transit eyepiece.

An equatoreal mounted as completely as the one we have attempted to delineate and describe would almost certainly have a clockwork movement to drive it in opposition to the diurnal motion of the earth, and so to keep a star apparently immovable in the field of view; but we have omitted a clock in our sketch to avoid needless complexity. In practice, the motion of such a clock would be controlled by a conical pendulum, in which the friction of an arrangement analogous to the governor of a steam engine, against the inside of a cone, supplies the regulating power. An equable motion thus obtained would be communicated by light shafting to the endless screw $a\ j$; and so the hour circle H C (and with it, obviously, the whole instrument) caused to rotate at precisely the same rate as the earth, but in an opposite direction. We shall presently speak, too, of a spirit-level, but as every one who is likely to use our directions for the employment and adjustment of the equatoreal must almost certainly be familiar with this in some form, we abstain from its illustration and description. It only remains, then, that we should formally exemplify the meaning of the terms right ascension and declination, before proceeding to the immediate object of these papers; that of explaining the best and most available mode of getting a telescope equatorially mounted in correct adjustment with reference to the heavens.

Obviously, we must have the means of identifying a star; and for this purpose *two* co-ordinates, of some sort, are absolutely indispensable. Now, the north and south poles P and P' Fig. 1, may be considered as fixed points in the celestial sphere; consequently the equator Æ E Q (same figure) is a fixed circle therein. Furthermore, every one who has ever opened a book on astronomy knows that the axis of the earth is inclined 23° 27' from a perpendicular to its orbit; and that, consequently, such orbit must form that angle with the equator, or (as it is called when projected on the concave face of the heavens) equinoctial. The immediate effect of this is to cause the apparent annual path of the Sun through the heavens, the ecliptic, to cut the equinoctial in two parts, 180°, or 12 hours, apart. The Sun is *on* the equator on the 21st of March; after which he continues to travel northward until the 21st of June, when he attains his greatest distance 23° 27' north of it; after this he descends again, once more crosses the equinoctial on the 21st of September, travels down 23° 27' south by the 21st of December, begins to ascend again, and so on. Now, the point of the equator, which the ecliptic crosses on March 21, is called the first point of Aries; and from this right ascension is reckoned *eastward* on the equinoctial. Perhaps the simplest definition of right ascension that we can give is, that it is the interval in time which elapses between the transit of this first point of Aries over the meridian of any given place, and the arrival of the body whose R. A. is to be determined on the same meridian. Declination is the distance of a star, or other heavenly body, north or south of the equinoctial; for example, in our first figure Æ d' would be the north declination of a star d', while Æ a' would be the south declination of another one a'. In many fixed observatories north polar distance is employed in lieu of declination as a second co-ordinate; but, as the *Nautical Almanac* uses declination, and as, moreover, all the chief popular lists of double stars, &c., give the element in this form, we shall, ourselves, invariably use it in our subsequent exposition. Should the student have access to a celestial globe, reference to it will materially facilitate the understanding of what we have been endeavouring to explain.

(*To be continued.*)

THE MUSEUMS OF LONDON.—II.

SOUTH KENSINGTON MUSEUM (1).

THIS Museum is under the direction of the Science and Art Department of the Committee of Council on Education, and the chief offices of the department adjoin the Museum. It is situated at South Kensington, near the site of the last great International Exhibition. The Museum is strictly educational, and is one of the most popular of similar institutions in the metropolis. This will be seen from the following statistics of the number of visitors.—In 1857 (the first year of opening) the number was 268,291; in 1862 (the year of the Exhibition), 1,241,369, the highest yearly total yet attained; 646,516 in 1867; 1,014,849 in 1870; and in the first six months of the present year 710,111; a total up to that time from the opening (June 22nd, 1857) of 12,355,470.

The nucleus of the Museum was a collection of objects of art in connection with the schools of art held in Marlborough House, about the year 1852. In 1857 the collection was removed to temporary buildings at South Kensington, popularly known as the "Brompton boilers." This temporary building is in course of being replaced by a permanent structure, parts of which, as completed, are successively thrown open. The temporary arrangement, as might be expected, was inadequate and inconvenient, but the new buildings are large, airy, well lighted, and adapted for the purposes for which they are intended. When completed, and the old buildings removed, the South Kensington Museum will take its place amongst the architectural features of London. In rooms connected with the Museum are the National Art Training Schools—the various working rooms of which are open to public inspection on Saturdays from 2 p.m. till dusk—and the Naval School; a new block of buildings for a Science and Naval School is now nearly completed. The new buildings are all of bright red brick, which shows very conspicuously in comparison with the neighbouring stone and plastered buildings.

Turning to the interior we find that the whole of the collections fall into two divisions; those belonging to the art department comprising paintings, sculptures, architectural models, &c., which occupy the bulk of the building, and a smaller division, comprising objects belonging to a more general and elementary education—*e.g.*, school fittings and materials. Connected with each of these divisions is a library and reading-room. Not only is there a permanent collection exhibited in the Museum but a special feature consists in having usually on view loan exhibitions of various classes of objects, an excellent means of making the public acquainted with the art treasures which are scattered about the country in the possession of private individuals. As examples of these loan exhibitions we might mention those of fans, the Duke of Edinburgh's collection during his voyage, school furniture, ancient and modern jewellery, and musical instruments: the last two at present on view.

On Mondays, Tuesdays, and Saturdays the Museum is open free from 10 a.m. till 10 p.m.; Wednesdays, Thursdays, and Fridays are set apart as students' days, when certain privileges are granted to persons wishing to make copies of the objects or paintings; the public are admitted on payment of sixpence. It may be as well to mention, persons who have obtained a certificate for drawing in the second stage, or a science certificate in the advanced stage, can, by application to the Secretary of the Science and Art Department, obtain a ticket which will insure them free admission to the Museum on all days when it is open, and also to the two libraries. On students' days the closing time is 4, 5, or 6 p.m., according to the season. During the whole of Easter week, Whit week, and Christmas week the Museum is open free till 10 p.m., and the number of visitors at each of these periods is very considerable.

Entering the building by the principal entrance in Cromwell-road, we first come into the temporary portion from which a corridor on either hand leads to the larger rooms. Looking through the window facing the entrance the new front of the permanent building may be seen. Let us leave the art collections for the present and turn to the left to the educational series. English and German domestic life of the seventeenth and eighteenth centuries are strangely portrayed in two cases in this entrance hall, one being a large doll's house without a front, plentifully stocked with miniature furniture and utensils, which was made for a daughter of an Archbishop of York in the reign of Queen Anne; the other being a somewhat similar toy-house made at Nuremburg in the seventeenth century. Near the window in the hall one of the daily reports and charts of the meteorological office is hung, and the observations of temperature and pressure are taken at the Museum.

The corridor is lined on both sides with bookcases, filled with modern volumes on the various subjects included under general education. The reading-room opens on the left, and is accessible to teachers, school managers, students with tickets, and subscribers. The works included are, as a rule, given by the various publishing firms, together with educational periodicals. New additions are for a short time placed on an open table in the room, after that they are consigned to the various cases; to obtain them then it is necessary to fill up a printed form. Farther on, the corridor contains specimens of school desks and seats, and a few cases illustrating the late Professor Henslow's method of teaching elementary botany. On the wall, on the same side, are large botanical diagrams and specimens with description, a very useful adjunct to the textbook; the wall on the other side is occupied by drawing models, and amongst other things a collection of the postage stamps of the British Empire. A small passage on the left contains examples of the weights and measures of several European countries, and a series of metrical weights and measures, as here shown, in a school would be the best means of making the scholars familiar with the advantages and applications of that system, and would enable them to compare these with our present standards. Here also is a specimen of a somewhat strange educational apparatus for assisting in the grammatical construction of sentences for translation into another language, the principal being that with the knowledge of a few words a large number of sentences can be constructed. It was brought out about seven or eight years ago under the name of the "Metabolical Machine," and consists of a certain number of cubes, having a different word on each of their faces, those on the same cube being interchangeable. They are arranged in separate divisions of a box with glass front, so that by a movement of the box one or more of the cubes can fall over and exhibit a fresh face.

In the rooms on the right-hand side of the main corridor the bulk of the educational collections will be found. The end room contains a collection of educational appliances from Sweden, and of school harmoniums; and on the wall a case, also, is well worthy of attention. It contains the skeleton of a fish (cod), bird (duck), and mammal (cat), taken to pieces and arranged and numbered so as to show the homology of the various portions. A similar case has recently been placed in the geological museum, and we need scarcely point out the value of such (unfortunately unusual) specimens to the student of comparative anatomy. In the succeeding room is a series of geographical accessories, maps (amongst which we would direct attention to Sydow's beautiful relief maps), globes (terrestrial and astronomical), topographical models, &c. At the base of one of the windows, with mirrors set so as to properly reflect the light, is a photograph of the moon, arranged as a stereoscopic object by Dr. De La Rue, and presented by him, forming a highly interesting illustration of the telescopic appearance of our satellite. Among a series of mathematical, optical, and meteorological instruments in the wall cases will be found the identical quadrant which the famous Capt. Cook employed in his voyage round the world. The floor cases contain small collections of shells, mineralogical specimens, and geological cabinets; and one has a number of flint implements, and casts of engravings on horn, made by the cave men in the south of France during the reindeer period. These floor cases are not the usual flat, or nearly flat ones, so commonly seen, but are higher, narrower, and have one or more shelves filled in, thus greatly economising ground space. In another of the cases will be seen a graphical representation of the principles of perspective; the figure on the picture plane (represented by an upright piece of glass) is shown to be produced by the intersection of lines of sight (represented by cotton threads) from the various parts of the object (models of bridges, &c.) to the observer's eye. The next room contains several very complete series of instruments used in the majority of chemical and electrical experiments, and also a series of working models of various simple machines and pieces of mechanism. In a small case by itself will be seen a strange-looking mass of wheels intricately fitted together, and with three vertical rows of wheels in the front, having the digits marked in order round their circumference. This is Babbage's famous calculating machine, exhibited by the Board of Works. Near to this are a number of small pieces of apparatus designed to illustrate practically such astronomical principles as the cause of the seasons, eclipses, and the precession of the equinoxes. In this room, too, is a small map of London of a date antecedent to the Fire, with an engraving of the old St. Paul's Cathedral. The last room in this department is filled with a very miscellaneous collection, the most important of which is a series of iron working models exhibiting many of the first principles of mechanism, as the nature and uses of cams, cogs; several modes of obtaining reversing and reciprocating action, &c. This part of the Museum we have been describing is always closed at dusk. The remaining portion of the Museum we must leave for a subsequent paper.

W. H. W. T.

DR. CARPENTER ON OCEANIC CIRCULATION AND THE GULF STREAM.

IN Mr. Proctor's argument for the superior efficacy of equatorial heat over polar cold, in producing the *vertical* oceanic circulation—which, equally with myself, he recognises,—he appears to me to have left out of view one very important consideration. If his view be correct—that the excess of evaporation in the intertropical area produces, as in the Mediterranean, an *inflow* of water from an extraneous source—such excess ought to show itself, as in the Mediterranean, in an *increase* of specific gravity. Now, as all trustworthy observations agree in showing that the specific gravity of equatorial water is *lower* than that of tropical water, I cannot see how Mr. Proctor's thesis can be sustained.

But further, if, as I gather from his criticism on my experimental illustration, he considers that the removal of equatorial *surface*-water by evaporation *draws in* polar water at the *bottom*, it would be necessary that the *whole intermediate stratum* should first rise towards the surface in order to *make room* for it. Now this hypothesis is open to the *prima-facie* objection of violating the principle of "least action," which I had urged against Professor Wyville Thomson's hypothesis that the deep flow of polar water towards the equatorial area is an *indraught*, replacing that which has been swept off from the surface by the action of the trade winds in producing the Gulf Stream. This question was discussed last year in Section A of the British Association; and as three of the most eminent physicists in this country—Sir William Thomson, Prof. Stokes, and Prof. Tait—agreed with me that any such loss of *surface*-water *must* be replaced (in the open ocean) by a *surface*, not by a *bottom*, inflow, I must venture to maintain my previous conclusion, that the "creeping flow" of polar water towards the equatorial area is due to the excess in the specific gravity of the polar over the equatorial column. And that this excess is maintained rather by polar cold than by equatorial heat, seems evident from the fact that while, as all recent observations concur in showing, the temperature of the sea in high latitudes, where not affected by any special currents, diminishes from 36° at, or little beneath, the surface, to below 30° at great depths, the influence of equatorial heat is not in the least perceptible at 200 fathoms' depth, as I learn from the temperature observations made last year in the school-ship *Mercury*, kindly communicated to me by Prof. Draper, of New York. This fully justifies Sir J. Herschel's very significant (*not* humorous) remark on the "more intense action" of polar cold.

Now, since the specific gravity of equatorial surface-water is rather *under* than over that of extra-tropical water, the question arises how the enormous loss of water by evaporation in the inter-tropical area is replaced. In assuming that it goes to supply the rainfall which feeds the rivers of Europe and North America, it seems to me that Mr. Proctor neglects two very important considerations: (1) that the greater part, if not the whole, of the rainfall of Europe and North America may be accounted for by the evaporation of the Mid-Atlantic beyond the region of the trade winds, say between 20° and 40° N. lat.; and (2) that there is an enormous rainfall in the region of "equatorial calms," which is attributed by Sir J. Herschel to the deposit of the waters taken up by the N.E. and S.E. trades. For, he says, "these winds arrive from higher latitudes, deficient both in heat and moisture, and take up both in their progress towards the equator, while they return little or none of the fresh water so taken up in the form of rain, till their arrival at and near the equator itself. There, however, they at once precipitate a large proportion of the water so absorbed, a process which, being in constant operation, must in some degree freshen the surface." (Physical Geography, Section 20.) It seems to me a pity that before committing himself to any "prediction" as to the superior efficacy of surface-*heat* over surface-*cold* in producing a vertical circulation, Mr. Proctor had not *tried the experiment*. If he will do so, he will (I venture to say) be rather astonished at the way in which the introduction of a piece of ice causes the surface-stratum close to it at once to tumble down (no other expression will so well describe the movement) to the bottom, where, as each new fall takes place, it creeps onwards to the other end of the trough. On the other hand, the application of surface-heat, in any way that can be devised, does not *per se* produce any rise from below; the only movement it produces being a slight surface-flow *towards* the heated area, to replace what is lost by evaporation. It is only when it acts *in combination* with the surface-cold at the other end of the trough, that it helps to maintain the vertical circulation, by keeping up the antagonism of temperature. For if there were a constant renewal of cold at one end of the trough, without any restoration of heat at the other, there would be a continued reduction in the temperature of *the entire mass of water in the trough* (supposing its bottom and sides to be non-conducting) until the whole comes to be as cold as its coldest part In making this assertion I am justified by the authority of the greatest master of Thermotics in this country; for after the discussion in Edinburgh Sir William Thomson gave me authority to state that he entirely accorded in my view of the matter.

As Mr. Proctor is, so far as I know, the only man of science in this country who agrees with Captain Maury in attributing the Gulf Stream to some other cause than the impelling force of the trade winds, I would strongly recommend him to study the "Wind and Current Charts of the Atlantic," published two years ago by the Admiralty. He will there find that the *predominance* of easternly winds in the area of the equatorial current is so enormous that to say that they will *not* produce a powerful drift-current is to run counter to all we know of the action of wind in giving surface-movement to water. No one (so far as I am aware) questions the action of the predominant south-westerly winds in giving a N.E. drift to the surface-water of the North Atlantic. But *their* predominance is far less than that of the N.E. and S.E. trades. The *general direction* of a drift-current will, of course, be determined by the *excess in the whole movement of the air in one direction* above its whole movement in *any other direction*. And until Mr. Proctor can show that there is no such westerly excess in the intertropical area, I must take leave to express my coincidence with Sir. J. Herschel in an expression of surprise that "there can be any possible ground for doubting that the Gulf Stream owes its origin *entirely* to the trade winds." It happened to me in early years to make a voyage to the West Indies, and I found the regular sailing course to be to keep as nearly *south* as possible until "the trades" were entered, a perfect reliance being felt that *they* would do all the *westing*. This was fully justified by what, after an interval of nearly forty years, is still among the pleasantest recollections of my life—the "run down the trades" with a steady breeze on the quarter, making every sail draw, that carried a heavily-laden merchant ship at the rate of eight or nine knots an hour for ten or twelve days continuously. And if any interruption to the regular trade-winds should occur, all experience shows that it is *local*, the *general* westerly movement being undoubted by every navigator I have ever met.

WILLIAM B. CARPENTER.

MECHANISM.*

(Continued from p. 533.)

IT is obvious that, whilst we have been forming these and similar curves, and taking portions of them for teeth, we may continue them, and it is possible we may find such continuations useful in their character of sliding surfaces. They reappear in that character, and receive the name of cams. A cam consists, generally speaking, of a curved piece, which conveys motion to a pin or to another curved piece. If, now (the lecturer referred to a model), this curved piece went round in that direction, it would raise the bar between the two guides, but if the curved piece came back again it would leave the bar at the point to which it had been raised. Place, however, a curved piece on the other side, and by that means the bar would be brought back. That is generally called a constrained cam. The curved cam may drive a shaft, or it may move an arm. If the curve forming a cam was passed round on a flat surface, it would form what is called a flat screw-wheel. It may also appear in another form, and this form is a very instructive one. Here is a piece of board, about 10in. by 6in., and we will suppose it to represent a page of printed matter in two columns. There is through the board a groove which passes as from the bottom left-hand corner of one column to the top right-hand corner of the same column. Let there be a pin in this groove, and let it be fixed on a bar constrained to move parallel to the lines on the page. Suppose the grooved wood to be slid for its whole length parallel to the binding of the volume, then will the end of the bar have travelled the breadth of a column of type. In this is a straight-line cam, and it is one of a very old form. It seems to have passed out of use for a long time, but has been reintroduced. If you put it round a cylinder it becomes a screw. In certain processes the screw is not conveniently available, and there are two cases known to many of you in which this flat or inclined plane cam is used for the purpose of generating screws—in the case of rifling guns, for instance. The rifling down the gun is a very long kind of screw, similar to the one on this old Chinese cotton gin, and that rifling is obtained by the use of this straight cam. In the fusee barrels of watches and clocks, the screw that takes the chain is also obtained from the straight cam. You have this same straight cam in the Archimedian drill.

As was said just now, motion is given to pins or bars by means of these cams. It is easy to see that if one pin is not of sufficient strength two may be put side by side, or three, or four, until at length you reach the form which ultimately develops into half a nut, and that half nut is used in Sir Joseph Whitworth's lathes, and is the mode by which the cutting tool is adjusted upon the lathe, the half nut being used because it can at any time be lifted out of gear so as to allow the slide-rest to go rapidly back. We may multiply or increase the length of this half nut and diminish the length of the screw, and we then reach the rack; for as the nut increases it extends into a rack, and the screw works upon it, causing it to travel (Fig. 18). We may also curve the rack round a ring, as in Fig. 19, and then it becomes what we call a worm-wheel, and we get the ordinary worm-wheel motion. This mechanism, therefore, has altogether resulted from a straight slit in a board moving on a plane, simply by throwing the elementary parts upon curved surfaces. The screw may take two forms, so as to work either from right to left, or from left to right. In this piece the screw or worm is revolving on a shaft in a horizontal direction, and it communicates motion to a shaft at right angles to itself.

We found the same mechanism in that old Chinese churka, or cotton gin; it is very oddly made, and of very rude construction. In it are two screws, viz., a right-handed one gearing into a left-handed one, acting as if they were toothed wheels, and so causing two shafts to rotate parallel to each other.

FIG. 18

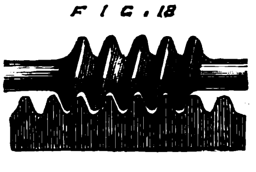

FIG. 19

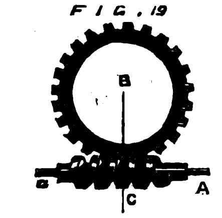

FIG. 21

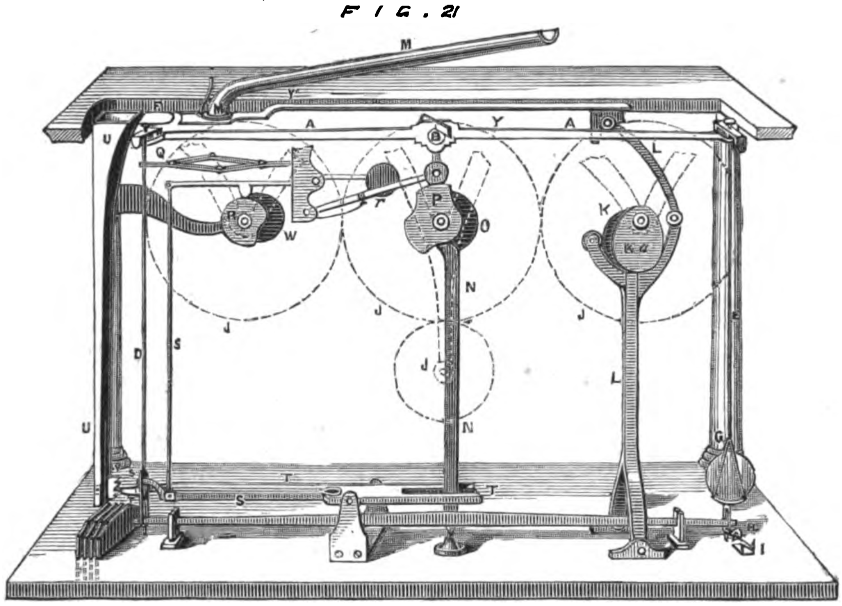

FIG. 20

This worm-wheel motion appears in a variety of forms, and it is generally employed in reducing speed; for one revolution of the shaft only allows one tooth of the wheel to pass. You may remember it in the crane kindly sent from Crewe. There was a very high velocity, which had ultimately to be very materially reduced; and the latter part of the reduction was by means of one of these worm-wheels. This is therefore a mode of converting velocity into power. The perfection to which these screws have attained is very great; so great that practically what we have hitherto called "clearance" is dispensed with.

This is one of Mr. Whitworth's standard measuring instruments. We have a screw perfectly made, working in a nut perfectly made—that is, as perfect as hands can make them. There is a certain number of threads upon the screw, say 50 in an inch If, therefore, this wheel, which is divided into 100 graduations, be keyed on the end of the screw, it would divide one inch into 100 times 50 parts, which would be 5,000; so that one of these divisions on the wheels would indicate the 5000th part of an inch. The manufacture of the apparatus is so perfect that it is capable of dividing an inch into 10,000 parts. It is used for the purpose of determining gauges, and is a case of cam motion applied as a screw.

These cams are also employed in another way very different to that, and here is a Swedish machine intended to represent some of the phenomena of light, heat, and sound. It consists of three rows of levers, which at one end work in a series of cams on rollers, and by turning these cams the wave-like motion which you see is produced.

This is another very useful development of the same thing. Here you have the mode by which the thread is laid on the bobbins in cotton spinning.

* By the Rev. ARTHUR RIGG, M.A., being the Cantor Lectures delivered before the Society of Arts.

You will find the pin which originated the nut in this case is one only, but extended to a flat piece, and the grooves of the screw are so arranged that there is a return motion which gives a varying direction to a bar.

Here, again, is another which differs both in form and name. On turning a handle at E in Fig. 20, the upright bar, G, remains steady,* but by changing the angle of this plate, F, an up and down motion is produced. This is a cam acting parallel to its axis; it is called a "swash" plate.

In this machine, Fig. 21, are the arrangements by which gold and silver coins are weighed before being issued from the Mint. It is upon a much larger scale than the actual machines, and has been kindly lent by the Master of the Mint. It may be well to preface any explanations of the cam contrivances in it by a statement of the circumstances under which the machines are used.

In the process of coining, some of the coined pieces may be too heavy, and some too light. Such irregularities in weight must be within very narrow limits, and by means of mechanism, constructed as this large machine, it is determined which coins are too heavy or too light, and must not be allowed to pass into circulation, and which may so pass.

The coins are placed in heaps; they pass down a spout; and the machines take coin after coin, and give a verdict which consigns the coin to the public for use or to the crucible for remelting. The mechanism is self-acting, being driven by power derived from heat. The coins are weighed at the rate of about twenty per minute. In the Mint there are nineteen of these self-acting machines at work, capable therefore of weighing 22,800 coins per hour.

As an illustration of what is required from the mechanism, we may take the case of arrangements being made for weighing sovereigns:—

	Grains.
The legal weight of a sovereign is	123·2744
Less allowance	·2
Therefore the weight of one blank or counterpoise is	123·0744 (A)
Making a similar allowance of ·2 grains for excess, has led to the adoption of a weight consisting of a platinum wire, and called "the remedy," of	·4
	123·4744 (B)

All coins below the weight marked (A) are too light and must be rejected.

Again, all coins above the weight marked (B), are too heavy, and must also be rejected. It will be observed that a coin heavier than the blank and "remedy" combined must be rejected. Hence one blank and one "remedy" wire constitute the weight on one side of the beam.

Mechanism similar to this is in use at some banks, and actuated by electricity. In one mechanistic respect it differs; for its judgment is only invited as to a coin being too light. The machines at the Mint are expert at keeping from the public coins too heavy. Therefore, where the Mint mechanism has three courses of decision open to it, the bank machines need only one.

Let us now turn to the mechanism, and follow the operations in weighing these metal blanks, which are our representative sovereigns:—

It will be observed that at the lower end of D there are two slits, and at the lower end of E only one slit.

A horizontal bar, rigidly fixed to the vertically guided rod N N, has its ends passed through the lower end of these two slits, consequently, if at any time the scale-beam is out of level, a depression of this vertical bar N N will restore the beam to the level.

L is a rocking bar attached to a horizontal slide, Y L Y. If this slide be moved from the reader's left hand towards his right it will be withdrawn from below the coin at M. If now it be moved from right to left, the coin will be advanced, and placed upon the scale-pan, F. Beneath that scale-pan is a pair of nippers, marked Q, by the action of which the pendant D, and consequently the beam A A, can be held in any position.

Such is an outline of the contrivances attached to the "weighing." Let us now turn to another class of contrivances which have reference to the determination of the destiny of the coin being weighed. Passing one through and the other near the upper of the two slits in the pendant D, there may be seen in the general drawing two pieces marked respectively S S and T T. The one marked S S passes through the upper slot in D. The one marked T T passes outside the slot in D, and carries the chisel-shaped end T, which is so counterpoised that when free the right hand end preponderates. S is called an indicating finger; T is called an indicator. S may, when permitted by the mechanism, fall on the lower part of the slot in D, and so by a projecting piece (not shown) carry down with it the indicator, T.

If we now pass to the extreme left of the figure, a curved spout, having at its upper end a wide mouth, may be traced. It is lettered U U. At the lower end of this spout and fixed to it may be seen three notched steps. The spout is free to move near its upper end about a horizontal axis perpendicular to the plane of the paper. Dependent upon the position of the lower extremity of the spout is decided into which of the three troughs (shown on the base-board of the machine) any coin passing down the spout may be discharged. These three troughs are the respective entrances to the vessels arranged to receive the light, the correct, and the heavy coins.

Having thus described the general construction of the essential parts of the weighing and distributing arrangements, we may turn our attention to the wheels and cams by which the whole of the previously described parts discharge their appointed duties, and in the required order.

J J J J are four small-toothed wheels, the three upper ones being of the same size. On the axes of each wheel are two cams, lettered K and Ka, P and O, W and R. The cams have very varied portions of their circumferences struck with the same radius, and therefore when that portion of the circumference is upon the arm no motion is communicated. K and Ka cause the bar L to rock, and thus one coin is placed on F, and slid off by the second coin put on in consequence of a second rocking. Assume that a coin is on F, and that it is too heavy, the scale beam will be depressed. This depression will have raised not only the blank counterpoise in G, but also "the remedy" in H. So important and sensitive is the action on the remedy that the bearings shown at I, Fig. 23, on which the small "remedy" wire rests must be truly horizontal. This is secured by the three levelling screws, as shown in Fig. 23, which is placed under H in Fig. 22. To return to the weighing.

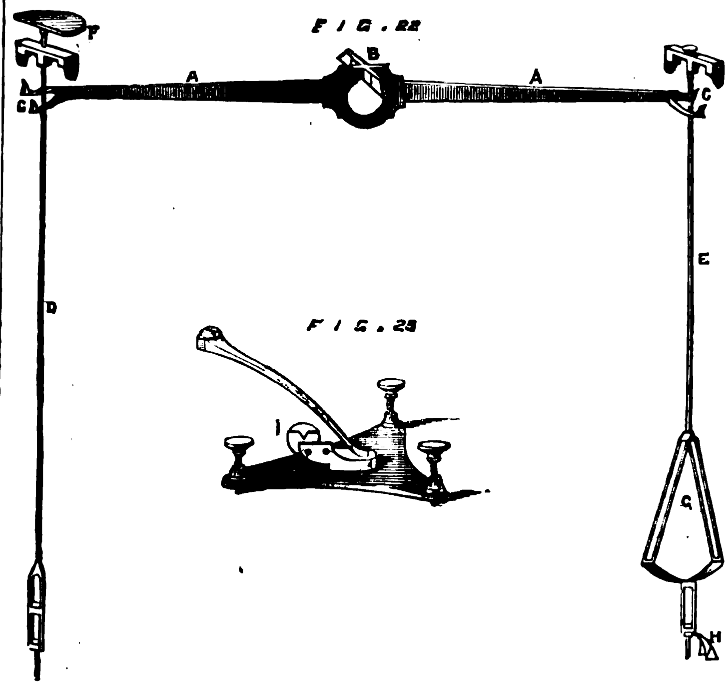

FIG. 22

FIG. 23

The action of the cam P releases a little weight which closes the nippers Q and holds the beam. The cam, R, then acts, and S falls upon the upper slit in D, carrying with it the chisel-shaped end, which is outside of the slit in D. The cam, W, now allows the spout U U, to fall, and, in the case assumed, the lower notch in V would rest upon the chisel end. (The drawing shows the middle notch so resting.) The destiny of the coin is now determined, and the scale beam may be restored to its proper level. This is accomplished by the cam O, which lowers the leveller attached to the vertical rod N N, the cam P having previously opened the nippers Q. This leveller, pressing upon the lower slots in the pendants D and E, restores the beam to horizontality. It will now be seen why the portion S S, which decides the drop of the spout, is double, for the levelling of the beam at this stage does not disturb the chisel end in the notch.

The beam being levelled, the cam P again permits the nippers to close. The cam K advances the slide Y Y, and with it another coin. Thus the one on F is displaced—it falls into the spout U U, and being too heavy is guided into the receptacle for heavy coins. The cam W returns U U to its first position; the counterpoised end of T T causes the chisel-shaped end to rise, and the apparatus is restored ready for another operation.

The lecturer illustrated the description by weighing metal blanks, some of which were too heavy, others too light, and others correct, and said the instrument is produced as an example of the uses in mechanism of cams, affording, as they do, periods of rest or of impulsive action. These cams are found in many machines. They have also been employed in the form of tappets, for the sudden opening and closing of the valves of steam engines, where it was considered that the action of the excentric (another name for a particularly formed cam) was too gradual.

There are, however, few if any machines, in which cam actions have been more successfully employed than in the large one now before us. It is for the making of those wire combs called cards, used for laying the fibres of cotton parallel to each other. A consideration of this machine must be postponed for a future occasion.

(*To be continued.*)

DISINFECTANTS.

WHAT may appropriately enough be termed the "battle of the disinfectants," if still unsettled in this country, may be regarded as approaching a satisfactory solution in France. What with the old-fashioned chloride of lime, carbolic acid, Condy's and other fluids, chloralum, and sundry other inventions, patented and otherwise, each said to be the best by interested persons, the uninitiated public is in a perfect quandary as to which to use, for of course the public is anxious to have the cheapest as well as the most reliable article. The commission appointed by the French Academy to inquire into the relative merits of the various disinfectants when employed in eradicating contagia report that the first place among agents for attacking and destroying infectious germs must be accorded to hyponitrous acid. Extraordinary precautions must, of course, be observed in making use of this dangerous gas; the doors and windows must be carefully sealed with gummed paper. When disinfecting a room containing 40 or 50 cubic yards, the materials are taken in the following proportions: 2 quarts of water, 3¼ pounds of ordinary commercial nitric acid, and ¼ pound of copper turnings or filings. A stoneware vessel is employed, holding two or three gallons. The exit doors are carefully pasted up, and the room left closed for 48 hours. The person opening the room at the expiration of the time should be protected in some way from breathing the gas, by a suitable respirator.

Carbolic acid, however, is cheaper, more easily used, less dangerous, and has proved equally efficacious. It is best employed mixed with sand or sawdust—one pound of acid to three pounds of an indifferent substance. The mixture, placed in earthen vessels, was used for the same purpose as the hyponitrous acid. Carbolic acid, diluted with 15 or 20 parts by weight of water, was found useful for daily sprinkling of the floor and bedclothes.

An interesting case is mentioned in the report where neither chlorine nor hypochlorous acid was able to destroy or render odourless the gases given off from the corpses in the Paris Morgue during the heat of summer. The object was attained by dissolving a quart of liquid carbolic acid in 500 gallons of fresh water, contained in the reservoir, and used to sprinkle the bodies. Putrefaction was entirely stopped.

Devergie found that water containing only one part to four thousand of its weight of carbolic acid sufficed to disinfect a dead-house, even in the hottest weather, when six to eight corpses were in it.

For fumigating linen, mattresses, and other bedding with chlorine, Regnault's latest method was used—namely, one pound of chloride of lime (bleaching-powder) is sewn up in a strong bag of sail cloth, holding about a quart, and put in an earthen pot containing a quart of common muriatic acid (specific gravity 1·15) and three quarts of water.

As soon as the acid comes in contact with the chloride of lime the room is closed, and the things exposed to the action of chlorine gas for 24 hours; the room is then aired for 48 hours. Ten such earthen pots give off about 14 cubic feet of chlorine, sufficient to disinfect from 20 to 25, more or less, dirty mattresses.

* In the model the plate F could be moved about (c) and placed at right angles to E, or in a horizontal plane.

ECONOMY OF FUEL IN STEAM NAVIGATION.*

THE writer stated that he had often been struck by the indifference to the question of economy in fuel which for so many years prevailed among the constructors and the users of marine steam-engines, and by the fact that, whilst wonderful progress was made in the increase of the speed of the ships, the quantity of fuel burned seemed not to be cared about, and excess in this respect was not looked upon as a reproach to marine engineering. In these days, when ships were tried for speed at the measured mile so carefully to ascertain the last portion of a knot that could be got out of them, the question as to the quantity of coals burned in obtaining this speed was never raised, and the suggestion that there was still a more important trial to be made—a trial as to the consumption of fuel—was never thrown out. The astonishment that was felt on looking back at this long-continued apathy as to the consumption in marine propulsion was increased when it was considered that the mine owner, the waterworks engineer, the locomotive superintendent, and—last, by no means least—the manufacturer of portable agricultural engines, had all along been trying to find out to what extent economy could be obtained, although not one of them had really so much cause to search after saving as had the proprietors of ocean-going steamers or the builders of marine engines. He believed this indifference to have arisen from various causes, amongst which was the fact that steam navigation in the outset was confined to coasting voyages or passages across the Channel, and, under the circumstances, the quantity of coal to be stored in the bunkers was comparatively small, whilst owners were content with a very slow rate of speed. The opening of new outlets for industry, requiring boats that could perform long voyages, led to a demand on the part of steamship owners for more economical steam-engines. There was a general opinion that marine engines were not suitable for the use of high pressure steam; but compound engines having been tried, with the use of high pressure steam, the beneficial results obtained induced owners almost universally to adopt them for vessels going long voyages; indeed, so great were the advantages found to be, that most of the large steamboat companies had the original single-cylinder engines in their existing ships replaced by compound ones. It was still an open question, however, whether the same effect obtained by the compound cylinder could not be obtained by the single cylinder working expansively, either arranged so that the expansion could not be tampered with, or else put into the hands of truly intelligent men who would not throw the expansion out of the gear. Theoretically, there could be no doubt that steam could be as advantageously expanded in one cylinder as in two, and even more advantageously, on account of a certain loss in the passages between the two cylinders of the compound engine, which loss did not arise when the expansion was made all in one cylinder.

The writer then proceeded to trace out the history of the compound engine, describing the various arrangements which have been from time to time brought into use, such as the original arrangement of Woolf, the modified plan of McNaught, and the various forms which have been given to compound engines as applied to marine purposes. The last arrangement described was that now most generally adopted for commercial steamships—namely, the steam-hammer type, with but two cylinders and an intermediate receiver. Mr. Bramwell also showed that, whereas the average consumption of the best marine engines of nine years ago was 4·5lb. of fuel per horse-power, the same results were now obtained with a consumption of 2·03lb. The construction of marine boilers for bearing higher pressure, he said, was a subject of essential importance in efficiently carrying out the advantages of high expansion in compound engines, and in connection with that subject there were important questions, such as care in the manufacture of the plates, their thickness and durability, and other matters; but they could not be entered upon in this paper.

DISCUSSION.

In the discussion which followed, Mr. Jamieson said there was no doubt there had been very great changes in engines since 1854, much greater even than Mr. Bramwell had stated. He was now aware of four-cylinder engines working with one-third of fuel used for engines in 1855. In a voyage to Valparaiso and Panama and back n the mail service in 1855 the consumption of coal was 1,080 to 1,200 tons, and this had been reduced to 550 and 600, and even to 300 and 400 tons. No doubt a great deal had been done in the last ten years, and even in the last five years, and it would be well to look at the effect of the adoption of the two cylinder engines on commerce. It was evident that the compound engine was the engine of the day for marine purposes, and in the future, attention must be directed to the further improvement of the engine and the boiler connected with it, with a view to a greater reduction in the economy of fuel. They must see if they could not get a better boiler, and a forced combustion in smaller tubes. He had reason to believe that in the next decade they would see the figures reduced as much as in the last.

Mr. Crampton urged that the only test of the performance of an engine which they should take into consideration was the amount of water or weight of steam used per indicated horse-power per hour. The quantity of coal used to evaporate that water depended upon the quality of the boiler, and in considering the performance of the engine it should be left out of the question altogether. Mr. Crampton proceeded to describe a series of experiments he had carried out on a small pumping engine doing a uniform duty, and capable of being worked with steam at pressures varying from 35lb. to 70lb. per square inch. The experiments were made with steam at the different pressures, the degree of expansion being varied so that in each case the engine was made to develop the same effective power. Each experiment lasted a week, and the results at which Mr. Crampton arrived were that practically nothing was to be gained by employing steam of more than about 40lb., pressure expanded six-fold. He also subsequently pointed out the importance of employing heavy reciprocating parts in single-cylinder engines working very expansively, and stated that in the case of the pumping engine to which he had alluded, the great length of the pump rods caused the reciprocating weight to be unusually large.

Mr. Thomson, in answer to an inquiry as to why some single cylinder marine engines, which had been built to work with high degrees of expansion had not succeeded, stated that the engines were given up in consequence of its being found impossible to get the valve gear to stand properly.

Mr. Head called attention to the practice of stoking by hand. He said he had never seen a stoker putting on coal in front of a blazing fire without thinking that it was a practice which ought to be put a stop to. He was told that not more than one man in three could endure the work in tropical climates, and that in the Red Sea it was not unfrequent to see the firemen drop down dead at their work. He appealed to the authority of Professor Huxley in saying that a human being who was undergoing severe physical exertions in extreme heat lost 2lb. or 3lb. in weight per hour. The application of steam power was brought very near to the stokehole, and the operation of taking up coal and putting it on the fire seemed only to require a little mechanical skill. It was not more complex than what had been achieved in the construction of the sewing-machine, the steam plough, and many other applications of steam power. In the interests of engineering, and also of common humanity, attention ought to be directed to the subject, and he should be glad to know from the marine engineers present whether there was any prospect of mechanical firing being applied to marine engines.

Mr. William Laird said the firm of which he was a member had been engaged for many years in the construction of engines, and of late years they had found that nothing but the compound engines were called for for commercial purposes. The great economy which had followed their introduction had been of such immense advantage to those who had applied them that the compound engines had really displaced altogether the old system of engine. In some cases an opportunity had been afforded of testing practically the economy obtained in the use of compound engines as compared with the old system, by the substitution of the modern for the old engine in the refitting of ships, and the result in a series of voyages had been that the quantity of coal consumed was about one-half the consumption with engines of the old type. This, he thought, was conclusive proof that the adoption of the compound engines had been of immense benefit to commerce, and the result was that almost all the large steamship owners in Liverpool had, more or less, adopted them for their vessels. In some companies all vessels refitted had been supplied with the compound engines, while they had been adopted in the new vessels. Without entering into details, he merely wished to intimate the general and successful adoption of the compound engines, and he felt satisfied that if they receded from the stage at which they had now arrived, and used a lower pressure for engines or another system, they would make a great mistake.

Mr. Crampton said that in the statement made by Mr. William Laird the point was ignored that the engine taken out might be the worst type of single-cylinder engine.

Mr. William Laird said, in making the statement, he only meant to show how generally the compound engine had been adopted in Liverpool, and he thought it was sufficient to put the matter in a general way. Perhaps his way of stating the matter gave too great an advantage to the engines on the compound system. He merely mentioned the fact to show, in a commercial sense, the great advantage which had been gained through the introduction of the compound engines, and the state of perfection to which they had been brought by engineers throughout the country. He did not intend to claim any special credit for Liverpool.

Mr. Ramsbottom said as to the abstract view of the question there was no room perhaps for two opinions, as far as theory went, because no doubt an advantage was to be derived from the increased pressure of steam, and from its earlier cutting off; but whether it was done by one cylinder or two was, he thought, a matter of very little consequence. It became a question whether they could get materials which would do something more than the materials now known; but he thought they had pretty nearly reached the practical limits of commercial economy. He did not think they were likely to reduce their pressure much below what they had now attained, and he should be glad to see that they were likely to increase materially upon it. If they could find materials, the mode of construction would be speedily hit upon, and they might look for higher pressure and corresponding economy. With regard to experiments, those which were isolated, and of merely a few hours' duration, were of very little value. He attached very little importance to speed mile trips, the truest and safest results being, he thought, found in more lengthened working, such as actual sea voyages.

Mr. Bramwell, in replying on the discussion, said he thought there had been too much of the tone of finality about it. With regard to the observations of Mr. Ramsbottom in depreciation of mile trials, and in favour of long voyage trials, he most entirely agreed with him, if the thing to be tried was not a steamboat. He thought a six hours' trial, carefully conducted, was a better test of what engines could do in the way of economy of fuel than the test to be derived from a long voyage. Assuming that the continuous indicator could be relied upon for giving good results, he trusted that steamship owners would go to the expense of fitting their steamers with implements of that kind, so as to arrive at truthful results. The getting a better evaporation of water for the fuel burnt was at the root of economy. As to mechanical stoking, alluded to by Mr. Head, he most thoroughly agreed with the suggestion, and he could not help thinking that it was a problem which ought to be solved. If they succeeded in doing so they might get a more regular combustion of fuel. At the shows of the Royal Society he had seen as many as from thirty-five to forty firings in an hour; they endeavoured to get by rapidity of hand stoking the uniform and good effects obtained from efficient apparatus. Mr. Bramwell also deprecated anything like finality in scientific discussions, and in illustration quoted some exceedingly amusing extracts from evidence given by some of the leading engineers early in the present century on the occasion of a Parliamentary inquiry, this evidence going to show that the use of steam of higher pressures than 4lb. or 5lb. was unnecessary and absurd, and that cast iron was far preferable to wrought iron as a material for boiler making, although one witness admitted that wrought-iron boilers possessed one advantage, inasmuch as "each rivet formed a safety-valve."

* Abstract of paper read by Mr. F. J. BRAMWELL, before the Institution of Mechanical Engineers at Liverpool.

AUTOMATIC GASLIGHTING.

A NEW patent apparatus for the instantaneous lighting or extinguishing of gas-lamps has just been, it is said, successfully tried at Preston. The apparatus constituting the invention looks like a moderate-sized globular inkstand of glass, surmounted by a tube of the same material, with a metallic top; and by screwing off the burner it can be very easily attached to any lamp, chandelier, pipe, or ordinary gas jet. The base or globular portion is filled with a deep red coloured liquid—a simple chemical mixture, with no combustible properties, almost without smell, and so cheap that threepennyworth of it will serve one lamp for twelve months. Over this liquid, and within the glass tube, there is a plate of zinc, along with a piece of graphite or gas carbon, and between these and a thin coiled platinum wire fixed over the cap of the general vessel into which a gas burner is inserted galvanic communication is obtained. A pipe, to be screwed to that up which the ordinary gas supply flows, runs through the base of the vessel to about the centre of the surmounting tube; pressure brought to bear upon the gas in this pipe causes, by small collateral openings, a simultaneous depression upon the chemical solution which occupies a lower level in two side tubes; the gas occupies the vacuum caused by the displaced liquid, and then ascends to a chamber in connection with the burner; whilst the displaced liquid is pressed into two side tubes effecting contact with the zinc and graphite, generating galvanic activity, which is communicated to the platinum wire, and exciting the catalytic power of the wire, which, when exposed to the ascending jet of gas, results in immediate, almost instantaneous, ignition. Each lamp requires one of these appliances: but, as stated, they are cheap, and the price of the requisite liquid may be termed nominal. The apparatus is virtually self-acting; it requires no skilled hands to superintend its operations; it may be attached by a novice; it may be replenished at any ordinary chemist's shop for a few pence per year; it needs nothing but fixing, and then being subjected to the simple action of gas pressure.

SCIENCE IN SEARCH OF COALS.

SCIENCE, says the *Daily News*, is about to attempt the solution of a problem which is of immediate interest to every householder in London and the South. It is nothing less than a search for coal under the rocks of the South-Eastern counties. A committee of the British Association has been appointed to discover what is the order in which the strata lie under the Wealden which occupies a great part of Kent and Sussex; and a boring is to be commenced in the latter county on occasion of the meeting of the Association at Brighton in the present week. This boring is intended to go through the Wealden and the underlying secondary rocks to the Palæozoic strata which are supposed to lie still farther down at a depth of from 700 feet to 1,700 feet. It is expected by many geologists that at that depth coal-measures will be found which will be practically a continuation of the Belgian coalfields on the east and the Somerset coalfields on the west. There is little doubt that at some time the coal-measures have been there, and the question is whether, as the late Sir Roderick Murchison believed, they have been swept away by the extensive denudations which preceded the deposit of the chalk. Up to the present time no coal has ever been discovered south-east of a line which may be drawn from Bath to Stamford and continued thence to Yarmouth. The whole area thus marked off is occupied by strata far newer than the coal-measures; and though thin beds of shale and lignite have been found, and beds of sandstone strongly resembling those which overlie the coal, all attempts to discover coal have hitherto been useless. Some curious efforts have been made. Nearly two hundred years ago the Rev. Giles Thornbury bored for coal at Guildford. In grubbing up the roots of an old oak, he had found some pieces of lignite, and the discovery at once suggested the search for coal. According to Aubrey, the coal was actually found—"a kind of rocky coal," he says, "like that which they call Kennell coal, which burns like a candle." But when the borers got to the coal the irons broke, and as fast as new irons were put in they snapped off; and as Mr. W. Lilly, the astrologer, thought the irons were broken by subterraneous spirits, the attempt was abandoned. In the first years of this century a shaft was sunk to the depth of 164 feet at Bexhill, in Sussex, and two seams of lignite were met with; but the mine was drowned out, and the scheme was abandoned. About thirty years ago an attempt was made to get up a colliery company to sink a shaft 150ft. deep at Worplesdon, near Woking, through the Bagshot Sands; but it of course failed. Mr. Joseph Prestwich, in an article in the current number of the *Popular Science Review*, states that among experienced coal miners an impression exists that coal is to be found in the Lower Tertiary strata, between the London clay and the chalk; but that all these expectations, founded as they are on the presence of irregular seams of lignite, are necessarily futile. Coal is never to be found in these newer rocks. It is a relic of an earlier condition of the planet's surface; the buried ruins of an older world.

The failure of previous efforts to find coal in the south-east of England is, however, no reason for believing that coal does not exist. It has never yet been looked for in the right place. The coal-measures are the upper part of the Palæozoic series of rocks, and those rocks underlie the Tertiary and Secondary series, when those series are present as they are in this part of England. Speaking roughly there are some fourteen of these strata which come in regular succession, and which are altogether between 7,000 and 8,000 feet in thickness. On the assumption, therefore, that the coal-measures which lie to the east of us in Belgium, and to the west of us in Somerset and South Wales, are continued under us, it was estimated that they would lie at some 8,000 feet below the surface. But it has now been discovered that a good many of these intervening strata are absent. In a well sunk at Kentish-town a few years since, which it was hoped would pierce the water-bearing formation of the Lower Greensand, it was discovered that there was no greensand to penetrate; indeed, all the lower secondary strata were absent, and at 1,113 feet deep, what was supposed to be the Old Red Sandstone, which underlies the coal-measures, was found. At Harwich, a year or two later, a like discovery was made, though the rock found at a depth of 1,025 feet was mountain limestone. This is very nearly the depth at which the same Palæozoic rocks are found on the other side of the Channel, and it at once suggests the very strong probability that in some parts of the southern counties the coal-measures themselves may be found at a similar depth. The Somerset coal seams are lost at a point between Bath and Frome, at a depth of 500 feet. Between that point and London no trial pits or wells have been sunk to anything like a thousand feet, yet it is after going to at least that depth that the chances of finding coal begin. There is a well near Reigate 900 feet deep, another at Chichester 945 feet, and one at Southampton which is still in the chalk, at a depth of 1,317 feet. It is intended that the boring now to be set on foot shall be continued to the depth of about 2,000 feet. It may or may not pierce a seam of coal; but it will at least show in what order the older strata lie, and will give geologists facts which will enable them to point out where coal may be found, or to decide that it cannot be found at all.

Happily the chances are that coal will be found. The general drift of scientific opinion during the last few years has been towards the belief that there are workable coal seams under a great part of Kent and Sussex. Mr. Prestwich, indeed, places them under Essex and Hertfordshire; Mr. Godwin Austen, who, as long ago as 1855, brought the subject before the Geological Society, places them in the line of the Thames valley, parallel with the North Downs, and believes that they continued thence under Reading and the Kennet valley to join the Bristol coalfield. Wherever they are, the coal is likely to be plentiful and good—more like the Somersetshire coal than that of either the Midland or the Northern counties. In report D attached to the Report of the Royal Commission on Coal Supply, Mr. Prestwich, who ably supports Mr. Godwin Austen's argument, estimates the area of the supposed coalfield at 150 miles in length, by a breadth varying from two miles to eight. Such a coalfield would be no insignificant addition to our national resources. Even though it should lie at a depth at which coal is at present only occasionally worked, it would be cheaper and more available to us in London than the nearest coal now worked. It would be premature to speculate on the social and industrial results of the discovery of a vast coalfield at our doors. To make coal as cheap on the Thames as it is upon the Tyne, as plentiful south of London as it is north of the Trent, would probably be to cause the rise of a belt of manufacturing cities round London. But the first thing, of course, is to ascertain whether the coal is there. There is almost every scientific probability in favour of its existence; and should the geologists of the British Association succeed in finding it, or even in pointing out where it will be found, they will do the greatest service that science has yet rendered even to a generation which it has so greatly instructed and enriched.

PYRO-PLATING.*

THE end of pyro-plating, like that of all other methods of plating, is to affix to a baser metal a sheet of one of the superior metals; but this method is applicable where none of the other methods can be applied with success. "Close plating," whether with hard or soft solder, cannot be applied with success to any cutting instrument, as a knife or a pair of scissors, &c. Hard soldering would completely destroy a knife-blade or a pair of scissors. The soft solder plating can be applied to a knife or a pair of scissors without destroying the steel, though with difficulty; with the scissors the first attempt to cut would shear off the plating, and with the knife, if it were sharpened so that it would cut, the plating would chip off in using it. Common electro-plating is not applicable to steel or iron, as by that method these metals cannot be got perfectly clean, that is—chemically clean, therefore, by that method no adhering coating can be obtained.

In fact, for all manner of plating or soldering, the first requisite is, that the two metals that are to be applied to each other must be chemically clean, or no proper adhesion can be obtained.

This cleanness is obtained in various ways: In soldering by various fluxes; in electro-plating to such metals as that method is applicable, by dipping the article in an acid which will readily dissolve the metal of which it is made—and not only so, but the salt formed by this solution of the metal in the acid used must be readily soluble in water, or no clean surface can be obtained. There is still another condition to be considered, that is when the surface of the metal has been made thoroughly clean, it must be protected from contact with the air in its transit from the cleansing-baths to the solution wherein it is to be coated. This condition not being recognised in the first attempts at electro-plating caused many failures and much trouble, till it was discovered that a film of mercury prevented the contact of the air with the cleaned metal. Moreover, mercury has this advantage, that it amalgamates with the metal to be coated, and with the coating, though this amalgamation is not absolutely necessary, yet it facilitates the coating of metals with other metals by electro-deposition, when the two metals will readily amalgamate.

There are cases where amalgamation is not possible; for example, where one of the metals will not amalgamate, as with steel and iron coated with copper, gold, or silver; or when neither will amalgamate, as with steel or iron coated with aluminium or nickel; not that it is impossible to form an amalgam with these metals, for even steel can be amalgamated by the intervention of sodium, but it is not possible for plating purposes, as a diluted solution of a mercuric salt must be used.

Now, for all such cases as these where the amalgamation process cannot be used, pyro-plating is especially applicable. The name pyro-plating is given to this process to distinguish it from the electro-plating process, and because the coating is driven into the surface of the metal on which it is put by means of heat and pneumatic pressure. It is not confined to coating with silver as its name might indicate, but it is at present applied to coating with gold, platinum, silver, nickel, aluminium, copper, brass, or bronze and aluminium bronze.

The rationale of the process is very simple; but the various details require much care and attention. The end to be obtained is simply this. That the metal to be coated shall be "chemically clean" when immersed in the solution in which it is to be coated. There are several ways in which the attainment of this end may be prevented: By inadequate means for cleansing, by the passage through the air of two or three feet after being cleansed, by the metal being positive in the coating solution—in this case the metal is fouled on contact. This refers to cyanide solutions, to sulphate and chloride solutions, to double sulphates and chlorides, as of nickel and ammonia, and of platinum and potash or soda. All of these may be used in certain cases for pyro-plating, but they are *not* used. There is a special solution used for pyro-plating in all cases, because most of these solutions leave matters in the metal that is being coated, if it be in the slightest degree porous or "roaky," as is the case with steel that has been badly faggoted, and on the article passing through the furnace these matters volatilise, and cause an irruption in the coating. The method used for cleansing steel and iron articles is as follows: They are first boiled in caustic alkali to free them from grease; they are then mechanically cleansed with fine flour emery and brushes in water; they are then brushed with steel wire brushes under a stream of a solution of carbonate of soda; then they are wired and hung in the same solution ready for being made chemically clean. This is done by means of nascent hydrogen in a hot alkaline solution. The water of solution is decomposed on the article by means of a strong current of electricity, the article being made negative. If the solution be kept strong and not carbonised, a film of this solution is sufficient to protect the article from contact with the air in its quick transit from the last purifying process to the solution wherein it is to be coated. The time for it to be transferred can easily be seen by the experienced eye; the article assuming gradually a more silvery appearance. After the proper amount of metal is put on in the coating bath the articles are taken out and washed and dried. The amount of metal put on is ascertained by having a test-surface put in with the articles, and the exact time of putting in and the exact weight of the test noted, and this test is carefully weighed from hour to hour till the amount desired is put on. After being dried, the articles are put into the furnace to have the silver or other metal driven into the surface of the coated metal. The firing furnace, as it is technically called, is of simple construction. The conditions to be observed in its construction are two, namely, to obtain a bright red heat in the chamber where the articles are put, and to secure the articles from coming in contact with the fuel or products of combustion. In firing knife-blades and other cutting instruments care has to be taken that they are not carried higher than between 450° and 500° F. This is ascertained by trials on a pad of prepared test paper; a blade is taken out from time to time and tried upon the pad and the colour is noted—whether it scorches it straw-colour, yellow, pale brown, deep brown, or black. Alum-water is used for regulating this paper as to the colour for the proper degree of heat. After the proper heat is attained the blade is instantly quenched point downwards in cold water, and all that were in the firing chamber with it. For articles that do not require tempering, or that are made of metal that will not temper, as iron, copper, good brass, or German silver, the heat may be higher. Even if a steel article should be carried so high as to soften it, it can be re-hardened and tempered with the silver or other metal upon it, without in any way injuring the coating. The theory of this part of the process, which is technically called "burning in," is this: The coating metal in all cases is one of the superior metals as compared with the coated metal, and is less porous whether cold or hot.

The article being heated, it naturally expands and becomes more porous, as of course both article and coating do, but their relative porosity remains the same, consequently on expansion there will be an infinite number of small cists into which by atmospheric pressure the coating will be driven on attaining the proper heat. Then on the instantaneous quenching in cold water, the coating is seized and retained by the suddenly contracting under metal. This is seen to be the case on filing or grinding the coating off the under metal; for though the coating may be filed or ground off till both coating and under metal are filed or ground off together, yet the under-metal remains spotted all over with an infinity of little points of the coating metal.

* By J. Baynes Thompson in *Chemical News*.

SOMETHING WRONG WITH THE SUN.*

WHEN we consider the intense heat which has prevailed in Europe during July, and the circumstance that n America also the heat has been excessive, insomuch that in New York the number of deaths during the week ending July 6 was three times greater than the average, we are naturally led to the conclusion that the sun himself is giving out more heat than usual. Though not indorsing such an opinion, which, indeed, is not warranted by the facts, since terrestrial causes are quite sufficient to explain the recent unusual heats, we cannot refrain from noting, as at least a curious coincidence, that at the very time when the heat has been so great, the great central luminary of the solar system has been the scene of a very remarkable disturbance—an event, in fact, altogether unlike any which astronomers have hitherto observed.

Now certain Italian spectroscopists—Respighi, Secchi, Tacchini, and others—have set themselves the task of keeping a continual watch upon the chromatosphere. They draw pictures of it, and of the mighty coloured prominences which are from time to time upreared out of, or through, the chromatospheric envelope. They note the vapours which are present, as well as what can be learned of the heat at which these vapours exist, their pressure, their rate of motion, and other like circumstances. It was while engaged in some of the more difficult and delicate of these tasks that Tacchini noticed the strange occurrence now to be described.

"I have observed a phenomenon," he says, "which is altogether new in the whole series of my observations. Since May 6, I had found certain regions in the sun remarkable for the presence of magnesium." Some of these extended half-way round the sun. This state of things continued, the extension of these magnesium regions gradually growing greater, until at length, "on June 18," says Tacchini, "I was able to recognise the presence of magnesium quite round the sun—that is to say, the chromatosphere was completely invaded by the vapour of this metal. This ebullition was accompanied by an absence of the coloured prominences, while, on the contrary, the flames of the chromatosphere were very marked and brilliant. It seemed to me as though I could see the surface of our great source of light renewing itself." While this was going on Tacchini noticed (as had frequently happened before in his experience) that the bright streaks on the sun which are called faculæ were particularly brilliant close to those parts of the edge of the disc where the flames of the chromatosphere were most splendid and characteristic. The granulations also, which the astronomer can recognise all over the sun, when a large telescope is employed, were unusually distinct.

Tacchini concludes (and the inference seems just) that there had not been a number of local eruptions of magnesium vapour, but complete expulsions. Only we would venture to substitute for the word "expulsion" the expression "outflow" or "uprising," since it may well be that these vapours rise by a quiet process resembling evaporation, and not by any action so violent that it could properly be regarded as expulsive.

In whatever way, however, the glowing vapour of magnesium thus streamed into the envelope of the sun, it would seem that the aspect of our luminary was modified by the process—not indeed in a very striking manner, or our observers in England would have noticed the change, yet appreciably. "More than one person," says Tacchini, "has told me that the light of the sun has not at present its ordinary aspect; and at the Observatory we have judged that we might make the same remark. The change must be attributed to magnesium."

It is impossible to consider attentively the remarkable occurrence recorded by Tacchini without being struck by the evidence which it affords of solar mutability. We know that during thousands of years our sun has poured forth his light and heat upon the worlds which circle around him, and that there has been no marked intermittence of the supply. We hear, indeed, of occasions when the sun has been darkened for a while; and we have abundant reasons for believing that he has at times been so spot-covered that there has been a notable diminution of the supply of light and heat for several days together. Yet we have had no reasons for anticipating that our sun might permanently lose so much of his heat and lustre that the inhabitants of earth would suffer. Tacchini's observation reminds us, however, that processes are at work upon the sun which admit of being checked or increased, interrupted altogether or exaggerated so violently (as it were), that the whole aspect of the sun, his condition as the fire and lamp of the planetary system, may be seriously affected.

If we only remember that our sun is one of the stars, not in any way distinguished, unless perhaps by relative insignificance, from the great bulk of the stars which illuminate our skies at night, or are revealed by the telescope, we shall learn to recognise the possibility that he may undergo marked changes. There are stars which, after shining with apparent steadiness for thousands of years (possibly for millions of years before astronomy was thought of), have become suddenly much reduced in brightness, or after a few flickerings (as it were) have gone out altogether. There are others which have shone with equal steadiness, and have then suddenly blazed out for a while with a lustre exceeding a hundredfold that which they formerly possessed. It would be equally unpleasant for ourselves whether the sun suddenly lost the best part of his light, and presently went out altogether, or whether he suddenly grew fifty-fold brighter and hotter than he now is. Yet in the present position of sidereal astronomy, it is quite impossible to assert confidently that one event or the other might not take place at any time.

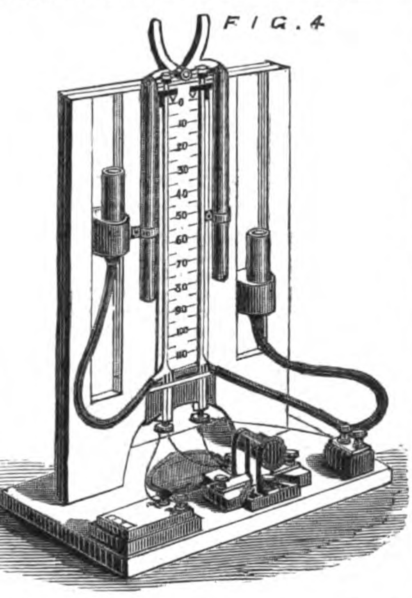
Fortunately, we may view this matter (just as astronomers have learned to view the prospect of mischievous collisions with comets), as a question of probabilities. Among so many thousands of stars there have been so many sudden outbursts of light and fire, so many sudden defalcations of splendour. Our sun is one of those thousands, and so far as we know, takes his chance with the rest.

* From the *Spectator*.

ON MEASURING TEMPERATURES BY ELECTRICITY.*

(*Concluded from page 534.*)

ALTHOUGH I have explained that by means of a differential galvanometer and a variable resistance (constituting in effect a Wheatstone bridge arrangement) the increasing resistance of the platinum spiral may be measured, it was found that the use of a delicate galvanometer is attended with considerable practical difficulty in iron works and other rough places where it is important to measure elevated temperatures, or on board ship for measuring deep sea temperatures. I was, therefore, induced



to seek the same result by the conception of an instrument which is independent in its action from tremulous motion, or from magnetic disturbance caused by moving masses of iron, and which requires no careful adjustment or special skill on the part of the operator. This instrument is represented by Fig. 4, and may be termed a chemical resistance measurer or "differential voltameter." The immortal Faraday has proved that the decomposition of water in a voltameter, expressed by the volumes of gases V, is proportionate in the unit of time to the intensity I of the decomposing current, or that

$$I = \frac{V}{T}$$

According to Ohm's general law, the intensity I is governed by the electro-motive force E, and inversely by the resistance R, or it is

$$I = \frac{E}{R}. \text{ It is, therefore, } \frac{V}{T} = \frac{E}{R} \text{ or } V = \frac{ET}{R};$$

or the volume V would give a correct measure of the electrical resistance R if only the electro-motive force E and time T were known and constant quantities. But the electro-motive force of a battery is very variable; it is influenced by polarisation of the electrodes, by temperature, and the strength and purity of the acid employed. The volume of gases obtained is influenced, moreover, by the atmospheric pressure, and it is extremely difficult to make time observations correctly. It occurred to me, however, that these uncertain elements might be entirely eliminated in combining two similar voltameters in such a manner that the current of the same battery was divided between the two, the one branch comprising the unknown resistance to be measured and the other a known and constant resistance. The volume of gas V^1 produced in this second voltameter, having a resistance R^1 in circuit, would be expressed by

$$V^1 = \frac{ET}{R^1}$$

and we should have the proportion of

$$V : V^1 = \frac{ET}{R} : \frac{ET}{R^1};$$

or E and T, being the same in both cases, may be struck out, and the expression will assume the simple form

$$V : V^1 = R^1 \div R.$$

The constant resistance R of the one circuit being known, it follows that the unknown resistance R^1 is expressed by $\frac{R^v}{V^1}$; that is to say, by a constant multiplied by the proportion of gas produced in the two voltameters irrespective of time, or strength of battery, or temperature, or the state of the barometer.

The resistance R and R^1 are composed each of two resistances—namely, that of the principal coils, which we may term R or R^1, and of the voltameter and leading wires, which is the same in both cases, and may be expressed by y. The expression should therefore be written as follows:

$$V : V^1 = R^1 + y^1 : R + y,$$

R^1 being the unknown quantity.

The mechanical arrangement of the instrument will be understood from the diagram, Fig. 4; and the whole arrangement of the pyrometer, with its leading wire and resistauce measurer, from the general view given in Fig. 5. The voltametric resistance measurer consists of two calibrated vertical tubes of glass of about three millimetres diameter, which are fixed upon a scale showing arbitrary but equal divisions. The upper ends of the tubes are closed by small cushions of indiarubber pressed down upon the openings by means of weighted levers, whereas the lower portions of the tubes are widened out and closed by plugs of wood, through which the electrodes in the form of pointed platinum wires penetrated to the depth of about twenty-five millimetres into the widened portions of the tubes. By a side branch the widened portion of each vertical tube communicates by means of an indiarubber connecting pipe to a little glass reservoir containing acidulated water, and supported in a vertical slide. In raising the weighted cushions closing the upper ends of the vertical tubes, and in adjusting the position of the small reservoirs, the acidulated water will rise in both tubes to the zero line of the scale. In turning a button in front of the tubes the battery current is passed through both pairs of electrodes, the one circuit comprising the permanent resistance R and the leading wires up to the pyrometer, and the other the leading wires and the pyrometer coil. If the resistance of the pyrometer coil should be equal to the permanent resistance R, the $R^1 + y$ will be equal to $R + y$, and therefore, $V = V^1$, but as the resistances differ, so will the volumes. Necessary conditions are: that both reservoirs are filled with the same standard solution of pure water with about ten per cent. of sulphuric acid, that all the electrodes are of the same form and size, and that their polarity is reversed frequently during the progress of each observation, in order to avoid unequal polarisation. With these precautions, which involve no particular skill or knowledge of electrical observation on the part of the operator, very accurate results are obtained; but in order not to incur considerable error of observation it is advisable to continue the current, reversing the same, say twice, until at least forty divisions of gases are produced in the least activated tube, which operation will occupy from two to three minutes, if a battery of from four to six Daniell elements is employed. The volumes V and V^1 being noted, after having allowed half a minute for the gases to collect after the current has ceased, the weighted cushions upon the tubes are raised in order to allow the gases to escape, when the water levels will immediately return to their zero position, to make ready for another observation. By inserting the observed values for V and V^1 into the expression above given, the unknown resistance R^1 can be easily calculated; but in order to facilitate the use of the instrument I have prepared a table which gives at a glance the resistance due to any two observed volumes, the volumes V governing the vertical, V^1 the horizontal columns, and the resistance being read off at the point of intersection. At each point of intersection the resistance is marked in black, and the corresponding temperature in red ink.

It now remains only to be shown what is the relation between the resistance and temperature in heating a platinum wire. The researches of Dr. Matthiessen, who has made the latest investigations on the effect of temperature upon electrical resistance, are restricted to the narrow range of temperatures between 0° and 100° Cent., nor do they comprise platinum. He adopted the following general expression for the pure metals:

$$R = \frac{R_0}{1 + xt + yt^2},$$

* Read at the Royal Institution, by Mr. C. W. SIEMENS, F.R.S

which, in determining the specific values of x and y for each metal, gives a close agreement with observation between the narrow limits indicated, but is wholly inapplicable for temperatures exceeding 200° Cent., when the value t^2 commences to predominate and to produce absurd values for R_t.

It was necessary for my purpose to undertake a series of elaborate experiments with a view of finding a ratio of general application. Coils of thin wire, of platinum, iron, copper, and some other metals, were gradually heated and cooled in metallic chambers containing the bulbs of mercury thermometers, and for higher temperatures of air thermometers, and the electrical resistances were carefully noted. The progressive increase of electrical resistance was thus compared directly with the increasing volume of a permanent gas (carefully dried) between the limits of zero and 470° Cent. and a ratio established, which is represented by the formula.

$$R_t = \alpha T^{\frac{1}{2}} + \beta T + \gamma,$$

in which T signifies total temperature counting from the absolute zero, and α β and γ specific co-efficients for each metal. According to this formula the electrical resistance is a constant at the absolute zero, and progresses in a ratio represented graphically by a tipped-up parabola, approaching more and more toward a uniform ratio at elevated temperatures. Although the comparison with the air thermometer could only be carried up to 470° Cent., the general correctness of the ratio of increase just stated has been verified by indirect means in measuring progressive heats, and by comparison with the platinum ball pyrometer.

It is important to mention here that great care must be exercised in the selection of the platinum wire for the measuring spiral, platinum wire having been met with conducting only 4·7 times better than mercury at zero, Cent., and others; conducting 8·2 times better than mercury, although both samples had been supplied by the same eminent makers, Messrs. Johnson and Mathey. The abnormal electrical resistance of some platinum wire is due chiefly to the admixture of iridium or other metals of the same group, and it appears that the platinum prepared by the old welding process is purer, and therefore better suited for electrical purposes than the metal consolidated by fusion in a Deville furnace.

In conclusion, I shall show some working results of the pyrometer in measuring by means of the same protected coil a mixture of ice and water, boiling water, molten lead, and the fire itself by which the lead is melted, the readings produced being 2° Cent., 98° Cent., 330° Cent., and 860° Cent. respectively. The latter temperature signified a cherry red heat, as may be judged by the appearance of the tube when withdrawn from the fire. The instrument which I have had the honour to bring before you this evening has already received several useful applications. Through its first application an important telegraph cable was saved from destruction through spontaneous generation of heat. Prof. Bolzani, of Kasan, has made some interesting applications of it for recording the temperature at elevated points and at points below the earth's surface. Mr. Lowthian Bell has used it in his well-known researches on blast furnace economy; and at several ironworks pyrometer tubes are introduced into the heating stoves, and permanently connected with the office, where the heat of each stove can at all times be read off and recorded. These and other applications are sufficiently self-evident, if the soundness of the principles upon which I rely is conceded; but I feel that the shortness of time at my command has hardly enabled me to do more than to pass these in review, while endeavouring to demonstrate the results obtained of recording the temperatures of distant or inaccessible places, including furnace temperatures.

SPONGES.

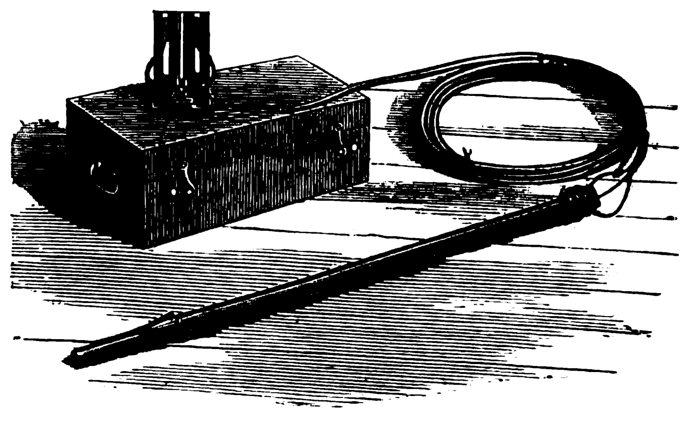
VERY few among the thousands who are now seeking recreation at the seaside are aware of the immense variety of life the sea contains, or the wonderful and interesting character of the marine plants and animals that are within reach of the hand upon every part of the coast. Thus, says the *Gardener's Magazine*, on all our coasts sponges abound, yet the fact is scarcely known except to the naturalist. They are to be found growing on seaweeds, on the backs of crabs and lobsters, on and within the empty shells of whelks and cockles, and upon rocks and sand everywhere. The seaweed collector will meet with sponges at every turn, whether in gathering from the deep sea or from the tidal pools. Seaweeds and sponges are, however, far separate in organisation and their respective sequence of development, though constantly in proximity as products of the waters. The first are true vegetables, the second true animals. We know somewhat, though perhaps but little, of the first, but of the second we know next to nothing; and yet the sponges carry us farther into the realms of romance than the seaweeds do, for they were doubtless among the earliest and most industrious builders of the world, and have left their frail skeletons as memorials of their existence in the "white cliffs of Albion," every separate flint being, to use a homely phrase, a "petrified" sponge.

Take a thin slice of flint, properly prepared for the microscope, and let the instrument unravel its history. If used to the detection of fossil infusoria, you will hardly fail to find them in it, and you gain one step towards an answer as to its history.

Organised forms have had something to do with its formation; at some time, very far back in the past, there has been animal life there, and that life was marine. But you cannot account for the formation of separate and independent nodules of silica, scattered over a bed of chalk, by the help of these infusoria. Try a splinter of flint broken off in the rough; but be very careful not to spoil your object-glass by bringing the two surfaces into close contact. Now what do you see? Remains of shells, and here and there distinct traces of a sort of reticulated structure, sparry incrustations of a contour which you cannot but believe is derived from some organic form, long since annihilated. These appearances are repeated in various specimens, and have a general relationship one to the other, especially in the interlacing lines and spiculæ of which they consist.

Life may be said to begin or end in the sponges; they are the very lowest in the scale of animated

FIG. 5



nature; but it is quite certain they are not members of the vegetable kingdom. Take a piece of sponge, such as is commonly used on the toilet table, and dip it into a thin solution of size, and you have a fair resemblance of its condition when living. The sponge proper is the skeleton, the gelatinous coating is organised and animal; and the best proof of the fact is afforded by the microscope, which reveals ciliary motion, and there is an end of the difficulty as to what place it should occupy. The openings in the sponge are chambers, interlaced with silicated fibres, and, by the play of the cilia on the gelatinous surface, the water is made to circulate from chamber to chamber, so that the sponges obtain their food by the same process as a vorticella or rotifer—namely, by creating currents through the agency of cilia. The exterior film is the life of the sponge, the skeleton is a deposit.

But the film must be understood as pervading the inner as well as the exterior chambers, so that the currents of water pass through the entire mass, and carry nourishment to all the mouths for which the cilia work so incessantly. A very dead sort of creature is a living sponge. It has none of the organs of sense which distinguish terrestrial animals; and not even the irritability which makes a sea-anemone of so peevish or spasmodic a temper. But it has its history, however brief, like others of the great class of zoophytes. The sponges increase by gemmation. Little buds appear within the openings of the reticulated mass, and these at last detach themselves, and exhibit the same play of cilia as their parents.

But instead of at once becoming fixed, the action of the cilia causes the sponge to spin about in the water, so as to have a real locomotive power of finding for itself a site, where it casts anchor, and for the rest of its days never knows either the pleasures or the pains of travel. If every separate flint was once a separate sponge, this locomotion accounts for their detachment and their subsequent concretion in distinct nodules.

LIGHTNING AND LIGHTNING CONDUCTORS.

IN a letter on this subject to the *Times*, Mr. W. H. Preece, of Southampton, gives the following information:—

I wish to express merely the results of my own study and experience. If, however, twenty years' training in that profession which, according to one of your correspondents, "lives by lightning," if the personal inspection of innumerable lightning accidents, of the erection of lightning conductors (not in tens or hundreds but in thousands), entitle one to express an opinion, then I trust your readers will believe that what I say is not mere sciolism, but the lessons of that best of all teachers—experience. I said, "Every one can, if he choose, at the expense of a few shillings, render his house absolutely safe with a perfect system of lightning conductors." I will now show how this can be done.

But, first, what is lightning? It is, like thunder, one of the effects of electric discharge. It is not the destructive discharge itself. The amount of misconception and error in the public mind on the subject of electric storms is astonishing. We read of the "electric fluid" being attracted by this thing and by that—at one time by the lamp irons on the ends of a railway carriage, at another time by the looking-glasses, which are carefully removed; we hear of "ascending" lightning, its course is traced —it entered here and went out there, and "so off to the clouds overhead;" "it struck her face, passed to her chest, and crossed over the region of her heart;" it objects "to turn round sharp corners;" and so on. All such statements are scientific absurdities.

Modern physicists know no such thing as the "electric fluid." Electricity is no more matter than is heat, or light, or sound. The laws of its transmission are simple and thoroughly well known. Thunderstorms are but gigantic repetitions of drawing-room experiments; they are simple electrical phenomena, differing only in degree from the ordinary spark exhibited by a lump of sugar. There must be two masses in opposite electrical states, separated by a non-conductor. Two "thunder" clouds, or the earth and a thunder cloud separated by the air, gives these conditions. When the intensity of the charges becomes too great for the intervening non-conductor to prevent their neutralisation by combination, or when its thickness, and therefore its resistance, is sufficiently reduced by the charged bodies approaching each other, we have discharge and its effects—light, heat, mechanical energy, and sound, or thunder and lightning and its destructive effects. The so-called "electric fluid" can no more be said to ascend from the earth to the cloud than to descend from the cloud to the earth. The discharge invariably occurs along the line of least resistance, and it is continuous and instantaneous along the whole line. The line of least resistance may be made up of metals, bricks and mortar, trees, or animal flesh. Whatever offers the least resistance will be the chosen path. The chief function of a lightning conductor is to furnish this path. But it has a much higher and important function. It dissipates the conditions which determine discharge. In fact, it prevents lightning. This it does in virtue of the principle of points. A pointed body directed towards an electrified conductor reduces its charge, so that when a thunder-cloud passes over a lightning conductor its charge is silently, quietly, and continuously neutralised. If a galvanometer were inserted in this conductor at such a time it would give indications of the presence of an electric current. Telegraph wires are invariably occupied with currents on such occasions. The presence of a storm at Newfoundland was observed at the extremity of the Atlantic cable in Ireland.

Hence the conditions that determine a perfect conductor are that it shall expose in some prominent position of a building a metallic point, and that it shall offer from this point to the ground a path of little or no resistance. I say that the ordinary galvanised iron wire known as No. 4, which is ¼in. in diameter, tipped with a gilded brass point or cone, is amply sufficient for any dwelling-house. It costs about 1d. per yard, and the brass cones would cost about 6d. each. Thirty shillings would pay for all the materials required for an ordinary house.

My reasons for recommending this wire are these: —When telegraph poles were first erected in this country they were protected with lightning conductors. This practice was subsequently found to be too expensive, and was abandoned. Such "earth wires," or conductors, were, however, found to effect another and very important object, and their use was continued on all main lines. I have never known a case of a pole so protected being damaged during a thunderstorm, whereas scarcely a thunderstorm occurs without some unprotected poles being injured. I remember, near Romsey, twenty unprotected poles being shattered by one discharge, and upon the Basingstoke and Andover line 15 per cent. were found to have been struck. The line was renewed and earth wired, and not one single case of damage has occurred since, though some years have elapsed. A pole was very recently found in South Wales with 8in. of its top shattered — the earth wire only went so far; the charge from that point went harmlessly to earth through the wire. The cross arms are frequently found damaged as far as the earth wire, never beyond. I could multiply instances *ad infinitum*, and as the wire used is generally No. 8 (·170in. in diameter), and sometimes even smaller, I think I am fully justified in saying that No. 4 wire, which is twice as thick and offers half the resistance, is amply sufficient for the protection of our houses. The precautions to be used in fixing conductors are those:—

1. The conductor must be solid and continuous from its gilded point to the ground.

2. Its connection with the ground must be sound and good. It may be connected with the iron, gas, or water mains, or be buried several feet deep in a bed of coke, or be attached to a mass of metal in moist earth, or be carried down a well.

3. Each conductor, if there be more than one, should make a separate earth if possible, and they should all be connected together below the surface. The lead roofing and all external masses of metal should be connected with them.

4. All joints and connections should be soldered.

It is better that each chimney stack should have its own conductor, and they should be periodically examined to see that their points remain intact, and that their metallic continuity is perfect. The custom is to fix them and then to leave them to chance.

The precautions that are not necessary are these: —1. It need not be copper. 2. It need not be insulated. 3. It need not be carried externally to their disfigurement in the cases of church spires, columns, and chimneys. I never pass Trafalgar-square without regretting the disfigurement of Nelson's statue. It is, however, better to carry the wire externally in the case of dwelling-houses, lest it pass too near the lead gas-pipes, which, being good conductors and soft metal, might be fused. The wire can go round a corner as well as through it, but acute angles are best avoided. The more direct the course to the earth the better.

The area protected by a conductor is said to be that whose radius is equal to twice the height of the conductor from the ground; but it is safer to take the radius as equal to the height of the conductor. Thus, for small houses one conductor is enough, but it is safer to attach one to each stack. If it project a yard above the stack it is sufficient, and it is within reach for inspection. The stack pipes down the sides of a house are convenient conduits for the wire, and there is no reason why it should not be carried down to the ground inside them, so as to be out of sight. If there be no convenient stack pipe, the wire can be run up and stapled to the brickwork or stone. With 30s. for materials and 10s. for labour any intelligent man can, with these directions and precautions, safely protect his house from the destructive effects of thunderstorms.

The effect of thunderstorms upon our telegraphs is not very serious, though the extension of such a network of wires, 130,000 miles in length, over the whole country would lead one to expect considerable damage. All the telegraphic apparatus in the Postal Telegraph Department—and there are 8,500 in use—are supplied with lightning protectors. The wires themselves are excellent protectors. Accidents are due either to imperfect apparatus, careless construction, or neglect of instructions. The percentage of instruments damaged is very small. It was before the transfer of the telegraphs to the State 3 per cent.; it is now decidedly less. The Postal Telegraph Department possesses about 3,500 stations of its own; scarcely half-a-dozen have been injured throughout the whole of this severe season. At two or three stations the wires were carelessly carried parallel to the lead gas-pipe. As sparks passed from the wire to the pipe the pipe was fused and the gas lit. At Berwick, some years ago, not only this happened, but over the gas-pipe was a lead water pipe, which was fused by the gas, and the water which escaped extinguished the flame.

During thunderstorms the wires are active. Every discharge disturbs them by induction. Frequent and powerful currents pervade them. Brilliant flashes are observed about the apparatus, but no injuries occur to the manipulators, though shocks are sometimes felt. I have known one or two clerks knocked down, but principally by fright. If there were any truth in the popular notion that metal attracts lightning telegraphists would lead but a sorry life during thunderstorms. During a recent very severe thunderstorm I was watching its effects in a large office. Not one clerk left his post or shirked his duty, and all appeared perfectly indifferent to the roar and fury of the elements outside.

In suggesting "putting grates to earth," I advise a telegraphist's cure. An external system is better and cheaper, though this plan would add an additional and material security to the house. The grate must be taken out, and a pin tapped into the back of it, to which must be welded the galvanised iron wire. Separate wire should be carried from each grate straight down the side of the flues, and united together at the ground line, and thence taken "to earth." The wire should not be allowed to go near any lead gas-pipes.

Mr. Hyett's plan is an admirable one, and his pipe is an excellent conductor. The right angles are harmless if the pipe is carefully rounded at those places. Points and sharp edges are alone to be avoided.

LETTERS TO THE EDITOR.

[We do not hold ourselves responsible for the opinions of our correspondents. The Editor respectfully requests that all communications should be drawn up as briefly as possible.]

All communications should be addressed to the Editor of the ENGLISH MECHANIC, *31, Tavistock-street, Covent Garden, W.C.*

All Cheques and Post Office Orders to be made payable to J. PASSMORE EDWARDS.

"I would have every one write what he knows, and as much as he knows, but no more; and that not in this only, but in all other subjects: For such a person may have some particular knowledge and experience of the nature of such a person or such a fountain, that as to other things, knows no more than what everybody does, and yet to keep a clutter with this little pittance of his, will undertake to write the whole body of physicks: a vice from whence great inconveniences derive their original."—*Montaigne's Essays.*

**** In order to facilitate reference, Correspondents when speaking of any Letter previously inserted, will oblige by mentioning the number of the Letter, as well as the page on which it appears.*

WEBB'S CELESTIAL OBJECTS AND PROCTOR'S STAR ATLAS.

[4699.]—M. C. GAUDIBERT is doing very useful work in noting the places, &c., of certain double stars, which he has observed on divers occasions. But I would venture to suggest that he might find a better way of classifying them than (let. 4688, p. 542) as "objects not in Webb's 'Celestial Objects' nor in Proctor's smaller atlas." His present method suggests to many that in each several instance he is indicating a flaw or blemish in the two works above-named. Of course he does not intend this; since he must be perfectly well aware that for every object which *could* be inserted in such a book as Webb's or such an atlas as my smaller one, there are dozens discoverable by very moderate telescopic power. Webb indicates this at p. 170 of his work, and no one can use a telescope for an hour on a good night without finding it out for himself.

I may take this opportunity of correcting a misapprehension, which I find very prevalent, as to my smaller atlas. When I say in the preface (2nd edition, p. viii) that the atlas is "specially intended to serve as a companion to Webb's charming work," I do not intend to indicate *that* as the primary purpose I had in view in planning the atlas. The scheme of the atlas was fully matured, and the larger atlas was completed, before I had had the advantage of reading the "Celestial Objects." My main object was to construct an atlas on a plan combining several qualities of great importance which had hitherto been (unaccountably) neglected; and the plan actually adopted was the result of the geometrical determination of the *one single method* by which those qualities *could* be combined. Having devised a plan fulfilling that *general* purpose, I thought I could not do better than make the larger atlas serve the *special* purpose of being a companion to Admiral Smyth's "Celestial Cycle," while I made the smaller serve the *special* purpose of being a companion to Mr. Webb's "Celestial Objects." These respective special purposes are quite distinct from the general purposes which the atlases were primarily intended to fulfil.

It will, perhaps, be understood that having given much time and thought to the invention of an atlas quite distinct from anything previously published (and, as I venture to think, the only atlas ever constructed on a really sound plan), I have to some degree objected to find my smaller atlas commonly spoken of as though it were a mere offshoot from another work, however highly that work is justly estimated. All the same I congratulate myself very much on the "happy thought" which led to the addition of an important special character to my smaller atlas. For it is as easy to conceive of an observatory without a telescope as without Webb's charming work.

RICHARD A. PROCTOR.

THE MOON IN PICTURES, ON HORIZON, &c.—To "M. A."

[4700.]—"M. A." (let. 4622, p. 509) has raised a question of considerable interest.

There can be no doubt, I think, that the size of the sun or moon in pictures depends a good deal on the artist's judgment. We have an ideal moon or sun. Moreover, the presentation does not equally well satisfy all who look at the picture. To my own judgment, for example, the moon introduced in some of Leech's pictures appears monstrous; yet it is probably enlarged only about as much as is just for pictorial effect.

I think all these points depend on ideas unconsciously formed as the result of a more or less trustworthy past experience, and the judgment is exercised as if on the intuitive assumption that those ideas are just.

For example, we see weathercocks ordinarily in a position which leads us to form the idea that they are smaller than they really are; but we have tolerably exact ideas of the dimensions of church doors, porches, buttresses, and so on. Hence, when we see a weathercock close by a church door, porch, or buttress, the mind is struck by the fact that the weathercock takes up more space than one would have expected.

Again, it has been shown by optical considerations that the sky near the horizon is mentally estimated as being between three and four times farther away than the sky at the zenith. Now we usually see the moon high up, or where the sky is apparently nearer. When it is near the horizon, still seeming on the sky, the mind entertains the impression that the moon is much farther away, and as it subtends (appreciably) the same angle instead of a much reduced angle, the mind receives the impression that the moon is larger than she had before been conceived to be.

Now, in pictorial representations of the moon there is precisely the converse of the case of the horizontal moon. The horizontal moon seems much larger than usual, and really subtends the same angle (appreciably to common observation); the pictorial moon seems about the right size, and really subtends a much larger angle. May not this be because, whereas in ordinary observation the horizontal sky seems much farther away than that overhead, the sky of a picture always seems much nearer than the natural sky?

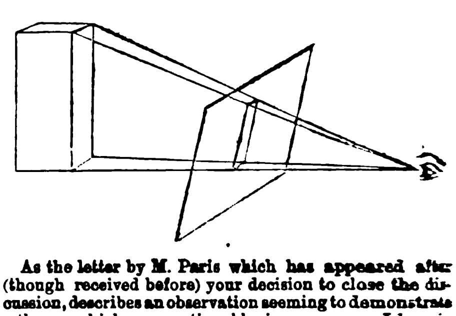
Everything seems consistently explained by the views here presented.

"M. A." is, of course, quite right in dwelling on the fact that a swiftly-moving body offers no *resistance* to deflection. He justly urges also the great objection to the term "centrifugal force," in cases where in reality *inertia* (or *absence of force*) is the essential feature. It is not quite true, as "C. H. W. B." says, that there exists no such force as "centrifugal force," but it is certainly quite true that what is commonly so called is no force at all. RICHARD A. PROCTOR.

ERRATUM AND ADDENDUM ABOUT PERSPECTIVE.

[4701.]—I NOTICE in my letter about perspective (4621, p. 509) an erratum, which arose from my adding a parenthetical remark without having the figure before me. Of course the sentence beginning "that M. Paris may not," &c., relates to the parallelism of the lines C A, D B.

As our common object is to get true ideas either established or promulgated, you will permit me, I trust, to indicate that the views of Sir David Brewster, quoted by M. Paris (let. 4623, p. 509), are strictly correct. M. Paris has misunderstood them. It is quite true that when we stand close to the base of a square tower and so direct our vision as to take in the whole tower in the most convenient manner (that is, with the head thrown slightly back), the perspective view we then obtain shows the sides of the tower converging, and they would so appear in a photograph if the prepared plate were placed in a correspondingly inclined position; or in a picture, if the plane of projection were supposed to be inclined, as shown in the accompanying figure. The disadvantages of such a mode of projection are too obvious to require discussion. Every picture so drawn would require half a page of explanatory matter to make it intelligible.



As the letter by M. Paris which has appeared after (though received before) your decision to close the discussion, describes an observation seeming to demonstrate a theory which unquestionably is erroneous, I beg, in the interests of your younger readers, who might otherwise be misled, to be permitted to point out that the result of M. Paris's observation with a plumb-line would have very fitly illustrated my paper on "Self-deception in observation." It is mathematically demonstrable that he cannot have seen what he supposes he saw, any more than he could have seen two straight lines enclosing a space. Indeed, if only it be granted that the perspective view of a straight line is also a straight line (which I suppose M. Paris will not question), it can readily be shown that according to his theory two straight lines can inclose a space. Thus, let there in a lofty square tower of equal width throughout, and let the observer be stationed at an upper window of a house close by so as to be opposite the middle of the tower. Then the top of the tower subtends a smaller visual angle than the middle; therefore, according to the theory, the sides bounding the nearest face must converge towards the top of the picture, and if produced far enough will meet in *that* direction. But the bottom of the tower being farther from the eye than the middle also subtends a smaller visual angle. Hence, according to the theory, the sides bounding the nearest face must converge towards the bottom of the picture, and if produced far enough will meet in *that* direction. Hence two straight lines will meet in two opposite directions, and, therefore, will inclose a space. This is usually regarded as impossible.

RICHARD A. PROCTOR.

PERSPECTIVE.

[4702.]—SINCE you have somewhat departed from your original intention of closing the discussion on perspective I hope you will be able to spare space for a few more letters on this interesting and far from exhausted subject. Mr. R. A. Proctor sends a diagram with his reasoning thereon, which certainly proves that the vertical lines are parallel in his diagram, but does not prove that vertical lines are optically parallel in nature, which Mr. Proctor seems to assert to be the case in the latter part of his letter, in which he speaks of the tower's sides being parallel. I know that the idea of a plane of projection is a useful, and perhaps the only admissible, idea in the theory of practical perspective, but in nature there is no such thing as a plane of projection. The only plane on which objects can be projected in the same way as they appear to the eye is, as Paddy says, no plane at all, but concavo-convex—concave interiorly and towards the eye, convex exteriorly and towards the object, and the plate of glass representing this so-called plane must be shaped like a watch-glass, with a curvature conformable to the sphericity of the eye, and equally conformable to the periphery of the sphere of vision, or the limit of man's vision in every direction. Diagrams, therefore, founded on the idea of a plane of projection, are only convincing as far as regards practical perspective, for the simple reason that on no other idea can we work out the rules of perspective, so we say, "Let it be granted" that there is a plane of projection, and on that postulate we form our rules, and according to our rules all vertical lines are to be represented vertical and parallel, notwithstanding that optically they are not so. Possibly, if an artist were to deviate in a very subtle and imperceptible way from this rule, and make his vertical lines very slightly converge, it might convey to the spectator the idea of greater height, while he would not know the reason why, but the artist, in order to be absolutely true to nature, must not make his converging lines straight lines, but curves, for all vertical lines in nature converge to the zenith in curved lines; but I do not know how the artist is to find out this curve, as it is that singular curve that eternally approaches a straight line but can never cross it. I think the artist would find the whole matter a bother about nothing, and stand upon the ancient way of representing the lines of vertical objects vertical and parallel, as it is not part of the artist's vocation to portray the imperceptible.

"E. L. G.," in his letter 4654, p. 586, makes the assertion that the optical convergence of vertical objects is neither slighter nor anywise less sensible than horizontal convergence in a street. Now this I consider as wantonly throwing down the gauntlet to fact. "E. L. G." must surely know that horizontal convergence in a street is obvious, perceptible, and patent to any one who gives any attention to the subject, while the convergence upwards within the cone of vision is imperceptible to the senses, although we know from optical rules that it does exist. Suppose a column 100ft. long laying on the ground, let the spectator stand at one end of it, the convergence is obvious, because the distance from the spectator to the other end of the column is 100ft.; now let the column be set on end vertically, and let the spectator stand at 200ft. distance then the column will be within the cone of vision, but the difference of distance from the spectator of base and summit will be only 25ft.; does "E. L. G." mean to assert that the convergence resulting from 25ft. distance is equal to that resulting from 100ft.

BONO.

[4703.]—MR. PROCTOR admits that the top of the tower is (setting illusion aside) optically narrower than the base. Now, we are not dealing with anything but the appearances to be represented by the sketcher. He is, therefore, I submit, not justified in making in his diagram the line A B equal in length to the line C D, and if not, all his reasoning is vitiated. Mr. Proctor states that there is no point on the plane of projection indefinitely extended to which the projections of the tower's sides converge, but the plane of projection so extended must reach the zenith, and the vanishing-point of the sides of the tower is the zenith. If the part of the plane not representing the tower be cut away we obtain a small tower coinciding with the real one, and how, then, can the zenith be the vanishing-point in one case and not in the other? Again, Mr. Proctor admits that the vanishing-point of any plumb-line is the zenith, but the plane of projection may obviously be considered as a number of plumb-lines placed side by side. Now, the sides of the tower may be looked upon as plumb-lines converging in the zenith, yet the lines on the plane, also plumb-lines, according to him, do not converge there. If the top of the tower subtends a smaller visual angle than the base the lines A C and B D cannot be parallel, and the plane of projection cannot make them so. The question now is, is Mr. Proctor justified in making in his diagram A B equal to C D? I say certainly not, and that mistake is fatal to his demonstration M. PARIS.

PARALLELOGRAM OF FORCES.

[4704.]—I THINK the Professor in the Andersonian University had probably another reason for leaving "Marine Engineer's" question (let. 4649, p. 515) unanswered than the mere desire to shirk a difficulty.

"M. E.'s" difficulty is based on two mistakes. The first is the common one which confounds the parallelogram of forces with the parallelogram of velocities. The law called the "parallelogram of forces" asserts nothing whatever about the time in which a body will traverse the diagonal A D (see the figure illustrating let. 4649). In too many of our catechisms on mechanics the question of time is dragged into the explanation, and even into the enunciation of this important law. "Marine Engineer" correctly enunciates the law (for the case in question), but what follows after the word "therefore" is a *non sequitur*; and if the theory of velocities were correctly stated by "Marine Engineer," the true *sequitur* would be, therefore the body under the action of the two forces will *not* reach D in the same time, &c. But his reading of the theory of projectiles is quite erroneous. Whenever a body's inertia is all that has to be overcome by a force, the velocity acquired in a given time is proportional to the force, and not to the square root of the force. The experimental law in gunnery that the velocity varies as the square root of the charge (other things being equal) depends on a number of circumstances altogether independent of the inertia of the ball. Into these matters "F.R.A.S." will probably enter at length, since on more than one occasion he has shown a knowledge of the theory of gunnery, to which I can lay no claim.

I am glad to see "C. H. W. B.'s" protest against the use of the term "centrifugal force." It has misled many. RICHARD A. PROCTOR.

[4705.]—I CANNOT but think that "Marine Engineer's" difficulty (let. 4649, p. 515) arises from a confusion between the work done in consequence of a certain velocity, and the power imparting that velocity. Referring to an illustration in "The Constitution of Nature" (p. 457 of ENGLISH MECHANIC), a man pitching up a brick with an initial velocity of 64ft. a second, will make an effort or do an amount of work four times greater than another man who throws up a brick of equal weight with only half the initial velocity, 32ft. a second, inasmuch as an equal weight will be raised in the former case to four times the height that it will be raised in the latter case. But the first brick will rise for one second, while the second brick will take two seconds in travelling its quadruple distance. Consequently, we have four times the amount of work performed, not in the same time, but in double the time, so that the force is not quadruple but only double.

V. B.

[4706.]—I TRUST the following will show "Marine Engineer" (let. 4649, p. 515) that the theory of projectiles and the parallelogram of forces are in complete harmony with each other.

The line A D in his diagram truly represents the resultant of the forces A B and A C, both in direction and intensity; but his statement "that a body under the joint action of the two forces must reach D in the same time it would have reached B or C, under the action of a single force," is only correct when the body acted on is moving in vacuo, but when moving in air the line A D merely represents the resultant force in propertion to the other two forces, and has nothing to do with the time occupied or distance traversed by the body.

In the theory of projectiles the resistance of the air has to be taken into account, and this increases (speaking roughly) as the square of the velocity, and to double the range of a projectile, four times the original force is required; but the velocity—that is, the initial velocity—is, I believe, in direct proportion to the amount of force used. Therefore, referring to "Marine Engineer's" diagram, if the line A C represents the space traversed in a certain time by a projectile acted on by a single force, the projectile under the influence of the combined forces (the resultant being nearly double) would not travel nearly 2 A C in the same space of time, but only about $1\frac{1}{2}$ A C, though it would have started at double the initial velocity to that which the single force gave it.

L. H. O.

[4707.]—IN answer to "Marine Engineer" (let. 4649, p. 515), it appears to me that his difficulty lies in the assumption that to produce a double velocity requires the expenditure of a fourfold force, which is only true when the space through which the force is exerted remains constant. If we employ the usual symbols of P for a uniform moving force, M for the mass of a body acted on, V for the velocity generated, and S for the space through which the force acts, then by a well-known formula, $P = \frac{MV^2}{2S}$, hence if S remains constant, and V is doubled, P must be increased fourfold; but if V and S are both doubled, as in the case of the diagram in "Marine Engineer's" letter, P will only require to be doubled also. I hope this explanation will remove "Marine Engineer's" difficulty. T. E.

THE DEATH OF THE CRANK.

[4708.]—THE crank is doomed at last—after all the attempts of disappointed would-be inventors; in spite of the money and time wasted by mechanicians in fruitless efforts to discover a substitute. The fortunate discoverer of the means of doing without the crank and avoiding its "defects" is a Mr. Thomas Morton, a member of the Senior Class of Racine College (U.S.), whose invention, according to the *Wisconsin Argus*, is deemed by many practical engineers and scientific men likely to prove one of the most valuable and useful inventions of the age. But I must quote the *Argus*, for I am afraid I might not do justice to the transcendent merits of the invention and the inventor:—

"Mr. Morton's improvement [it is said] does away with the dead points entirely, and keeps the power continually upon the long lever, or as engineers call it, the half-centre, thus nearly doubling the power, and so saving a great amount of fuel in engines. It can be applied to all kinds of crank machinery, engines, lathes, sewing-machines, &c. The simplicity of the arrangement is almost ridiculous, and makes one laugh and wonder why it was never thought of before. It consists of a ratchet wheel, which takes the place of the crank; over this ratchet wheel runs a frame, in the two sides of which are movable cogs or pawls. When the connecting rod drives the frame out the cogs on one side act upon the teeth of the wheel and carry it half way round, while, at the same time, the cogs on the opposite side, working in a contrary direction, when touched by the teeth of the wheel, are thrown out of the way, and the instant they scrape the teeth of the wheel they adjust themselves by their own weight, or by means of springs, and so are ready to carry the wheel the remaining half-revolution when the connecting rod is drawn in. Thus a revolution is obtained with every stroke of the piston, and no time is lost" (!)

There is just a little piece of information wanted to make this "mechanical triumph," as it is termed, complete. Mr. Morton may have "got up the invention and demonstrated it in two days," but has he tested it in actual work on any ordinary scale for two days? Pending an answer I think we need not yet alter our crank shafts. G. J. H.

TO "THE HARMONIOUS BLACKSMITH."

[4709.]—I MUST confess my full belief in "Hollowtonism," but not in shutting up poor Jack in a box, or contrarywise, allowing him to "waste his sweetness on the desert air." There is some semblance of classical authority for the creed. Has "The Harmonious Blacksmith" ever seen the famous group of statuary of the "Laocoon" (or cast thereof)? And does he know why this Trojan priest incurred the punishment thereby represented?—that it was for "fiddling" with the ribs of the wooden horse left by the Greeks as an ambuscade at the siege of Troy. What has all this to do with the matter? Not much; for mind the story is but a poetic fiction; but I am coming to the ideas of the poet Virgil (though draw a long-bow he might), to show that he was a "hollowtonian." As translated by Wharton, he says, describing the said fiddling match—

Swift at the word his pond'rous lance he threw,
Against the sides the furious javelin flew,
Through the wide womb a spacious passage found,
And shook with long vibrations in the wound;
The monster groans, and shakes the distant shore,
And round his caverns roll'd the deafening thunder's roar.

It may be very unclassical to give poor Laocoon a fiddlestick, but "The Harmonious Blacksmith" will perhaps take the arrangement in another sense, and say "a fiddle-stick for Laocoon"—never mind the bow. Laocoon was evidently represented as having a powerful tone, and with Virgil at my side, if I fall beneath the spear of "The Harmonious Blacksmith," I shall meet my fate in good company.

That the "box" in some shape or other is applied to every musical instrument acting by vibration of string or parchment for the purpose, and with the effect of increasing the volume of tone, seems a clear fact. Witness Æolian harp to piano, tambourine to big drum. The advantage of a sound-hole is established, and its size regulated by experience. Opening the back doors of the harp gives it what was before wanting—a sound-hole. So also in the grand piano elevating the lid is employed with the same effect. The case and soundboard here modify the "box."

Does "The Harmonious Blacksmith" really think that depriving a piano of its case (leaving the soundboard), a violin of its back, or a kettledrum of its "nether end" would improve the power of their tones? Truly, the kettledrum's matrimonial alliance of brass and parchment must be very ill assorted if improved by loss of its "better half." It is not clear that the cutting proper sound-holes in any drum, and increasing the thickness of the cylinder in the middle, that perchance also adding bass-bar or sound-post in the interior might not add to the drum's power.

As to tambourine and drum being like child and man, this is exactly corroborative of hollowtonism. The poor little child has no voice, his ribs are not grown to man's estate, nor his body long enough, while his mouth is so large and open that his puny voice "vanishes into empty air." Let the child grow and assume by degrees the proportions of the man. It will surely happen that the poor little drum or tambourette, if he grows even to a side-drum, will have a louder voice, to be increased by becoming a big drum.

I never before heard of an Irish fiddle without a back; it seems akin to the Irishman's Bath-chair without a bottom, on emergence from which, after a journey, Pat is reported to have said, "Sure and if it hadn't been for the honour of the thing, I might as well have walked." "The Harmonious Blacksmith" is assuredly joking, and I will then unfailingly convince him of the efficacy of the box principle. Let him make the experiment for himself: take a small boy, and apply a box to his ear, if the urchin does not give out his best tones, why I shall follow the bad fashion of the day and be "out upon strike." Extract the backbone of a "Strad" (as doctors serve the frogs), fancy the groans and screams of the unfortunate patient deprived of his backbone! "The Battle of the" Soundboards may, however, be more readily determined upon the modern mode of arbitration or experiment. Let "The Harmonious Blacksmith" make his invention perfect, as I before suggested, it would not be a long operation, and if successful add to the laurels he has already won by his ingenuity and pleasant contributions to the MECHANIC.

SUFFOLK AMATEUR.

[If those who controvert the opinions of "The Harmonious Blacksmith" are allowed to indulge in his style, we shall be mistaken for a comic journal. "Suffolk Amateur" does not often transgress, and the above letter has not, therefore, been severely dealt with. We warn "The Harmonious Blacksmith" that any allusions in his reply to "Vulcan," in connection with the Laocoon difficulty, will be ruthlessly excised.—ED.]

GREENHOUSE FLUES.

[4710.]—IN order to further "Saul Rymea's" very useful hints for the construction of mechanics' greenhouses (letter 4662), I venture to supplement them with a plan of flue construction which obviates all difficulty as regards the relative level of flue and furnace. The plan I propose is thoroughly accordant with sound principle, and I have thoroughly proved its practical value. No excavations are required. If there be a room on one side of a greenhouse, the furnace may open into it, whether the floor of the room be higher or lower than that of the greenhouse or level with it, and the flue may descend to any reasonable depth from the fire.

I furnished a plan to a lady a few years since, in which the furnace opened into the harness room, the floor of which was, perhaps, 2ft. higher than the flue. The mason had objected to the arrangement on that account, and great was the amusement elicited by my plan, until the fire was lit and the flame was seen curling downwards. And what is the rule by which a flue and furnace may be thus adapted, with full assurance of success, to any position; and the whole question of stokeholes and levels be summarily set aside? It is simply this. See that the arrangements are such that the bottom of the chimney shall be at once and thoroughly heated or warmed.

It is well known that greenhouse flues, which terminate in a chimney which derives warmth from a kitchen fire or from other chimney in a house which is much used, draw well: but heat slowly and partially making way through a mass of brickwork must not be trusted to in the case of a descending greenhouse flue. It is also well known that a return flue terminating close to the furnace, and in some cases passing over it before it enters the chimney, draws well. The bottom of the chimney is heated by this arrangement. But even in this case, when once the chimney is thoroughly cold, the flue sometimes draws badly until hours have elapsed and the mass of brickwork which separates the furnace from the base of the chimney is at length warmed thoroughly. These are but imperfect applications of the rule. They go to show that the rule is not new, also to encourage a more perfect application of it, and also to prove how little it is understood, and how slow men are to trace out a sound principle and make the best of it. A few words may suffice to show how a flue may be forced into instantaneous and perfect and constant action. Let the separating matter which divides the greenhouse chimney base from the furnace be a good conductor of heat instead of a bad one: an iron plate, for example, at one side of the furnace, if the chimney abuts against that side; or on the top, if the chimney is built immediately over the furnace. The last is the best arrangement. The first action of the fire is thus on the plate of iron; as the flame licks the metal the heat passes through, the air in the bottom of the chimney is heated and expands upwards. It is lightened and displaced by the pressure below. Instantaneous draught is established. If the flue descends much from the furnace, make the chimney a little higher on that account. I made assurance of success doubly sure in the case above described, by making a slide in the iron plate (a damper), so as to open direct communication between the furnace and chimney. If this is opened on the lighting of the fire, when all is cold, the flame draws through at first directly into the chimney and heats it. The slide being then closed the draught takes the course of the flue.

Nine-tenths of the whole difficulties attaching to commonly constructed flues are got rid of when this rule is fairly applied. I have cured smoking flues over and over again by acting on it in one form or another. When good draught is thus insured, flue construction involves no excessive care in making it air-tight. Leave a chink open to prove this, and hold the flame of a candle to it. Greenhouse flues, being used only to keep out frost or for drying and ventilating the house occasionally, are usually cold when the time comes to employ them. How important, then, is instantaneous action. How much more when severe frost demands instant attention, and warm air rather than poisonous smoke and vapour among the plants.

Seer Green Vicarage, near Beaconsfield.

THE WOOLWICH INFANT.

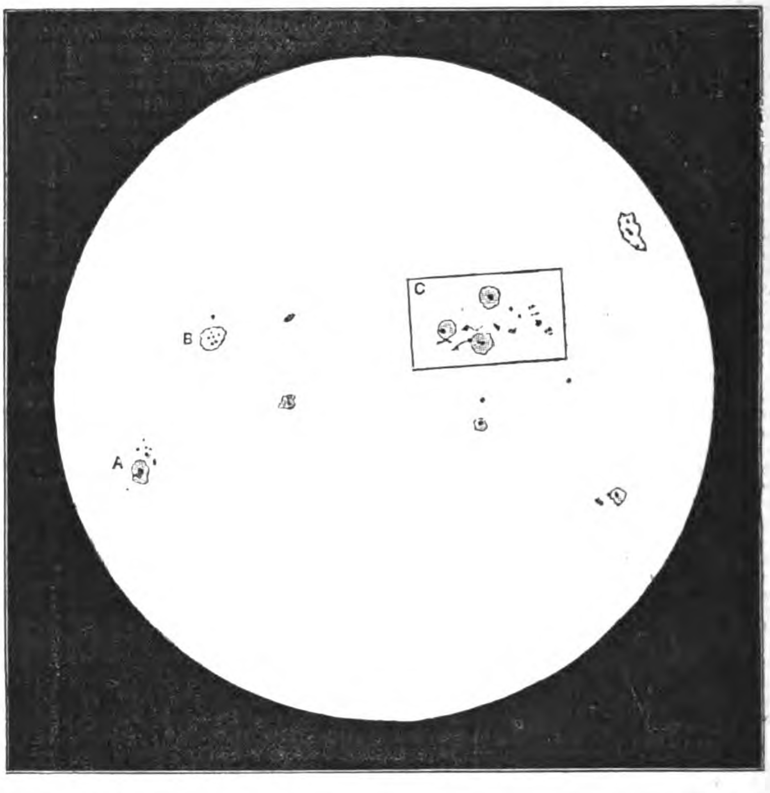
[4711.]—I INCLOSE a paragraph cut from a newspaper, which may be of some interest to our friend "The Harmonious Blacksmith" and others who take an interest in artillery. It confirms the opinion expressed by him and myself on the disadvantage of the "increasing twist" system of rifling, and the use of studded projectiles:—"Artillerists will be interested to learn that a hardened gun-metal stud, extracted from a recovered 700lb. projectile, is now to be seen at the Royal United Service Institution, Whitehall-yard. As the shot was supported and rotated by the studs, no part of the iron touching the bore, the injuries marked upon them show the irregular motions of the projectile in the gun. This particular stud is misshapen by the powerful wedge action in overriding the grooves about 1in., and displays a shear corresponding with the increasing spiral of the rifling. This explains the accumulation of gases in the powder-chamber which caused the crusher gauges to vary their register from 27 to 66 tons when firing only 120lb. of mild pebble powder. The sample stud speaks for itself, and the wonder is not that the 35-ton gun is now in the factory being rebuilt, but that its strength was sufficient to withstand nine such wedges without being rent to pieces."

ARTILLERY CAPTAIN.

GROUP OF SUNSPOTS.

[4712.]—ON August 6, at 10 a.m., I made the accompanying drawing of a very remarkable group of spots on the sun. The telescope employed was the Sheepshanks' equatorial 47/10in. aperture, lent to me by the Royal Astronomical Society, for star gauging. The air was not steady, but at intervals the definition was excellent, the granules showing better than I have yet seen them with this telescope. In the drawing, however, I have only presented the less delicate features, as a great bank of clouds approaching from the west left me in no doubt as to the shortness of the interval at my disposal.

I had time after completing the drawing, and the rough low-power view which accompanies it, to re-examine the picture, and to test the groupings by a sort of mental triangulation, taking the spots in sets of three, and comparing the shapes of the triangles so formed with the telescopic view. I can vouch for the accuracy of the drawing in all essential respects.



The most remarkable feature was the immense number of small umbræ, and their very peculiar arrangement. I may remark in passing that I have often noticed a tendency, in spots of this sort, to an arrangement of the umbræ into curved lines forming prolongations of the outer boundary of the penumbra, which are (in such cases) incomplete where the streak of umbræ appears, the main umbra being there trenched upon by very brilliant white masses, forming bridges, projections, &c. The contrast between the two great spots of this nature and the round spot with its comparatively uniform penumbræ is very marked. It is also noteworthy how a long train of irregular penumbral matter and broken umbræ extends from the space between the two great irregular multiple spots.

On Wednesday I had a momentary view of the group, which was then much changed in character—much simplified, so to speak.

In the low power view, C represents the space included in the other drawing; A was a spot remarkable for the way in which the penumbra was broken right across on the side nearest the sun's limb by an irregular extension of the umbra. The space B was occupied by a group of many small umbræ—very remarkable in its general aspect.

RICHARD A. PROCTOR.

EYEPIECES.

[4713.]—DURING my stay in Manchester a German gentleman showed me an eyepiece of the kind suggested by "Betsy Summercity" (letter 4634, p. 513). He told me that it was made by Steinheil. It was a small compound achromatic microscope, and when used as a microscope had a magnifying power of sixty diameters, its power as an eyepiece would, therefore, be equivalent to a single lens one-sixth of an inch in focal length. It was composed of a brass tube about ¾in. diameter, and about 4in. or 5in. long, as nearly as I can remember, into one end of which was screwed an object-glass, and into the other an eyepiece. The object-glass was composed of three lenses cemented together forming a solid cylinder of glass about ¼in. long, and of about the same thickness, and I think it was convex on both faces; the eyepiece also was peculiar, resembling the Huyghenian in external appearance, but being composed of a field-glass and two lenses, instead of the ordinary single eye-lens. I had no opportunity of testing this apparatus as an eyepiece in the telescope, but Mr. David Gill, F.R.A.S., of Aberdeen, showed me some similar ones, and spoke very highly of their performance with his 12in. reflector. They have, however, the disadvantage of erecting the image, and are, therefore, somewhat awkward to use at first.

A. WOOLSEY BLACKLOCK, M.D.

High-street, Godalming.

THE ORGAN BUILT.—IX.

[4714.]—It will be better now to make the pedal-board, and although I intend to describe a radiating one, because I look upon it as the easiest to play upon, yet the same plan will do to lay out a straight one if preferred. Get twenty-five bars of pine, 1¼in. by ⅞in. and 2ft. 2in. long, fifteen bars of American birch, 1in. by ⅞in. and 1ft. 6in. long, and ten pieces also of birch, 3in. by ⅞in. and 4in. long. Make an irregular-shaped frame, 2ft. 5in. long on the front side and 3ft. long at the side next the organ (see Fig. 1), divide it out into twenty-nine equal spaces, and make a mark in the centre of each space, and then obliterate the sixth, fourteenth, twentieth, and twenty-eighth marks, counting from the bass side; by obliterating these marks a proper space will be left between the B and C, and also between the E and F notes. Next insert pins of iron wire in the marks. The size of the wire should be No. 12, and the front row of pins on which the pedals are centred should be 1⅝in. long, and driven in so as to stand 1¼in. high. The guide-pins should be 3in. long, and go ¾in. into the top and bottom rails. Drive them tight into the bottom rail, which should be of oak, and let them fit loosely into the top rail, so that the rail may be lifted off when necessary. On one end of the pine bars glue a piece of ¼in. birch, 2in. long, and the width of the bar—viz., ⅞in.—and under each piece of birch bore a ⅜in. hole through the pine, so that the top edge of the hole just touches the birch (see Fig. 2). In the centre of the birch cut a small mortice, ⅝in. long and the exact width of the wire used for pins, and on the under side of the pedal bore a round hole that will just let the pin into it. After boring the hole very slightly, countersink it; if the mortices are nicely cut and fit the wire well, it prevents the pedals twisting over. Bore a hole through the pedal for the guide-pin to work in; the hole should be ⅜in. diameter, and lined with cloth to prevent noise. In the rail in front of the guide-pins cut a small groove for the end of the spring to work in. Having got the holes for the guide-pins finished, put all the bars in their places and mark the positions for the pieces of birch to be glued on (see Fig. 1), where the black lines show the birch, thus leaving the naturals higher than the sharps along the tread of the pedal, while the toe-piece on the sharps is sufficiently raised to clear the natural. On the under side of the pedal mark the place for the end of the spring, and also mark the end of the bars, so as to cut them to an even length. Take the bars off the frame again and glue on the proper pieces of birch and fix in the spring, which is only a piece of No. 15 iron wire, and if the pedal-board is to be fixed to the organ, insert a piece of thick upper shoe-leather in the end of the pedal, as shown at A, Fig. 2; but if the pedal-board is to be loose so that it may be lifted up out of the way —for the benefit of the housemaid—do not insert the leather. I intend showing the action for a movable board: Before putting on the pedals again, fasten a thickness of felt or baize on the rail on which the pedals work, and two thicknesses on the rails where the guide-pins are—viz., two below the pedals and two above. If the baize is not thick enough, use three, or even four. Nothing is more disagreeable than to hear the movement clattering when playing, and a well-built organ may be as silent as a piano. Good carpet felt is sufficiently good for the pedal-board. The end of the pedal-frame is shown by the dotted lines Fig. 2. Now make a rail, 3ft. long, of ⅞in. pine, and fasten makogany rails to it (see B, Fig. 2, in which the front vertical rail and also the broad rail at the back are mahogany). Make twenty-five levers, 7in. long, and cut grooves in the rails exactly opposite the end of each pedal. The lever is fixed into the back rail by a wire running through a bushed hole, and pinned down to the rail with wire hoops or staples. The front rail is merely a guide rail, and the grooves must be cut down far enough to allow play to the levers. In each lever insert two loops of whipcord to hook the trackers to. To insert them, bore a hole with a bradawl in the proper place, enlarge it on the under side with a taper bit, draw the whipcord through and drive in a small wedge dipped in glue in the enlarged side of the hole, then cut it off neat and close. By using whipcord a silent and at the same time a strong attachment is secured.

J. D.

FIG. 1

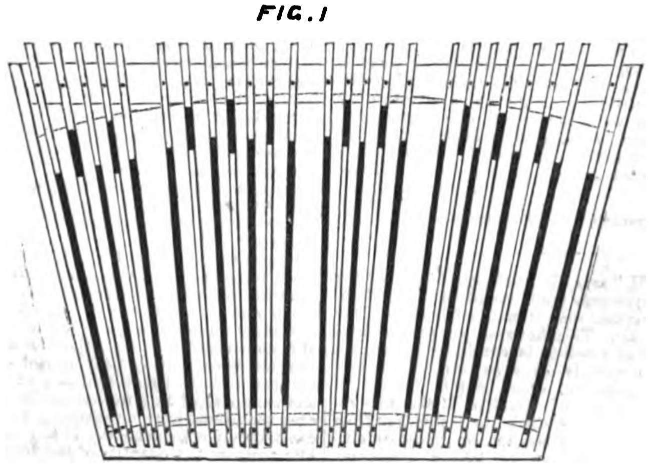


FIG. 2

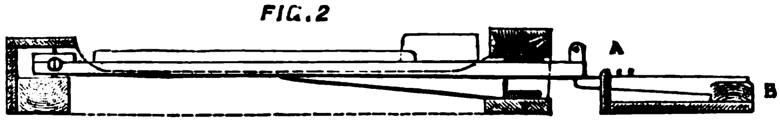


LUNAR OBJECTS FOR OBSERVATION, SEPTEMBER, 1872.

[4715.]—Sept. 5, Mare Crisium, direction and appearance of central ridges. Sept. 6, Azout, Alhazen. Sept. 7, Macrobius, Proclus, Mount Glaisher, the highest of the Coxwell range east of Proclus named by the late Dr. Lee to commemorate the *highest* balloon ascent. Sept. 8, Altai Mountains, Polybius, Beaumont. Sept. 9, Aliacensis, Reaumur, Werner. Sept. 10, Palus Nebularum, Palus Putredinis. Fine mountain scenery in the neighbourhood. See English Mechanic, Vol. XIII., No. 322, May 26, 1871, p. 222. Sept. 11, Sasserides, Pictet, Sassure. Sept. 12, Carlini, Lambert, ridges from La Place to Heraclides. Sept. 13, Riphean Mountains, Euclides. Sept. 14, Anaximander, Galileo, Lehmann. Sept. 15, Bettinus, Kircher, Wilson. Sept. 16, Zuchius, Hansen, Bailly. Sept. 17, Wilhelm Humboldt and Phillips just east of it, may probably be seen under the evening illumination.

The *degree* of luminosity of the bright spot in Werner is an important point to ascertain, and it would be well for an observer who has the requisite leisure to observe it regularly every lunation. It should be compared with other bright spots in the neighbourhood, and its position in brightness should be placed on record, the names or designations of the spots compared being arranged in the order of brightness. The time of each comparison should be stated.

The bright spot Mösting A (Beer and Mädler) in lat. 3° 11′ S. long. 5·13 E., or 95° 13′ from the west or preceding limb in mean libration, has been recommended as a fundamental or reference mark in selenographical investigations. Bessel selected it for his researches relative to the moon's librations. He described it March 31, 1839, as very bright *seen* in full moon, and of a sharply-defined form. This was two nights after full. It is suggested that this spot should be made the subject of a similar series of observations as the bright spot in Werner.

The precise objects for which Mösting A should be considered as a point for reference does not clearly appear whether as a standard of brightness or size, or as a point to which all measures should be referred. As regards measurements, those for the determination of points of the first order are by far the most important; but at present none are made, nor have any been made since Mädler's great work. Each set of measures for this object is quite independent of every other, and therefore a reference point as regards them is quite unnecessary.

W. R. Birt.

CENTRIFUGAL FORCE.

[4716.]—Letter 4646, p. 514 ("C. H. W. B.").—No one in these days does maintain there is such a force. Writers sometimes use the term because it is well understood, and no other short term has been agreed upon. I proposed rectilinear tendency, and employed it in a recent letter.

M. Paris.

THE GYROSCOPE.

[4717.]—I do not agree with "E. H." (let. 4619) that because a writer has not full time for the complete (misprinted "proper") discussion of a subject he should let it alone altogether, for very often it may happen that a hint thrown out at a certain stage of a discussion may be of considerable use. As to what I threw out in this way I am certainly not prepared "either to admit that I have been in error or to put forward a convincing demonstration of its accuracy." But I am quite prepared to consider objections, if they are urged in a fair and courteous manner. So long as "E. H." refused to believe me when I pointed out that he had misunderstood me, it was hardly to be expected that I should care for the discussion; nor were matters improved when he said that he was prepared to see me "change my front" yet again. But in his last letter he avoids that objectionable tone.

In passing, let me remark that in saying that I am "quite right" as to a certain fact, but that "no one has disputed the fact in the current discussion," "E. H." seems to imply that no fact may be mentioned until it has been disputed. I fail to see the force of this.

The subject of the gyroscope came naturally to be discussed in my papers on the "Earth, her Figure and Motions" (I should have much preferred leaving it out altogether, but could not), and any one who will refer to my article (English Mechanic for January 21, 1870, pp. 445 and 446) will see how little I pretend to give a complete explanation. Moreover, I refer the reader to the true author of the general explanation there suggested. Nor was what I said a few weeks ago an attempt to explain the matter. Strictly speaking, I have made no attempt whatever to give a popular explanation of gyroscopic action; on the contrary, I have several times distinctly said that I believed no such explanation to be possible. Yet once more, I have not advised that "E. H.'s" explanation "should not be published." I advised him not to send it for publication, which is a very different matter.

Again, I have not said that I "have no doubt mathematical analysis would explain" the action of the gyroscope, but, *absolutely*, that mathematical analysis does explain that action—a very different matter.

"E. H." should be careful in making such statements, because a word or two introduced or omitted may quite alter the meaning. He has wasted space in making wrongly-worded statements, and has compelled me to waste more in correcting them.

As to the facts which "E. H." is supposed to be questioning, I do not wish to accuse "E. H." of quibbling; but what sort of answer am I to make to the remark that I ought not to have said "that the motion of one particle under the action of gravity would tend to shift the plane in one direction, and that of the opposite particle in precisely the opposite way;" since, says "E. H.," "the fact is that gravity tends to make both particles shift in precisely the same way—namely, in circular arcs having the point of support for their centre"? When I wrote the sentences (let. 4587, p. 460) which "E. H." supposes himself to be here fairly representing, it occurred to me that certain passages were so important as to require underlining. If "E. H." had seen the MS. instead of the printed matter I should have supposed he took the underlining for erasure. Does he suppose that when words are italicised they are meant to be overlooked altogether? Again, what he says about the particles moving in the same way is mere wording, not argument: in one sense, we may say that the particles of a grindstone in rapid motion are moving in the same way, though some are moving upwards and some downwards.

I maintain my original statement, not as a mere opinion, but as the statement of a fact, and one bearing importantly on the subject of rotating bodies, and tending to throw light on the apparent resistance which they oppose to the direct action of a force tending to change the position of the axis of rotation. If "E. H." chooses to imagine that in throwing out this hint I was pretending to offer a full popular explanation of the phenomena of gyration (and that in the very letter where I said I did not believe any such explanation could be given) it is not my fault. With a gyroscope within arm's reach as I wrote I did not need to be told that the axis of rotation *does* gyrate, even if I had not been for years perfectly familiar with the phenomena of gyroscopic motion. If I had meant what "E. H." seems now to suppose, the fact that when the gyration is checked the axis sinks, would be fatal against my reasoning. Yet this fact is one of the elementary ones of the subject.

If "E. H." really has a popular explanation, at once complete and clear, why does he not produce it without so much preliminary parade? He tells us that two years ago he showed the various proposed explanations to be faulty—including mine (akin to "takken the breeks aff a Hielander")—and was content with that achievement. *Why?* I know that he then claimed to have satisfied himself of the true explanation; and but for his assurance I should have said he tried to present a new explanation and failed. This not being the case, I withdraw my "Don't."

Richard A. Proctor.

[4718.]—On page 542 "E. H." writes an answer to "Gy's" question on page 484, and shows thereby that he is not a practical top-spinner. Moreover, it is quite wrong to say of "top or gyroscope" that "the axis would maintain the same inclination to the vertical." There is a very great difference between a gyroscope and a top in a very important respect. In the former both ends of the axis are supported, and, therefore, the fly-wheel may before spinning be placed in any desired position, and it exhibits no inclination to remove from that position when spun, so long as no external force is applied, such as hanging a weight to one or other bearing of the axis; in fact, the fly-wheel, whether spinning or not, is cut off from that attraction of the earth which makes a top fall instantly when you try to balance it on its peg. If one of the bearings of the axis of the gyroscope were suddenly removed the instrument would become a top to all intents and purposes, and I think any one will admit that it would be impossible for the instrument to continue spinning under such altered circumstances in the same manner as it did when it had two bearings to support it. Now to "Gy.'s" letter (4581). So far from the axis leaning more and more until the top falls over, it does precisely the contrary; in fact, the *upright* position is the one affording the least resistances to the top spinning, and the one which a top always assumes very quickly in whatever manner it may happen to have been spun at first, and it then, as the schoolboys call it, "sleeps." A good top-spinner can make a top spin at will, by a dexterous movement of the hand, after he has picked it up and has it spinning in the palm of hand, or in corner of thumb nail, or better in a tiny saucer, such as you buy gold paint in, with the axis inclining to right or left at pleasure, and on that dexterous movement ceasing the top gradually but quickly will stand spinning upright again. "L. H. O.," on p. 509, also seems to think that the axis of top will remain in *one* position, from what he says in line 28 *et. seq.* of his letter, which on the above showing is all wrong. He leaves the nutation out of the question; but it must not be left out, for as the axis of top, at first supposed to be inclined, does eventually come upright, and cannot possibly become so suddenly or in a straight line, the only possible line in which it can come up is a volute, or, what is the same thing, the nutation gradually decreases till it becomes nil. I leave "E. H." to practise and find out in what the "dexterous movement" mentioned above consists. There used to be a conjurer about the streets, whom I first saw in Hyde Park on the day after the Coronation of her Majesty, and who used to spin a large top in the air, catch it before it reached the ground, and then place the end (spherical) of its peg in a recess in the end of a long rattan cane, which moreover was considerably bent, and this he used to balance on his chin, and by moving up and down would make the top dance to the extent of two feet or more, and then would make it gradually deflect from the perpendicular till nearly horizontal, the little round knob on the end of the peg preventing it quitting its socket in the end of the cane, and then by holding quite still, allow it to resume the upright position. I may here remark that I never yet saw a London street boy spin a top decently (there being at least three ways of doing it). It may be from the fear of splitting tops on the hard stones and of breaking windows with the resulting fragments, that tops in London are universally, as far as I have seen, spun "underhand" in one of two ways, instead of with the bold stroke from far above the right ear, right down to the left hip, that was in vogue at "our" school some 33·3 years ago. We also used fine whipcord instead of the thick string sold at toyshops for the use of top-spinners, and with great advantage as regards velocity of rotation. I am sorry to say in the last sentence of letter 4691, "A., Liverpool," appears to me to "maintain" rubbish, which he will probably not get "Sigma" to attempt to "controvert." J. K. P.

[4719.]—The "curious contradictions" which were found by "E. H." in my letter (4510) are simply curiosities of misapprehension, traceable, perhaps, to some possible obscurity of the language in which I apologise for my own departure from "established ideas." I do not intend to charge "E. H." or others with doing so. I quite agree with "E. H." that the ideas embodied in the "ordinary theory" which I abandon, are not established by sound proof. I spoke of their establishment in men's minds by common acceptance. They crop up plentifully in one form or another, when the subject of the spinning-top is under discussion, and are found in Lardner's "Mechanical Philosophy." I think with "E. H." that Mr. Proctor's theory, so far as we can gain it by venturing to peep into the very little window which he has opened, is the same as "A.'s."

In reply to Mr. Proctor, I beg to say that I am not "eager to invalidate" established laws. I wish to see a new, because a more truthful, application of them to the subject. Without infringing on the rules of politeness, I may well inquire whether he has said anything in his letters to make one satisfied with old solutions? What the soundness of the theory may be which Mr. Proctor holds may be judged fairly from that "one feature" of it which he offers, and which must needs be treated as an essential part of it. I compare two sets of statements, which, in my poor judgment, directly contradict each other. "The moon" (let. 4509) "yields to the earth's attraction as obediently as a pebble drops from a child's hand," and this notwithstanding her distance from the earth, and the consequently diminished force of attraction. Her direction of motion is continually being changed. Here is one set of statements. On the other side are these spoken of: "A top flung through the air;" "the top's weight has time to act, and *eventually* (the italics are mine) "does so act as to change the direction of flight;" it is "insufficient to change the direction in a brief interval." The points of contradiction are surely conspicuous here. The moon's direction is being *continually* changed, the top's direction only *eventually*. The moon yields *obediently* to the earth's attraction, though that attraction is greatly diminished by distance. The top, though within the full influence of that attraction, is not heavy enough, it is evidently inferred, to submit so obediently. "Its weight is insufficient to change its direction in a brief interval." Yet, while the top's insufficient weight is to exempt it from the *continual* change to which the moon is subject, the pebble dropped from the child's hand (and which may well be less heavy than the top) is taken as the example of obedient submission of matter to the earth's attraction from which even the moon is not exempt.

It seems to me that there is no place either for "depths" or shallows of "misapprehension" in such statements as these, and that if the moon in her falling towards the earth crushes "A.'s" philosophy, the flinging of the top, or the dropping of the pebble from the child's hand is equally fatal to Mr. Proctor's. My own glass-house being demolished, I may venture to retaliate on Mr. Proctor's little window, with the pebble he provides me with. I acknowledge the full force of his remark on "action and reaction" with thanks, which I also render to "L. H. O." for his experiments in weighing the top, which seem equally conclusive against both my theories. "L. H. O.'s" explanation does not, however, seem to meet the case. Perpendicular lines are wanted in his explanatory figure (4620), to show the [independent] action of gravitation on the particles at the ends of the diameter of the disc.

Another question, however, and perhaps an important one, grows out of the suggestion and experiments of weighing the top both at rest and when spinning at different angles of inclination to the earth. The whole weight of a top seems to rest on its point of support when spinning at an acute angle with the earth. This would be the position of a falling tree. In this latter case is the whole weight—that of the falling tree—exerted against the support at the base, until the position of absolute prostration is attained, or not? A top spinning on the scale of a balance at an angle (say) of 45 degrees, requires a weight equal to that of the whole top to balance it. If this is not so in the case of the falling tree, or other falling object, by what laws of force or matter is the whole weight of a top [spinning] in the same position transferred to the point of support? Every machine in which the wheel and axle receive rapid motion would be liable to be affected more or less by those laws which regulate the position of the spinning-top. Is this found to be so by the watchmaker and others? J. M. Taylor.

Seer Green Vicarage, near Beaconsfield.

[4720.]—"E. H." says (let. 4690, p. 542) that the axis of a top or gyroscope would maintain the same inclination to the vertical were it not for friction and the resistance of the air. This, however, can only be true when the velocity of rotation is considerable, for if a very slow motion only is given to a top it will fall. There must be, therefore, some definite velocity of rotation, above which the inclination of the axis remains the same, and below which the inclination from the vertical increases, and the top or gyroscope ultimately falls down. Suppose we take a gyroscope, whose entire mass is contained in a ring 1ft. in diameter, and suppose that the distance of the centre of the ring from the point of support is also 1ft., and the inclination of the axis from the perpendicular is 30°. What would be the least velocity of rotation sufficient to keep it from falling, and how is this velocity to be calculated? Gy.

WATCH REPAIRING.

[4721.]—"Aberdeen Watch Jobber" (let. 4609, p. 489) states that I have not made it quite clear *how* to "bump" a Geneva escape-wheel so as to avoid "a smash." If he will refer to p. 421, probably his opinion may change; for at line 13, column 3, he will read that I foresaw the remark, and so dealt with the "bumping" process; then at line 15 I say in other words, "Don't." If this be insufficient, I will write again.

Concerning the bulging of pinion when it is a soft one, "Aberdeen Watch Jobber" is perfectly right so far; but then if the "jobber" should be so unfortunate as to strike the punch with "too much" force, the result will be as he states; but I never saw an escape-wheel so much out of flat as to require so much riveting as would destroy the pinion, as he states. When they are so, in most cases they are originally left so by the makers, the escapement-maker having fitted the rivets too easy in the escape-wheel, and to tighten it had to rivet the pinion so as to bulge the pinion-head. Therefore my remarks concerning "low-priced" Swiss watches are borne out, in which I stated that the materials were left very soft in order to produce them quickly. Seconds' Practical Watchmaker.

TEETH OF WHEELS.

[4722.]—The gentleman who writes "Mechanism" says, on p. 533, first column, half-way down, that the clearance between the teeth of wheels is sometimes wrongly called "backlash." Of course, if it is no more than it should be, "clearance" is the word to use; but may I ask what is the proper word when the clearance is excessive, or else varying in amount from the teeth being badly formed? As I wrote on April 19, p. 125, on the subject of "lantern pinions," and there in third column used the word "backlash" in the latter sense, I think it not improbable that the writer of "Mechanism" had me in his mind when he found fault with the use of the word as above. J. K. P.

DEAR COAL.—HOW IT MAY PROVE A BENEFIT.

[4723.]—Even in warm weather the great price of coal is a misfortune to many, and an inconvenience to more; when winter comes on it will be to all who find it difficult to make both ends meet an addition to that difficulty. Unusual cost of fuel does more mischief, moreover, indirectly than directly, by enhancing the cost of numberless articles for the production of which coal must be consumed, more especially of such articles as iron, bricks, lime, &c. The evident causes of the rise in price of coal are increased cost of getting it and a temporary excess of demand above the supply, the consequence partly of increased consumption, partly diminished supply from shortened hours of pitmen's labour. Coal being an article which many cannot, and more will not, do without, the price may be very considerably raised in consequence of only a small deficiency in the usual supply, as appears to be the case at present, the increased cost of getting coal being considerably less than its increased price. This will doubtless produce its own remedy, for increased earnings will naturally induce other labourers to become coal-getters, until the cost of labour is reduced again to its natural level, unless that be successfully impeded by the operation of the unions of the miners; we must, however, expect, I think, a continuance for some considerable time of the high price of coal, and possibly, at least, a temporary rise.

It is an interesting question whether or not we shall learn the "uses of adversity," and turn our present embarrassment to account, both by diminishing the cost of getting coal and preventing part of its excessive waste, both of which are easy to do if wisely set about, and if done even in a moderate degree would restore the balance between production and consumption, without putting any part of our population upon painfully short allowance. If, as is not improbable, the unions of pitmen attempt with any marked success to impede the reduction of their present unusually high wages by deterring other labourers from sharing in them, an impulse will probably be given to the introduction of coal-cutting machines by which the cost of coal-getting may be permanently reduced, and the tyrannical power of the unions effectually broken. This will, I hope, be one of the lasting good results from the temporary evil; another will be, if many be now compelled to be more economical in the use of coal because it is unusually dear, to learn how to make less coal do the work of more, and if they do learn that useful lesson effectually, a very large permanent saving will be the result of a comparative small temporary loss.

I have before shown that much more than half of the heat produced by the coal usually burnt for warming our houses is allowed uselessly to escape up the chimney, and that a large part of that which is not wasted in that manner is by using single instead of double-paned windows. Coal for mere warming is, however, burnt during part only of the year: during the rest little is burnt in houses except for cooking, and the waste of fuel for cooking is generally greater even than that burnt for warming, besides being more constant and more general. If any one doubts this let him compare the quantity of fuel burnt in an English with that in a French or Belgian kitchen, or in other countries either I dare say, but I speak of those I have seen. I do not know the average quantity of coal burnt in English kitchens, it varies so very much, but I do know that in my own kitchen by the use of a half-open stove instead of range, the cooking is better done with a consumption of about two-fifths of the coal formerly burnt, and that if I chose to look after it myself the consumption might be still largely reduced. I once used a closed stove (more economical, but less agreeable to use than a half-open one), in and on which two small joints and half a dozen smaller dishes could be cooked at once, with coke costing (at present prices) about three halfpence a day. It is impossible to save much out of so small a sum, but I have often doubted the expediency of lighting a fire at all when not desired for warmth, unless for cooking a large dinner. If I had time to spare I would try carefully the relative economy of coal and gas for cooking. I like best meat cooked in hot air or in steam, which is done very easily, either by using Captain Warren's cooking apparatus, or a common pan. The first consists of a smaller pan contained in a larger one with a double lid, when meat alone has to be cooked in it, or with a compartment above for vegetables, when they also have to be boiled in it. A little boiling water is put into the larger pan, which must be kept boiling, and the meat in the inner pan supported so that it is well out of the gravy. The steam surrounds the inner pan, and fills the compartment above it, and the space of the double lid. The meat is thus kept in air at the boiling temperature, and is gradually very nicely cooked. It is as tender as if boiled, and nearly as tasty as if roasted; sometimes we brown it before the fire to make it more like roast meat, which it then closely resembles, except being unusually tender. Now it is evident, if this cooking pan were covered with felt, and if escape of steam were nearly prevented, that the water in it might be kept hot with very little consumption of gas, indeed, I am not sure that it might not be kept hot enough without any additional heat at all, as in a Norwegian cooking-box. In either case it seems very probable that the cost of cooking would be trifling, and nearly all the fuel now burnt for cooking saved. A very simple saving is effected by letting the fire out as soon as the dinner is cooked, very little gas being needed for merely boiling a kettleful of water for tea, or for making coffee.

Gas, though a costly fuel in proportion to the heat it actually produces, is often a cheap one to use, because it need not be lighted before or burnt after it is wanted, while the quantity burnt may with care be nicely adjusted. It would be very much cheaper than other fuel for many purposes, especially for cooking in summer, when heat for warming is not desired, if it were supplied at a price little higher than the cost of making it, as it easily might be with profit to the gas companies. Those companies are, of course, obliged to charge for gas consumed at night far more than the cost of making, often more than twice as much, because the cost of management, the interest and repairs of pipes, and of gasometers to hold gas made at day to be burnt at night must also be paid for, but for gas to be supplied in the daytime, and especially in summer, as gas for cooking would be almost exclusively, no extra cost for pipes or gasometers would be incurred, and any charge for it beyond the mere cost of making (and for a slight increase of leakage if more pressure were wanted) would be clear profit. It would be very easy for consumers who wished to burn gas at a reduced price for cooking, to have a second meter, and not difficult to prevent gas so supplied being used for illumination. The effect of such a change would be a more steady business for the companies, and a great convenience to the public. The winter consumption of gas would be but little increased, because when heat for warming as well as cooking is desired, coal or coke would be generally more convenient and economical, but in summer, when far less gas is used than in winter, and when consequently many of the retorts wanted in winter are standing idle, it would be easy without any increase of the works to make more gas than is at all likely to be burnt for cooking, even if the practice of cooking with gas became general. If it did, not only would there be a great diminution in the consumption of coal, but, what many would value still more, in the production of smoke. The air of London might in summer be as clear as that of Paris, where wood and charcoal are so much burnt, our rain water might be fit to wash with, perhaps even to drink; we might grow flowers in our windows and courtyards, and the trees of our parks and squares would not lose their leaves in early autumn.

The consideration of other modes of saving fuel must be deferred for a future letter if you can spare room for it. PHILO.

COAL IN IRELAND.

[4724.]—THE great advance in the price of coal is a matter which affects almost every one in a pecuniary point of view. The supply of coals falls short of the demand, and any means of increasing the supply and lowering the price would be a benefit to the public. We lately exported coals to Belgium, now we import them, and the question is mooted if it would pay to bring coal from America. In Belfast we are now paying about 30s. a ton for coals which used to cost 18s. I observe, however, that some tons of very fair coal from Coalisland were sold a few days ago in Belfast for 12s. a ton. This brings me to the subject of Irish coal. The coal-fields of Ireland, although much less extensive than those of England, are yet of considerable importance, especially at the present crisis. There is one in Leinster, two in Munster, three in Ulster, and one in Connaught. The coal formation of Leinster extends over large portions of the counties of Carlow, Kilkenny, and Queen's County. The Kilkenny coal is anthracite or stone coal; that of the other counties bituminous. The Leinster coal area is estimated in Griffiths' survey to be 5,000 acres, and to contain about 63 million tons of coal.

In Tipperary there is a coal-field which may be regarded as a continuation of the Kilkenny coal; it is 20 miles long, and six broad at its widest part; a line of railway is being constructed between Clonmel and Thurles to connect the Great Southern with the Limerick and Waterford, which will open up communication with this coal-field. This coal costs 20s. per ton at the mouth of the pit, but the expense of carriage has hitherto prevented it coming into extensive use. The Munster coal-beds occupy parts of the counties of Limerick, Kerry, Clare, and Cork. Sir Robert Kane, in his work "The Industrial Resources of Ireland," says: "They are the most extensive development of the coal strata in the British Empire." There are six layers of coal in this district, according to Griffiths' survey, but the beds are not thick; the coal is softer and more slaty than the Kilkenny coal, but is a kind of anthracite. In Ulster we have a coal-bed in the County Tyrone—viz., Coalisland; its area is about ten square miles. The thickness of the seam is 20ft. to 30ft.; it is situated about 600ft. below the surface; it is used now by the Newry Gas Company. The Connaught coal-field occupies considerable portions of Sligo, Leitrim, and Roscommon; it is about 200 square miles in extent. At the time of Griffiths' survey this coal was sold at the pit's mouth for 4s. a ton! It thus appears that the coal-fields of Ireland are worthy of much greater attention than has hitherto been given to them, and are not unworthy of the consideration of the capitalist. PHILANTHROPIST.

ECONOMY IN USING COAL.

[4725.]—COAL dust or slack may be readily burnt if mixed with clay (say three-fourths dust to one-fourth clay; it throws out great heat, but takes some time to burn up. It would be extravagant to dry it before putting on the fire, as it then burns out rapidly and does not appear to me to throw out so much heat. It is best applied in the shape of large balls. The clay and dust must be well mixed.

At this present time I am burning "culm" (I believe the dust from stone coal), mixed with slime from the seashore, and so partial am I to it that could I obtain it when I leave here I would not burn anything else. The cost is as follows:—

2 tons culm at 9s. 6d.	0	19	0
1 load slime at 1s.	0	1	0
Carting culm and slime	0	3	0
Mixing and slacking	0	2	0
	£1	5	0

The month's supply for three fires.

Shall have pleasure in answering any inquiries.

INLAND.

COAL FOSSIL PLANTS.

[4726.]—WILL you kindly allow me to call the attention of your geological readers to the fact that I shall be exceedingly obliged if any friend could let me have small pieces of calamite, dictyoxylon, sigillari, and the like, suitable for grinding down for microscopic examination, and I should be happy to give a *quid pro quo*. I want them as soon as possible to enable me to go on with some papers on geology and the microscope.

12, Margaret-street, Hull. H. P. H.

GREATLY ELONGATED PROJECTILES FOR RIFLED GUNS.

[4727.]—I SHOULD be sorry to oppose my opinion to that of "The Harmonious Blacksmith" (let. 4652, p. 515), but I must confess that I see one or two defects in his projectile, which I will point out. In the first place, the "ogival" form of head is considered the best, as it offers the least resistance in passing through the air. In the second place, although Mr. Whitworth employed shot which tapered towards the rear with advantage, it has been found that too great a length (with tapering rear) is attended with one great disadvantage—namely, the rear of the shot, being lighter than the forward part, is liable to be blown aside by a moderate wind, and the head turned to windward, causing the gun to shoot to windward in a slight degree. In the next place, the point of the shot, besides not being the best for flight, is a bad one for penetration. Whitworth's flat-headed shot were as good as any for penetration. The "Sabot" might answer as far as it is itself concerned. Wooden bottoms have always been used for shells with smooth-bore guns, also for siege guns with both round shot and shell, and all brass field-guns.

We have some very long projectiles in the service—for instance, the 7in. double-shell is 27·2in. long; it is cylindrical, with ogival head and flat base. Although a very long projectile is theoretically the best, it is found that a shorter one, with quicker spin, is in reality better: for, in a military arm, stability under all circumstances of wind and weather must be the object.

Although the above are the generally-accepted opinions of those in the service, I may say that the best form of projectile is not yet finally settled. If "The Harmonious Blacksmith" could make any experiments with his new form of projectile, I should be very glad to hear the result, and if this letter be not quite satisfactory or not sufficiently comprehensive, I shall be happy to write again.

ARTILLERY CAPTAIN.

[4728.]—"THE HARMONIOUS BLACKSMITH'S" bullet (let. 4652, p. 515) would be all very well if it could be fired without altering its shape. Suppose a "Sabot" could be made strong enough (which I doubt, unless made of some hard metal) to withstand the blow it receives from the charge, the bullet itself would be "set up," and instead of leaving the bore a fine tapering bullet, it would leave a crushed-up lump of lead, anything but fit for passing through the air. This "setting up" action takes place in all rifles where soft lead bullets are used; but, as they are only a very little smaller than the bore, and supported by it, they simply leave the muzzle a trifle shorter than when loaded. I am afraid that a mechanical-fitting soft lead bullet would be too much of a good thing; besides, it would be some trouble to place it properly in the grooves when loading. ARTILLERY GUNNER.

A TOUR ON THE CONTINENT.

[4729.]—AT the present time, when strikes and lock-outs are unfortunately so general in this country, I have found it extremely interesting to travel on the Continent, and notice the difference which exists between German, French, and English workmen, as regards their hours of work and the manner in which such work is done. Travelling is as cheap, though not so rapid, as in this country, and with the aid of Cook's hotel coupons the expenses of living are quite as moderate as in England. With a knowledge of German and French, or indeed with French alone, it is possible to travel, of course, very much cheaper than we can do in this country, for to know the language is to have a double purse. With economy in the way of living, a great extent of ground can be got over, and much valuable information gained from a fortnight's tour through Germany, France, and Belgium; indeed, I know of no route where £15 can be so profitably invested by an English mechanic anxious to obtain valuable information, and a pleasant change of scene at the same time.

Let me mention Antwerp, the first city I stopped at. I got up there on a Monday morning, and found the shops open at 6 a.m., the Cathedral open, and the usual morning services proceeding. The market is generally over by 8 a.m.; indeed, all travellers complain that they are always being disturbed by the ringing of the church bells, and the tinkling of horses' bells in the early hours of the morning, which is to be heard in most continental cities. The working men seem to have an endless week of toil; frequently, have I noticed masons at work after 7 p.m., and Sunday only brings rest to those who can afford it; indeed, in Paris men generally work by the month, taking a day's holiday at the end, sometimes half a day in the middle. It is perfectly astonishing, and very sad, to see the uninterrupted manner in which work of all kinds is carried on day after day in the gayest capital of the world. It made a great impression on me this ceaseless toil, and the value of our English Sunday came to my mind as I had never experienced before. It must be necessary to man's health, to say the least, that he should have one day in seven as a day for rest from his daily work. In Germany, many kinds of work are carried on through the Sunday—harvest operations, for instance; almost all the corn is cut by hand, so that the hands have to be kept continually at work. Of course, there is a difference, and those who can afford, go to church or mass in the morning, and to the open-air Secular Concert in the evening, and appear to enjoy themselves; but, altogether, the value of a pause in the usual daily labour is very little appreciated on the Continent.

I was not in a position to visit any of the large factories at Cologne, or the Iron Works at Liège (the Birmingham of Belgium), consequently, I cannot speak technically of the actual hours of work in such establishments, but that the hours of labour are much longer than they are in England there can be no doubt, if we take the ordinary labouring mason as an example of the usual hours worked; while, as far as I have been able to form an opinion (after visiting Antwerp, Brussels, Cologne, Mayence, Strasburg, Metz, Sedan, Rheims, Paris, &c.), the men have a quiet contented look, and seem submissive to, if not contented with, their lot.

The custom of having the land let out in small lots, and the imperfect and awkward agricultural implements still used in Belgium, Germany (south), and some parts of France, appear to Englishmen certainly singular. The only reaping machine which I saw during my tour was in a large field some 20 miles out of Paris on the Northern Railway, and I naturally conclude that during unusually hot summer weather the corn must ripen too fast for the manual labour employed to cut it. Query, whether an English implement-maker would not make a good thing by sending some reaping machines over for the harvest time.

One word about the battle-fields. Those who expect to see marked traces of the bloody encounters which took place scarcely two years since will be greatly disappointed. Corn now waves and potatoes thrive on the plains of Forbach and the fields of Gravelotte. Little black wooden crosses here and there mark the resting places of the slain. At Saarbrück and Vionville, these crosses are massed together, and form cemeteries, near to which monuments are now in course of erection. The heights of Spicheren, however, should certainly be visited; and as the tourist climes the slippery side, studded with black cherry trees, he may well wonder how any general could have expected such a position to be taken except at a fearful sacrifice—it must have been complete butchery. One large mound I measured was 12 yards long by 5 wide; the base of the hill is dotted with numerous smaller graves, while monuments to commemorate the event now crown the summit. But I must conclude with the remark that the tourist should visit Saarbrück and Metz; Strasburg, too, if he should go as far south as Baden-Baden, but not otherwise, as it is of little interest except for its really splendid Cathedral, from the spire of which a most capital view can be obtained of the Museum, Library, Prefecture, and other buildings destroyed during the siege.

The beautiful scenery of the Rhine, the gaming saloons of Wiesbaden, and the ruined Chateau at Heidelberg, should be duly visited, and will, no doubt, call forth the same feelings of admiration and surprise as I experienced myself. Take all money in English gold, which is the best coinage to carry anywhere on the Continent; don't trouble to get a Continental Bradshaw, as you can get any information respecting the departure of trains at your hotel, but, instead, procure a little book, entitled "The Rhine and its Battle-fields, and Paris," which the traveller will find most useful; the cost is only one shilling, and it is published by Simpkin and Marshall, London. I found it more generally convenient than the large guide book of Baedeker, which gives very full and minute accounts of all the principal places of interest.

In conclusion, permit me to wish your readers pleasant company and fine weather, both of which I was fortunate in obtaining during my late visit.

JOHN HUGHES.

Ivy House, Hendon, London, August 7.

AN ECONOMIC CARRIAGE LAMP.

[4730.]—I HAVE been experimenting on a method of producing a light for carriage lamps which may be worthy the consideration of some of our readers. A frictional electric machine is caused to revolve rapidly by means of a belt and pulley fixed on the nave of the carriage wheel; the stream of sparks collected by an isolated conductor are caused to pass between two small brass balls sufficiently separated, and fixed in the focus of the lamp reflector, where the candle or oil flame is generally placed. Of course, as the carriage moves the light is evolved, and the objection to it is its weakness or want of brilliancy.

A magnet might answer better, but this I have not tried. I submit the idea which, as far as I know, is original, to the readers, hoping amongst them some one will be found to add more light to this most economic lamp. E. B. FENNESSY.

MR. PROCTOR'S GULF STREAM MAP.

[4781.]—The second sentence of Mr. J. Wilson's letter (4657, p. 537) shows the evil of an error I had intended to point out in the "equal-surface projection" chosen by Mr. Proctor for his twice-repeated map, pp. 478, 499. There was no kind of call or excuse for the distortion and excessive lengthening in latitude or compression in longitude, supposing the true ratios of surface the quality most needed. The preservation of equality in *areas* is consistent with any angular opening that might be chosen for the meridians in this projection; while an approach to correct *forms* was only possible by making the degrees on the mean parallel (or that of 40° for the particular extent of map Mr. Proctor had chosen) of their true length relatively to the longest on the scale of chords that divides each meridian, and this would have separated the meridians to about double the opening he has given them, those at the 30° intervals being inclined about 24°, whereas he has compressed them to little more than 12°. This at once alters immensely all the angles, and accounts for Mr. Wilson's remark on the false direction wherewith the current is made to impinge on the British Isles. Some error of this nature, however, would be inevitable in the upper and lower latitudes of any "equal-surface" projection, and leads to the very obvious conclusion, I think, that this kind of projections, instead of being fit, are extremely unfit for this particular object, and indeed nearly the worst that could be chosen for it. They ought to supersede the absurdly deceptive Mercator chart indeed, for most of the purposes of popular maps; for distinguishing political divisions, for giving all the possessions of one power (as in Chambers's capital little map of the British Possessions), for natural history maps, of mineral, vegetable, animal or human distribution, density of population, relative extent of races, religions, languages, staple cultivations, &c. For all these, while Mercator's (by strange perversity the most commonly applied to them, is of all possible projections the most outrageously falsifying and misapplied) "equal-surface" projections are the sole right ones. It would be worth while to place side by side two pairs of figures I once made but cannot now lay hands on, one of Ceylon and Spitzbergen to an identical scale, the other as these two islands appear on Mercator; Ceylon being about six times the larger of them in reality, and Spitzbergen about six times the larger on nearly all maps made at present to include both. But for this particular purpose of Mr. Proctor's to show the *forms* of currents (or, indeed, any forms) I must contend that the proportionality of areas is a very minor advantage compared to *identity of angles.* Now to keep all angles on the map identical with those on the globe, we are not driven to the miserably misapplied "Mercator." There is another projection quite as easy, which keeps all angles identical with their true size, and yet with so slight variation of scale for surfaces that even if extended to include half the world (which it can easily do, and the hemisphere round any point we please) it only doubles the areas at the very border compared with those at the centre. This is the perspective projection from the antipodes of the map's centre (the earth being supposed transparent), the only perspective that makes all circles, whether meridians, parallels, or any other, project themselves by circular curves on the map, and therefore entirely to be drawn with compasses; even a simpler operation than the straight-lined Mercator frame. In applying this to the whole North Atlantic and 10° of the South, or all that Mr. Proctor had to represent, the very extremities, Wellington Channel, Guayaquil, and the Bight of Biafra, would have their surfaces barely a third larger scale (superficial measure) than the Azores or Sargasso Sea; a difference truly immaterial.

What Mr. Wilson says about absence of beaches on all the Atlantic coasts of Ireland and Scotland is very singular, if true, and I suppose will be soon contradicted if not so. But we must remember it is not usual for primary rocks to form any sea-beach, and these are precisely the parts of the British coasts that happen to be primary. Again, there are certainly shores and beaches to the North Cornwall and Devon coast opposed to the current as directly as any part of Ireland. The only secondary cliffs I know totally destitute of beach are those of Portland stone for the few miles between Durlstone Head and S. Adhelm's (miscalled Alban's) Head, Dorset, and these by no means meet any gulf stream, but turn towards the sheltered south-east, looking straight across to Cherbourg, which is said to be sometimes visible from them. So great a length of coast as half that of Ireland, without beach, would surely be a phenomenon almost unparalleled on the globe. E. L. G.

THE HARP.

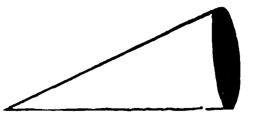
[4782.]—I had no intention of disparaging the harp in general, but merely that defective form of it which can be played in only one major key. This may have done well enough for King Brian and his contemporaries, but it can never hold its own in the nineteenth century against instruments of far greater capabilities. Almost all music that is worth anything, except quite plain simple airs, undergoes some sort of modulation, and then it cannot be played at all on such an instrument as the Irish harp. Transposition would, where accidentals occur, serve no purpose whatever. Would it not be better to sacrifice a few notes in compass and fit the harp with strings for sharps and flats? It might then be capable of becoming a really general favourite, as it is, it is simply nowhere.

Vertumnus.

IS THE MOON SPHERICAL?

[4783.]—I don't know what Ch. Rabache (let. 4639) may be driving at, the moon may be a sphere or not, or green cheese. I'll never be able to go up to see, but I have read two most extraordinary things, which I would like some of our astronomical authorities to deny or confirm. I think it was some Italian savant who told this tale. Observing an eclipse of the sun, when totality took place, he suddenly saw a bright spot burst out in the centre of the moon, and believed this could only be caused by the disc of the sun being seen right through a hole in our satellite. This, I think, is the best example of "moonshine" I ever heard; but such a careful selenographer as Mr. W. R. Birt, I should imagine, could settle this.

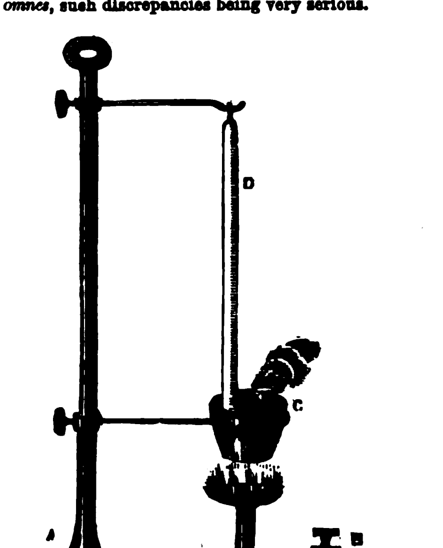
The second stunner was what may be Ch. Rabache's idea, that the moon was of shape shown in the sketch,



with the shaded part turned to the earth. We know there are irrefragable evidences of the presence of water at one time; but my authority said the reverse side of the moon was a great valley into which the water flowed, and may, for all we know, be inhabited by a set of lunatics, and may have lakes, rivers, railways, steamboats, &c., but that the inhabitants never can see us or we them. Except some lunar Livingstone could crawl up to and look over the edge at us when he ought to see a big blue wall in space—blue on account of the colour of our atmosphere. I believe it has been stated that, with our present telescopic power, we could see a building as big as St. Paul's if it existed. Now, Mr. Birt, what do you say to all this? I call it unmitigated trash. M. A. B.

THE IGNITION POINT OF EXPLOSIVES.

[4784.]—In your number for July 26th I perceive an article on the above subject to which, as a patentee, I have devoted considerable attention for many years, and thinking the matter might be interesting to your readers, I send you a drawing and explanation of a very trustworthy apparatus I devised, which appeared in a London magazine some five or six years ago. I am induced to do so the more on account of the very high temperatures assigned to the various explosives given by the gentlemen named in that article, which so astonish me that I fear the method adopted was very faulty. Fibrous gun-cotton, for instance, is put down at 428° Fahr., whereas by my method, which is exceedingly delicate, it is only 320°. So *ex uno disce omnes*, such discrepancies being very serious.



References.—A, retort-stand; B, gas-burner and regulator; C, tin oil-bath to hold thermometer and little porcelain igniting-cup; D, thermometer, ranging to 600° Fahr.

As the accompanying diagram states, I use olive oil as the caloric bath, which will absorb 600° of heat before it boils. Mercury would also do, but is objectionable on account of the fumes, which may salivate a person. The manner of using the apparatus is as follows: Having placed the thermometer and little cup in the oil, proceed to heat the oil up to, say, 300° Fahr., the thermometer being graduated in degrees and half degrees, then let your assistant (for there must always be two persons engaged) project into the little cup as much of the explosive under examination as will lay on the point of a penknife. If it ignites instantly at that point, the temperature must be lowered, and a fresh trial made, and so on. Two or three trials at most will suffice to determine the precise point of ignition. This method has been so far verified that it is now in general use.

John Horsley, F.C.S., Analytical Chemist.

Cheltenham, Aug. 9.

ELECTRICAL SPARKS.

[4785.]—I am in receipt of June number; seeing that the sparks are still flying, permit me to confirm the statement of "Philo's" friend (see let. 4105, p. 199) in regard to lighting the gas by electric sparks from the finger. It is quite possible in this "Canada of ours;" but, so far as I know, only in the winter, in houses heated by steam, and of course only when the steam is on—that is, when the building is warm, at which time and in such houses much electrical amusement may be obtained, such as getting a shock when shaking hands, or when touching the brass knob on the steam radiator, &c. If in the winter any of your buildings in England are heated by steam please try the experiment. To light the gas no special preparation is needed, further than first remove the glass globes (if any), then have some one near to turn on the gas-tap, as you must not touch glass or metal yourself when trying the experiment, now walk up and down the room a few times in your ordinary slippers, rubbing your feet on the carpet as you go, then approach the gas bracket, have the gas-tap turned on, carefully place your finger over the jet, but pointing down into without touching it; do not try the experiment with a crystal gaselier, as the metal pipe is usually disconnected. The truth of this I can prove in the strongest possible way if required. If your readers desire any experiments tried during the coming winter let them state clearly what they wish done, and, if not too difficult, we will try to carry out their suggestions.

I know that this experiment has been tried by competent parties in houses not heated by steam, but unsuccessfully.

Since writing above I have read the letter of "Traveller" (4168, p. 228), and beg to say that I am writing from Canada, and, to be more precise, I may say Montreal, where these facts are not known to all the intelligent persons. I refer, of course, to electrical sparks. I think "Traveller" must be mistaken in regard to the house being warmed by hot-air stoves; nor do I think the presence of sharp frost or snow is needed further than at such times the steam would be sure to be on. His statements about shocks, rubber combs, &c., are quite correct.

I should be glad to have "Sigma" come out here next winter to investigate this matter, when we would introduce him to electrical and other sparks, give him some sleigh rides, toboganing, snow-shoe tramps, and send him home as "happy as a sand boy."

Montreal. Canada Bear.

MATHEMATICAL PROBLEMS.

[4786.]—May I be allowed to make a suggestion which will be, I am sure, acceptable to readers of the English Mechanic? For some time past a chess problem has been weekly inserted for solution, and great interest has been taken in the chess department by many of our friends. I would suggest that a quarter of a column of your valuable space be devoted, in a similar way, to a mathematical problem every week, and to the best solution of the problem of the week before. The problems might be in geometry, algebra, trigonometry, mechanics, elementary differential calculus, &c.—that is, of such a nature and degree as to be of interest to mathematical students and mechanics who love to dabble in the science. The query to which I inclose an answer is a fair specimen of such a problem. I am sure such a mathematical corner would have a great attraction for very many readers. I should be happy to send, occasionally, problems of my own and of Cambridge friends, and should even be willing, for a few weeks, to look over and report on the solutions which would be sent. Aleph.

AURORA BOREALIS.

[4787.]—I last night witnessed from the east pier, Ramsgate, a fine display of the aurora borealis between the hours of 9.30 and 10 p.m. I should be glad to learn if this phenomenon, so unusual at the present season, has been observed elsewhere.

Deal, Aug. 9. A. E. L.

[4788.]—There was a fine aurora visible here for a short time last night, lasting from 9.50 till 10.10 p.m. The longest streamers reached up as high as the pole star. The maximum brilliancy, however, was a little westerly, just underneath the two hind wheels of the Wain.

Plymouth, Aug. 9. LXXXVIII.

INTERNAL RESISTANCE OF A BATTERY.

[4789.]—Will your correspondent "Pi," who notices my method for finding the internal resistance of a battery (as given on p. 359), kindly describe the methods proposed by Mance and Fitzgerald. I should then be able to judge as to their comparative advantages in practice. I may add that, supposing a Thomson's reflecting electrometer to be at disposal, I have found that instrument by far the most rapid and accurate in practice for finding the resistance of a battery. It is merely necessary to note the deflection given with this instrument, and then to adjust a shunt to the battery until the deflection falls to one-half, when clearly the resistance of shunt is that of the battery. I may note that I have tested my method (p. 359) with a reflecting galvanometer, and checked the result with the electrometer, with a satisfactory agreement. S. T. P.

P.S.—The remarks of "O." and others on matters connected with electric science are of general interest.

ON TUNING, AND REDUCTION IN THE SIZE OF MUSICAL INSTRUMENTS.

[4740.]—It is acknowledged by all that it is impossible to tune any instrument perfectly where chords are required to be played on a fixed series of strings, pipes, or reeds. This has become so great a nuisance that I am surprised our makers have done nothing towards remedying it. Often have I heard that the piano and organ would be more enjoyable if they were only in tune, although it is remarkable how many instruments are allowed to remain in a painful state of discord, and, shocking to relate, are continually played upon, to the detriment of player and hearer. All this has been premised by the remarks of "F. R. C. S." on page 487, but I have thought on the subject, and believe something can be done by altering the construction and at the same time making a little sacrifice of perfection—viz., the present regular series having a string or other medium for every tone. I do not believe in perfection in nature, but conceive that all our knowledge of perfection will be more utilised as we study imperfection and try to remedy it as far as we can. I shall now direct the attention of our readers to the fact that there are two notes (not tones) in music that seldom if ever are played together. It matters little whether I take the old notation or any other notations to express my meaning. We must take the key note, and represent it by the figure 1, or by the term doh, or by a dot on or off a line. Now, this key note has another directly under it—for instance, the key C has B next to it, and although by our keyboard and notation no difference is apparent in the relative value or distance of such notes, yet in fact they are the closest or nearest to each other of all the notes in the scale of C. So again, if we take F for the key note, we shall find that E is the nearest in the scale of F, and if we take any other key we shall be sure to find the same rule in force. Do not mistake the note (or tone) above, for that is vastly different, and comparatively a long way off the key note. I have noticed that in ordinary music these two notes, being so closely together, are never used together, and I know of few instances in operatic or classical music where they are to be found so used: I think Beethoven and Mendelssohn to be the greatest users of this discord, but they could not afford this luxury very often. The question is, first, cannot this fact be taken advantage of, and next, could no more efficient tuning be produced by the method? Let us take a pipe or whistle with one hole, to be opened or shut so as to make the two notes, or a string with a lever to act like a finger to use open or shut, or a reed with an appliance for lowering the tone when desired. These contrivances would have to act before the wind enters the pipe, or the hammer strikes the string, in fact, before the tone is produced, or we should hear two notes where one only is required. This is not so difficult as may be supposed, because the notes are so close together that we can play with them more than any of the others in the scale. A string may be played as tuned, although a piece of whalebone is placed lying on the string, when by a little pressure on the whalebone the next tone will be produced instantaneously. According to the pressure used, so would the tone be either higher or lower, and as much as the hole of the pipe was covered or uncovered so would the tone be again. If, then, this idea could be applied, so as to have only one medium for two notes, the size of our musical keyed instruments would be lessened one half, we should be able to play in tune, for every tone would be under the control of the player as in the violin, and we should be able to produce a better shake, trill, or thrill, than we can now, for in organ playing a good shake is impossible at present, while on the flute or clarionette it is quite practicable.

I think the great defect in the violin is a weakness of tone, especially in solo playing or in out-door music. For this reason I thank "The Harmonious Blacksmith" for his new fiddle, and think that if the string could be made to move all the soundboards, a great effect would be produced; and as for the box principle, one piece down each side would convert the spaces quickly enough. A wire string might do, but a bow could not move the string; this without doubt is the difficulty.

I saw lately a piano which cost £100, whose strings were placed slanting instead of upright, with action to correspond, a most laborious piece of work. In another piano I observed that while the strings were upright, the grain of the soundboard was slantwise. The tone of the last is superior to that of the first, and it cost less than a third, besides being more simple in its construction. FIDDLER.

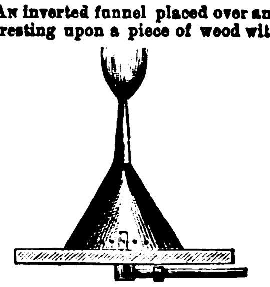
TESTING PLANE AND CONVEX SURFACES.

[4741.]—From time to time the columns of the ENGLISH MECHANIC have contained elaborate descriptions of various methods of grinding, polishing, and testing concave specula, but I do not remember having seen any particulars with reference to convex or plane surfaces. Some little time ago Mr. Tydeman promised us a description of the method of working planes for optical purposes, but his letter has not appeared yet. In the course of my reading I have managed to pick up a few facts with reference to the working and testing of planes, and, of course, the processes for working concave surfaces are almost all that can be required for convex ones, but I can find no account of how to test a convex surface, or how to distinguish between a spherical, elliptic, parabolic, or hyperbolic convex surface, or how to produce or to modify these peculiarities, or even how to distinguish between a regular and an irregular figure. Any particulars will be thankfully received by A. WOOLSEY BLACKLOCK, M.D.

High-street, Godalming, August 8.

A HANDY ATMOSPHERIC BURNER.

[4742.]—An inverted funnel placed over an ordinary gas burner, resting upon a piece of wood with a small

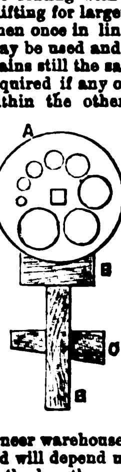


hole to admit it in the centre, as in sketch, will give an intense heat with little trouble of fixing. TINTUB.

ORNAMENTAL TURNING.—XIII.

[4743.]—In my last letter I referred to the mode in use amongst cabinet-makers in glueing and veneering small table tops. Before I leave this subject I will describe a table pillar not in very general use. Teak is the best wood. Turn a rod of teak, 2ft. in length, 1¼in. in diameter. Cut out a pattern No. 1 in cardboard, 18in. in length, the pattern to be, when cut, 1in. wide the whole distance. Procure a board of teak, 1in. thick, mark out six pieces from the pattern No. 1. When cut out, either with fret, band, or bow-saw, round off the edges with a spokeshave and paper them with glass-paper. Make them as round and as neat as possible. When finished, fix the rod upon the bench, plane off a portion of the rod top and bottom, on the underside, likewise the rod, then glue and brad the sweep upon the rod and follow on until the six are fixed. The sides at the top and bottom will require paring so that the six may fit within the circumference of the rod. When the six are fixed and the glue dry, fix the rod in the lathe in the same prong-holes as before, with the long corner of the chisel cut through the sweeps top and bottom until the rod is reached. Care must be used not to touch the brads; let them remain in, a touch with the hammer and punch will sink them below the surface. At the bottom a fillet or rabbet should be turned to allow a small collar to be fixed. The use the pillar may be put to is in every respect the same as that of an ordinary table pillar. A, the pattern; B B, the rod; C C, where to fix the sweeps. The length of the sweep may be varied to suit the fancy.

To turn a fishing-rod (common): Many of "our" readers may be aware that a goodly number of the common fishing-rods are turned in the lathe. The woods most suitable are hickory, lancewood, and yew; but our amateur turners may turn a common rod from ash sticks. I have turned a few out of ash. The wood sold in bundles I found the best. We called them sticks. I paid about 1s. 4d. to 1s. 8d. per bundle, containing about twenty-five to forty sticks, varying according to the thickness. For the purpose of turning these rods a boring collar will be required, to be purchased for two or three shillings, fixed as shown in sketch. The centre of the hole in collar should be in line with the centre of the mandril nose, or it will be impossible to turn properly. The seating for the boring collar can be made of a piece of dry beech, cut out as described, and may be fastened with a wedge under the lathe-bed. The collar or plate should be fastened to the seating with a bolt and nut, for the purpose of shifting for larger holes. If the plate is properly made, when once in line with the headstock any sized hole may be used and still remain in line, as the centre remains still the same. One or two long augers will be required if any of the rods are required to slide one within the other. The cheapest plan is to purchase four augers, say ¼in., ⅜in., ¾in., and 1¼in., take them to a blacksmith, tell him to cut them and strut a piece in, say 18in.; they will be handy at any time required. Those who do not wish to take the trouble to make the rods to slide, may fix them between strut and centre, turn them in proportion, and ferrule each end, or only one end; but two ends look neater. If the ferrules will not fit, file them down a bit while the lathe is in motion. The ferrules are best fastened with needle points—a small hole punched and a needle point driven in and filed off smooth (needle points to be had at the veneer warehouses). The size of the thick end of the rod will depend upon the taste of the maker, as well as the length required; but it is best to make the last joint of lancewood. The ferrules may be made from brass rod, cut to the length required either with a circular saw or an old file. Description of sketch: A, the boring plate, with eight holes of different size; B B, the frame or seating, the lower part B cut to fit between the lathe-bed, also cut with a groove to allow a wedge C to fix to the lathe-bed where required.



SAMUEL SMITHER.

FALL OF A BULLET.

[4744.]—The letter of Francis Lewis (4682, p. 541) deals with a new question. It was assumed that the figure of the earth was not to be considered. Practically it does not greatly affect the result, because if a cannon ball be fired horizontally from a place not much above the level of the ground, the range will not be great enough to give appreciable dip for earth's curvature.

A ball propelled fast enough might go round the earth, precisely as a cow's tail, if it were long enough, might reach to the moon. We can conceive these things. We cannot, however, conceive of those other motions which Mr. Lewis speaks of without first conceiving the law of gravity to be changed. Under gravity no ball could "revolve round and round the earth receding from it every revolution and part of a revolution." A ball might recede continually, but in this case it would not go "round and round;" if it went once round it would *then* be at its starting point—no farther away under any circumstances whatever.

If "A., Liverpool," wishes to retain his views (let. 4691) there is nothing on earth to prevent him. They are not likely to be very generally adopted. If they were, we should be put where people were before the laws of motion began to be recognised. "A.'s" letters are well worth studying, however. They show where beginners are likely to make mistakes. The writers of elementary text-books cannot too carefully note these points, for mistakes of the sort are much more common than one would imagine to be possible. "A." will forgive my setting him as a "horrid example." One has no choice where the ill-informed do not ask for information but undertake to teach.

It would be a useful exercise for "A." to inquire what keeps a kite afloat in such a way that the string rises *above* the point of support. When he has obtained a just answer to this question he can return with advantage to his light globe tied to a string. He will *then* scarcely suppose that such a globe illustrates quite exactly (or at all) the motion of a cannon ball.

RICHARD A. PROCTOR.

OCEANIC CIRCULATION—CARPENTER v. MUHRY.

[4745.]—In two letters, one of which appeared in the ENGLISH MECHANIC of October 6, 1871, p. 72, and the other in *Nature* of the previous day, p. 446, I showed that we were not justified in acceding to Dr. Carpenter's wish to have himself considered the original inventor of a certain theory on the above subject, but I regret to see a constant inclination on the part of English writers to ignore the statements that, in the cause of truth, I ventured to publish. Among those writers I particularly regret to see one so distinguished as Mr. Proctor, and I would ask him whether it is that he did not read my letters (the one in *Nature* appeared immediately under one of his own), or that having read them, and having consulted Dr. Mühry's pamphlet to which I referred, he found my conclusions incorrect.

I am led to my present remarks by Mr. Proctor's late articles on "Oceanic Circulation," where he regards Carpenter, and not Mühry, as the originator of the theory in question. At the same time, while thus complaining, I must say that I fully recognise the ability with which he puts forward his general views on a most difficult subject; and we must all admire the genuine wit and reasoning with which he deals with a certain reviewer, and demonstrates the ignorance of an egotist.

J. B.

[4746.]—I have read with much interest Mr. Proctor's articles on the circulation of the water in the Atlantic, &c. He does not, however, give the cause for the principal motion, which seems to be the primary cause of all the subsequent surface currents—viz., the current which sets from the Gulf of Guinea to the coast of Brazil. Perhaps he would kindly enlighten on this point, such of your readers as stand in need of the information with myself, in a future number.

POPULARIS.

IMPROVED BEEHIVES.

[4747.]—Thanks to Mr. Abbott for his letter (4502, p. 433). I should have written sooner, but waited for his promised photograph and description. Reply 12450, p. 519, however, tells us to spell patience.

Thanks, likewise, to our Danish friend for noticing my difficulties (letter 4628, p. 511), and describing his "centrifugal" honey-taker. This last, I cannot but think, might be much simplified. Would some one describe the American honey-taker which was said (p. 32, No. 366), to be a necessity to full success in bee management?

In spite of thunder and rain this year seems likely, in some localities at any rate, to be a good bee year; if so, we may have to moderate the sanguine expectations which Mr. Cheshire (letter 4629) and others might lead young beekeepers to entertain.

E. T. GRAYS.

NEW DOUBLE STARS.

[4748.]—As my observatory has been under repair, I have hardly done anything with the telescope for the last few weeks. On July 20th, however, I managed to get a set of measures of Mr. Burnham's new double star 11 Scorpii, with the following results:—P = 78·20°, D = 3·75″. The double star 12 Scorpii, to which Mr. Burnham refers in his letter (4549, p. 462), was observed by the late Sir John Herschel, at the Cape of Good

Hope, and is No. 4839 of the "Cape Catalogue," where the components are described as of the 7½ and 10 magnitudes. P = 84·5°, D = ·3″.

In reference to M. Gandibert's remarks (let. 4548, p. 462), I may say that on May 15th I turned my 7¼in. equatorial on μ^2 Boötis, and with mag. powers 425 and 605 thought the components almost if not quite separated. I estimated the angle of position to be about 150°, and the distance 0·6″ or 0·65″. I fancied it rather more open than ζ Cancri; but in this I may have been mistaken. δ Cygni is certainly a rather difficult star to see well, unless the atmospheric circumstances are good, from the disparity of the components. I think that it improves under red illumination. My measures last autumn gave P = 337·92°, D = 1·690″. Epoch 1871·74, mean of four sets.

GEORGE KNOTT.

Woodcroft Observatory, Cuckfield, August 6.

NOTE ON THE LIGHTNING OF JULY 25, 1872.

[4749.]—THE day was very hot throughout. At about 7 p.m. a storm came up from the SSE., accompanied with thunder and lightning (the drops of rain being very large), but it soon passed over to the NNW., the lightning, however, continuing in the N. From a little after 8 p.m. till past 9 p.m, I watched the magnificent display of lightning which took place. There were four distinct groups of cloud between N. by W. and E. by N., from which the lightning emanated. After a while these clouds seemed to merge together, but still there were the four distinct centres where the lightning was produced. I counted the number of flashes in a second and minute; three and four flashes per second were very frequent, sometimes five, and twice I counted six; I also counted forty-six and forty-two in a minute. The lightning lit up the whole group of cloud in which it was produced, which seemed to become glowing and incandescent; but a few small cumulus clouds, just in front, were not at all affected by it, but stood out looking very dark. The lightning continued more or less throughout the night.

Greenwich. W. N. M.

LIGHTNING CONDUCTORS.

[4750.]—THERE have been several letters lately on this subject in the *Times*, and one of the most recent, I think on August 10th, recommended the use of ⅝in. or ¾in. gas barrel, particularly on account of its cheapness. I cannot quite agree with the writer, for a ½in. round iron rod will conduct as well as a ⅝in. barrel, and, including the sockets for joining it together in the same manner as gas barrels are joined, would not cost more than five farthings per foot, instead of the 4½d. per foot of the writer in the *Times*. For a conductor built into the thickness of the wall, I think 1in. or 1¼in. flat bar, ¼in. thick, lap-jointed together, and riveted with two rivets, or bolted with a couple of ordinary ⅜in. or five-sixteenth inch bolts, would come in best, as it would not involve any cutting of bricks. As "Sigma" says, on p. 14 of the current volume, copper, no doubt, is better, size for size; but it would cost at least ten times as much, weight for weight, and is heavier too. I imagine a ½in. iron rod would be as good as a copper one of ⅜in. diameter, and, if inside a house or built in the walls, would last as well as copper would outside a a building. J. K. P.

LIGHTNING FROM THE EARTH.

[4751.]—SPEAKING of the loss of life by the recent thunderstorms the *Globe* says:—"It would certainly appear that the lightning came from the earth and not from the clouds. The body of man or beast acts as a conductor from the overcharged earth. Do not the clouds frequently change from negative to positive electricity, and influence at times those parts of the earth near them so powerfully as to draw lightning from the earth?"

During the late storms I have repeatedly seen, in addition to the ordinary descending forked lightning, ascending flashes likewise forked; but I never saw them in such abundance as during the last great storm, when the ascending flashes outnumbered the descending forks by eight to one. They were sent up in batches of from three to six, while the descending forks were only rarely double. The idea present to my mind the whole time was that Jupiter Tonans grasping the lightnings in his sculptured hand had thrown them together perpendicularly upwards. AMATEUR.

PIANOFORTE TUNING-KEY.

[4752.]—"BEDCA" has produced an implement that is a lever without a fulcrum, and is in the same condition as that of Archimedes when he demanded the ποῦ στῶ. What is wanted to enable it to act is a long lever attached to the central stalk E F, and held by some one else or resting against something solid. As it is represented, turning the handle would merely produce a rattle of wheelwork, resembling what you hear in your eight-day spring clock when the line breaks. J. K. P.

THE WOODEN HOUSE AT NORTH TAWTON.

[4753.]—ON page 445, present volume, you gave some particulars about a wooden house that came from Norway, for a gentleman of North Tawton, North Devon. It was stated that all the workmen required for fixing it came from Norway. But this is incorrect, there being only two foreigners on the building, all the others being men of this town. Living within five minutes' walk from the site, I can guarantee the truth of this statement. The house is being rapidly put together, and I should think from present appearances it will be a nice looking structure. When finished I may, perhaps, give your readers a fuller description with a drawing.

L. W. D.

ANCIENT MUSICAL INSTRUMENTS.

[4754.]—THE following is a list of certain and sundry ancient musical instruments which are *not* in the Loan Exhibition at South Kensington Museum:—

Clavitherium.
Clavicembalo. Specimens are said to exist.
Manichord.
Trumpet marine.
Transposing harpsichord or spinette.

Models of Marius' various piano actions; models of combined harpsichord and piano actions. These are said yet to exist in Paris, and doubtless the "liberal" French Government would gladly have lent them.

Specimens of Silberman's and Steen's pianofortes; the harpsichord made by Tschudi for the King of Prussia, A.D. 1765. Probably Bismarck or the new Emperor of Germany—who are almost as "liberal" as the French Government—would have lent these.

Lyrichord, invented by Plenius.
Screws for tuning harpsichords, &c., Wakefield.
Celestina harpsichord, Walker.
Hammer harpsichord, alias combined grand piano and harpsichord, Merlin. Marius seems to have anticipated this invention.
Celestial harp (extant A.D. 1837), Merlin.
Harpsichord and piano combined, Gillespie. Almost certainly anticipated by Marius.
Transposing guitar, Claggett.
Harpsichord and piano combined, Stodart.
Grand harmonica, Cheese.
Pianoforte with its hammers striking punches which strike its strings, Walton.
Celestes for pianos (some of them with very *un*-celestial effects), Bury.
Teleochordon, Claggett.
Piano, harpsichord, and celestina, without strings, Claggett.
Organised pianoforte, J. Crang Hancock. The inventor was probably related to Crang, who made the organ harpsichord now at South Kensington.
Piano, clavichord, and spinett combined, Gieb.
Grand piano with harpsichord action added, Davis.
Piano with harmonic octave stop, S. Erard.
Upright grand piano whose hammers and dampers are returned by counterweights, W. Stodart.
Harp with a keyboard, Southwell.
Metronome, Eckhardt.
Grand pianoforte with metal bracing (the earliest), Smith.
Volti subito, Antis.
Springs for maintaining the tension of musical strings, Litherland.
Upright pianoforte, about 4ft. high, with strings reaching nearly to the floor, complete metal framing with counter-tension bolts, key-frame made to turn upon pivots, screw apparatus for tuning its strings both singly and for altering the pitches of many strings at once, "soundboard exposed to the air on both its sides" (*i.e.*, not "boxed" in), and rendered capable of producing continuous sounds by hammers which are caused to repeat their blows at intervals too minute for observation, J. J. Hawkins.
Claviol with gut strings, horse-hair bows, pedal keys, harmonic octave stop, knee levers for rosining its bows, &c., J. J. Hawkins.
Apparatus for recording performances on keyed musical instruments, J. J. Hawkins and Earl Stanhope.

But for the Commissioners' perhaps wise rule, which, by the way, has been departed from in the case of her Majesty, I could largely extend this list, and could myself have contributed a terpodian, said to have been invented by Bushman, of Hamburg, about A.D. 1810, also a sostinente pianoforte.

THE HARMONIOUS BLACKSMITH.

ERRATUM.—"Ornamental Turning," p. 332, read 9d. to 10s. instead of 9s. to 10s.

ERRATA.—In letter 4651, p. 515, 5th line, for "16*a* to 7*a*," &c., read "16*a* – 7*a*," &c.; and in the 23rd line, "*a* inches" should be "3*a* inches."—PHILANTHROPIST.

Leroy's Non-Conducting Composition.—We have frequently had occasion to speak of the virtues of this compound as a covering for steam boilers, and more than once have drawn attention to its usefulness in preventing radiation of heat from roofs to the interior of houses. Further records of the results obtained from its employment are published by the *Times of India*, from which we learn that the temperature of a police chowkey, the roof of which was covered with Leroy's composition, was found on an average of seven days to be nearly 93° Fahr. at noon, while in a similar hut, but without the covering compound, from readings taken on the same days at the same hour, the average temperature at noon was 104⁴/₇°, or say 104½° as against 92½°—a difference which could not fail to make itself felt. The temperatures were also taken at 9 a.m. and 5 p.m., and the general average shows a still better result in favour of the composition covered roof. These are facts which speak for themselves.

REPLIES TO QUERIES.

*** *In their answers, Correspondents are respectfully requested to mention, in each instance, the title and number of the query asked.*

[11621.]—**Killing Roots of Trees.**—In the region of Lake Superior they practice the following:—In the autumn bore an inch or an inch and a quarter hole (according to the size of the stump) vertically into the middle of the stump, 18in. deep, and put into it an ounce to an ounce and a half of saltpetre; fill the hole with water and plug it up; in the spring take out the plug and put into the hole half a gill to a gill of kerosene and ignite it; it will go on burning without any blaze until the whole stump to the extremity of the roots is consumed, leaving nothing but ashes. The stump must be moist, as an old dry stump will not be penetrated by the saltpetre.—CANADA BEAR.

[11849.]—**Printing in Canada.**—From reading this query I presume that "A Country Printer" desires to begin business in Canada as a printer. I think this would be unwise until he had spent a year there as a workman. Good workmen readily find employment in Canada; the wages in Montreal are from 10 dols. to 14 dols. per week (for good men)—that is (say) £2 to £3 English money. It would not do to bring material, as it is manufactured here, therefore bring money. Prospects good.—CANADA BEAR.

[12054.]—**The Needle Lock.**—I do not think that "Saul Rymea" need wonder at my crying out against the word unpickable, though he did not use it himself, because in the original query, to which the above number refers, the description of "the needle unpickable lock" was asked for, and the needle lock was the manufacture of "The Unpickable Lock Company." Against the idea of a lock being unpickable I protest strongly, and hold that opening a lock with a fictitious key is to all intents and purposes picking it. But, instead of being unpickable, the needle lock is not so secure against the simplest ordinary methods of lock picking as any common lever lock. The ease with which it may be forced by other and more simple means than a complicated "Jack-in-the-box" (these means I need not particularise), to which "Saul Rymea" refers, and which but few of the artists in burglary would care to take the trouble to use; also the ease with which it lets itself get of order, and refuses to answer to its own key, are reasons which make me demur to the needle lock being called "one of the best locks ever invented." The same means of forcing that I have hinted at would not have the remotest effect on the Citadel lock, neither would Chubb readily yield, while the needle lock would at once be at its mercy, and this by such an instrument as may be carried in the waistcoat pocket. The Unpickable Lock Company spent large sums in the production of this lock, but it would seem that the public found that it did not bear out the promise of its name, for the sale has been almost *nil*, and the manufacture of it has been, I believe, given up for many years. All the principal improvements in modern locks have been directed mostly to the protection from force, and this appears to have been especially studied in the Citadel lock, a specimen of which I would ask "Saul Rymea" to procure and study, both as regards its security from the effects of force, and also the simple manner in which it places difficulties in the way of the expert in lock picking, so that he may confess that the delicate though clever needle lock cannot hold even the subordinate place of "one of the best locks ever made."—Q. YORKE.

[12144.]—**Timber Houses.**—As "Philo" wished to be informed, on page 441, if I had tested the difference of a thick and thin layer of inclosed air, I beg to call his attention to the results of a couple of experiments which I have just made with different-sized bell-glasses (such as are used by confectioners) and two thermometers. (I was sorry I could not get a third thermometer as a check on the indications of the other two; but "Philo" may conduct some similar experiments on a less rough method for greater accuracy.) In the first place I stood the thermometers on a thick mahogany table, and placed a bell-glass over each, keeping the instruments as nearly as possible in the middle of the glasses. Both thermometers indicated the same temperature at the outset, and rose and fell with the variations of the weather during a very changeable day, though not to a precisely similar extent. By observing each thermometer attentively I noticed that the one inclosed in the small bell-glass, which was only 6in. in diameter (the other being a foot, and nearly 4in. higher), was more susceptible to a slight change in the outside temperature, but the difference in degrees as indicated by each was hardly appreciable. I then took out a thermometer from under the small glass and hung it on the wall of the room, and the mercury in it fell at once to a degree lower than the other still under cover, which I supposed to be air-tight. This was in the evening, when the weather grew somewhat colder than what it was a few hours before. There was no fire in the room, which was the most central in a large four-storied house. Bringing the thermometer from the top to the bottom story, and to the outer rooms, slightly variable readings were obtained, while the mercury in the thermometer under the cover remained for the time stationary. I then obtained a large box and placed it over the bell-glass, covering one thermometer, while the other was left uncovered. Removing the box after a few hours an almost imperceptible change was noticed in the position of the mercury, while that in the other had fallen considerably. In all cases I made the wooden and glass covers as air-tight as possible by inserting long strips of rubber under the edges.—Rat-Tat.

[12181.]—**Violin Case** (U. Q.).—See answer to query 12459, p. 519, present volume. The best thing for you to do is to get an American cheese-box from your grocer's. These are made of various tough woods, such as birch, rock elm, ash, &c.; they work up beautifully for such purposes.—Jack of All Trades.

[12198.]—**Extracting Iodine from Seaweed Ashes.**—The ashes or kelp is lixiviated with water, and after separating all the crystallisable salts there remains behind a dense oily-looking fluid, called "iodine ley," to which sulphuric acid is added, and after standing a day or two the acid ley is placed in a large leaden retort and gently heated with black oxide of manganese. Chlorine being produced very slowly liberates the iodine.—Horatio.

[12201.]—**Reducing Pith to Pulp** (U.Q.).—A rather difficult job, I should imagine; worse than cork. Treat it to a bath of caustic alkali or nitric acid; then drive it through a pair of sand stones, running horizontally, the same as mill stones.—Jack of All Trades.

[12210.]—**Manufacture of Blacklead** (U.Q.).—This material can be reduced in a runner, as described some time ago for foundry black. Some of the finer sorts, I believe, are reduced by mixing with chlorate of potash, and calcined in a crucible. Ingredients used for adulteration: Sulphate of lime, charcoal dust, and soot; finished by pressing into polished steel dies.—Jack of All Trades.

[12220.]—**Superheater** (U.Q.).—The querist does not say what class of boilers. If Cornish, place either a circular or else waggon-shaped one in the flue end. If boiler-plate chimney ends, have a tabular one.—Jack of All Trades.

[12222.]—**Iron Castings** (U.Q.).—I presume that "Caster" means the solid moulds taken from wax figures; if so, I was informed years ago that those beautiful iron and bronze figures, knights in armour, filigree work and drapery, are done in that way in Italy and Berlin.—Jack of All Trades.

[12231.]—**Iceland Spar** (U. Q.).—Iceland spar can be cut and polished upon a lapidary's or diamond-cutter's wheel.—Jack of All Trades.

[12234.]—**Hairsprings** (U. Q.).—Yes, they have gauges. The wire for hairsprings can be got upon reels of any size required. You cannot do better than put them the same as before.—Jack of All Trades.

[12243.]—**Turpentine and Wood Naphtha** (U.Q.).—The former is used for paints and various varnishes. The same with the wood naphtha, as well as lacquered and japanned goods, waterproof hats, bodies, and French polish. The first is got in various ways, principally from the distillation of the juices or sap of firs, which is collected for that purpose. It can be got likewise from cobs, foliage, and loppings, subjected to destructive distillation in a retort, the products being acid, a light spirit called camphine, and turpentine; the residue, pitch. Wood naphtha is got the same way from oak, ash, beech, &c. Products: Pyroligneous acid, naphtha, a dead oil, and pitch. I know of no work upon it.—Jack of All Trades.

[12245.]—**Chemical.**—Olefiant gas may be separated from marsh gas by passing it through Nordhausen sulphuric acid—that is, the fuming acid. Common oil of vitriol does not succeed so well, as the gas must be kept in contact with the acid for some time before complete absorption takes place. R. Terret may also change olefiant gas into marsh gas by passing it through a red-hot tube filled with pumice-stone, but should the temperature be very high, acetylene, or even hydrogen gas, may also be produced; a pale red heat, but not a white, is the proper temperature.—J. W. J.

[12246.]—**Seven-keyed Tuning-fork** (U.Q.).—This must be tuned to G when the slides are home to the bridge.—Jack of All Trades.

[12248.]—**Sheet-iron Fireproof Deed Box** (U.Q.).—This should be treble; an air space between the outer skins and between the inner; nothing better than loose fire clay.—Jack of All Trades.

[12254.]—**Aerostatics** (U.Q.).—Such a vast surface of the atmosphere must be acted upon before we can get anything like buoyancy, and the friction is so great that it requires an enormous amount of power to overcome the friction of the atmosphere; but if the weight is sustained, a power can be applied that will drive it where you like with little expense. The time is not far distant when those who feel inclined for an aërial trip may take it.—Jack of All Trades.

[12272.]—**Electrotyping.**—If "Zoo Andra" refers to p. 20, Vol. XIII., he will find some information which will help to put him right. This volume contains what I may term the "whole art" of electrotyping. In the electrotypes used by printers, "Zoo Andra" may rest assured that the copper is *not* deposited on the lead backing; neither is rosin used as a flux. Solder and chloride of zinc are the means usually employed to unite the backing with the film of copper. Heating the shell without spoiling it is the great difficulty for an amateur.—Saul Rymea.

[12289.]—**Electric Bell** (U.Q.).—I send an extract from the descriptive book of Tyer's bell instrument, which will explain the construction to "J.W.T." Of course, any suitable battery can be used with these instruments; but the mercury cell is that generally employed, requiring no porous partition. A series of ordinary preserve pots would of course do. The chemicals required are zinc, mercury, sulphuric acid, with platinised silver and guttapercha-covered wire. In the bell instrument the "exterior indicator on the dial is moved by a piece of soft iron, not permanently magnetised, and therefore cannot be demagnetised or its polarity reversed by lightning. It is actuated by transitory currents of electricity traversing a suitable coil of thick wire, and is only rendered magnetic at the moment of the passage of such current, by which means it is deflected either to the right or to the left as the case may require, and is retained in its position by a powerful permanent magnet of the horse-shoe form; and these being fixed away from, and out of the influence of the coils, are not affected by atmospherical charges of electricity, and, having their 'keepers' constantly attached to the poles, retain their magnetism for a prolonged period; and by a recent and very simple arrangement, these permanent horse-shoe magnets can at any time be recharged to saturation without disturbing the instrument or sending an inspector to perform this duty. The indicators can likewise be retained in their position by a very simple looking apparatus, so that no unusual vibration of any kind can alter their position. The coils, also, being wound with wire of considerable sectional area, allow ordinary charges of lightning to pass freely to 'earth' without injury to the instrument."—Tagee.

[12291.]—**Nature Printed Leaves** (U.Q.).—"Bobo" will find a description of the carbon printing process in the Photographic Almanacs for 1870. He can also obtain Mr. Johnson's specification from the Patent Office, "Manufacture or Production of Photographic Pictures," 1869, or go there and look at it. But possibly some of your readers will write a short description of a process which has not, I believe, been described in the English Mechanic.—Saul Rymea.

[12311.]—**Hydraulic.**—Some of the answers to this query exemplify the absurdities into which the mere theorist is often led. Let me ask H. Meyer and "C. R." to stir a little sawdust with a glass of clear water and then suck the water up through a tube. They will observe the sawdust crowding in from above, beneath, and from all sides—of course following the water. They can then draw their own inferences. "C. R." talks of the surface-water descending "in obedience to atmospheric pressure." Now, the atmosphere acts in the same way as a solid piston on the surface of the water, pressing it down, and the reaction of the bottom of the well presses the water up as much as the atmosphere presses it down. Let us suppose a particle at the mouth of the tube kept in equilibrium by opposite equal forces all round it. When the pump is worked, and consequently the downward force on the particle partially removed, the upward force, which was before neutralised, now forces the particle upwards, and fresh particles rush from all sides to supply its place. Thus the liquid at the mouth of the tube being sucked up, water rushes in in all directions. For a full explanation of the phenomenon further particulars would be required. If an ordinary well, the water would quickly subside to the level of neighbouring springs, and would not wait to be pumped out. One thing is certain, the water would be homogeneous from top to bottom. The following theory would explain the facts stated. The ordinary water level being 10ft. from the bottom, the rain would raise the water level of the neighbourhood another 10ft. (say). During the continuance of showers the surface of the well would be above the gradually rising water-level, so that there would be a percolation from the well outwards which would purify the water in the well, so that finally it would be filled with nearly pure rain water. The lowering of the surface of the well from the daily domestic use would about keep pace with the sinking of the whole water-level of the neighbourhood, so that there would be but little percolation through the sides. When, however, the water had sunk 10ft. (that is, to the natural level), the consumption would lower the surface of the well below this level, and the percolation of spring water would render the well again brackish. There would be a more constant supply at the natural level. This being a very interesting subject, further particulars from "Glaston" would be of general interest. Does he think the theory will fit the facts as he sees them?—Aleph.

[12311.]—**Hydraulic.**—From what source "C. R." derived the information embodied in his reply to "Glaston" (see p. 513) it is not easy to imagine. It seems rather one of the old sort of foolish practical jokes that have been condemned by all sensible correspondents cropping out again. "Glaston" can hardly wonder that when to his usual 10ft. of water, of "brackish and salt" quality in the well, an addition is made of pure water 15ft. deep (sufficient to fill the well), the quality of what he obtains by pumping is greatly improved. This improvement will remain unaltered until he has drawn the water down again to its old level of 10ft. deep, because in the mean time, so far from any more water entering the well from the springs or the drainage of the water-bearing stratum, the water of the well is, on the contrary, percolating outwards, from the fact of its surface-level being higher than that of the water in the ground outside. As soon, however, as the well is drawn down to the old level of 10ft. deep, then for every gallon pumped out a gallon of brackish and salt water enters from the surrounding ground, and the quality of what is pumped up will very rapidly return to its normal condition, or what it was before the rain-water was allowed to run into the well. "C. R." says truly enough that the end of the suction-pipe being near the bottom or high up does not matter generally. In any case the water immediately opposite and surrounding the entrance to the pipe is first drawn in; and I have known of a brick-bat that had fallen into a well being sucked right up the pipe into the valve-box, in a case where the pipe which was only 10in. diameter had to supply three 10in. pumps working at high speed; but then the end of the pipe was very deep in the pump-hole, and had no basket round it. I need hardly say that the pump broke down instantly.—J. K. P.

[12339.]—**Veneers.**—"Shanington" can obtain veneers any size and quantity as well as quality, at a warehouse in Shoreditch, or the Curtain-road, London, at prices to suit his pocket. If in the country I will execute a commission for him free of charge, less the cost and packing—that is, if he advertises his address in the Mechanic.—Samuel Smither.

[12347.]—**Stroke.**—I should like to make a few remarks on Molesworth's formula for the weight of the fly-wheel; if I should be in error, "P. W. H. J." or others will kindly put me right:—W = weight of the rim in cwts. $= \frac{PS}{45\,D}$ (1), P being the total average pressure on piston in pounds, S = stroke in feet, and D = mean diameter of wheel in feet, D = stroke × $3\frac{1}{2}$ or 4 generally. Suppose D = 4 S, and substitute in the formula (1), we get $W = \frac{PS}{180\,S} = \frac{P}{180}$, an expression in which W is made to depend on P. Now, it is evident that W should depend also on the speed of the engine, and also on the number of revolutions per minute, and thirdly on the degree of regularity of motion required, according to the purpose for which the engine is intended. A rapidly-moving fly-wheel has, *cæteris paribus*, more *vis viva* than a slowly-moving one, and if of the same weight will cause the ratio of the least velocity to the greatest to be more uniform. In the case of a pumping-engine irregularity does not matter much, but in some manufactures a very regular motion is required. No fly-wheel can produce a uniform motion. Would not some secondary compensation be useful along with the fly-wheel?—Philanthropist.

[12352.]—**Centrifugal Pump.**—Before assuming the duties of monitor to correct an error which "A., Liverpool," presumes or fancies, from rather indifferent grounds, that I have formed, he should have tried a simple experiment with water confined in a tube in the manner suggested. The arrangement I proposed is more like the principle of an ordinary injector than the spray apparatus to which he alludes. Doubtless, if an orifice for the escape of the water was provided, about an inch in diameter instead of 6in. or so, the water would be driven out in the form of spray, through the opening, supposing no considerable length of pump to be attached; but if this spray be made to pass through a bent tube, or a coil, water issues out in an undivided column. "A., Liverpool," may also try the following as a way of getting him to understand what sort of an arrangement I wished to suggest to "Teachable." Procure a copper or brass pipe a couple of inches in diameter. To this solder a tube somewhat larger, and of any shape, or screw both together, which is the best plan. Dip the end of the apparatus thus formed in a vessel containing water, and allow steam to enter a little below the joint. The steam feed is to be pointed upwards towards the top of the tube bent in the form of a siphon, and I could guarantee all the water will pass through the apparatus in a few minutes. Of course the condensed steam will have mingled with the water raised, but in pumps for mines, quarries, and general drainage works conducted underground, this, in my opinion, is a desideratum, as the exhaust steam is thus easily got rid of. For a drinkable fluid condensed steam from an iron boiler is very pure, and when mixed with other water tends to destroy germs and remove or precipitate impurities. But as I do not wish to enter on dangerous and forbidden ground, over which Montaigne holds undisputed sway, the question of purification by condensed steam may be left out of consideration until some other time. "A., Liverpool," may confine the water to be raised in a reservoir, natural or artificial, which is covered over air-tight with an iron or air-tight lid. At the bottom of the vessel form an opening, and attach a valve opening inwards, through which the water enters to find its own level. To an opening at one side, near the bottom, an exhaust pipe is to be attached, with a ball valve and metallic saddle a little above the junction. When the water has filled the reservoir to within about an inch of the top allow steam to enter through the lid, from a pipe communicating with the boiler. The water will at once raise the ball valve, and ascend through the pipe from the pressure of the steam above, while the bottom valve is closed simultaneously from the same cause. In this experiment the steam does not so soon condense as in the former, but expands and fills the space formed by the forced descent of the water. "A., Liverpool," may hold a different opinion, but when steam does not immediately mingle with a cold fluid or water of colder temperature, but merely rests upon it, as it does in this case, no condensation takes place until a comparatively long period has elapsed, and the upper surface of the water has time to influence the entire volume. In fact, the heating and compression of the thin layer of inclosed air at the top tends to maintain the temperature, and if steam is admitted when this space is filled, and instantly cut off, the quantity admitted from the force of expansion will be sufficient to empty the vessel if not disproportionately large. To obtain a continuous supply from this sort of pump the reservoir might be partitioned off in two divisions, and furnished with double valves, feed, and exhaust pipes. Or "A., Liverpool," may take two cylinders of equal dimensions, fitted with bottom and ball valves in the same manner. In the inside of each cylinder insert a floating air-tight piston. The action of the floating piston is thus explained: Water is made to enter the bottom valve with such force as to raise the float. To this is attached an upright rod, which, when raised with the piston to a certain distance, lifts a sliding cover from the face of the steam feed, and allows steam to enter, which at once forces down the piston, which at a part of its stroke brings down the sliding cover and closes the feed-pipe, while a corresponding rod attached to the opposite side of the piston opens the exhaust port. In none of the above experiments is the steam "instantly condensed," as "A., Liverpool," appears to think in one case where he makes an opening for the raised water above the steam nozzle. If I understand "Micawber" rightly, he says a continuous jet of high-pressure steam divides and passes through a fluid body of any temperature, like a bar or sheet of red-hot metal. It cannot then on entering be "instantly condensed."—Rat-Tat.

[12356.]—**Malleable Castings.**—The cast iron from red hematite is generally preferred for making malleable castings, finely-divided peroxide of iron being the acting agent in the process, removing carbon from the surface. The castings, which are very brittle when removed from the moulds, are packed in cast-iron crucibles with powdered red hematite, and submitted to heat in a furnace somewhat like a cementation chamber. All the apertures are closed and heat slowly applied and continued for from three to five days, according to the depth of malleability required. Castings prepared in this way become brittle on being heated, and are generally worked cold. M'Haffie has adapted the process in the construction of various portions of machinery, and it is largely employed in the manufacture of keys, buckles, gun-locks, toothed wheels, screw-propellers, &c. It is possible to case-harden the articles when finished, so that steel, malleable, and cast iron are to be found in the same article. If the goods are more than ⅜in. thick, a kernel of very soft cast iron is always left in the centre. Any description of good cast-iron can be made malleable by this process I believe.—B. M. J.

[12408.]—**Quill Pens.**—There are two methods of preparing goose-quills for pens. In one the quills are suspended in a strong vessel containing water which reaches nearly to the ends of the quills. This vessel is capable of being closed perfectly steam-tight. After submitting the quills to three or four hours' hard boiling in this position they are withdrawn and dried. The next day they are cut and the pith withdrawn, they are then polished with a piece of cloth, and stoved. This plan yields the best pens; but in ordinary practice the quills are merely plunged into hot sand (212° Fahr.) for a few seconds, scraped with a blunt knife, polished with a piece of woollen cloth, and stoved. In both processes the stoving must be very mild.—Tages.

[12432.]—**Testing Beer and Spirits.**—"J. W. F." can ascertain the strength of a sample of beer or spirits by Sykes's hydrometer. Price, with tables (glass), from £1 to £1 10s.; (metal) from £1, second-hand, to £4 4s. new. The beer and the spirits should, if they contain sugar, salt, or any other matter in solution, be distilled, and the original bulk made up with water before the hydrometer is used. The operation is conducted as follows:—Take a glass flask holding sufficient liquid to float the hydrometer, make a mark in the neck, and fill to the mark with the beer or spirits. Transfer to a retort, washing out the flask with water, the washings to be added to the sample in retort. Distil over in the retort (using the marked flask for a receiver) till about two-thirds of the liquid has come over; fill the flask up to the mark with water, and test its contents by means of the hydrometer. Should "J. W. F." require further information I shall be happy to give it. If he requires to test the beer to find its original strength before fermentation the process is more difficult. The above operations should be conducted at or near a temperature of 60°.—R. H.

[12432.]—**Testing Beer and Spirits.**—The reply by "M. A. B.," p. 519, is erroneous. Sykes's hydrometer will test spirits only. A good instrument cannot be purchased so low as the highest price he states; the prices range from 40s. to 90s. Beer can only be tested by distillation, and is the method used by the Excise to find the original gravity. The saccharometer is used to try the wort, but after fermentation it would not show the strength. It would show porter much stronger than ale, although the first might be the weakest.—Inland.

[12436.]—**Chromo-Lithography.**—In the following short description of this art it is as well to commence at the beginning—the quarry. The stones used are a kind of limestone; their qualifications are—to effervesce with an acid, easily affected by grease, and absorb water readily. They are found in various countries, but the best come from Solenhofen, in Bavaria. They are there sawn into various sized blocks of the average thickness of 3in. or 4in. When they arrive at their various destinations they have the appearance of ordinary paving-stones. The history of the invention may be summed up thus: Aloys Sennefelder, a poor author, residing at Munich, in Bavaria, about the year 1796, being anxious to publish his writings cheaply, experimented for this purpose. He found that soap, wax, and lampblack melted together, made into ink, when written on plates of various metals, and allowed to dry, resisted aquafortis. His mother on a certain occasion wished him to take an account of some linen that had to be sent to the laundry. Having nothing else at hand, he wrote it on a stone with the above ink. After he had written it, the happy thought occurred to him to try and print from it. He eat away the uncovered surface of the stone by strong acid, and printed from the writing which remained. This, in short, was the beginning of poly-autography, as it was at first called. This eating away by acid he afterwards found unnecessary; and it may be as well to state that every original idea—*i.e.*, the foundations of this art—was invented by Sennefelder alone, the introduction of improved machinery, &c., being common to many other inventions. The chalks, which are similar in appearance to the ordinary crayons, as also the ink, are composed of tallow, virgin wax, shellac, common soap, and lampblack, in various proportions. The printing ink is composed of burnt oil or varnish, and lampblack, or whatever may be the colour required. The stone is made to possess a very flat-grained face on the one side for drawing on; by placing over it another stone, the upper one is kept in motion, and the sand which is placed beforehand between the two produces with water the fineness or coarseness of granular surface sought after. The stone, when dry, receives the drawing by the artist, who proceeds exactly in the same manner as he would on paper, with a crayon (only more carefully, as every mark that is placed on the stone will afterwards print), a painting or drawing to be reproduced having been previously placed before him. In a simple white and black representation the subject is all drawn on one stone; where there are more colours than one, a separate stone is required for each, as it involves a fresh printing for every hue; there is one colour only to a stone. In a picture containing a dozen there will be as many stones, but the number of tints or colours vary very much. There is first the key drawing, having the main outline, and such parts finished which may appertain to it; this is, in fact, a map of the whole. This key or map is printed and then transferred or "set off" to all the other stones wanted to complete the picture, as many impressions from the key-stone being taken as there are transfers wanted. The artist proceeds to draw in each tint in its proper place, in relation to the painting before him as copy (all the parts of the drawing which may be in one tint), one colour only to a stone. On the key-stone, near the edge, he draws certain marks which are transferred with the key drawing to the others. Exactly on these marks on every stone the printer drills a small hole, sufficient to drop a needle point into. In each succeeding impression the marks which are printed from the key-stone to the paper are pierced by the needle, and so carried with the paper to the new stone; the needle drops into the hole. He does this with great care, by lifting up the edges of paper, &c., to see if all is right; the needles are then abstracted, and the paper left on the stone. This, properly done, is technically termed a correct register. The stone, which is in a moving tray, having been previously damped, then inked by a roller, the leather tympan is shut down over it, the whole drawn very tightly beneath a boxwood or other hard scraper (this gives great pressure), and so on for every impression to the end of that particular colour. And, again, this process is begun and carried through with every stone required to perfect the copy of prototype. A litho-press, by the way, somewhat resembles the ordinary Stanhope printing-press. The leather which is pulled down on to the stone in the lithographic answers to the tympan in the other; but in the ordinary letter-press simple downward vertical force is used—in the other the stone is moved by a handle over a roller and under the fixed scraper. There remains to be described the process between the time of its leaving the artist and the arrival at the printer's. In order to render the drawing capable of being printed from, a weak solution of acid is poured over the surface, which unites with and neutralises the alkali or soap contained in the chalk or ink, and renders it insoluble in water, otherwise it would all wash out. When the printer is about to take an impression, he first wets the entire surface with a sponge filled with water, and where the drawing is, being greasy, remains dry; every other part of the surface absorbs the moisture. A roller, properly covered with printing ink from a slab, is now moved over the whole upper surface of stone; the oil or varnish contained therein attaches itself to the portions where the drawing is—nowhere else. The damped paper is then laid over it as before described. To render this account more definite, it ought to be stated that the same sheet of paper that receives the impress from the key-stone (not the transfer sheets—that is a different business altogether) receives also the impress from each and every other of the colour stones separately, till it has obtained all their contributions, and so the cromo-lithograph is brought to perfection. Lastly, the principles involved in this art are the mutual aversion of grease and water, and the absorbing power of the stone for both.—A Working B.

[12438.]—**Chess.**—Of course any re-entering (or endless knight's tour answers this query, and it is easy to invent no end of re-entering as well as of nonre-entering ones; but it seems to me impossible for a tour of the whole board to form a symmetrical pattern, and I should like to know if any proof of this impossibility exists. It is easy to render Mr. Meyer's tour (p. 546) a regular pattern, by turning two of the white lines, namely, instead of those going from *7a* to *6c*, and *5b* to *4d*, let the former go to *5b*, and join *6c* to *4d*. But then it becomes two separate endless tours, of 32 steps each. Again, I find it easy to cover symmetrically 62 squares, either with a re-entering tour or one whose ends are separate, and *any* 62, I think. But it seems essential to omit 2 squares. Is this dependent on 64 being an "evenly even" number? Can it prove necessary for a symmetrical pattern to cover an "oddly even," or one whose half is odd as 62?—E. L. G.

[12444.]—**Day and Night Telescope.**—The word "unveiled," in reply on p. 519, should be "inverted."—Philanthropist.

[12457.]—**Geometry.**—To inscribe the largest rhombus in a given triangle A B C, with one angle of the rhombus at A, you have only to bisect that angle, and the line will meet B C at the point whence parallels to A C and A B will form the rhombus. "P. W. H. J.," p. 546, only produces a rhomboid.—E. L. G.

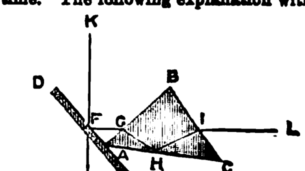
[12458.]—**Blowing Apparatus.**—If "P. W. H. J." (p. 519) will kindly show a working plan of his arrangement, taking an old engine cylinder as a basis of operations, he will confer an additional favour. We may add, there is a three-horse engine on the premises, which can be used for working his air-pump.—Simplex.

[12467.]—**Nitrate of Soda.**—This is likely to fall in price before December. Liverpool is the best market to buy in, export and import ship, but it depends where the purchaser resides. It has been at 13s. per cwt. this season, 15s. in July, and 14s. 6d. on the 1st of August.—Soda.

[12481.]—**Wax Moth.**—"R. A." can destroy the maggot of the wax moth in his empty combs with cyanide of potassium (poison). Break up a couple of ounces of the salt into small pieces, strew them on a board, and place the combs so that the vapour given off may readily permeate them, covering over the whole with two thicknesses of wet cloth, and leave it thus for 12 or 14 hours. I thus destroyed upwards of 300 silk-worm chrysalides in their cocoons, so as to preserve the silk uninjured, and fit to wind off.—George Fox.

[12482.]—**Integral and Differential Calculus.**—Without some knowledge of the integral and differential calculus it is absolutely impossible to peruse works on natural philosophy, in which the effects of the laws that are observed to govern the material world are reduced to calculation. The ordinary processes of geometry and trigonometry are sufficient for the mensuration and discussion of straight lines, and of figures contained by straight lines; but these methods fail when we come to discuss curved lines, and figures bounded by curved lines. In mechanics we can consider only uniform forces, but must obtain the assistance of the calculus in treating of forces which are continually varying from one moment to another. The circumferences and areas of circles, as well as the surfaces and capacities of cylinders, cones, and spheres, are calculated by the method of the calculus. The different curves whose properties it investigates are very important. The logarithmic curve is useful in exhibiting the law of the diminution of the density of the atmosphere, the cycloid in investigating the laws of the pendulum, and the fall of the celestial bodies towards the centre of the earth. In general, treatises on the calculus are divided into two or three courses, each of which is suited to a different class of readers. Those who merely wish to acquire a knowledge of the calculus sufficient to understand the elementary parts of physical science may confine their attention to the differentiation of functions of one variable successive differentiation, the theorems of Taylor and Maclaurin, the effects of particular values of the variable upon a function, maxima and minima, and the application of the differential calculus to plane and spherical curves, arcs and areas, with corresponding integration. A previous knowledge of the elements of geometry, algebra, plane and a little of the spherical trigonometry, with a tolerable knowledge of conic sections. I should recommend a beginner to use Ritchie's "Principles of the Differential and Integral Calculus," or Todhunter's Calculus. For those who may not have read a treatise on conic sections, Ritchie's would be a very admirable book, for he supplies this want. After mastering the contents of this book, the learner could apply his knowledge to a variety of useful purposes.—W. H. C.

[12504.] — **Sketching from Nature.** — "A Working B.," in his answer to Thomas King (p. 520), says that the great objection to a camera lucida lies in the difficulty of seeing both the image of the object reflected and the point of the pencil at the same time. This difficulty is caused by rays from the object giving an image which is farther from the eye than the pencil, and can be corrected by placing between the eye and prism a lens, which gives the same divergence to the rays from the pencil and those from the object. The eye must then be placed very near the edge of the prism so as to divide the aperture of the pupil into two parts, one of which sees the image and the other the pencil. There is another form of the camera lucida, devised by Amici, which is preferable, as it allows the eye to change its condition considerably, without ceasing to see the image and the pencil at the same time. The following explanation with reference to the diagram will explain it:



A B C a rectangular glass prism, having one of its perpendicular faces turned towards the object to be drawn, while the other is at right angles to an inclined plate of glass, D E. The rays, L I, entering the prism, are totally reflected from its base at H, and emerge in the direction G F. They are then partially reflected from the glass plate at F, and form a vertical image of the object, L, which is seen by the eye in the direction K L′. The eye, at the same time, sees through the glass the point of a pencil applied to the paper, and thus the outline of the object may be traced with great exactness.—E. B. H.

[12504.]—**Sketching from Nature.**—I have used the instrument described by John Hopkins where great accuracy was required. It is not necessary to have it so large; all that must be attended to is its relation to the size of the canvas or paper. If your canvas is 2ft. long you may employ the frame 2ft., 1ft., or only 6in. long, remembering that it must be held before the eye, as the canvas must be, at the distance of its length. But it is rarely required. The best plan is to place your paper or canvas at the distance stated, but so low as to allow you to see over its upper edge some prominent objects. Mark their places on this edge. You can then, if you like, do the same with the sides, holding your drawing material up before you at the right level. By this means you can obtain with your T square intersections, and fix very accurately the position of a number of objects. The intermediate spaces can then be filled in by the eye. A square eyeglass held at the right distance from the eye I have also employed. It is very useful in estimating the size of animals. It represents one of the imaginary squares into which your paper is divided.—M. PARIS.

[12507.]—**Cricket-Bat Making.**—The ordinary common cricket-bat is made from willow well-seasoned. Cut out nearly the shape with a two-handle, one-edge paring-knife; the bat is then fixed in the lathe, the handle turned, then finished of with a plane and spoke-shave, and papered, refixed in the lathe, the handle bound with waxed hemp, finished off with two or more coats of brown hard varnish, papering down each coat before laying on the next. Of the superior sort of bats I can give no opinion; never had any hand at them, but always understood the best bats had cane handles.—SAMUEL SMITHER.

[12511.]—**Gas.**—"R. A. H.," at p. 520, says very truly that the poorness of gas and the consequent increase of gas bills require to be thoroughly ventilated. I am interested both as a producer (shareholder) and consumer of gas, and am one of those who believe that honesty is the best policy in this as in other cases. It is evidently unjust for gas companies to sell bad gas at the price for good, but neither is it just for consumers to pay for gas, and complain if they do not get good. Evidently, the right plan must be that gas should be sold by measure, but paid for in proportion to its quality. For example, if the authority quoted by "Saul Rymea" at p. 529 be correct, a thousand feet of coal gas is worth hardly more than half as much as a like quantity of cannel gas, but the latter, though dearer to the producer, is cheaper to the consumer. How can we best reconcile these immediately conflicting interests? The plan tried of subjecting gas companies to penalties that supply gas of less than a minimum illuminating power, does not work well, and has no tendency to produce improvement beyond the standard. If the price chargeable were a fixed amount per thousand feet, multiplied by the average illuminating power of the gas supplied, there would be a constantly acting motive to supply gas of the most economical quality both to make and use. If we assume that to be 20 candle-power, and the fair price of 1,000 cubic feet of such gas to be (say) 5s., 1,000 cubic feet of gas of 12 candle-power would be worth only 3s., while that of 22 candle-power would be worth 5s. 6d.; it would then be soon decided what quality of gas it is best to make, which will depend upon the relative cost of the place in question of cannel coal and coke. There would then be no temptation to draw off the last dregs of poor gas to increase its quantity to the injury of its quality. The consumer would pay as he ought to do in proportion to the light he gets, and the producer would profit, as he ought to do, in proportion to his success in producing the light needed at the least cost. I believe if this simple and just principle of payment were adopted, it would be found more profitable to stop the process of gas making as soon as the poorer gas begins to be formed, so as to leave that in the coke, thereby rendering it a pleasant fuel for household use. If coke could thus be rendered a generally acceptable fuel, a great deal of the smoke by which we are annoyed and injured would be prevented, and thus another great benefit be secured by a simple act of justice and fair dealing.—PHILO.

[12515.]—**Mowing Machine.**—I am made to state that a piece of iron struck repeatedly on one place will drop in two pieces. What I meant to write, if I did not, was that if a rod of iron be struck repeatedly on one end it will drop in two pieces. I will undertake to cause a ¾in. round rod, 12ft. long, to fall in two pieces in less than ten minutes by merely striking it on one end with a hand hammer, and a new knife-box will break as soon as a well-mended one from the cause I stated, as, to my annoyance, I have proved.—OLD PLOUGHMAN.

[12516.]—**Mathematical.**—The querist says that the more 1's you affix to the ·1111 the nearer it approaches unity, but he might with equal truth say the nearer it approaches 2 or 1,000,000, and hence argue that ·1111 *ad infinitum* is = 2 or a million. Of course no number of the 1's can quite make it $= \frac{1}{9}$, but "C. H. W. B." has given the rigorous proof.—E. L. G.

[12516.]—**Mathematical.**—It by no means follows that because the numerator continually becomes slightly greater that it should ever equal the denominator, in fact $\frac{1}{9}$ is the limit it approaches, $\cdot 111 = \frac{111}{1000}$ The numerator has as many 1's as the denominator has ciphers, and evidently no matter how many places we take it never becomes greater than $\frac{1}{9}$, or even quite equal to it, much less then equal to one.—PHILANTHROPIST.

[12516.]—**Mathematical.**—It is absurd to suppose that the numerator will ever be "theoretically equal to the denominator," for it will evidently always have one figure less. Stated in a form different, though radically the same, we have $\cdot 1 = \frac{1}{10}$, $\cdot 11 = \frac{1}{10} + \frac{1}{100}$, $\cdot 1111$, or $\cdot\dot{1} = \frac{1}{10} + \frac{1}{100} + \frac{1}{1000} +$. The sum of the infinite series on the right is $\frac{1}{9}$.—ALEPH.

["Xenophon" has also answered this query.—ED.]

[12517.] — **Mathematical Machines and Tables.**—The calculating machine made calculations of tables of logarithms, &c., I understand, and when it made an error it gave notice of it in some way, either stopping or ringing a bell, or some such way. It was left incomplete from the Government declining to give further aid to its construction. It took several years to make it.—PHILANTHROPIST.

[12517.] — **Mathematical Machines and Tables.**—I read some years ago a minute and lengthy description of Babbage's machine in a book, the title of which, to the best of my recollection, is "The Boy Philosopher."—EXCELSIOR.

[12518.]—**The Island of Hayti.**—All that I can say respecting your query is that Hayti comprises two separate states; the Republic (formerly the empire) of Hayti, capital Porzan Prince; and Dominica, capital San Domingo. It was formerly divided between France and Spain, but acquired its independence during the French Revolution, after the most dreadful cruelties on the part both of the negroes and the French. Hayti, the west part, is still independent; but Dominica is reunited to Spain.—F. S. M. W.

[12519.]—**Acarus Crossii.**—The following extract is from a letter sent by the late Andrew Crosse, Esq., to the Electrical Society of London, which I find in an old periodical called the *Magazine of Science*, in the number for March 13, 1841, with an illustration, of which I inclose a rough tracing:—"Amongst other contrivances I constructed a wooden frame, of about 2ft. in height, consisting of four legs proceeding from a shelf at the bottom, supporting another at the top, and containing a third in the middle. (See Fig.) Each of these shelves was about 7in. square. The upper one was pierced with an aperture, in which was fixed a funnel of Wedgwood ware, within which rested a quart basin on a circular piece of mahogany placed within the funnel. When this basin was filled with a fluid, a strip of flannel wetted with the same was suspended over the edge of the basin, and inside the funnel, which, acting as a siphon, conveyed the fluid out of the basin through the funnel in successive drops. The middle shelf of the frame was likewise pierced with an aperture, in which was a smaller funnel of glass, which supported a piece of somewhat porous red oxide of iron from Vesuvius, immediately under the dropping of the upper funnel. This stone was kept constantly electrified by means of two platinum wires on either side of it, connected with the poles of a voltaic battery of nineteen pairs of 5in. zinc and copper single plates, in two porcelain troughs, the cells of which were filled at first with water and 1-500th part of hydrochloric acid, but afterwards with water alone. The lower shelf merely supported a wide-mouthed bottle, to receive the drops as they fell from the second funnel. When this basin was nearly emptied the fluid was poured back again from the bottle below into the basin above, without disturbing the position of the stone. The fluid with which I filled the basin was made as follows:—I reduced a piece of black flint to powder, having first exposed it to a red heat, and quenched it in water, to make it friable. Of this powder I took two ounces, and mixed them intensely with six ounces of carbonate of potassa, exposed them for fifteen minutes to a strong heat in a black-lead crucible in an air-furnace, and then poured the fused compound on an iron plate, reduced it to powder while still warm, poured boiling water on it, and kept it boiling for some minutes in a sand bath. The greater part of the soluble glass thus fused was taken up by the water, together with a portion of alumina from the crucible. To a portion of the silicate of potassa thus fused I added some boiling water to dilute it, and then slowly added hydrochloric acid to supersaturation. . . . On the fourteenth day from the commencement of the experiment I observed, though a glass lens, a few small whitish excrescences, or nipples, projecting from about the middle of the electrified stone, and nearly under the dropping of the fluid above. . On the twenty-second day these appearances were more elevated and distinct, and on the twenty-sixth day each figure assumed the form of a perfect insect, standing erect on a few bristles which formed its tail," &c. The letter then goes on to describe further experiments made by Mr. Crosse in the same direction.—G. C. C.

[12519.]—**Acarus Crossii.**—If I recollect right, these supposed new insects turned out to be common book worms, which swarmed in Mr. Crosse's library.—PHILO.

[12520.]—**Fluid Lens for Photography.**—The focal points will be on the mirror, and is reflected on to the ground glass. You can make one that way, but will not get a very brilliant effect, compared with the other kind when well made.—W. O.

[12520.]—**Fluid Lens for Photography.**—The focal length would be from L^1 to the plate, measuring in the direction a central ray took first to the mirror m''', and from that to the plate P. Of course, moving the object nearer to or further away from M would alter the focus; for a convex lens, the formula is $\frac{1}{u} + \frac{1}{v} = \frac{1}{f}$ where f is the focus for parallel rays, u the distance of the object from the lens, and v the distance of the image of it from the lens, all distances being considered positive. Why use sulphuric acid in a watch glass? Although it is very heavy fluid it does not follow that it has the greatest refractive power, it is dangerous and corrosive. Bisulphide of carbon has great refractive power, but Mr. Bottone could tell you better about this subject than I. There would be a great loss of light by the four reflections from mirrors.—PHILANTHROPIST.

[12528.]—**Hay Asthma.**—I pity and sympathise with your fair correspondent "Kate." I have for more than twenty years suffered from hay fever, in various forms, principally in the form of influenza, but also as asthma. I believe there is no cure, but I can suggest a great relief. Let "Kate" get a friend to blow the spray of sulphurous acid (one part to ten of water) through one of the toys sold to throw a jet of scent in her face (eyes shut) three or four times a day; also take three times a day about thirty drops of strong spirits of camphor on sugar. Let her also keep her head cool, get plenty of fresh air, and splash the chest with cold water. Sea air is after all the only real means of getting rid of this painful complaint.—OLD BOOTS.

[12528.]—**Hay Asthma.**—"Kate" ought to try a few inhalations of "laughing gas." It has cured many cases of asthma.—RAT-TAT.

[12528.]—**Hay Asthma.**—If "Kate" were a gentleman I would advise (1) During the paroxysm smoke an havannah, some returns, or cut cavendish; (2) once a day inhale for five minutes the vapour arising from twenty drops of creosote in half a pint of boiling water; (3) avoid smells, and go for a fortnight to the sea-side.—LAMBDA.

[12528.]—**Hay Asthma.**—If "Kate" refers to the number for May 31st, on p. 280 she will find a remedy that has been very beneficial to me, a fellow sufferer, from violent sneezing fits in the summer season.—CHIME.

[12528.]—**Hay Asthma.**—Pour some water or equal parts of vinegar and water boiling hot over some herbs, as balm, hyssop, mint, southern wood, sage, or horehound, in a narrow-mouthed pot, and inhale the steam upon retiring to rest.—JACK OF ALL TRADES.

[12528.]—**Hay Asthma.**—This complaint is supposed, not I think proved, to be sometimes excited by the pollen of grass or other plants that flower during the hay season. I suspect it is also excited by chill when in a state of perspiration. I think it wise to guard against either risk by using Dr. Stenhouse's charcoal respirator, by day, and sleeping surrounded by net curtains by night, wearing a thin woollen or merino dress, and using a cold bath every morning, and having plenty of fresh air always.—M. R. C. S.

[12530.]—**Name of Plant.**—Probably *Reseda luteola*. Dyer's weed.—TRESSILIAN.

[12531.]—**Flatting.**—Use a little alum in the paint.—RAT-TAT.

[12531.]—**Flatting.**—Gold size is the best to mix with it, or a small portion of oil varnish; it requires very little, and great care and regularity in laying it on.—JACK OF ALL TRADES.

[12532.]—**Republican Months**:—

French Months.	Signification.	English Months.
	AUTUMN.	
1. Vindemaire.	Vintage.	Sept. 22.
2. Brumaire.	Foggy.	Oct. 22.
3. Frimaire.	Frosty or sleety.	Nov. 21.
	WINTER.	
4. Nivose.	Snowy.	Dec. 21.
5. Pluviose.	Rainy.	Jan. 20.
6. Ventose.	Windy.	Feb. 19.
	SPRING.	
7. Germinal.	Springing or budding.	March 21.
8. Floreal.	Flowery.	April 20.
9. Prairial.	Hay harvest.	May 20.
	SUMMER.	
10. Messidor.	Corn harvest.	June 19.
11. Thermidor.	Hot.	July 19.
12. Fructidor.	Fruit.	Aug. 18.

[12534.]—**Spring Furnace.**—Cannot "A. E." make a hollow fire upon his hearth with bricks and small coal?—JACK OF ALL TRADES.

[12535.]—**Spots on Whitechapel.**—This may proceed from contact with soapy water before dry, the use of a soapy sponge in rubbing down before varnishing, and bad varnish, or from a varnish brush that has been cleansed with soap or stood in soapy water.—JACK OF ALL TRADES.

[12535.]—**Spots on Whitechapel.**—The trap has become greasy or sweated the oil from being left under a warm cover for such long periods. Have it rubbed dry before washing.—RAT-TAT.

[12538.]—**Electrotyping.**—There are so many causes that prevent the regular deposit of the solution upon the mould, that it is almost impossible to prescribe a definite remedy for the bad deposit of which "Duplex" writes. However, as I have had to contend with a similar difficulty, I will readily give such information as I possess. I premise that a good constant battery is used; for, to obtain a fair deposit, the current of electricity must be continuous. If the deposit is granular, as seems to be the case, I should try a less amount of metal in the solution and let the surface of the metal, which resupplies the solution with the amount of metal it loses by the deposition on the mould, be smaller. Perhaps the deposition is obtained too quickly on account of the too high temperature of the solution. It was invariably the case with my own moulds, if I allowed the temperature to be too high, that they were coated with a rough deposit. Provided that the battery be in proper working order, the deposit will generally be very regular in cold weather, but of course slowly formed. If you use a solution for silver deposit, the colder the weather is the better. It would be a good plan to move the moulds about in the bath now and then, and rather quickly. When the hollow parts of the mould are insufficiently coated rinse the mould in clean water, and apply a scratch-brush (which may be attached to a lathe), and make the solution a little stronger, taking care to move the mould frequently in the solution.—W. H. H. C.

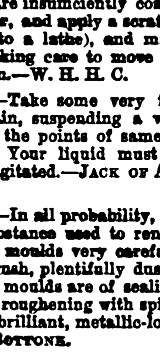
[12538.]—**Electrotyping.**—Take some very fine wire and conduct from the main, suspending a wire into the deep recesses, allowing the points of same to touch the bottom of recesses. Your liquid must be perfectly clear and frequently agitated.—Jack of All Trades.

[12536.]—**Electrotyping.**—In all probability, the cavities have not taken the substance used to render them conducting. Brush the moulds very carefully and thoroughly with a soft brush, plentifully dusted with fine plumbago. If your moulds are of sealing-wax they may require slightly roughening with spirit. All depends on getting a nice brilliant, metallic-looking coating of plumbago.—S. Bottone.

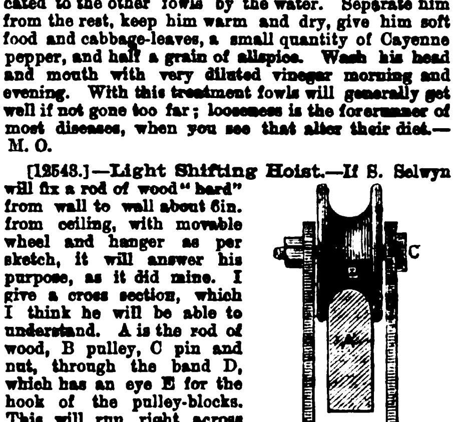
[12539.]—**House Fly.**—Neither.—S. Bottone.

[12540.]—**Poultry.**—If the fowls are kept clean, well-sheltered from wind and rain, have sufficient soft food, with greens, and a constant supply of good water, they will generally be free from disease; but if your fowl has the roup, it is caused by wet and wind, and terminates with a discharge from the nostrils and eyes, a thickening of the tongue; it is contagious, communicated to the other fowls by the water. Separate him from the rest, keep him warm and dry, give him soft food and cabbage-leaves, a small quantity of Cayenne pepper, and half a grain of allspice. Wash his head and mouth with very diluted vinegar morning and evening. With this treatment fowls will generally get well if not gone too far; looseness is the forerunner of most diseases, when you see that alter their diet.—M. O.

[12543.]—**Light Shifting Hoist.**—If S. Selwyn will fix a rod of wood "hard" from wall to wall about 6in. from ceiling, with movable wheel and hanger as per sketch, it will answer his purpose, as it did mine. I give a cross section, which I think he will be able to understand. A is the rod of wood, B pulley, C pin and nut, through the band D, which has an eye E for the hook of the pulley-blocks. This will run right across the room, and the band D prevents it from capsizing. This is same as the smiths have fixed to their crane.—Sting.



[12543.]—**Light Shifting Hoist.**—I send a diagram of a plan which will, I think, suit S. Selwyn, which is both simple and cheap. Two cast-iron brackets something like A, with slot-hole cast in centre of each to receive a flat bar of wrought iron (say) about 2in. by 1in., marked B in diagram, upon which to run a double-flanged pulley C (say) about 4in. diameter, with a turned spindle through it to support the two forks of



the strap D, through the eye of which hook your blocks. The bar of iron must be of sufficient length to allow the blocks to move from where the box is to be lifted from to the table, so that in lifting and lowering the blocks will hang perpendicular; of course it must be placed with one end over the table and the other over the trolley. The bar must be fixed in its place by letting it project through the brackets at each end, and putting a pin through it. I should recommend a pair of Weston's patent differential blocks, or some other kind of self-sustaining blocks which will sustain the load at any required height without making it fast to anything. A pair of 5 cwt. ones would be more than sufficient, but no smaller are made. E and F are the joists; if it should be required to run it across the joist the brackets would require packing down to allow the flange pulley to clear the joists, or they might be left as shown, and the bar cranked down at each end. If this plan should suit S. Selwyn and he should require any further information I shall be most happy to give it. By a slightly different arrangement he might, perhaps, be able to dispense with the trolley. If he wishes I shall have great pleasure in sending a diagram.—Vircas.

[12544.]—**Taraxacum.**—Dig up the dandelion roots; clean thoroughly; cut up into dice about ½in. square. Spread out to dry in the open air. When dry, roast in a coffee roaster till of a fine dark brown all through. Grind.—S. Bottone.

[12544.]—**Taraxacum.** — Gather the dandelion roots and wash, dry them in the sun, break them up short, and roast them in a revolving cylinder, either over or upon the fire.—Jack of All Trades.

[12546.]—**Protection for Steam Boiler.**—Take marl burnt, forge ashes, and horse droppings, or cocoa-nut fibre, chopped straw, or hair, of each alike, and mix in proportion five of these to one of lime, used the same as mortar.—Jack of All Trades.

[12547.]—**Pasting Cloth to Maps.**—I succeeded very well by thoroughly wetting the back of the map on a drawing-board, then putting thin paste on it, thoroughly wetting thin white calico to remove the dressing from it, and carefully lay on pasted back of map pressing wrinkles of air out with blotting-paper; dry slowly on top of a press under pressure. A little corrosive sublimate (10grs. to ounce) in paste if map is not tinted will preserve it from insects.—M. A. B.

[12547.]—**Pasting Cloth to Maps.**—"C. W. J." must get a piece of fine calico a little larger than the map, stretch the calico on a smooth board, and tack it all round as he stretches it with tin tacks, then paste the map and lay it on the calico, and take a sheet of paper larger than the map, lay it on the map and rub down with the palms of the hands, when dry give it two coats of white size, and when that is dry use white varnish, after that cut it on the board.—C. Colby.

[12547.]—**Pasting Cloth to Maps.**—Get some very common calico, cut it roughly to size, lay it on a smooth, clean board—a table leaf is first rate—sponge it with water till it lies quite smooth on the board. Paste the map, and lay it on the calico, then rub with a clean handkerchief till all the air-bubbles and wrinkles are gone. Leave it on the board till quite dry, when it will almost fall off and be perfectly smooth. Proved.—A. S. Boyd.

[12548.] — **Flexible Black Varnish for Leather.**—This is made of linseed oil and asphalte, in what proportions I know not. The blackness does not depend upon the varnish, but upon the ground coat, for which purpose use lamp black; never throw away old oil-cans that are seemed up, as that muck, as many throw away and call it, is invaluable for such purposes, and is easily dissolved with turps and heat.—Jack of All Trades.

[12548.] — **Flexible Black Varnish for Leather.**—I use Brunswick black, or as some places term it black Japan; if too thick, thin it with turps. I find nothing to excel both for cheapness and durability. I use it for the wings and dash-boards of my carts and gig, and find it answers well.—Samuel Smither.

[12550.]—**Seaweeds.**—See back number, p. 317, No. 325, Vol. XIII.—A. G. Boyd.

[12550.]—**Seaweeds.**—The weeds must be washed in two or three waters; then place each specimen on a card, holding the roots against the card, and float them on the surface of the water, and spread out with a fine pointed instrument, after which well dry and press.—Horatio.

[12550.]—**Seaweeds.**—Treat them to a bath of strong alum water, and well wash in several waters, then dry.—Jack of All Trades.

[12550.]—**Seaweeds.**—Place the specimen on a sheet of white letter paper or cardboard, having previously washed the weed in fresh water; while still wet arrange it nicely on the paper, separating the branches with a pin; then press it gently down on the paper.—Philanthropist.

[12551.]—**Picture Framing.**—Cut the moulding into the required lengths as nearly as possible at an angle of 45°. This is done by means of a "cutting-board," or by a bevil. The lengths are then "tried up" on a "mitreing board," which you can borrow of any carpenter, or easily make yourself. Two lengths properly tried up will form right angles to each other. Prepare four wood corners shape of letter L, same thickness as the moulding, and place one at each corner of the frame, passing a stout string four times loosely round the whole. Glue up, and compress by twisting the strings up tightly with slips of wood; allow to dry twenty-four hours, and then finish with two brads in each corner, or key with a slip of veneer.—W. S. B.

[12551.]—**Picture Framing.**—I find the best way is to cut the joinings in the lathe with a fine saw; this way they can be done remarkably quick and clean.—M. O.

[12552.]—**Aquarium.**—The writer, who is passionately fond of the aquarium (or, properly, aqua vivarium), would earnestly recommend "W. B.," supposing he intends having but one, to "go in" for a larger tank than specified, providing it is convenient to do so. When about it the extra cost will not be much. I would recommend the following—viz., 3ft. long, 1ft. 6in. wide (two cubes joined) × 1ft. 8in. deep. The [illegible] and ends should be of slate, which may be purchased for about 9d. per superficial foot, ready grooved and moulded. Thickness of bottom, 1½in. The glass should be best plate, and strong, not less than 7/8in. thick (I forget the number of ounces per foot). For cement, nothing will beat the old-fashioned recipe—viz., boiled linseed oil, litharge, red and white lead, using the greater proportion of the latter. After the cement is properly dry, give, in succession, three coats of japanner's gold size. Previous to putting in the creatures, &c., the tank should be soaked for about ten days, changing the water (say) three times. Cover the bottom with clean washed shingle to a depth of 2½in. A little rockwork, composed of tufa or coke cemented tastefully together by first dipping the coke in a batter of Portland cement, may be introduced, and has a very pleasing effect. If made of coke, it must be well soaked in water, frequently changed, previously to placing it *in situ*. Use no plants except the following, which must be planted in the shingle—viz., *Vallisneria spiralis* and *fontinalis*, and the three *Lemnas*, minor, trisulca, and polyrhiza, together with a few plants of *Hydrocharis morsusranæ*, which float on the surface and send their fine thread-like roots downwards. Now for the inhabitants thereof. Minnows (which, in spite of what "H. O'B." may say to the contrary, thoroughly enjoy the still water of the aquarium and grow fat), Prussian carp, and small eels (N.B.—No sticklebacks); a couple of tritons (*Christalus*), male and female; a few *Hydrachna* and diving water spiders; for scavengers, a few *Planorbis* of the various sorts, *Paludina vivipara*, and the *Glutinosa*. I find one or two of the small beetles can be tolerated, and give a variety to the scene. A pair of the *Hydroaspicens* also do well. The fish, &c., require to be regularly fed, or mischief will soon result. These are the principal or permanent inhabitants, but a few novelties may be introduced when in season, such as tadpoles, very small frogs, shrimps, &c. But the great thing to be guarded against is trying to keep too much animal life, and experience alone will teach how to preserve the proper balance. If intended to stand in a window during summer, a piece of green tissue-paper should be pasted over the glass next the light. The only thing now required, besides supplying water to compensate the loss from evaporation, is to let the aquarium take care of itself, and it will remain a "thing of beauty" and "a joy for ever."—Busy B.

[12552.] — **Aquarium.** — "W. R." has opened a large field, but I will give him my experience: (1) the best material for the bottom is generally considered to be slate; (2) I should advise him to get glass of a tolerable degree of thickness; (3) many recipes for cements have been given in back numbers of "ours;" (4) do not get your fish too large, the smaller are the most lively—minnows and young dace are capital, gudgeon are quite useless. The best weed is *Stratiotes*, a native of Italy. It is known as the water soldier, and can be obtained in Covent Garden. Next to this comes the *Anacharis*, which now chokes England's ditches, rivers, and ponds. I generally cut off the dead bits every now and then. There is a very useful little animal, called the fresh water shrimp, which I advise "W. R." to get. It is supposed to act as a scavenger. The small scarlet water spider looks very pretty. If he keeps a newt it will require a small worm occasionally, as will the fish if they are of any size. Dutch weed looks nicely on the top, it harbours animalcula, which are good for the fish. I should not let it spread over the whole of the water. A green curtain hung over the side of the aquarium exposed to the light is useful for regulating the light. The large water beetle, or *Dytiscus*, is handsome but ravenous. A small eel lives for a long time. "W. R." will find out more by experience than by any amount of writing, but before I conclude I must tell him one thing, that he should carefully boil all gravel or sand for the bottom of the aquarium, which should be about 2in. deep. I wish him success in this most interesting amusement.—V., Cambridge.

[12552.]—**Aquarium.**—I know of one made [illegible] years since still quite perfect, of plain but hard mahogany, the corners 1½in. squares into which rails are framed top and bottom. The bottom, a board of [illegible] mahogany, the top a frame movable, kept in place by four dowells, sides and ends rabbeted inside for glass (patent plate or patent sheet), bedded with white lead, not putty, bottom screwed firm to frame, the bottom edge of which frame was first coated with white lead; the inside of bottom also coated over with white lead and a sheet of glass laid upon it; well fitted this keeps water from the wood effectually, any small portion of wood work inside exposed to wet to be well painted; both bottom and top large enough to form suitable projecting moulding. Outer angle of uprights rounded, rabbet for glass of top must be outside, flat ball under each corner, but good workmanship essential. Gold and silver fish, few pieces of coral or rock, keep it usually in the dark part of your room, light of a window kills the fish, it is unnatural. Water-plants are pretty, but grow fast and give much trouble; the one referred to has a fountain, this is right in a greenhouse but inconvenient in a room.—Aqua.

[12552.]—**Aquarium.**—Let the bottom be [illegible] plate-glass sides, cemented with caustic lime and boiled oil beat up in the shape of stiff putty.—Jack of All Trades.

[12552.]—**Aquarium.**—Zinc is the best for the bottom and angle bars, use stout glass (plate, if possible), cement with red lead putty, fix it on any stand after dry and painted.—M. O.

[12555.]—**Packfong or Chinese White Copper.**—It is an alloy of 7 parts of zinc, 2·5 parts of copper and 6·5 of nickel. It has a great resemblance to German silver, and is used for plating metals. The remainder of the query I am unable to answer.—Vircas.

[12555.]—**Packfong or Chinese White Copper**—Contains nickel, copper, tin, and a small quantity of arsenic. It is much used for making those elegant mirrors, for which the Chinese are so famous, also for gongs, &c. The value of this alloy is not exactly known to me; I only know that the mirrors themselves can be bought at about 1s. each.—S. Bottone.

[12555.]—**Packfong or Chinese White Copper**—I have heard it stated is a composition of cobalt and copper, another told me it was composed of one part of bismuth and copper, and that they forge it into gongs and various articles as we forge Muntz metal. I for one hope to get some information upon this.—Jack of All Trades.

[12555.]—**Packfong or Chinese White Copper.**—This is an alloy of the metals arsenic and copper, formed by fusing together in a closely covered crucible 2 parts of metallic arsenic, and 4½ to 5 parts of copper clippings or filings, both by weight. The metals are usually arranged in alternate thin layers in the crucible, when the whole is capped with a thick layer of either common salt or powdered charcoal. The product is a white, hard, and slightly ductile, metal, permanent at ordinary temperatures in the air, and susceptible of a high polish; but it is decomposed by a temperature considerably below redness, yielding copious fumes of arsenious acid or white arsenic. Packfong was formerly much used for the scales of thermometers, quadrants, and other instruments, dial-plates, candlesticks, &c. Use in China similar. As it contains 10 to 12 per cent., or more, of metallic arsenic, and is readily acted on by acids, it is quite unfit to be used as a material for drinking vessels, household utensils, &c. In these realms it has long been superseded by the alloy of nickel and copper, commonly called "nickel silver" or "German silver."—Arotes.

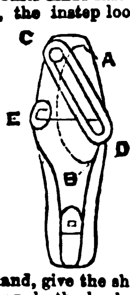
[12556.]—**Soda Water.**—The above generally sold, except by medical halls, is only common water charged with carbonic acid gas by a machine. Mineral water makers generally have four numbers of soda, they contain various quantities (4grs. to 20grs.) of soda carbonate per bottle. These are not wholesome to be constantly drinking, except under medical advice.—M. A. B.

[12557.]—**Nickel Silver.**—The alloy generally used for spoons, forks, &c., is a mixture of copper, nickel, and zinc. Having a nearly white colour it is called German silver, and sometimes nickel silver. All but the commonest goods are electro-plated. German silver is the only alloy of nickel in general use. An alloy of nickel and iron has recently been deposited on fenders and similar goods. Pure nickel unmixed with other metals is never employed. It is a magnetic metal, resembling iron, and having a high fusing point.—Alfred H. Allen.

[12557.]—**Nickel Silver.**—Is an alloy which contains variable amounts of nickel, ranging from 4 to 20 per cent., according to quality.—S. Bottone.

[12558.]—**Boot and Shoemaking.**—I have very large feet. When young, I was foolish enough to persist in wearing shoes not quite big enough, an effect of which has been to cause the joints of my big toes to be swelled and tender as "Irish Mechanic" says his are. My shoemaker overcame the difficulty he complains of by padding the inner part of the shoe, behind the swelled joint, so that there is no difficulty in withdrawing the last, the middle part of the shoe being made wide enough; the padding also diminishes the apparent size of the swelling. If this be insufficient, could not "Irish Mechanic" have his lasts made in three pieces longitudinally, so that by drawing out the middle pieces the others would be made quite loose in the shoes?—Philo.

[12558.]—**Boot and Shoemaking.**—Nothing easier. See the following sketch:—Supposing you have a bunion at E, a prominent big Ben at C, a ticklish little one, outer joint, the shoemaker should pare and rasp your last down at or from A to B, and fit a stout instep leather upon it, coming half way up the block, then put your risers on from C to D. Your bunion should be made fast to the block of last that it might be drawn with it; the risers for toe joints made fast at C, the remainder loose across to D, the instep loose from A, but fast at B. Now to draw your last, even if your foot was half as large again at E and D across the joints as across the instep, you could get it out. Take the block out as usual, with that out comes the bunion, and if not the instep leather, take the pincers and draw the leather, which will undermine the riser, which will drop down upon the edge of last where the block left it, and keep that from biting the upper or tearing it. Turn the boot bottom upwards, and taking the heal in the palm of the hand, give the shoe a blow with a hammer in the waist, apply the hook in the usual way and it is done.—Jack of All Trades.



[12557.]—**Nickel Silver.**—A superior sort of German silver, nickel and spelter.—Jack of All Trades.

[12559.]—**Cleaning Oil Paintings.**—This I have done with good effect by sprinkling them with common table salt and exposing them to the night dew. Wash with sponge and pure water. No soap.—Jack of All Trades.

[12559.]—**Cleaning Oil Paintings.**—If they are valuable don't do it, unless you are well acquainted with the manner in which the picture was painted, or you may spoil it altogether; you might lay a damp cloth on it over night and clear off the dirt in the morning; this is about all a man unacquainted with pictures ought to do. It takes years of study to be a good picture cleaner. He must understand the painting of pictures as well as an artist, but need not be able to paint.—M. O.

[12560.]—**Varnish for Marbled Edges.**—They are never varnished, but burnished with an agate stone. If you hammer the back of your book properly, the front will become a nice hollow without steps. This should be done after the boards are put on before covering.—M. O.

[12560.] — **Varnish for Marbled Edges.**—"Semper Paratus" must put the book between boards, and screw up tight in a press, and use an agate burnisher, pressing it very hard backwards and forwards; the top part of handle must rest on the shoulders. Keep your boards ¼in. above the edge of book.—C. Colbey.

[12560.]—**Varnish for Marbled Edges.**—Use glaire and burnish with a tooth. A dog's tooth, the old masters would say; but I have used any I could get so long as the enamel was perfect.—Jack of All Trades.

[12560.]—**Varnish for Marbled Edges.**—These are not varnished, but burnished with an agate.—S. Bottone.

[12561.]—**Curving Book Edges.**—This process, called rounding, is as follows:—Having put on your end papers, glued up the back, and cut the fore-edge, lay the book on your press, or other solid support, with the back to the left, beat the upper edge of the back over towards the fore-edge with the hammer, helping it over with the thumb of the left hand from top to bottom; turn the book over and treat the other side the same way; repeat this till you have a nice round on the back, and the fore-edge will have a corresponding hollow curve. The shoemaker's flat faced hammer is the best adapted for bookbinding. Let the glue on the back be pretty dry, and don't hammer too hard.—Vandyke.

[12561.]—**Curving Book Edges.**—After the book is sewn the back receives a thin coat of glue. When dry cut the fore-edge. Place your hand flat on the side of book, and hammer the back gently. At the same time draw your hand to you; you will soon see what kind of fore-edge you will have. Cut head and tail afterwards.—C. Colbey.

[12563.]—**Rough Skin.**—From the description you give of the morbid condition of the skin of your face, I suppose it is a mild form of a skin affection, called "psoriasis." I believe you will receive benefit from the application of liniment of iodide of potassium and soap, B.P. You can obtain it from a respectable chemist and druggist, or you can prepare it for yourself by the following formula:—Hard soap and iodide of potassium, each, one and a half ounce; glycerine, one fluid ounce; oil of lemons, one fluid drachm; distilled water, ten fluid ounces. Rub it well over the affected part at night before going to bed, and allow it to dry. Wash it off next morning.—Medicus.

[12563.]—**Rough Skin.**—Don't use soap to face, or very little white curd soap only. A popular remedy is a handful of tansy (a hedge weed) steeped in buttermilk, to wash the face, but I think "F. Acel" will be better pleased by using a little glycerine on a damp towel.—M. A. B.

[12563.]—**Rough Skin.**—Always wash with cold soft water; use a little oil to the skin.—M. O.

[12563.]—**Rough Skin.**—I have heard it stated that if a raw potato be cut in two and rubbed upon the cheeks every night going to bed it will cure roughness of the skin. It may, perhaps, appear too much like an old woman's cure, but I think it is worth a trial.—Vircas.

[12563.]—**Rough Skin.**—Take the old woman's remedy, "brimstone and treacle" internally; externally apply a pomade made with olive oil and flowers of sulphur, ½oz. of sulphur to 1oz. of oil.—S. Bottone.

[12563.]—**Rough Skin.**—Use less soap and partake freely of salads or cress, and less flesh meat. If you have been taking some of those blood purifiers with iodide of potassium in leave it off, the sooner the better, and look upon it for the future as you would a rattlesnake.—Jack of All Trades.

[12564.] — **Photographic.** — Do you "splash" your developer on the centre of the plate so as to wash away some of the free nitrate?—S. Bottone.

[12564.]—**Photographic.**—The negatives may be either under-exposed or under-developed, lacking proper density. Give a longer exposure in the camera, develop more fully, and, if necessary, intensify in the usual way, or if they are dense in the lights, with heavy shadows, the bath or developer may be too acid. Or there is a too direct light used, and a reflector is required to soften the shadows. In taking the negative a white sheet hung at a short distance from the sitter on the dark side will do.—W. Marquand.

[12565.]—**Sticks.**—Boil them and lay them over a brisk fire for a few minutes. Pass them either into holes in a stout block of wood that has been rounded off at the angles for the purpose, and lash fast until dry.—Jack of All Trades.

[12565.]—**Bending Sticks.**—Steam them. When bent to the required shape keep them so until perfectly dry.—M. O.

[12566.]—**Bees.**—If the swarm of bees took possession of your hive, they are undoubtedly your property, unless the owner had followed and kept in sight of them till they settled in your garden, in which case they belong to him.—J. W. S.

[12566.]—**Bees.**—I should say, Yes. Because in the case of game, if you pursued a hare off your estate and caught it on my estate, you would be locked up for poaching.—R. A. H.

[12567.]—**Brick and Tile Glazing.**—This is done in many instances with litharge, silica, and sulphate of lime, and assisted by throwing a little salt into the kiln. In some cases red lead is used instead of litharge; the proportions I know not.—Jack of All Trades.

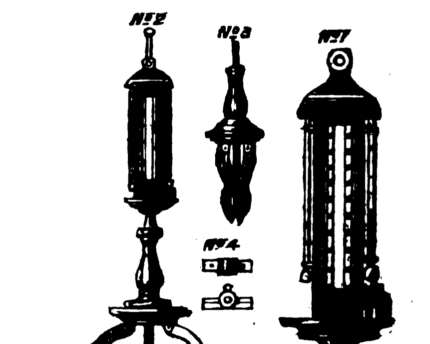
[12568.]—**Smoke and Light.**—The variation in the background causes the difference; in the same way that a cambric handkerchief looks beautifully white till laid on fresh-fallen snow.—A. G. Boyd.

[12568.] — **Smoke and Light.** — I should say sometimes owing to the effect of complementary colouring, sometimes to the transmission and non-transmission of light, coal smoke looks brown against the sky, blue amongst dark trees.—M. Paris.

[12568.]—**Smoke and Light.**—More light is reflected from the white background than from the dark one, and thus the smoke in the former case is viewed more by transmitted light.—Philanthropist.

[12570.]—**Sunrise and Sunset.**—If "Delta" will look among "Replies to Queries" in the English Mechanic, for the last week of January or the first week of February, he will find two methods of finding the time when a heavenly body will attain any given altitude. They will hardly, however, apply to the moon, whose rapid motion in right ascension complicates matters considerably. Before applying these methods we must know the right ascension and declination of the heavenly body, and the latitude of the place of observation.—V. B.

[12573.]—**Hygrometer.**—As the prices range from one to three guineas (Leslie's being the lowest), I will furnish diagrams. The hygrometer is one of the most useful inventions, as it indicates the temperature, dryness, and humidity of the atmosphere. If the air be very dry, the difference of the two thermometers will be very great, if moist less in proportion, when fully saturated both will be alike. Should the wind be strongly blowing upon the instrument, the degrees of dryness observed, multiplied by 2, give the absolute dryness (the excess of dryness being omitted in the calculation), because a strong current of air makes the instrument indicate the excess of dryness which is necessary to be added in a calm atmosphere. If the absolute dryness of an apartment be required, the instrument must be placed in the shade, and the dew point found, which, subtracted from the temperature of the apartment, will



give its absolute dryness. The reason is obvious, and arises from this law—namely, that air has its dryness doubled for every increase of temperature corresponding to 20° of Fahrenheit's thermometer, and in proportion for all intermediate temperatures. In diagrams sent it will be seen are two sensitive thermometers, the bulb of one being covered with silk, with a thread dipped in distilled or boiled water, which keeps the silk moist around the bulb, while the other is dry; the water should be renewed at least once a month. All draught and heat should be avoided if possible, and the instrument should not be too exposed to extreme frost. No. 1 for hanging up on wall; No. 2 mounted on pedestal for room table; No. 3, pedestal with tripod legs folded or shut up; No. 4, side and front view of clips to be fastened on. Back of instrument, and adjusted with small thumb-screws; this small tripod pedestal should be made of polished brass.—Joseph William Fennell.

[12576.]—**Buffalo Pickers.**—Is it not green hide lightly treated to a bath of alum?—Jack of All Trades.

[12577.]—**The Iris or Rainbow.**—It appears circular because the majority of, not all, the drops, are there in the position required for refracting. If all the drops were truly spherical, the colours could not be seen in any other part, but as we may observe by looking at dewdrops on the grass the colours may be refracted at any angle. This question reopens the great rainbow controversy which raged in the English Mechanic some time ago, and will probably awaken that sleeping lion, "E. L. G."—sleeping in this part of his brain only.—M. Paris.

UNANSWERED QUERIES.

The numbers and titles of queries which remain unanswered for five weeks are inserted in this list. We trust our readers will look over the list, and send what information they can for the benefit of their fellow contributors.

' Since our last "Jack of All Trades" has answered 12181, 12201, 12210, 12220, 12222, 12231, 12234, 12243, 12246, 12248, 12254; "Tages," 12289; "Saul Rymes," 12291.

QUERIES.

[12642.]—**Ice Cream.**—Will either you or one of your subscribers be kind enough to inform me through the medium of your journal the construction of an ice machine for the manufacture of ice cream, and also the materials used in the making of the cream?—Icicle.

[12643.]—**Dictionary of Scientific Terms.**—Will any one say whether there is a cheap and portable book explanatory of scientific terms?—Plough Driver.

[12644.]—**Harp Making.**—Would some kind subscriber to this paper please inform me how to construct a harp, where to begin, how to begin, how to get the right shape, and what would be the probable cost of making one—a medium size one? By doing which he will oblige—John Williamson, Bolton.

[12645.]—**Utilising Old Paper.**—Will any one of your readers inform me whether old newspapers and other paper upon which there is printed matter can be again made useful for the printing press? Is there any process known by which the printer's ink can be got rid of so that the paper pulp may be again utilised? Is it now done anywhere in England, and if so, where?—Inquirer, Baden-Baden.

[12646.]—**Alcohol.**—What is the best method for purifying and strengthening methylated spirit so that it can be used for the various processes in which it is needed in chemical analysis; for example, separation of Ba from Sr,Ca?—Y. A., Kew.

[12647.]—**Temperature of the Sun.**—At page 465 it is stated that the eminent French physicist, M. St. Claire Deville estimates the temperature of the sun at 6,000° to 8,000° C. Can any of your readers inform me how this result has been obtained? Father Secchi's mode of estimating the temperature is explained at p. 266 of his finely illustrated book on the sun. By inclosing a black bulb thermometer in a cylinder kept at a known temperature, and exposing the bulb alone to the sun's rays, the temperature of the bulb rises say θ degrees above the inclosure. If there were two suns the rise would be $2\,\theta$ degrees, if 100 suns it would be $100\,\theta$, and so on up to 183,960 suns, which would just cover the whole sphere of the heavens. The temperature of the thermometer would then be the same as the photosphere of the sun—viz., 183,960 times θ. θ varies according to the altitude of the sun and the climate. In this country, during the summer at noon, it is from 10° to 12° C. In India it is more than double. The air that surrounds the bulb deprives it of heat otherwise than by radiation, and the atmosphere intercepts an unknown amount, so that although θ cannot be less than 80° C., it may be a great deal more, for to deduce the temperature of the sun from θ, its value would require to be taken in a vacuum and outside the atmosphere. The effect of the air in reducing the value of θ from conviction has been made the subject of observation, but the screening effect of the atmosphere is not well known. Why should the atmosphere of India be so much less protective than the atmosphere of Britain? The amount of vapour dissolved in the atmosphere is much greater in India, so it is in vain to suppose that aqueous vapour acts as the parasol. Aqueous particles suspended in the air no doubt would be very effective, but it does not appear how there should be more aqueous particles in our sky when clear than in that of India. An instrument to enable the value of θ to be obtained readily is a desideratum of meteorology worthy the attention of some good instrument maker.—F. R.

[12648.]—**Moisture on Tin Surface.**—I have a large tin cistern used for warming water heated by a gas stove. As soon as the flame comes into contact with the bottom of the tin a large quantity of moisture forms around it, so much so, that on one occasion I was about to empty it to discover a supposed leak. What is the cause of this? I thought at first that it might be similar to the formation of dew upon grass, but according to the acknowledged theory the circumstances are reversed, dew being caused by a withdrawal of heat, while this is an application of heat.—Tintub.

[12649.]—**Kites.**—Will some one give me a hint how best to make a kite to fly for my boy; one in the shape of a bird or any other device?—C. Hillary.

[12650.]—**Government School.**—Will one of your correspondents kindly inform me the necessary routine to be observed for obtaining admittance for a lad to the Government School (I believe Woolwich) with a view to be educated as a naval engineer?—W. M.

[12651.]—**Piano Construction Without Down-Bearing of Strings.**—Can any fellow-reader inform me what results when the strings of a piano are in the same plane throughout the whole of these portions of their lengths between the wrest-plank bridge, and where they rest on the string-plate or bent side. Of course, they are supposed to be firmly clamped to the belly-bridge by sufficient side bearing against considerably inclined bridge-pins, or by screw clamps. In his patents A.D. 1741, No. 581, and A.D., 1745, No. 618, prices 4d. each, Plenius—the ingenious harpsichord maker, who probably constructed the first grand piano made in England—says all the strings of the said instruments are laid in "right horizontal lines" from the bridge which rests on the belly to the tail—query, hitch—pins; notwithstanding, every string has the required lateral pressure for producing its true sound—(*i.e.*, its vibrating length determined by side-bearings)—against two pins on its bridge near together, "so that the strings, having no downward pressure on its belly, it (the belly) is at full liberty to vibrate more equally (query, freely) than the bellies of other instruments." Query, must this necessarily diminish the loudness of the sounds; it would, I think, conduce to their longer continuance. There is some interesting information to be obtained by reading Plenius' specifications. He seems to have been the first to double pin his belly-bridges through, an improvement which did not exist in a square piano made by Tomkisson in 1814, formerly in my possession. He also seems to have been the first maker who clothed the mortices in the keys to prevent them from rattling; and was, I believe, the first harpsichord maker who employed a weighted-cranked lever for maintaining the tension of the strings of that instrument and the lyrichord.—The Harmonious Blacksmith.

[12652.]—**Merlin's Musical Instruments.**—Can any reader inform me what has become of the collection of musical instruments, or any of them, formerly in the possession of the celebrated John Joseph Merlin? These instruments were sold by public auction, A.D. 1837, by a Mr. Mills, whose family I have been unable to trace. Among them were the "celestial harp" and "full band of keyed-stringed instruments, having the power of a full orchestra, and made to sound by a catgut(?) band worked by brass circles." Also "Merlin's original private harpsichord," said to contain some remarkable examples of that rare constructive and executant ingenuity for which he was so renowned.—The Harmonious Blacksmith.

[12653.]—**Poultry Keeping.**—I keep, and have kept for several years, a lot of poultry—fowls, ducks, and geese—in an out-building. Can any of your correspondents say what is the best way to prevent thieves breaking in? I want a practical answer from some one who has lost a portion of his poultry, but has saved the remainder by his method of terrifying or catching the depredators. Profitable poultry keeping depends more upon "quiet possession" than the respective merits of barley meal, Indian corn, or refuse wheat.—Padlock.

[12654.]—**Tenoning Machine.**—Will some one tell me if the tenoning machine patented by Mr. Lloyd is in use, and where it may be seen, and what are its properties?—Paddington.

[12655.]—**Core Box.**—Will any of our engineering readers oblige me with instructions in what form to make a core-box? I am about to make a pattern for the casting of a cylinder, and wish to have the portways cast in it.—Electro.

12656.]—**Photographic.**—I want to make my transparencies (for lantern) a good black. There are a great many formulas for intensifying and toning in Vol. XII., No. 6. Most of them I have tried, but they are not for transparencies, they are for printing on paper. I have also tried the sulphuret of potass, recommended in a back number, but it does not make them black to my satisfaction; if either of our readers will give me the best formula, with a due regard to economy, I shall feel grateful.—Kent.

[12657.]—**Cutting Cylindrical Glass as Bottles and Chimneys.**—I have one of Palmer's small cylindrical-shaped candle lanterns, the glass of which is broken, necessitating my using it in-doors only. As I want to use it mostly for out-door work, I wish to cut a quinine bottle or paraffin chimney so as to fit it. Would any kind correspondent help me out of the difficulty? I have no diamond, and cannot get one.—W. Pike.

[12658.]—**Chemistry of Tea.**—I am desirous of analysing tea into its several different component parts; as, tannim, theine, saccharine matter, chlorine, phosphoric acid, sulphuric acid, manganese, manganic oxide, lime, potassa, magnesia, peroxide of iron, soda, silica, carbonic acid, theobromine, nitrogen, and ash. How am I to set about it, and which are the simplest instruments to be used to obtain the results? Will Mr. Bottone, Mr. Davis, or any able chemist tell me?—W. Pike.

[12659.]—**Water Pressure.**—We have a pressure of 300ft. through a 4in. meter. We wish to get the best supply of water, and one person says we shall do it by laying down from the meter 6in. pipes in the first mile, 7in. the second mile, and 8in. the third mile. Another says reverse the pipes—that is, commence at meter with 8in. first mile, 7in. second mile, and 6in. the third mile, will give us the best supply. Please say whether the small or large pipes from the meter will, in your opinion, prove the best.—W. Rhodes.

[12660.]—**Aerated Bread Making Machine.**—Can any brother subscriber give me a plan or description of the above machine, or whether I could utilise a mineral water machine for the purpose?—L.W.D.

[12661.]—**Beekeeping.**—May I ask Mr. Abbott to send plain directions for constructing his bar-frame hive? To mention that it is 20½in. by 17in., with thirteen frames, is scarcely sufficient to enable a "green hand" to construct one. What does he (or any other of the beekeepers) consider to be the best cover for hives? I use straw, but find it very inconvenient when feeding.—Mil.

[12662.]—**Steam Engine.**—I have made a horizontal slide-valve engine, and now wish to ascertain the power of it, and what size fly-wheel is required. Also, if it is capable of working a five inch gear lathe and planing machine, with eighteen inch stroke. The following are a few of the dimensions:—Cylinder 3in. by 4½in., with 6in. stroke and connecting-rod 15in. long; portholes 1½in. by ½in. I also wish to know which is the best kind of boiler, size required, and probable price. Will some brother reader kindly answer the above questions to oblige a constant subscriber?—F. Kitty.

[12663.]—**Sunrise, &c.**—Can "F. R. A. S." inform me of any work in which the calculation of the rising and setting of the moon and planets is given? I have a reader's ticket for the British Museum, so I have little doubt but that I could obtain the work if I knew the author's name.—Delta.

[12664.]—**To Stereotype Brass Blocks.**—Could some kind reader tell me a simple process of taking good sharp casts of brass blocks by the sterotyping process? Blocks are from ½in. to 8in. square.—J. B. Sharpley.

[12665.]—**Sea Sickness.**—Will any reader of "ours" kindly inform me the best way to prevent sea-sicknes on a voyage of twelve hours?—E. G. H. D.

[12666.]—**Works on Artillery.**—Will some reader be kind enough to give me the titles and authors of some good works on artillery subjects? I want the author's name for reference in the library of the British Museum.—J. W. Longford.

[12667.]—**Organ.**—Being about to construct a small organ, I feel a little at sea about the soundboard, and as far as I can learn from the directions of "J. D." I am first to get a piece of mahogany of the requisite size, and after planning out the position of the pipes from paper patterns, to divide it by glueing on strips of wood of certain dimensions, so as to divide it into fifty-four channels of the regulated dimensions. I then understand that I am to let in a piece of half-inch pine at seven inches from front between the bars, to form a base for the hinge of the pallets, after which I am to cover the bars carefully with strong cartridge paper, cutting it away where the grooves of the pallets occur. Are the pallets to be hinged on to the bars, and if so what forms the support in front for the pallet and guide pin? And after the wind chest is fixed on is there not a bottom board of pine to be glued and screwed on over the paper covering the bars to secure all? An answer to the above will be thankfully received.—W. L.

[12668.]—**Auburn Hair.**—I should be grateful for a recipe for turning dark hair to an auburn shade. I have an order for this, and am quite ignorant as to the way to manufacture it.—A Barber.

[12669.]—**Lottery Laws.**—Being very desirous to obtain a repeal or amendment of these laws, will any correspondent give me some information about them? I cannot see why raffling for pianos, fiddles, microscopes, and so on should be illegal. For a trifle given by many never missed, one person, at all events, might be made happier. Why should pictures be disposed of in this way and not a house? Government might make provision against mere gambling (and even otherwise the old lotteries were never so demoralising as our horse race betting), and make each ticket bear a penny stamp.—M. Paris.

[12670.]—**Engine-Turned Seals.**—What is the best way to prevent these deep engine-turned seals from turning black, and how can I prevent the sealing-wax from sticking to them?—C. H. L.

[12671.]—**Dressing Jack-Line.**—I have a new undressed jack-line. Will some reader favour me with a means of waterproofing it? I have rubbed on white wax, but by use it rubs off. With care, allowing it to dry, how long will one last? Any wrinkles in the fishing-tackle line will be useful.—J. D.

[12672.]—**Grove's Cell.**—What proportions and what forms of sulphuric and nitric acid should be used with Grove's cell to get the greatest power, with the least expenditure, in zinc or acids?—Semaj.

[12673.]—**Working Guttapercha.**—Will any one inform me how I can mould and polish a small article of guttapercha, and also how I can make the guttapercha a little harder than its usual quality?—N. K. R.

[12674.]—**Plant Boxes.**—A common but exceedingly pretty ornament in London may be seen in the form of an oblong box for containing window plants. The front is neatly decorated with what appears to be painted glass of various devices, the principal one of which is of alternate square of blue, red, and white, colours arranged after the manner of a draughtboard. Will some correspondent inform me how the above is made?—J. Griffin.

[12675.]—**Hay.**—There is no problem which so perplexes the farmer in this uncertain climate than that of drying hay in broken weather, of which certainly we have this year "an unlimited supply." I therefore submit the query to our readers, could not hay be sufficiently dried by pressure in a hydraulic press, or even by percussion beneath a great hammer? If such methods caused excessive exudation of the juices of the grass, could not such sap be collected, boiled into a syrup, and sprinkled over or amongst the pressed hay, thus reviving or restoring its nutrition and aroma? Hay might be dried in an oven with fire; but this method, or any modification of it which has yet been suggested, is open to the objection of cost. Simplicity and cheapness is the desideratum.—E. B. Fennessy.

[12676.]—**Book-Keeping.**—Can any one help me in the following difficulty? I took credit in my capital account when I opened my present set of books for what furniture I had on hands. I have a furniture account which is balanced at end of year, same as wages account and others, and carried to debit of profit and loss. The balance of the latter, if on credit side, is carried to same side of capital account, increasing that account accordingly. This last year I have laid out a large amount on new machinery, &c., so that the balance of profit and furniture will probably be on the other side, and thus the capital account will appear reduced. This will not give a fair statement of my capital, as I shall have the additional plant, though less cash in the bank. How should it be done?—A Book-Keeper.

[12677.]—**Stops in Telescope.**—Will any obliging correspondent in possession of a 3in. telescope take the trouble to measure and inform me how far (in inches) the second stop is placed from the object-glass, and how far the first is from the eyepiece when in focus? In my telescope there are two stops, which from some cause or other have slipped, and ever since I have not been able to see objects half so distinctly as formerly.—Tyro.

[12678.]—**The Bluecoat School.**—Will some of your correspondents favour me with information as to the nomination of candidates for Christ's Hospital? I wish to know at what age pupils are received, and what is necessary to render them eligible for entrance. Any information on this subject will be considered a favour.—Tawse.

[12679.]—**Papier Mache.**—A few practical hints to the preparation and manipulation of this mate-would oblige. "The Harmonious Blacksmith" has thrown out hints which lead me to put this query.—E. T. GRAYS.

[12680.]—**Darkening Graduations on Scales.**—I shall esteem it a favour would some of your practical correspondents inform me how to make and apply to vernier and other scales the needful blacking to darken their graduations. I have tried lamp-black with Lucca oil, but this mixture, continuing for some days after application in a moist state, easily comes out of the engraved parts when the scale is wiped. I presume a drying oil should be used, if so, what oil would leave the graduations filled with the darkening substance?—ARIES.

[12681.]—**Is the Interior of the Globe Vacuum?**—Will "C. H. W. B." or some one of your learned readers be so kind as to explain to me why it should not be so? Why should it be a solid body in preference? Why contain fluid or fire, as some assert? Take the globe at 8,000 miles diameter, put the crust, or earth, around at 550 miles thick, there is left for vacuum, or solid, fluid, or fire, 5,600 miles core. Please show me why it is not vacuum?—BALCAIRN.

[12682.]—**Evaporation of Water.**—Being about to make an experiment of a peculiar kind, the knowledge of a few facts here alluded to will be useful to me, and may possibly be the means of saving me a good deal of trouble. 1. About what rate does water spontaneously evaporate? 2. Is it in proportion to its bulk or its superficial surface? 3. Would it evaporate faster by increased pressure of the atmosphere or not?—TINTUB.

[12683.]—**Ornamental Turning.**—Will Samuel Smither show more distinctly the centreing of his holes in the ball of the table which he has shewn in Vol. XIV., p. 456, of the MECHANIC, as I cannot find out how the table can stand with the legs set all in one line?—T. A.

[12684.]—**Canoe.**—I shall be much obliged to any one for a design for a canoe 12ft. long, decked over, to carry only one, and suited for sailing; the sheeting in one case to be of wood, in the other strips of sheet zinc.—AQUARIUS.

[12685.]—**Garden Models.**—I have seen in gardens on the top of a pole models of a pair of sawyers at work, of a man turning a grindstone, &c., which, I believe, are worked by small sails something like windmill sails. I should be much obliged if some of "our" readers who have these things will inform me how they are made, and the different sizes and sort of materials.—A MECHANIC.

[12686.]—**Gravel for Aquarium.**—As I can get nothing but sea gravel I should like to know the best mode of treatment so as to entirely free it from salt.—J. COOK.

[12687.]—**Marking Ink.**—Having tried P. Fowler's recipe for marking ink (reply 7506, p. 217, Vol. XIII.) I find that instead of being black it dries brown. Will any reader kindly tell the cause of this, or suggest a remedy?—VANDYKE.

[12688.]—**Training for Bicycle Races.**—Can any one inform me how to train for running bicycle races?—R. M. D.

[12689.]—**Horses' Hoofs.**—I have a carriage horse which I am obliged to work on the road five or six hours every day, his feet are so very hard; the shoeing smith can make no impression on them with the knife, the consequence is they get broken very bad. I fear I shall not be able to use him for a time. Could any one tell me what I could apply to them to make them soft and tough, and procure a good healthy horn?—W. H. K.

[12690.]—**Fire Marks on Silver Goods.**—When I have repaired a silver article, such as spoons or mugs, and placed them to clean in the pickle (composed of sulphuric acid and water) I find upon taking them out that there are stains or fire marks upon them which no polishing will get out. What can I do to clean them thoroughly?—J. J. N.

[12691.]—**Sharpening Lawn Mower.**—Which is the best way to sharpen a "Climax" lawn-mower.—H. D. W.

[12692.]—**Deliquescents.**—Acetate of lead and sulphate of soda, if powdered and rubbed together in a mortar, deliquesce; so do acetate of lead and alum. Will S. Bottone kindly state any other pairs which behave in a similar manner; also which is the most deliquiescent of the salts given in reply 12188?—LXXXVIII.

[12693.]—**Yeast or Barm.**—German dried east as imported at the present time from Rotterdam and Hamburg being extremely high-priced, and of very inferior quality, I should esteem it a great favour if any of your numerous readers will furnish a really good recipe for making yeast that would be a substitute for the above.—SHENANGO.

[12694.]—**Fell and Meyer Engines.**—Can some one oblige with some particulars of construction, &c., of these engines? Also, particulars of comparative trials. A sketch, if possible, would greatly oblige.—A. B. BOYD.

[12695.]—**Verge Watch.**—Will any brother amateur kindly inform me how to alter the verge so as to give it more drop?—R. T. A.

[12696.]—**Atmospheric Pressures.**—Will any correspondent kindly name any work, not too costly, which gives a scale of atmospheric pressures, according to altitude?—J. M. TAYLOR.

[12697.]—**The Harp.**—Will "Ixion," "Vertumnus," or some other kind friend please tell me whether sheet iron or tin would do for the sound-box of the harp, and explain the tuning-pins, how they are fastened in, tightened, and what distance there should be between the strings?—UN BOUTS.

[12698.]—**Vermin.**—The parson has duties inside dirty cottages, and fleas have no respect to the cloth. Will any kind friend suggest a fluid remedy, harmless to clothing or bedding, which may obviate the nuisance?—SLEEPLESS.

[12699.]—**Onions.**—Does the "giant rocca" require to be sown in a frame, or will it grow if sown in an open bed exposed only to the south?—SODA.

[12700.]—**Bees.—Removing Supers.**—Can any of your bee-keeping readers inform me what is the best time of day for taking off a super from a Woodbury hive, and expelling the bees? My two great difficulties on former occasions have been to prevent the bees carrying the store below, when the super is raised over night on wedges, and getting them to entirely quit it after removal.—AMATEUR.

[12701.]—**Orbits of the Planets.**—I have been looking through back numbers of 1871 and 1872, and seek help for the following, with which no amount of books will supply me. Will "F. R. A. S." or one of our astronomical friends inform me at what period the two inner planets are at their brightest? This I know, that Venus transits at intervals of 113, 107, 113 years, and my meaning is in what length of time are these two planets best seen, and when will they be at their next extreme brightest, so that I can by adding reckon. Was Mercury easily visible on the 3rd, when at its greatest elevation from the sun, with a terrestrial telescope (my only instrument), and does Mercury always recede the same distance, as "F. R. A. S." in his notes of last year makes use of various angles of greatest elevation, and at what angle is it easiest discernible? Venus is most brilliant at 40°, and then (so says Guillemin) subtends a diameter of 61". The meaning of my question will now be apparent. Also at what different periods are the outer planets respectively in opposition? Mars, I notice, has not been well in view for a long time; I need hardly add that I want to know when they will next be in opposition? When will Mira Ocetus be at its brightest? May I venture a hint to "F. R. A. S.?" Could he not give every month, the first day, and the time on which Algol will be most brilliant?—T. H. SOMERVILLE.

CHESS.

ALL communications intended for this department to be addressed to J. W. ABBOTT, 7, Claremont-place, Loughborough-road, Brixton, S.W.

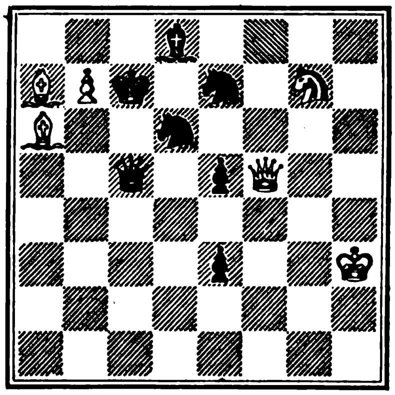
The death of Captain Evans is announced, at an advanced age, well-known in chess circles as the inventor of the "Evans' Gambit."

The score in the match now pending between Zukertort and Steinitz stands: Steinitz, 2; Zukertort, 0; drawn, 1.

We learn from the August number of the *Chess Players' Chronicle*, that a match of ten games has been arranged between Mr. Wisker and the Rev. John Owen.

PROBLEM XI.—BY R. A. PROCTOR.

Black.



White.

White to play and mate in three moves.

SOLUTION TO PROBLEM IX.

White.	*Black.*
1. R to K B sq.	1. P moves
2. B takes P	2. P moves
3. K to K B 2	3. K takes Kt
4. K to K Kt 3 dis. ch. and mate.	

EDROGRAPHY (Leicester).—Problem VIII. is quite sound, and admits of no other solution but that given by the author. The defence to your mate in *two* moves is (1) Q to R 7.

W. NASH (S. Neot's).—Thanks for pointing out the coincidence. Perhaps you will oblige us by sending the problem to which you refer.

C. W. (Sunbury).—Problems safely to hand, for which accept our best thanks.

M. L. MARKS (Swansea).—We infer, from the moves you send as the solution to Problem IX. that you must be joking; but, joking apart, we hope you will examine the positions more attentively before communicating with us.

F. C. COLLINS.—The problem shall be examined, and if up to your usual standard, it shall appear.

E. T. GRAYS.—Thanks for your courteous letter. The position shall be forwarded as directed.

G. C. HEYWOOD.—Quite right. It is far better to keep a problem for a month or two, and subject it to an occasional examination, than send it off the moment it is composed, for publicity. By adopting this plan you will become a careful composer, which is better than a prolific one.

CORRECT solutions to Problem IX. have been received from W. Nash (St. Neot's); W. N. P. (London); S.H.H. (York); J. L. (Lincoln); W. Airey (Worsley). All others are wrong.

ANSWERS TO CORRESPONDENTS.

*** *All communications should be addressed to the* EDITOR *of the* ENGLISH MECHANIC, 31, *Tavistock-street, Covent Garden, W.C.*

HINTS TO CORRESPONDENTS.

1. Write on one side of the paper only, and put drawings for illustration on separate pieces of paper. 2. Put titles to queries, and when answering queries put the numbers as well as the titles of the queries to which the replies refer. 3. No charge is made for inserting letters, queries, or replies. 4. Commercial letters, or queries, or replies, are not inserted. 5. No question asking for educational or scientific information is answered through the post. 6. Letters sent to correspondents, under cover to the Editor, are not forwarded; and the names of correspondents are not given to inquirers.

The following are the initials, &c., of letters to hand up to Tuesday morning, August 13, and unacknowledged elsewhere:—

E. T. S.—F. G. Dear.—W. G.—Wm. Dunlop.—Philo.—Amateur.—M. O.—J. E. Fitzgerald Kermey.—T. R. Leyden.—Richard H. Moore.—Hy. Downing.—G. Piggott.—H. P. H.—J. P. James.—Horatio.—A Windsor Subscriber.—Plymouthian.—James Grant.—Undecided.—J. H. Preece.—E. W. D.—L. L.—Superintendent.—Judson and Co.—Rev. J. Wardale.—March and Pattison—Ch. Rabache.—A. J. Burchardt.—Victor Buckley A. J. Dayman.—J. H. Booth.—Dr. J. Row Smith.—W. V. Eye.—B. M. Simpson.—J. B. Younger.—P. H. Jones—A Working B.—Fred Walton.—Veritas.—G. R. Dixon.—J. W. Johns.—Amateur.—J. W. W.—Francis Chrystie.—Joseph Brabazon.—C. R. Bree.—Julia.—Sucram.—James Hurte.—Ritualist.—Ada.—J. G.—Gillem.—Inquirer.—B. H. W.—Blackbeard.—Tim.—J. W. Durrad.—Mix.—C. E. S.—W.—Hy. Taylor.—Soda Water.—Philanthropist.—Duplex.—Gaucho.—F. W. Burnham.—Sting.—C. N. W.—W. S.—Rho.—Bro. Sam. No. 170.—Alfred H. Allen.—C. N. Abbott.—Jack of All Trades.—Optical Bricklayer.—Emigrant.—J. D.—Mechanical Equivalent.—P. R. C. P.—Tom-Tit.—D. P. L.—Yorkshire Amateur.—Opaline.—Daniel B.—S. Tolver Preston.—W. R. Birt.—A Reader.—F. R. A. S.—Dr. A. Woolsey Blacklock.—K.—Alastor.—Harmonious Blacksmith.—East-end Mechanic.—C. N. A.—R. A. Proctor.—Alliance.—J. W. Muggerige.—J. Alport.—Saul Rymes.—C. R. Wells.—C. S. Robertson.—F. R. Leyden.—H. R.—J. Pugh.—Mab.—Anxious Reader.—Poor Jack.—E. Johnson.—Canoeist.—G. W.—R. D. D. M.—W. Bull.—M. F. P.—G. A. W.—Stadaconor.—M. Paris.—James Tonkes.—T. T. M.—Hypo.—H. H. G.—E. L. G.—Geo. Dawson.—One That Tries.—No Soft Solder.—James Aulton.—D. E. F. G.—John Hopkins.—C Natural.—Excelsior.—Ventricosus.—Sedentary.—A. L.—Pianoforte Repairer.—Tremolo.—Will Hatch.—Bristol Subscriber.—Balcairn.—A Student.—R. C. Argenturo.—J. B. Clay.—W. E. C.—W. L. Brown.—Philanthropist.—G. A. Davidson.—Outgenious Whitesmith.—W. B.—Thetamu.—W. Welsh.—S. Trevail.—W. Q. R.—Apprentice Turner.—C. L. H. Hallett.—John Rei.—James Scaff.—Alex. B. Macdowell.—E. Erasmus Holden.—Semaj.—Ignoramus.—Horatio.—Initial.—Tub.—R. A. Proctor. John Thomas.—J. Stevens.—F. Virtue.—G. F. Chambers.—H.S.—Septimus Powell.

J. T. ATKINSON.—See ENGLISH MECHANIC, p. 509, Vol. XII., or write Secretary of Royal Microscopical Society, King's College, London.

ALFRED BARNES.—Your inclosure was not forwarded. See "Hints to Correspondents."

FRED. PRATT.—Your large diagram illustrating weather phenomena would not, in our opinion, be worth the tenth part of its cost to engrave. You conclude your letter with these words:—"Astronomic meteorology is one of the most interesting and valuable sciences ever offered to the public," and you sneer at "F.R.A.S." and Mr. Procter, who "go on with their sublime doctrine of chance." What is your doctrine but one of chance based on epileptic guesses, without even being sublime? Behind the "chance" of "F.R.A.S." and Mr. Proctor there is eternal, immutable, and irresistible law. We will give you another opportunity some day of airing your science of "Astronomic Meteorology" in our columns.

A. M. C., J. H. Gilbert, W. H. K., Horatio, Amateur and Edeos, are referred to indices to back volumes.

INQUIRER.—Culley's "Handbook of Practical Telegraphy," London, Longmans.

R. MURRAY.—If you wish to *describe* your spiral turning apparatus our columns are open to you; if you want an opinion on its merits "with a view to patenting it" they are not—except those devoted to advertisements.

W. PIKE.—We do not insert queries about advertised goods: this rule disposes of your first query. All the others are inserted except that on "Theory versus Practice," which would only bring on a profitless discussion, eliciting much empty argument, but no information.

JOHN COOK.—See reply 12552 in this number.

W. CRUICKSHANK.—You cannot now enter a caveat in the United Kingdom. Provisional protection, of course, practically secures the same object—viz., protection for a short period at small cost. Write to any of the agents advertising in our journal for a book of instructions, which they will send gratis, and if you are wise, employ one of them, or your evident ignorance of all connected with patents will probably end in loss and disappointment.

THOS. JOYNER (Poole).—Thanks. J. Pell's advertisement shall not again appear in our columns.

W. SHILLETO.—You ask about size of pipe, &c., for smoking opium. Have nothing to do with it. Shun it as you would sin or the devil.

THOMAS LATHAM would be much obliged to Zoo Andra by giving the offered information on printing in reply 12447.

HENRY CLARK (Derby).—Your letter on phrenology was rejected because it was silly. We, however, suggested a mode whereby you should test the truthfulness of your theory. You say that the skull conforms in external development exactly in proportion to certain biasses of character and intellect. We suggested a practical test. See our answer p. 523. Instead of accepting the challenge you quibble over it. We will now make another suggestion. We will put before you in a darkened room plaster casts of the heads of statesmen, philosophers, poets, engineers, navigators, soldiers, infamous convicts, &c., and we challenge you to pick out the head of the poet from that of the navigator, or the head of the philosopher from that of the scoundrel. If you cannot do this by manipulating the living head or casts of heads what becomes of the *science* of phrenology?

A SUFFERER.—Consult a medical man.

VERTUMNUS.—One of your contributions inserted: the other, on co-operative stores, would inevitably elicit a passionate reply.

BALCAIRN.—Vastly too imaginative for us.

F. W.—The query about suspended tramways was inserted not merely for "H. B.," but for any others who may be in want of similar information. We should therefore be glad to receive a reply from you, who evidently can well give it.

J. R. BURNE.—Write Trübner and Co., Paternoster-row.

J. YOULDON.—Declined with thanks.

T. R. THOMAS.—We don't answer by post. Ask one of our intelligent correspondents, and so word the question that the answer to it may be useful to others as well.

COMMON SENSE.—The extract is too long for our space.

Y. A. (Kew.)—You will find information on the best books for studying French and German in back volumes, particularly Vol. XIII. As you appear merely to desire sufficient knowledge to read works in those languages, probably Ahn's courses would suit you, and they are cheap. As to the time necessary to acquire this knowledge, that, of course, depends on the capacity of the pupil. Six months, six hours a week, of earnest study, ought to enable you to do what you require, with the occasional help of the dictionary, of course. But you will find your query answered over and over again in back volumes.

J. HATFIELD.—We believe there is a "Brassfounders' Guide" as you mention, but we have occupied some little time in endeavouring to discover the advertisement without success.

HYRAB SEN.—Your letter contains too many offensive epithets to be altogether palatable to the majority of the readers of the ENGLISH MECHANIC.

JOHN THOMAS.—"Lessons on Chemistry" appear on pp. 319, 395, 406, 438, 447, 460, 486, 497, 512, 538, 549, 578, and 589, Vol. XIV., and pp. 4, 29, 84, 111, 214, 241, 396, and 448, Vol. XV.

SEPTIMUS POWELL.—"A Practical Treatise on the Harmonium" appeared in Nos. 94, 96, 98, 100, 105, 109, 116, 118, 124, 126, 132, 133, 136, 141, 151, 158, 166, 172, 180, 190, and on pp. 25, 99, 178, 290, 433, 458, and 555, Vol. XI., and on pp. 5, 75, and 193, Vol. XII.

M. M.—See Vol. XIII., pp. 242, 267, 291, 446, for methods of drilling holes in earthenware.

ROBINSON CRUSOE.—In chess one king cannot move to a square adjoining the other king.

SUMMA says:—"In p. 518, let. 4639, there appears something like a challenge to Mr. Birt by Charles Babache, that latter gentleman wishing to prove the moon is not spherical. I hope Mr. Birt will not take up the challenge, but if he is fond of such discussions that you will not allow it to be discussed in the pages of 'ours.' We had some time ago something similar with respect to the earth, and I think most of our readers have had enough of that sort of thing, without going to the moon."

PLUMBER, W. S. C., Elias Jones, True Blue, J. Nelson, and Jasper. See Hints to Correspondents.

Y. A. (Kew.)—Can't say positively about chemical article.

F. L., A Coal Miner, W. H. P.—Your queries are advertisements.

Curious Phenomenon.—According to a correspondent of the *Madras Mail*, on the night of June 15 last the plain to the east, north, and north-east of Nandidroog was covered with "many thousands" of lights, which have been observed occasionally in former years. The correspondent compares the appearance to that of a large city brilliantly illuminated, and in one direction the scene, through a binocular glass, "looked like a view of part of the starry heavens, each flame being like a star." As many of the lights were from ten to fifteen miles distant from the reporter's point of view, he conjectures that each flame must have been 5ft. to 6ft. in length. An attempt is being made to find out the cause of the curious phenomenon, the most likely hypothesis being that the lights are "caused by the ignition of some inflammable gas escaping in jets from the surface of the earth."

THE INVENTOR.

APPLICATIONS FOR LETTERS PATENT DURING THE WEEK ENDING JULY 30, 1872.

2189 C. L. Desmolins, Charing-cross, for an improved portable chevaux-de-frise or barricade.

2190 D. Cunningham, Dundee, for improvements in the construction of breakwaters, sea walls, and other subaqueous works.

2191 H. Defty, Middlesborough-on-Tees, for improvements in furnaces for smelting, refining, and puddling iron or other metals.

2192 M. Benson, Southampton-buildings, for an improvement in a combined smut machine and grain separators. A communication.

2193 J. Imray, Southampton-buildings, for improvements in the arrangement, construction, and working of valves for steam-engine cylinders. A communication.

2194 H. Sutcliffe and W. Sutcliffe, Halifax, for improvements in moulding or constructing stench traps or siphon pipes.

2195 W. T. Thompson, Gracechurch-street, City, for an improved ventilating, disinfecting, and deodorising apparatus.

2196 L. Smith, Manchester, for an improved construction of elastic surface suitable for spring mattresses and other articles for sitting or reclining upon.

2197 J. Napier, Argyle-street, Regent-street, for improvements in apparatus to be used in lieu of a coffer-dam in laying foundations under water, and for excluding water for other purposes.

2198 J. L. de Negroni, Paris, for improvements in stoppering bottles and other vessels.

2199 A. J. Woodman, Massachusetts, U.S., for a new and useful improvement in jacquard or fancy looms.

2200 W. R. Lake, Southampton-buildings, for improvements in sewing machines. A communication.

2201 G. Cottino, Tolmers-square, Hampstead-road, for improvements in piston apparatus of wind musical instruments.

2202 J. Cordier, Paris, for improvements in the mode of reflecting, projecting, and diffusing light by means of globe reflectors.

2203 T. Linwood, Glasgow, for improvements in signal and other lamps.

2204 J. Cox, East Stockwith, Lincolnshire, and S. Cox, Camberwell, for an improved apparatus for the recovery and extraction of oils and fats, spermaceti, paraffin, and wax by the distillation of a volatile solvent through the materials containing them, and the recovery of such volatile solvent.

2205 H. A. Dufrene, South-street, Finsbury, for improvements in concentrating and evaporating sulphuric acid and other liquids, and in the apparatus employed therefor. A communication.

2206 J. Walker, James-street, St. Luke's, for improvements in machinery for raising and reducing ores, and extracting the metal therefrom.

2207 B. Hunt, Serle-street, Lincoln's Inn, for a new or improved apparatus or means for excavating, drilling, cleaning, filling, or otherwise treating teeth. A communication.

2208 W. T. Allen, Upper Thames-street, City, and D. G. Fitzgerald, Loughborough-road, Brixton, for improvements in the electro-deposition of metals, and in the application of electro-deposition to the protection of iron, also in the battery and apparatus used in electro-deposition, such battery being applicable to other purposes.

2209 F. Clarke, Canterbury, for improved apparatus or arrangements for charging or filling and drawing off liquids and fluids from bottles and other vessels, and for measuring the quantities of said liquids or fluids supplied to or drawn off from such bottles or vessels.

2210 W. R. Lake, Southampton-buildings, for improvements in refrigerating apparatus. A communication.

2211 H. A. Bonneville, Piccadilly, for improvements in apparatus for the manufacture and application of wire coverings for securing the corks of bottles containing sparkling wines or other fermented or effervescent liquids. A communication.

2212 W. A. Lyttle, The Grove, Hammersmith, for improvements in the means and apparatus for obtaining sea-water for bathing and other purposes.

2213 W. F. Stanley, Great Turnstile, Holborn, for improvements in electrical apparatus.

2214 J. Davis, Great Dover-street, Southwark, for improvements in apparatus for supplying steam boilers with water.

2215 J. Bartlett, Middleton-street, Clerkenwell, for improvements in printing.

2216 H. Walker, Greetland, Yorkshire, for an improved apparatus for signalling on railways. A communication.

2217 J. Vivian and H. S. Mackenzie, Falmouth, for improvements in mechanical arrangements for obtaining reverse rotary motion from one centre, particularly applicable to screw propulsion when more than one screw is adopted.

2218 H. B. Fox, Oxton, and R. L. Gurden, Birkenhead, Cheshire, for an improved guard for protecting the windows and doors of railway and other carriages and moving structures from draught and dust.

2219 A. M. Clark, Chancery-lane, for an improved wrapper garment for travelling and other purposes, and holder for carrying the same and other articles.

2220 J. H. Johnson, Lincoln's Inn-fields, for improvements in the manufacture of plate-glass. A communication.

2221 W. H. Phillips, Birmingham, for a new or improved apparatus for cooling liquids and fluids preparatory to being drawn off for use, particularly applicable for cooling draught ale, porter, cider, or other drinks held in casks or vessels.

2222 H. W. Atkins, Birmingham, for improvements in metal springs for spring mattresses, applicable also for chairs, couches, sofas, and other like purposes where an easy expanding force is desirable.

2223 W. R. Lake, Southampton-buildings, for improvements in apparatus for adjusting window blinds or shades. A communication.

2224 W. E. Blake, New York, for improvements in guns by which the gun can be used as well as a spade or shovel as for firing, together with other improvements.

2225 A. Turner, Leicester, for improvements in the manufacture of elastic fabrics.

2226 W. Turner, Leicester, for improvements in levels.

2227 M. H. Synge, United Service Club, Pall Mall, for improvements in deodorising apparatus.

2228 C. Weekes, Dublin, for improvements in the arrangement and construction of central-fire breech loading cartridges.

2229 C. D. Abel, Southampton-buildings, for improvements in self-acting spinning mules for roving fine spinning and double spinning. A communication.

2230 J. R. Cressey, High-street, Homerton, for improvements applicable to kitchen ranges, kitcheners, and fire stoves.

2231 G. P. Renshaw, Nottingham, for improvements in continuous brakes and signalling apparatus for railway trains.

2232 W. Rose, Worcestershire, for improvements in steam boiler furnaces, puddling furnaces, and furnaces for heating retorts for the manufacture of gas, which improvements may also be applied to other kinds of furnaces.

2233 E. Partington, Manchester, for improvements in the utilisation of the products of combustion for the production of motive-power, and in furnaces and boilers to be employed for such purpose.

2234 H. A. Dufrene, South-street, Finsbury, for an improvement in the mode of constructing carriages and other wheel vehicles. A communication.

2235 C. Levey, Sussex-road, Holloway, for improvements in printing presses. A communication.

2236 F. W. Hartley, Millbank-street, Westminster, for improvements in regulating the pressure and delivery of gas, and in apparatus therefor.

2237 W. R. Lake, Southampton-buildings, for an improved sewing machine and apparatus to be attached to the same for stitching button-holes. A communication.

2238 A. A. Leaker, W. Norman, and W. H. Leaker, Bristol, for improvements in coffins.

2239 J. de Dedulin, Southampton-buildings, for an improved writing machine.

2240 C. E. Spagnoletti, Paddington, for improvements in tell-tale, indicating, and registering arrangements and mechanism.

2241 C. A. C. Eckhold, Green-street, Leicester-square, for an improvement of an apparatus for drawing corks or bungs from bottles or any other vessel.

2242 J. Pullar, Little Love-lane, City, for improvements in appliances for raising sunken ships and other vessels.

2243 W. Abbott, Limehouse, for improvements in portable baths.

2244 H. C. Ashlin and C. J. Clover, Liverpool, or improvements in steam engines.

2245 H. C. Ashlin and C. J. Clover, Liverpool, for improvements in apparatus for registering the number of passengers carried on omnibuses and public vehicles.

2246 C. Smith, Muswell-hill, for a new or improved mode of lettering and ornamenting mirrors for advertising, decorative, and other similar purposes. A communication.

2247 T. Mortlock, South Hackney, for improvements in irons, applicable also for gas stoves for domestic purposes.

2248 S. Lees, Huddersfield, for a new apparatus for raising safety valves in cases of either high steam or low water.

2249 J. Rieber, Islington, for an improved brake for omnibuses and other vehicles, together with an improved arrangement of wheels and axle for use with such brake and otherwise.

2250 M. Volk, Brighton, for an improved apparatus for turning over the leaves of music.

2251 M. Mattson, Southampton-buildings, for an improved apparatus for administering varginal and other injections, and box for containing the same.

2252 F. C. Coxhead, Liverpool and J. J. Miller, Camberwell, for improvements in marine steam-engines.

2253 A. C. Henderson, Charing-cross, for an improved save-all, suitable to all kinds of candlesticks, candle or reading lamps, or chandeliers, burning wax, composition, or other candles. A communication.

2254 J. Fletcher, Portfield, Chichester, for an improved eye cup. A communication.

2255 I. MacDonnell, Dublin, for printing from types or by a special adaptation for printing from stone or other flat surfaces.

2256 C. Brakell, Manchester, for a ballot box or apparatus for the registration of votes by ballot.

2257 A. Woore and J. Watt, Birkenhead, for an improved combined apparatus for heating and moving or forcing liquids.

2258 J. Adams, Strand, for improvements in the construction of breech-loading revolver fire-arms.

2259 J. Edwards, South Hackney, for improvements in fastenings for carriage doors and parts of the same.

2260 C. Fairholme, George-street, Hanover-square, for improvements in the means of effecting electrical communication in railway trains and apparatus therefor.

2261 W. E. Gill, Salisbury-street, Strand, for improvements in treating vegetable juices and in the apparatus and materials to be employed therefor.

2262 T. R. Crampton, Great George-street, Westminster, for improvements in the manufacture of gas and fuel, and in apparatus to be used for this purpose.

2263 G. T. Bousfield, Sutton, for improvements in furnaces for deoxydising iron ores preparatory to their being worked into wrought iron. A communication.

2264 J. P. Hawley, Brixton, for improvements in cocks and sluices.

2265 A. M. Clark, for improvements in the manufacture of phosphoric acid and acid phosphate of lime, and the application of the same. A communication.

PATENTS SEALED.

278 R. Saunders, for improvements in anchors and their accessories.

298 M. Wigzell, for a new or improved drawing board for the purpose of stretching drawing paper (or other materials for drawing, tracing, or painting upon) on one or both of its sides.

800 A. M. Clark, for an improvement in cigarettes.

830 E. Gilyard, for improvements in furniture for locks.

849 J. L. Clarke, for an improved method of and apparatus for preventing candles from guttering.

854 A. L. Dennison, for improvements in watches and pocket chronometers.

878 H. Holland, for improvements in clippers for clipping or shearing horses and other animals.

994 J. F. Lafregne, for improvements in the manufacture of gas for lighting and heating, and in apparatus employed therein.

1079 H. A. Bonneville, for an improved mode and means for obtaining imitation paintings of tapestry.

1525 E. Solvay, for improvements in the manufacture or production of carbonates and bicarbonate of soda, and accessory products thereof, and also in apparatus used in such manufacture.

1669 J. C. Tucker, for improvements in a composition adapted to pavement and other purposes, and in apparatus for treating the same, and also other analogous pavement and material.

224 N. Lloyd, for improvements in fixing colouring matters on prepared fabrics or yarns.

227 J. S. Russell, for improvements in ordnance, and in projectiles and cartridges for the same.

248 H. Aylesbury, for improvements in stoppers for bottles.

253 D. A. Burr, for an improved diaphragm motor, and its application in automatically operating valves and levers in low-water detectors, air-compressing machines, supply or discharge pipes, double-acting vacuum pumps, and other hydraulic or pneumatic machines and engines, by means of an intermittent fluid pressure.

262 G. Weir and J. Weir, for improvements in steam boilers.

267 J. Woodward, jun., and J. Emme, for improvements in breech-loading fire-arms.

270 A. Annandale, jun., for improvements in the manufacture of paper and in machinery or appliances for the purpose.

289 J. Ward, for improvements in the mode and means for securing ear-rings to the ears.

294 J. Knowles, for an improved instrument for rooting up weeds.

296 J. Cooper, for improvements in moulding boxes used in making moulds for casting metal.

305 J. A. Jaques and J. Banks, for improvements in the manufacture of surgical instruments.

310 J. H. Johnson, for improvements in fluting or crimping machines.

321 W. R. Lake, for an improved burner for lamps and other illuminating apparatus.

357 J. L. Norton, for improvements in stables, sheds for cattle and slaughterhouses, and in paving or flooring for the same and other surfaces.

397 J. Harris and D. Normington, for improvements in the joints of metallic bedsteads, sofas, couches, and other articles of like manufacture.

401 N. P. Stockwell, for improvements in sewing machines.

487 W. Nuttall and T. Nuttall, for improvements in looms for weaving.

555 W. H. Cory and E. Cory, for improvements in the manufacture of artificial fuel blocks and in machinery for compressing the same, which machinery is also applicable for compressing other materials into blocks.

609 A. M. Clark, for improvements in machinery for finishing horse-shoe nails.

686 A. M. Clark, for an improvement in saws.

787 A. Longsdon, for improvements in ships or vessels of war and in forts, batteries, and other armed or military structures, apparatus for use on sea and land.

1002 W. R. Lake, for an improved method of and machinery for utilising the butts and other parts of railway rails.

1004 B. Hunt, for an improved method of and apparatus for indicating the speed of railway trains, applicable also for other similar purposes.

1049 W. R. Lake, for improvements in ditching or trenching machines.

1155 E. F. Goransson, for improvements in apparatus for obtaining motive power.

1198 S. Johnson and A. Johnson, for an improved plumb-rule and level.

1382 R. Fish, for improvements in the method of and apparatus for revivifying materials used in the purification of gas.

1509 I. B. Harris, for improvements in and connected with moulds for the production of indiarubber valves and such like articles.

1655 W. R. Lake, for improvements in kilns for burning bricks.

1691 G. Westinghouse, jun., for improvements in apparatus for working brakes and communicating signals on railway trains by compressed air, parts of which improvements are applicable generally for retarding locomotives.

314 A. V. Newton, for improvements in the mode of and apparatus for manufacturing terry and cut-pile carpets and other terry fabrics.

317 R. Punshon, for improvements in apparatus for measuring and registering liquids.

348 S. Cutler, for improvements in fastening and securing window sashes and preventing the rattling thereof.

353 E. Burgess, for improvements in apparatus for evaporating and incinerating alkaline lyes or solutions ordinarily used in the manufacture of paper, and in the treatment of such solutions when spent, for the purpose of recovering therefrom valuable chemical products.

381 W. W. Hulse and B. T. McKay, for improvements in and relating to the manufacturing of floorcloth.

422 E. A. Cook and N. M. Henderson, for improvements in treating hydrocarbon oils.

ARTICLES.

HEALTHY AND COMFORTABLE HOUSES.*

UNDER this attractive title Drs. Drysdale and Hayward have published accounts of the experiments made by them in the warming and ventilation of houses, and as these are accompanied by suggestions of practical value to the public, as well as to the architect and builder, our readers will, doubtless, feel interested in hearing what two well-known physicians have to say on subjects of such importance as fresh air and warmth in dwelling-houses. The important question how to construct a house which shall be at the same time healthy, comfortable, and not inelegant, has been answered in a variety of ways. Some have contented themselves with pointing out what the architect should do; others have put forward for his edification schemes more or less impracticable, which only their authors could repose confidence in; while others have told us what a house should be without showing us how to arrive at the desired result, so admirable in all respects—on paper. The authors of the present book do not come within either of these categories, for though they have, doubtless, theorised, speculated, and schemed, they have put their theories to the test of practice, and given us the results of their experiments. In 1861 Dr. Drysdale built a house in the suburbs of Liverpool, in which many of the defects of ordinary houses were avoided, and ventilation effected by what he terms a siphon-shaft, the foul air being removed from each room in the house by means of a separate pipe, and conveyed to a foul-air chamber in the roof, whence it was drawn by the "suction-power" or heat of the kitchen chimney. The house in question is a marine villa facing the sea, and is of two stories, with the main staircase in the centre of the plan. In a chamber under these stairs, a coil of pipes in connection with a boiler in the basement on the low pressure principle warms the air, which comes in through a flue opening to the external atmosphere. The fresh air passing through the chamber and becoming heated is distributed to the various apartments in the house through openings in the cornice near the ceiling, and through "hit-and-miss" gratings forming the upper section of the architraves of the bedroom doors. The vitiated air is conveyed from each room through a perforated ornament in the ceiling, by a zinc tube to a zinc drum about 6ft. by 5ft. in the roof. This drum communicates by means of a zinc tube and a shaft built into the wall with the bottom of the exhaust shaft, which is formed by constructing the smoke-flue from the kitchen fire of 14in. earthenware pipes placed within a square brick shaft, the intervening space forming the passage for the foul air, which finds an exit a few inches below the coping of the shaft. The fireplaces in this house are at the corners of the rooms, and no chimneys are placed in outer walls, while the windows are of thick plate-glass. The general result of the ten years' experience of different families who have occupied it is that it is warm and at the same time airy and comfortable, while Dr. Inman, who visited it on a bitterly cold day, says, in his "Preservation of Health," that he has never before or since been in a house which seemed so thoroughly comfortable. In the house built by Dr. Hayward, also at Liverpool, the same principle is applied; but in this a central lobby forms the ventilating shaft and divides the dwelling centrally. All the rooms on the three stories open into these lobbies, which, together, form a corridor extending from basement to attics, being connected by lattice work in the centre of the ceiling of each story and iron gratings at each side of the floor above. By this arrangement the warm air passes from the bottom lobby to the others, but the lattice work and gratings not being in line sufficient resistance is offered to its passage to compel an ample supply to pass into the rooms on either side of the corridor through a lattice enrichment in the respective cornices and perforations in the separating wall. Over the gaseliers are perforated plates connected to a zinc tube, which conveys the vitiated air to the chamber in the roof, whence it is drawn as before by means of the heated flue in the brick shaft.

This plan of ventilating and warming houses is not confined to any special description of dwelling, but may, as the authors point out, be adapted to the poorest class of houses by building them in blocks, just as easily as a common system of drainage is made applicable. But it is more especially to the "splendid blocks of offices" and workshops and warehouses, where graet numbers of persons spend a large portion of their lives, subjected to continual cold draughts and to the baneful influences of a vitiated atmosphere, that the authors desire to see their scheme applied. With respect to cost, the authors offer some sensible observations; for while acknowledging that the expense of the zinc pipes, and running them through and between the walls and ceilings, together with the other necessary appliances of the scheme, will amount to a considerable sum, they point out that a considerable saving may be effected in the brickwork and plastering of the house, which need not be so lofty or so large for equivalent requirements. Thus, living and bedrooms might be reduced in height, and the latter also in size, for with this system of ventilation a constant supply of fresh air is furnished, which more than compensates for diminished cubical capacity, especially where the air of the larger rooms is all but stagnant. But as things are, "what can architects do in changing the style of middle-class house building? They are constantly pressed to meet the requirements of the commercial value of a house as at present estimated, and forced to give as many and as large square boxes of rooms as will go under a roof and within four walls as can be got for the money. With such requirements, how can they study convenience, beauty, health, or comfort?"

We can, of course, only mention the principles of the method here, but ample details are supplied by the authors, and all necessary measurements given. The cost of this means of heating is said to be covered by savings in other directions; and lest some may think that the plan of ventilating would fail when the kitchen fire is not burning, it is desirable to mention that even when this is the case "there is still a sufficient amount of suction to keep up a good circulation of air throughout the house." Indeed, every detail of the scheme has been submitted to actual experiment, and all difficulties satisfactorily met. Several diagrams help to explain the method to the reader; and the book contains besides this, its main feature, much useful information on other matters connected with healthy houses, and a valuable appendix containing the methods of calculating the velocity of currents in hot air, with a record of the experiments carried out in the house built by Dr. Hayward, under the varying conditions of many, few, or no fires, open and closed doors, &c. Looked upon merely as a record of what has actually been done the book is worthy the attention of sanitarians.

* "Health and Comfort in House Building; or Ventilation with Warm Air by Self-acting Suction Power." By J. Drysdale, M.D., and J. W. Hayward, M.D.

INFLUENCE OF LIGHT ON PLANT LIFE.*

PLANTS grow by absorbing certain matters from the soil, and by decomposing, through their green parts, the carbonic acid gas in the air. Of this gas they assimilate the carbon and return the oxygen. This may be considered as plant respiration, and light is necessary to it.

Bonnet, in the eighteenth century, observed that plants always tend towards the sun, in whatever position their seed has been placed; also that plants immersed in water give out small gas bubbles in sunlight. In 1771, Priestly put a burning candle in a closed space, and after it had gone out (the air becoming unfit for combustion) he introduced the green parts of a fresh plant. In a few days the air was purified, so that the candle could again be lit. Ingenhousz further observed that the purifying of impure air by plants only commences after sunrise, diminishes towards sunset, and is suspended in the night time; that plants which are shaded do not purify the air, but give out a noxious gas; and that only the leaves and green parts have the purifying action referred to.

Senebier proved the precise nature of the gases absorbed and exhaled. De Saussure showed that the volume of oxygen liberated is less than that of the carbonic acid absorbed, and also that plants exhaled a certain quantity of nitrogen. In sunlight, plant-respiration takes place very energetically.

In 1848 MM. Cloëz and Gratiolet brought to light some new facts about aquatic plants. These do not give out carbonic acid gas at night. The instantaneity of the sun's action on their respiration was proved, the plant being put in water charged with carbonic acid gas, and the disengagement of bubbles from its surface observed when light was admitted. Diffuse light did not produce the decomposition of carbonic acid. Further, Van Tieghem has observed that the decomposing action, once commenced in sunlight, continues in darkness. The plant is thus capable of receiving, and storing up, as it were, some of the incident vibrations, these reappearing as chemical work. Many phosphorescent substances, and photographic processes, furnish analogous cases of conservation of force. The form of reappearance of the vibration-force varies in different bodies: it is sometimes luminous radiation, sometimes chemical work, sometimes mechanical work.

What is the influence of the various spectral rays on vegetation? The question has called forth much research, and is not yet fully answered. Daubeny, in 1836, was the first to examine the respiration of plants under coloured glass. He observed they exhaled less oxygen than in white light. The orange rays seemed the most energetic; then followed blue. Gardner, a few years later, put etiolated or blanched plants in the various spectral rays, and found that green coloration took place, with the yellow rays, in three hours and a half; with the orange, in four hours and a half; with the blue in eighteen hours. Thus the greatest energy of solar action (in this respect), does not correspond, either to the heat maximum at the extreme red, nor to the maximum of chemical intensity at the other extremity. Those radiations most chemically active influence least the phenomena of plant life. Prof. Draper, of New York, has recently shown that plants disengage most oxygen in the yellow and green rays; next follow the orange and the red. M. Cailletet thinks green acts like darkness in reference to plant respiration, and he thus explains the feebleness of vegetation in the shadow of large trees. M. Prillieux has studied the action of light from a different point. He sought to know the influence of lights having different colours, but of equal intensity. He inferred from his experiments that lights of different colours act in an equal degree, and produce an equal liberation of gas *for the same luminous intensity*. All the luminous rays cause reduction of carbonic acid gas in plants proportionally to their luminous power. Plants placed in obscurity become blanched and lose vigour, as if they were growing on a sterile soil. One effect of sunlight is a continual renewal of the moisture in the vegetable tissues. Where the moisture does not evaporate the plant becomes hydropical.

Sunlight produces numerous variations of the colour of flowers. The corolla of species which grow at a great height on mountains has more lively colours than that of the species found on lower parts. The sun's rays traverse the atmosphere more easily in the former case. In general, the vegetation in well illuminated places is richer in colour than where the light has little access. Some flowers, at first white, become coloured in the sunlight. The *Cheiranthus cameleo* is at first blue, then of a citron yellow, then violet-red. The flower of *Hibiscus mutabilis* is white in the morning, and becomes red during the day. Similarly, the colours of fruits are affected by light.

The mechanical effects of light on plants are various. The sleep of flowers, the inflexion of stems, the nutation of heliotrope plants, the intracellular motions of the chlorophyll, show, in this respect, a very delicate sensibility in certain species. Pliny refers to the plant which turned with the sun, and indicated the hour to labourers. Payer has made precise experiments on the motions of cresses under light. When put in a chamber lighted from one side, the stem curves rapidly. The upper part bends first, the lower remaining erect; this next inclines, while the upper part tends to resume its straightness, and the stem has finally a straight inclined position. If the light enters the chamber by two windows, the effects are as follows:—If the two are on the same side, and the light of equal brightness in both, the stem curves in a direction bisecting the angle of the rays meeting where it is placed. If one window lets in more light than the other, the

* Abstract of part of a paper in *Revue des Deux Mondes*, by M. Papillon.

stem tends towards it. If the windows are on opposite sides, and the light equal in both, the stem remains vertically straight; in the opposite case, it is directed towards the more intense rays. These motions appeared, moreover, to be produced by violet and blue rays, but not at all by red, orange, yellow, and green. M. Gardner has pushed this inquiry further. He sowed turnips, and let them grow in obscurity till they had a length of five or seven centimetres; then he cast on them the spectral rays from a prism. Those which were exposed to the red, orange, yellow, and green rays, became inclined towards the dark blue; while those exposed to the violet rays took an opposite direction. The plants had thus the appearance of a field of grain moved by two contrary winds. The turnips in the blue-violet region looked towards the prism. Thus it is the more refrangible rays that determine the flexure of young stems.

The stems of many plants grow in a spiral direction. This is generally from left to right, but not always, and the stems of some plants turn indifferently in either direction. Mr. Darwin has examined the influence of light on this phenomenon. If one of the plants referred to be put in a chamber and near a window, the extremity of the stem takes more time to describe the half revolution in which it is turned from the light, than the other half. Thus a convolvulus made an entire turn in 5 hours 20 minutes; the half revolution on the window side took a little less than an hour; and the other half 4 hours 30 minutes. M. Duchartre found that some plants which grow spirally in the light grow straight in darkness.

The sleep of plants, by which is understood the closing of the flowers and leaves, to expand again after a short lethargy, is not fully understood in its relation to luminous intensity.

The colouring matter of leaves and stems, called chlorophyll, consists of very small granules contained in the cells of these. Different shades in the colour are due to the greater or less number of these small grains in each cell. Sometimes they are very close together, covering the whole internal surface; sometimes they are fewer and more dispersed. In the latter case light, when introduced, produces a motion of the particles, in some cases agglomerating them to a point. M. Famintzin has studied these mechanical effects on leaves of mosses. During the day, the small grains of colouring matter are scattered over the upper and the lower parts of the cells of the leaves. In the night, on the other hand, they collect on the lateral walls. The blue rays act in this way less than white light, while under yellow and red rays, the grains remain in their nocturnal position. These intracellular motions take place in nearly all the cryptogams, and in many of the phanerogams. M. Roze has found that the grains of chlorophyll are joined by very fine threads of plasma, which he supposes to cause their change of position.

Biot, in 1807, exposed the leaves of a cactus in water charged with carbonic acid gas to a very strong artificial light, on which one could not look without being dazzled. No gas appeared to be disengaged. The vessel was carried into diffuse daylight, and the liberation of gas at once took place with great rapidity. He concluded that artificial light was incapable of producing the effects of solar light. But it has been recently proved that light from any source will cause the respiration of plants if only it be not too intense.

A. B. M.

LESSONS ON CHEMISTRY.*

By Selimo R. Bottone.

(*Late of the Istituto Bellino, Novara, Italy.*)

(*Continued from page 448.*)

206.—In order that the student may form a correct idea of the value of the discovery made by Messrs. Dulong and Petit, in connection with the aid which it affords us in fixing the atomic weights of the elements, it is necessary that he should call to mind a peculiar property, which different bodies have, with regard to the amounts of heat they can absorb, without showing a corresponding rise in temperature. It had been demonstrated by Dr. Black, Irvine, and others, towards the middle of the last century, that equal weights of water, iron, glass, &c., at an equal temperature, required very different amounts of heat applied to them, in order to raise their temperature by 1° Fahr.; in other words, the *capacity* which these bodies display for heat, varies with each. This capacity for heat is known under the name of the "specific heat" of the body. In 1819, Dulong and Petit announced that, according to the results of their experiments, "the product of the numbers indicating the specific heat of the different elements, multiplied by the numbers denoting their atomic weight, is a constant number;" in other words, "the specific heat of simple bodies is always in inverse ratio to their atomic weights."

To this constant number* the name "atomic heat" has been applied.

207.—Perhaps the most accurate method for ascertaining the specific heat of the elements is that of "cooling." Experiments have proved that on raising equal weights of different bodies to a given temperature, and allowing them to cool down to a certain point, the *times* required by them to reach this fixed point, are directly as their specific heat.

Taking the specific heat of water as unity, the following table, compiled from the researches of V. Regnault, Person, Favre, Silberman, and H. Kopp, shows the relative specific heats, atomic weights, and atomic heats of the more important elements:—

Name of Element.	Specific Heat.	Atomic Weight.	Atomic Heat.
Oxygen	0·250	16·	4·
Hydrogen	2·411	1·	2·4
Nitrogen	0·457	14·	6·4
Chlorine	0·180	35·5	6·4
Bromine	0·11294	80·0	6·75
Iodine	0·108	127·0	6·4
Sulphur	0·163	32·	5·22
Phosphorus	0·18870	31·	5·85
Selenium	0·07616	80·	6·4
Tellurium	0·04737	128·	6·4
Carbon	0·14687	12·	1·75
Antimony	0·0533	120·	6 4
Bismuth	0·03084	210·	6·4
Arsenic	0·08140	75·	6·11
Molybdenum	0·07218	96·	6·93
Tungsten	0·03342	184·	6·15
Uranium	0·06190	120·	7·43
Platinum	0·03243	197·	6·4
Rhodium	0·05527	104·	5·77
Palladium	0·05928	106·	6·28
Boron	0·2500	11·	2·75
Silicon (crystals)	0·17740	28·	4·97
Potassium	0·16956	39·	6·61
Sodium	0·29340	23·	6·75
Lithium	0·94080	7·	6·4
Thallium	0·03355	204·	6·84
Magnesium	0·24990	24·	6 00
Aluminium	0·21430	27·4	5·89
Manganese	0·12170	55·	6·69
Iron	0·11380	56·	6·37
Zinc	0·09555	65·	6·21
Tin	0·05623	118·	6·65
Cadmium	0·05669	112·	6·35
Nickel	0·11880	59·	6·50
Cobalt	0·10730	59·	6·30
Copper	0·09515	63·5	6·04
Lead	0·03065	207·	6·35
Mercury	0·03332	200·	6·38
Silver	0·05701	108·	6·16
Gold	0·03244	197·	6·36

208.—From this table we get at the relative atomic weights of most of the elements, independent of their compensating weights (11). Unfortunately, owing to their gaseous state, the specific heats of hydrogen and oxygen do not give the same constant as the majority of the elements, hence we are not able by this mode to state with certainty the relative atomic weights of these bodies. Consequently, though the theoretic law of Gay Lussac would point to their atomic weights being, relatively, 1 for hydrogen, and 16 for oxygen, *we have no proof*, as yet, that this proportion is more correct than that of 1 to 8.

Practically speaking, either mode of expression is equally correct; for it is indifferent in all chemical operations, whether we regard water as being composed of 2 parts of hydrogen, to 16 of oxygen, or of 1 of hydrogen to 8 of oxygen. Consequent upon the theoretic nature of the question involved, it behoves the student to bear always in mind, that although in all likelihood, the views of Gay Lussac, Avogadro, &c., are correct, yet we have no tangible proof that the volumes of hydrogen and oxygen are, respectively, equal to their atoms. Hence it follows, that the only certain basis we have for our calculations is the *fact*, that "elements will combine in certain fixed proportions only, or in multiples of these fixed proportions."

209.—The theory of *valency* is one which, up to the present time, admits of no positive proof, though many arguments may be adduced in favour of its existence. But though not supported by direct proof, it is of great assistance to the chemist in classifying various elements, and in enabling him to foretell, with considerable exactitude, the behaviour of certain bodies, when subjected to the different operations of the laboratory. Whether it be false or true, it has certainly conduced to the preparation artificially, of bodies hitherto supposed to be the products of living organisms exclusively, hence, while keeping our minds open to the reception of negative evidence, it is well to remember that this theory is the one which, up to the present time, gives us the most satisfactory explanation of the constitution of compounds, more especially of such as belong to the domain of organic chemistry.

210.—Let us briefly examine the grounds on which the theory of valency is based. When hydrogen is made to combine with oxygen, two compounds may be formed; the first is water H_2O, the second is hydrogen dioxide H_2O_2. As we have already seen (paragraphs 91 and 95), water is neutral, stable, and easy of preparation; while hydrogen dioxide is extremely unstable, is not neutral, and is very difficult of preparation. It is, therefore, evident that the second atom of oxygen is held much more loosely than the first, or, in other words, that the force of chemical affinity, saturating power, or whatever else we agree to call it, in the atom of hydrogen, is insufficient to satisfy to the full, the saturating power, &c., of the atom of oxygen.

Hydrogen combines with the chlorine in one proportion only (53)—viz., HCl, and here we find that the combining power of the one atom of hydrogen is perfectly satisfied by the combining power of one atom of chlorine. Carbon also can be caused to unite with hydrogen, and of the compounds thus produced the most stable and saturate is marsh gas CH_4, in which the combining powers of the four atoms of hydrogen are completely held in abeyance by the combining power of the one atom of carbon. We might adduce numerous examples, but the above will suffice to illustrate the subject.

211.—We find, then, that compounds do exist, in which the component elements show little or no tendency to *dissociate*, while in others (in which the self-same elements occur, united in different proportions) this tendency is very marked. The question naturally arises, On what do these peculiarities depend? The answer, as given by those who maintain the theory of valency, is as follows:—Each atom of the different elements is endowed with a certain fixed combining force. While the atoms of several of the elements possess similar amounts of combining force, and can, therefore, saturate one another when combining atom for atom, others are gifted with double, treble, quadruple, and even six times the amount of force; and hence, can satisfy the combining power of two, three, four, and six such atoms. Taking, as usual, hydrogen as the standard of comparison, and agreeing to consider its combining power, or *valency*, as unity, it follows that as one atom of oxygen can fix and saturate two atoms of hydrogen, oxygen must be possessed of *two* combining powers, or what amounts to the same thing, must be *bivalent*.

Chlorine can only unite with hydrogen in the proportion of 1 atom of chlorine to 1 atom of hydrogen, hence, we consider it as being possessed of only one combining power—that is to say, it is *monovalent* when compared with hydrogen. The same train of reasoning is applicable to nitrogen, carbon, &c., which satisfy, relatively, three and four atoms of hydrogen, &c.

212.—The intelligent student will immediately perceive that whether we take the modern atomic weights, or the ancient equivalents, as our starting point, similar conclusions may be deduced; but in the latter case, many elements which we now consider dyads will appear as monads, and those which we hold to be tetrads, will figure as dyads, &c.

213.—One point that must constantly be borne in mind, when making any application of the valency theory, is the fact, that the ratios expressed bear reference to, and are true only

* Regnault has shown that this is not really a constant, but varies within small limits, the average being 6·4. This variation is supposed to be due to the fact that the specific heats were not determined in all cases at equal distances from the fusing points of the bodies examined.

when compared with hydrogen; for it would appear that several elements which are markedly monads, dyads, and triads, when hydrogen is taken as the point of comparison, possess different valencies when combining with other elements. We have already noticed several of such cases (see paragraphs 62, 70, 71, 77), and many more will come under our observation in the course of these lessons. In closing these few remarks on valency, we cannot do better than quote the following passage from Professor Barff's "Introduction to Chemistry:"—"It must be borne in mind, that the explanation of properties by such terms as 'valency' is only a convenient method of stating what we know about them, and that the use of such terms may be only of short duration. It may be discovered that some of those substances, which we now regard as elements, are not elements at all, but compounds; and advanced knowledge may even substitute some theory which may have a more sure foundation than the atomic theory. It is well to remark this, as young minds are often apt to espouse warmly views of a certain school, and to regard as *facts* what are nothing more than *assumptions*. It is generally believed that the division of elements into those of even and uneven valency will stand; however the body, nitric oxide NO, is one which, for the present, at least, throws a doubt on this opinion, for nitrogen is usually trivalent, and oxygen divalent, and *here* one or the other must change its valency. It will be remembered that NO occupies two volumes, and this is strong evidence that *that* quantity of nitric oxide is the molecule."

214.—A few words in explanation of the mode in which the *names* of the various compounds which are formed by the union of the elements are built up, may not be amiss here. The elements are usually considered as belonging to two great classes—viz., those which are strongly electro-negative, such as oxygen, chlorine, fluorine, &c., and those which are more or less electro-positive.* Formerly it was customary to place first the name of the electro-negative, slightly modified by a termination in *ide*, then the preposition *of*, and lastly the name of the electro-positive element. Thus, for example, we had *oxide of iron* for a compound of oxygen and iron, *chloride of gold* for a compound of chlorine and gold, &c. In the modern nomenclature we begin by the name of the more electro-positive element, and place after it the name of the electro-negative element (changed as above) without any preposition. Thus, we now designate the compound of iron and oxygen by the name *iron oxide*, while the compound of chlorine and gold is called *gold chloride*, &c. In order to specify the number of atoms of either element which the compound may contain, abbreviations of the Greek numerals are prefixed to the name of the element of which it is required to fix the amount; thus, hydrogen *monoxide* is a compound containing one atom of oxygen in each molecule, hydrogen *dioxide* is a compound containing two atoms of oxygen in the molecule. The prefixes most in use are:—

Mono,	for 1 atom, &c.	
Di	" 2 atoms, &c.	
Tri	" 3	"
Tetra	" 4	"
Penta	" 5	"
Hexa	" 6	"
Hepta	" 7	"
Octa	" 8	"

The proportions in which both constituents of a compound occur in the molecule may thus be easily pointed out by the name, thus *dimanganic trioxide* is the name of a compound containing 2 atoms of manganese, united to 3 atoms of oxygen.

We do not lay much stress on nomenclature, as the rapidity with which the science of chemistry is extending itself renders it a matter of the greatest difficulty to find a system which meets *all* the requirements: in all probability a modification of Prof. Filopanti's atomic nomenclature (see p. 319, Vol. XV. of the ENGLISH MECHANIC) is the one most adapted to the present state of our knowledge.

It is necessary, however, to dilate somewhat on the terms *acid*, *anhydride*, &c., and on the terminations *ous* and *ic*, when applied to acids. In order to exemplify the subject, we shall make reference to the acids derived from sulphur and chlorine, as we have already had the advantage of passing them under review.

* It will be readily understood that this division is entirely relative; for, example, though iodine is electro-negative when compared with potassium, it is electro-positive when compared with chlorine. This observation holds good throughout the series of elements.

REVIEWS.

A Handbook of Chemical Technology. By RUDOLF WAGNER, Ph.D. Translated and Edited by WILLIAM CROOKES, F.R.S. London: J. and A. Churchill.

FEW Englishmen except those engaged in scientific pursuits, students of philology, and literary men, are acquainted with the German language. It is true that a smattering of it is taught in "commercial academies," but of the general run of average intelligent Englishmen met with in ordinary every-day life very few have any knowledge of German, whereas numbers have a more or less imperfect acquaintance with French. The great change in what is termed the "balance of power" brought about within the past half-dozen years will probably produce an alteration in this respect, and although it is useless to hope that German will become as familiar to Englishmen as the tongue of the latter is to our better educated cousins, there can be no doubt that it must be deemed of at least as much importance as French. Independently of the high-class literature which teems from the presses of Brunswick and Leipsic, and of the great beauties of what are known as the German classics, there is no language in which a larger proportion of valuable scientific works is written, and none which at the present day records more useful and interesting facts in the domain of "original research," the importance of which in connection with our manufactures was pointed out on p. 345. It is, perhaps, useless to look for a larger development of this stepping-stone to progress, until an acquaintance with the sciences underlying the processes and operations of our principal industries is more widely spread amongst the mass of workers. For this reason Mr. Crookes, in translating the "Handbuch der Chemischen Technologie" of Dr. Wagner, has done good service, and placed before the public a work containing abundant and reliable information on the subject of which it treats. In a volume containing some 750 pages, with numerous illustrations, the methods of preparing and working the various metals and their salts by the latest improved processes are described under the head of metallurgical chemistry, together with the application of the voltaic current to electro-metallurgy. Manufactures of such importance as the preparation of potash and soda salts, bleaching-powder, sulphuric acid, and the methods employed in recovering all that is of value from "waste" solutions and "rubbish" heaps, occupy prominent places. The manufacture of soap, glass, lime, stoneware, mortars, the technology of vegetable fibres, including paper-making, and the arts of brewing, distillation, dyeing, and others, all will be found explained in a necessarily concise yet ample manner. The subjects enumerated form but a portion of the contents of this book, which must be a valuable vade-mecum to the manufacturer and the student. That it has been fully appreciated in Germany is evidenced by the fact that the edition of which the present book is the English translation is the eighth, the first having been published in 1850. Mr. Crookes has edited the work carefully; all the improvements introduced since the publication of the German edition have been added, and the whole of the formulæ, which are molecular throughout, have been revised. At the conclusion of his preface the translator says: "We cannot let this work pass out of our hands without expressing the hope that, at no distant date, Chairs of Technology will be founded in all our universities, and that the subject will be included in the curriculum of every large school." With this aspiration all who wish to see British science and British manufactures not merely maintain their position but progress must cordially agree. Other nations are pressing us hard in the rear as regards industries which were once thought to be all our own, while in too many of the arts we are lagging behind. Technical education is the only thing that will enable us to keep our place, and such works as this Handbook of Chemical Technology will do much to supply us with that desideratum.

An Introduction to the Practical and Theoretical Study of Nautical Surveying. By JOHN KNOX LAUGHTON, M.A., F.R.A.S., &c. London: Longmans.

PROBABLY nothing is of greater importance to the mariner than a correct chart of the shores along which he coasts, or of the seas which he navigates, for if he becomes conscious of an error in his chart, the element of indecision is introduced into his tactics—an element which on board ship our readers will not require reminding is fraught with great danger. We believe, however, that the charts supplied to the English mariner, as a rule, are as correct as it is possible to make them; and in order to facilitate their construction on sound principles, the student who desires to obtain employment in nautical surveying is provided with the valuable "Introduction" to the study which forms the subject of the present notice. Mr. Laughton, who is mathematical and naval instructor at Portsmouth, mentions in his preface the dictum of an experienced and skilful surveyor that no officer can be qualified to take charge of the soundings of a survey with less than seven years' practice, and while acknowledging that practice and experience can alone give skill, he thinks, and rightly, that without a sound knowledge of the theoretical principles on which the skill should be applied, much of it will be thrown away on objects utterly useless. With the view of enabling the young officer, then, to obtain a sound knowledge of these theoretical principles, and to assist him in gaining a mastery of the science, Mr. Laughton has published what he modestly calls "only an introduction" to the art of surveying; but the introduction is of such a nature that the young officer who is well grounded in it will speedily find the advantage when he comes to handle the instruments in practice. Mr. Laughton is emphatically in favour of the student becoming an adept with the sextant before venturing to touch the theodolite, and he is so because, as he says, a complete survey may be carried on with the sextant alone, but not with the theodolite, while any one who is master of the former instrument will readily acquire facility and familiarity in using the latter. The text is illustrated with diagrams where necessary, and the student of nautical surveying will find this a very useful grammar of the art. Mr. Laughton, at the conclusion of his work, impresses on the commanders of vessels lying for any time in unfrequented harbours, the necessity of a verification of the soundings. This is more especially the case in volcanic districts, where, during one disturbance, the whole bed of the harbour may be suddenly altered. In these cases no reasonable opportunity of verifying soundings ought to be omitted, and we join with the author in expressing surprise that the Admiralty has never formally and imperatively ordered it to be done, for her Majesty's ships are rather costly emblems of power, and if their commanders are careless of their own safety, they might at least expend a little of their unexhausted energies in securing the safety of other, if less valuable, vessels.

The Noxious, Beneficial, and other Insects of the State of Missouri. By CHARLES V. RILEY, State Entomologist. Jefferson City, Missouri, U.S.A.: Regan and Edwards.

WE have had occasion to express our appreciation of the common sense displayed by the legislatures of several (we believe most) of the States of the Union in appointing scientific men to examine into and report upon the natural history of that portion of the earth contained within their boundaries. By this means, sound practical information is acquired of what is on the surface and what is beneath, of the mineralogy, the geology, the botany, the climatology, the natural productions and the animal life of the whole of the vast territory inhabited by Anglo-Saxons on the other side of the Atlantic. Not the least important of these annual reports is the one whose title is given above, being the fourth annual report of the accomplished State Entomologist of Missouri. The ravages effected by various predatory insects on the crops of the American farmers are only too well-known in that country, and have also been heard of here, in the shape of some marvellous tales, in which the authors had allowed their imaginations to overcome their appreciation of number; but making due allowance for the "tallness" of the accounts, the armies of insects which at times pass like tongues of fire across the cultivated fields of the States, cause sufficient destruction to crops to become matter for serious thought. Thus, take for instance the Colorado potato beetle, which was never so numerous as last year. In such numbers did this pest make its appearance that Mr. Riley says, "Before the potato leaves were fairly out of the ground the beetles were, as usual, after them, and the fighting on the part of potato-growers commenced with vigour, for it seemed that 20 bugs came to the funeral of every one slain." It is satisfactory to learn that by the use of Paris green, and the assistance of its natural enemies, aided by a hot, dry summer, there was a sudden disappearance of this bug, although the potato crop exhibited a falling off of quite 20 per cent. over the whole State. Having described the damage effected by this noxious insect, Mr. Riley then gives us a description of its natural enemies, with illustrations of them in their different states, so that the farmer may know exactly what to destroy and what to preserve. This system is followed throughout the whole of the list of noxious insects which Mr. Riley has been able to notice in the compass of the present report. The "beneficial" portion is this year occupied by an elaborate treatise on the silkworm, with some excellent page illustrations of the *Bombyx Yamamai*, the Ailanthus, Pernyi, Polyphemus, Cecropia, Luna, and sundry other of the silkworm moths. This life-history of these insects comes at an opportune time, when the *morus multicaulis*, or "silkworm fever," is again gaining ground in the States, in some parts of which there can be but little doubt the moths and worms might be successfully reared, and an important source of industry established. A few pages are devoted to "Innoxious insects," but we have not space to write more of a work which would deserve a page if it only applied to our own country. The money spent in obtaining these reports will return a high rate of interest in times to come.

Science and Commerce: their Influence on our Manufactures. By P. L. Simmonds. London: R. Hardwicke.

The statistical essays and lectures here gathered together in one volume have been delivered or published during the past twenty years, and appear to contain a fund of information of a popular nature on the subjects with which they deal. The articles on shells, the cotton, wool, and silk manufactures, on dyeing, and on nuts, are full of interesting matter. It is true some portions of the book are written in the "sensational" style, and Mr. Simmonds would do well to cut out unsparingly all passages of the kind. We do not appreciate the beauty or force of a simile which compares the ships of Britain to "enchanted castles (!) floating along her sea-girt shores," and it is quite possible to convey an idea of the result of submarine explosions without saying that the "obstructions are riven from their foundations, shooting upwards to the zenith with volcanic force into the aërial space!" Readers who can appreciate what there is of value in Mr. Simmonds' book will merely laugh at the high-sounding phraseology in which he at times indulges.

We have also received Nos. 1 and 2 of *Naval Science*, a quarterly magazine devoted to the subjects comprised under its title, containing able articles by competent writers, and edited by Mr. E. J. Reed; *A Standard Algebra*, with *Key*, by the Rev. John Hunter, M.A. (Longmans), forming volumes of the well-known School Series edited by the Rev. G. R. Gleig, M.A., which will be found not only adapted for their special purpose (school-use) but useful to the artisan whose education in this respect has been neglected. The size is suited to the pocket; *The Duke of Somerset's recent attack upon the Bible criticised*, by Rev. Joseph B. M'Caul, is a pamphlet which may interest those who delight in polemics; *As Regards Protoplasm*, by J. H. Stirling, F.R.C.S., LL.D. (Longmans), is an amended edition with additions of the author's pamphlet in reply to or rather attack upon Mr. Huxley; *Magnetism and Deviation of the Compass*, by J. Merrifield, LL.D. (Longmans); and *Plain and Ornamental Alphabets* (Brodie and Middleton), is a series of alphabets, the letters of which are of various designs and printed in different colours, of use to engravers, lithographers, painters, carvers, and others who require a guide in the construction of ornamental letters. We have also received *Life of Trevithick*, Vol. I. (Spons), and the *Battle of the Gauges Renewed*, by R. F. Fairlie (Effingham Wilson), notices of which must be postponed.

Black Bass in England.—Mr. Parnaby has succeeded in bringing sixty black bass fry home from America, and they are safely deposited in the tanks at Troutdale, Keswick; they are feeding heartily, so may now be considered safe. He found great difficulty in collecting the fry and bringing them safely across the Atlantic on account of the intense heat. Mr. Francis considers this the second greatest feat in pisciculture, the first being the conveyance of salmon to Australia.

THE WATCH, AND HOW TO REPAIR IT.

By "Seconds' Practical Watchmaker."

(*Continued from page 529.*)

The remarks in last article on this subject introduced us to that portion of the watch termed the escapement. Therefore, to render the following remarks somewhat more intelligible we introduce Fig. 6, which at A represents the balance. Many persons recognise this as the fly-wheel, though technically it is the balance. Through its centre is fixed a slender shaft, at each end having a small pivot for the purpose of working in the holes made for their reception, the lower one in the potence I, Fig. 1, and the upper one in a bridge above it. Immediately below the balance on this shaft—the verge—is a flat projecting blade, G, and at the lower end there is a similar one, both of which are termed pallets, the one near the balance being termed the upper, and the one below it, as might be supposed, the lower pallet. By referring to Figs. 1 and 2 there will be little difficulty in tracing the connection existing between the train and the wheels marked E F, Fig 6. Therefore, we now have to consider in what manner these two pallets of the verge, as well as the balance, serve the purpose of permitting the escape to take place.

The balance A is a rimmed wheel applied for the purpose of moving the verge and its pallets beyond that which would be natural to them without its application, for by its momentum it carries with it the verge, both being firmly riveted together. Now, the lower pallet must be first considered, as regards Fig. 6. The escape-wheel F has always an odd number of teeth, such, for instance, as 11, 13, and 15, which numbers are made use of respectively in connection with the relative numbers of the teeth of the wheels forming the train. It will be seen in the figure that the lower pallet has upon its face the point of

wheel's motion being horizontal, it is distinguished by this term. In Fig. 7, E represents a portion of the balance, and A also only a portion of the escapement-wheel. The shaft or central axis of the balance is seen at C, but may be more distinctly seen by the larger Fig. 8, which exhibits it without the balance being attached. A, the escape-wheel; B, the stem, which rises from the flat of the wheel with the tooth on its top; C, the cylinder; and D, the escape-wheel pinion. This constitutes the entire escapement, therefore the fourth or last wheel in the train acts into the pinion D, and hence motion is imparted to the escape-wheel, and the action is as follows: The escape-wheel teeth are wedges rising, as it were, upon upright pins or stems. Attached to the balance is a hollow cylinder K, Fig. 8, usually made of steel, the imaginary axis of which passes through the centre of the pivots which form the bearings. The teeth of this escape-wheel are of such length that they have very little freedom when inside the cylinder C and K, and the thickness of the cylinder is so made that there is the same freedom of the wedge teeth between the point of one tooth and the back part of the next, on the outside, as there is when the tooth is inside the cylinder. A notch or opening, K, Fig. 8, is made nearly half way down the diameter of the cylinder, the edges of which, made by this opening, are polished, the right-hand one being flanged inwards, and the left-hand one rounded, in order to allow the curved edge of the teeth to act easily, and with the least friction upon them. In this state of the cylinder, when the escape-wheel tooth entered it, the wheel could not pass, because the rim of it would touch the edge of the cylinder, therefore another opening has to be made lower down, as represented at M, Fig. 8.

While the vibration of the balance causes the cylinder to have common velocity with it, the wedge teeth being impelled by the mainspring

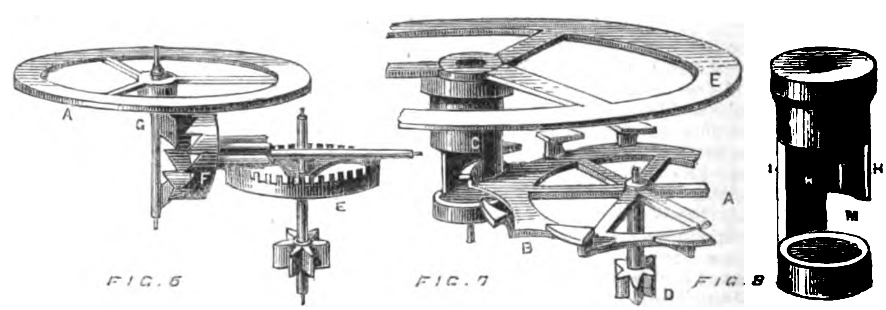

FIG. 6 FIG. 7 FIG. 8

the escape-wheel tooth, and as the train of wheels are exerting the power through the mainspring's force, that tooth must impel the balance forward in the direction of the arrow, and as the balance continues in its onward course the escape-wheel tooth, when it has passed over the entire breadth of this lower pallet, will slip or fall from it. At that instant the upper pallet will be in such a position that its face will be presented to the advancing tooth of the escape-wheel, and will receive it as it slips off the lower pallet, after which the balance, by its return motion, allows the escape-wheel tooth to fall from the upper pallet, and then the lower one is presented to receive another tooth of the escape-wheel, and this alternate motion of the balance permits the teeth of the escape-wheel to escape. Thus the utility of an arrangement termed the escapement, as has been previously stated, for without it the wheels would have revolved very rapidly; but by its introduction the time of their revolutions is considerably prolonged, for, as in the former case, the whole train of wheels would have completed their revolutions in less than two minutes. By its introduction we find that it would occupy about two days before the train required again winding up. But it may be said concerning this statement that a watch such as we have now under consideration does not continue to go for the term of two days. True; therefore when further attention has been called to the subject that important feature of the watch will be explained.

The wheel-work or train in the horizontal watch is very similar to that of the verge one. There is this difference: instead of the contrate wheel E, Fig. 6, which urges the pinion of the escape-wheel F, of the verge watch, in the horizontal one the escape-wheel is driven by a wheel termed the fourth wheel, which takes the place of the contrate wheel, and lies parallel with the frame and the rest of the wheels. Then, again, the escape-wheel itself is also parallel to them all, and that

force necessarily allow that wheel tooth to advance and enter the inside of the cylinder, and during the advance of that tooth its wedge shape presses the flanged edge H, and urges the cylinder onward, during which time the tooth succeeding approaches the opposite side of the cylinder, and the instant that the advancing tooth has left the wedge H of it, I is presented to the succeeding tooth, on which it drops; but the motion of the cylinder does not terminate at this point, for the momentum of the balance carries the cylinder onward, nearly half a turn on each side; therefore, during the oscillation of the balance, the point of the escape-wheel tooth will be resting on the circular portion of the cylinder. Then the tension of the pendulum spring will bring the balance back, and when at or near the centre of motion the succeeding tooth will commence acting on the rounded edge I of the cylinder, thereby impelling it until the point of tooth falls into the inside of it, there reposing until the balance has completed its extent of arc, and again returned to its quiescent point, at which another impulsion takes place, and thus successive lockings and escapings occur.

It may be easy to understand that, as most inventions become improved after a little time, the horizontal watch of Graham's became subject to the same rule, and so we find the fact, for although it held its place for a long time, and stood unsurpassed amongst all comers, scientific men of that and succeeding times directed their attention to improving the then best time-keeper, out of which the world has had presented to it an improvement in another form of watch.

In considering a watch of Graham's, and some even of a later date of the horizontal construction the escape-wheel calls forth from a practical person a little thought. In the first place, we find the majority of them made of brass, which is the worst material for such a wheel to be made of, for experience teaches us all that almost all cylinder watches, with steel cylinders and brass wheels, have their cylinders cut very rapidly, and hence, however correct the escapement may be made by the workman, so soon as the cylinder shows wear all is over with time-keeping. Again, the cylinder and escape-wheel teeth must have oil applied, else the watch would not go a month, that again conduces to wear the cylinder; and should the watch be one which has moderate motive power and a fair weight balance, there is the great drawback of the shape of the wedge forming the tooth, the angle being acute, the balance of such watches having about half a turn of motion, when at the best and just cleaned. Such were made by many London makers. But some few manufacturers introduced ruby cylinders, with gold or steel escape-wheels, and ultimately increased the angle of the wedge teeth; then with a little more strength of mainspring such watches kept time very well indeed. But it is very curious to observe that as the horizontal watch became gradually improved in the foregoing and a few other particulars, our French neighbours kept equal pace with us in that particular branch of industry; even the same angle of the wedge tooth was introduced from Geneva. Many still exist —of course very old watches—made by a firm in Geneva, and sold in London. Workmen may have many through their hands, and can readily distinguish such from their cases being very much bevelled off from the centre towards the edge. Such watches will never keep good time. They may also be recognised in many instances by the ratchet on the barrel, it being secured to it by three screws. Those who would wish to follow up this part of the subject more fully will do well to read "Cummings on Clock and Watch Making;" although an old work the horizontal escapement of that date is elaborately dealt with. Persons who may have Geneva watches to repair of a similar description to the foregoing will not be losers of time if they attend to a few little matters connected with the escapement. Let them be certain that the bridge which has the cylinder lower hole on it is screwed perfectly tight, for there are many which are minus the escapement adjusting screw; also that the end-piece screw is firm; these two little neglects often cause a deal of anxiety to young folk; but after the bridge of cylinder lower hole is secure, examine whether the escape-wheel is the proper depth, to ascertain which, screw the escape-wheel in the frame, and so adjust the bridge or bar that the point of the escape-wheel tooth passes exactly over the centre of the cylinder lower hole. That is a proper depth for horizontal escapement, for then the tooth, in falling from one side of the cylinder to the other, does so with the greatest mechanical advantage; but if the wheel were deep in the cylinder the blow from the escape-wheel tooth would be behind the centre, and impede the free motion of cylinder and balance, and if the wheel be very deep, I have known the pendulum spring's energy insufficient to bring back the balance for the escape, and hence the watch has stopped. Should the mainspring be rather strong that would be also greatly augmenting the defect.

THE PRIZES OF THE TURNERS' COMPANY.

THE Turners' Company of the City of London is determined to do something to encourage proficiency in the art from which it takes its name, and although the means taken may possibly not be the best for attaining the desired result, it is at any rate a step in the right direction. The competition for the silver medal and freedom of the company, which latter will include the freedom of the City, is thrown open to any workman or apprentice in England. We suppose that this is to be taken literally, and that the artisans of Ireland, Scotland, and Wales are debarred; if so, it is matter for regret, for the greater the number of competitors, the more honour will attach to the prize-winner. These competitions are to be continued annually, the materials on which the skill of the craftsman is displayed being varied each year, so as to include wood, ivory, metal, stone, &c., that for this year being "turning in hardened and tempered steel," as applied to horology—*e.g.*, the manufacture of pinions or escapements used in chronometers, watches, &c. Competitors are at liberty to select their subject for exhibition in turning and finishing, but it will be advisable to forward the complete escapement or train of wheels in position, to show the truth and accuracy of the work, the character of which will be judged of by the perfect truth, finish, and squareness of the parts, and as regards escapements by the accuracy of form and proportion for the purpose intended. Certificates will be required that the work has been done by the competitor alone during the period of the competition, and for their satisfaction the judges may require him to do a portion of similar work in their presence. In addition to the prize above named, the company's bronze medal will be awarded to the competitor whose work is found second in merit, and the company's certificate of merit to the third. The different objects must be delivered free at the Mansion House, London, during the week beginning Monday, October 21, and ending Saturday, October 26. They must be inclosed in a box or boxes, marked with a private sign or motto, and if more than one box, numbered consecutively. A list explanatory of the contents, and a sealed envelope bearing a corresponding sign or motto, and containing the name and address of the competitor, his age, if an apprentice, and in all cases a certificate of good conduct, as well as the certificate above named, must accompany the objects. This envelope will not be opened until the judges have made their report. Sir William Armstrong, Sir J. Brown, Mr. Jones, of the Strand, and Mr. S. Jackson, of Red Lion-street, Clerkenwell, will be the judges. The specimens will remain the property of the competitors, and must be removed within a week after the decision. Let us hope that one of our readers will carry off the prize.

TROTMAN'S HYDRAULIC GOVERNOR.

A NEW form of governor especially adapted for use in sea-going vessels, whether screw or paddle, has been recently patented by Mr. Trotman, who calls it the hydraulic governor to distinguish it from another of somewhat similar construction which he denominates the pneumatic governor. A really serviceable and reliable governor for steam vessels is certainly a desideratum, and whether Mr. Trotman has found a means of supplying this remains to be seen when his apparatus is tested by actual work in a rough sea. The advantages he claims for it are immediate automatic action in any position, non-liability to derangement, ease of application to any engine, and perfect command over the rate of working. Fig. 1 represents the hydraulic governor in longitudinal section, Fig. 2 being a transverse section through the middle, and Fig. 3 an elevation of the end at which connection with the throttle or steam-valve is made. A A are pump plungers working through glands into chambers, as shown; B B are cross-heads which connect the two plungers by means of rods working in guides, as seen in Fig. 2. D D are inlet or suction-valves to the pumps, and E E the corresponding outlet or delivery-valves. F is the hydraulic chamber with ram G, to the outer extremity of which the mechanism regulating the admission of steam is connected at the end H. I is a guide for the ram and a set-screw regulating the play of the spring which adjusts the ram G, tending to force it into the chamber F. P is a set-screw and conical plug limiting the area of the plug-hole connecting the delivery and suction passages S and T. V is a safety-valve capable of adjustment, and W, aperture through which the apparatus is filled with oil, water, or a saponaceous solution. With the diagrams and the foregoing explanations of the parts the action will be readily understood. The apparatus is connected to the engine or motive power by the pins C, shown in Fig. 2, and being filled with liquid and the aperture W closed, the governor is set by increasing or decreasing the amount of opening of P, by means of the hand-wheel, till the pressure in the chamber F exactly balances the counteracting pressure of the spring tending to force the ram G into the chamber F. It will be obvious, then, that if the speed of the engine is so great as to cause more of the liquid

FIG. 1

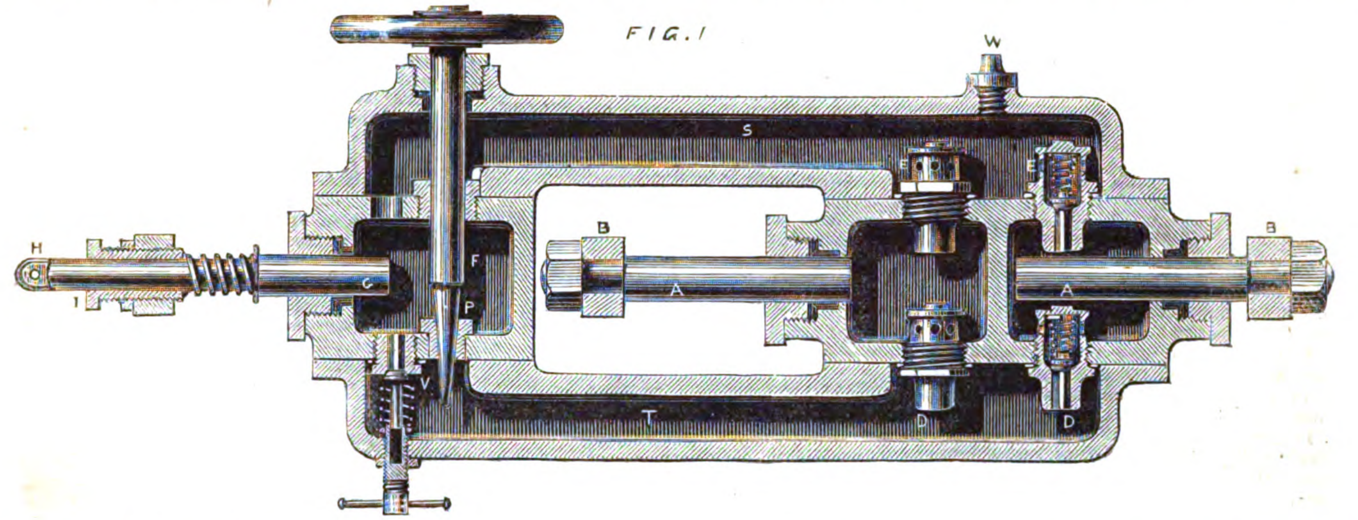

FIG. 2

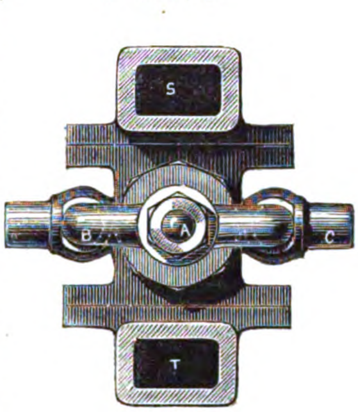

FIG. 3

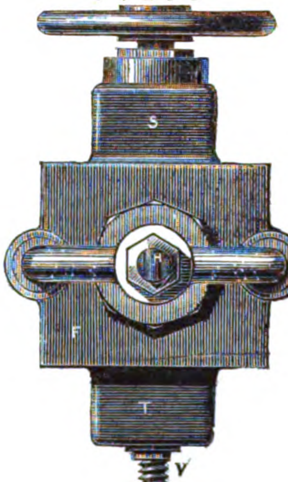


to flow through the passage S, by reason of the more rapid action of the pump-plungers A A, than can pass through the plug-hole P, the area of which is limited by the conical plug, the ram G will be forced outwards and actuate the throttle-valve or other mechanism regulating the flow of steam to the cylinders of the engine. On the contrary, when the piston is travelling slowly the pump-plungers will cause less liquid to flow to the hydraulic chamber F in a given time, the spring will force the ram G further into the chamber, and move the steam-valve in the reverse way. It will be seen that the action of the apparatus does not depend on any particular or special position of the governor, but will be exactly the same when applied to engines of any arrangement; and while from this fact specially suitable to sea-going vessels, it is also applicable to every description of machine requiring prompt and automatic regulation.

PROPERTIES OF THE GYROSCOPE.

1. IN the gyroscope, when the wheel rotates, and the ring rests on the pivot, two forces are at work—the *tangential*, residing chiefly in the rim, and the *deflective*, caused generally (not invariably) by gravity.

2. This deflective force, acting on the wheel, and impelling the free end of the axis downwards, produces an equal angular deflection laterally, in the top of the rim.

3. The deflection of the revolving matter in the top part of the rim is at right angles to the tangential force.

4. These two forces, by "composition," produce a resultant in the same plane, in an intermediate direction, determined by the relation of the angular values of the two forces.

5. Each particle of the revolving matter, in passing at the top of the rim, suffers the same deflection, and thus receives a new direction the moment the deflection takes place.

6. In other words, the tangential force is suddenly converted, or twisted, as it were, into an intermediate one; but the wheel, being rigid on its axis, can effect the change of direction which it seeks only by pushing the axis backwards horizontally to the same angular extent, *till the tangential force coincides in direction with the resultant.* (See movable diagram).

7. This receding of the free end of the axis constitutes, in fact, the *lateral, horizontal*, or *orbital* revolution of the whole apparatus, which commences immediately on its being placed upon the pivot, and left at liberty to take its own course.

8. The same deflection occurs at the *bottom* of the rim, at the same moment, in the same degree, and the effect is similar to, and conspires with, that already described.

9. The deflective force is commonly that of gravity, which is constant and accelerative throughout. Other forces, however, of an intermittent kind, may be applied, as a blow, or the upward, downward, or lateral pressure of the finger.

10. As to the remarkable self-supporting power which the wheel acquires when rotating, it is to be carefully noticed that the horizontal revolution of the axis and ring round the pivot, which has just been shown to be an *effect*, becomes immediately a *like cause* of a *like effect.*

11. Thus, while the lateral deflection of the *top* of the rim, combined with the tangential force at the same point, produces the retrocession of the axis (*i.e.*, the horizontal revolution of the ring), this revolution of the ring becomes instantly a similar deflection of the *side* of the rim, which, combined with the tangential force at *that* point, produces a like swerving of the axis *upwards.* (By *side* of rim is meant the point at right-angular distance from top or bottom.)

12. The force of the swerve upwards is equal to the primary tendency of the axis downwards, and thus one balances the other. (It is not the intention here to enter into extreme mathematical niceties.)

13. In this continued and reciprocal action consists the self-supporting power which excites so much surprise, and which can exist only so long as the orbital motion is unimpeded.

14. As the deflection of the *bottom* of the rim conspires in its effect with that of the *top*, so, in like manner, the deflection of *one side* of the rim conspires in its effect with that of the *opposite.* The same reasoning applies to every other point and its opposite—all the deflections tending to the same result.

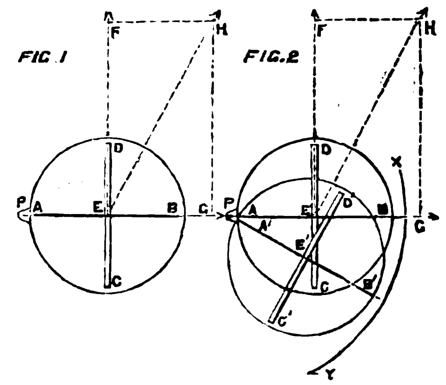
15. The law of rotation of a body on a movable axis, as illustrated in the gyroscope, though deduced in this paper from the "composition of forces," may be fully explained by the following general proposition of Frisi's, depending on the same principle. "When a body, revolving on an axis, is acted upon by a force tending to make it revolve on another, it will revolve on neither, but on a line in the same plane, dividing the angle which they contain into two parts, whose sines are inversely as the angular velocities which the body would have on the two axes, severally, under the separate conditions."

16. From the preceding explanations certain inferences follow, which may be easily tested by experiments.

(1.) When the deflective force is that of gravity, which is accelerative, the resulting orbital motion should be accelerated. This is always found to be the case.

(2.) The deviation of the resultant, and consequent receding of the axis, should be greatest when the deflective force, or downward tendency, is greatest in respect to the tangential. This, also, is conformable to experiment.

(3.) Therefore, to diminish the deflection by means of sliding weights on the contrary side of the wheel, is to lessen the orbital revolution. So, to reduce the deflection to zero, by an exact counterpoise, is to destroy the orbital motion altogether. Lastly, to increase the counterpoise so as to cause an opposite deflection—*i.e., negative* as respects the first direction—is to reverse the orbital revolution, or render it negative as respects is former direction. It may be remarked that the removal of the pivot to the opposite end of the axis, by reversing the deflection, reverses the orbital revolution.



(4.) As the tendency of the axis downwards produces the horizontal swerve, or orbital motion, and this motion in turn the upward swerve, it follows that to increase the orbital motion is to increase the upward swerve; and, *vice versa*, to hinder or destroy the orbital motion is to lessen or destroy the upward swerve or sustaining power. A very simple experiment proves this. Gently urge the receding axis with the finger, and the upward swerve will increase till the axis becomes vertical and the ring slides off the pivot. Evidently, the operation may be reversed.

(5.) If, instead of placing the apparatus on a pivot at one end of the axis, we balance it between two centres outside the ring, at right angles to the axis, and cause deflection by attaching weights or levers, we produce precisely similar effects to those already shown. In this experiment a second or outer ring is necessary to support the first, and must be left free to permit the orbital motion of the axis.

17. The gyroscope is simply a spinning-top differently mounted; that is, with distinct centres for wheel and ring. Teetotums, wheels, hoops, &c., belong to the same class of moving bodies, and are amenable to the same laws.

18. The conical motion of the axis of the spinning-top is identical with the orbital motion of the gyroscope.

19. This conical or oscillating motion of the common spinning-top is always the same way as the rotation—the centre of gravity being above the centre of motion and support. By raising the centre of motion within the body of the top till the centre of gravity falls below it the oscillation is reversed. There is here, in one respect, a resemblance to the slow motion of the earth's axis in the precession of the equinoxes.

20. The orbital motion of the gyroscope has always the *same direction as that of the rim on the side towards which the axis deflects.* Hence, if the free end of the axis deflects *downwards* the *bottom* of the rim determines its orbital direction, if *upwards* the *top.* This is an important fact to remember, as it not only includes the phenomena described in the last two propositions, but affords an *indication* of the *intentions* of the gyroscope in any given experiment. And here it may be observed how capricious those intentions seem. If when rotating it is held in the hand by a stem screwed into the ring it resists all attempts to move it in certain directions—straining and wriggling like a living thing, an imprisoned serpent—yet all the while aiming at one simple object, the *orbital turn of the axis*, on the principle laid down. It knows what it wants, and has a right to, by the laws of Nature, and it sets a good example by being content when that is attained.

The foregoing propositions, with others, can all, I am convinced, be understood and verified by any one who chooses to examine the subject attentively. They have been repeatedly demonstrated by the writer in years past by innumerable experiments, not one of which has proved inconsistent with the principles inculcated.

EXPLANATION OF DIAGRAMS.

Diagram, Fig. 1, represents the wheel and rim, as viewed from a point vertically above them. The circle is the open ring, CD the upper or visible half of the rim, E its top or highest point, AB the axis, B its free end, P the pivot EF, EG tangential and deflective forces, both acting at E; EH the resultant.

Diagram 2, a duplicate of the above, with a second circle movable about P, representing the ring in its changed position, after the orbital motion has commenced. XY denotes the direction of the orbit or line of retrocession, always contrary to the tangential force. In this figure it is shown how the axis recedes till CD, moving to C'D', has gained the same direction as the resultant EH.

N.B.—The lower circle is to be drawn on a separate paper, a pin passing through both papers at the point P.

Honley, Huddersfield. Wm. Hoyle.

IMPROVEMENTS IN PHOTOGRAPHY.

THE improvements in photography recently patented in this country by Mr. Vander Weyde, are attracting the attention of our principal professors of the art, large royalties having been paid in many instances for the exclusive right to use it in given districts. The new process, which the inventor describes as the production of mezzotint effects or "atmospheric stipples," consists in a method of combining and applying dry colours and crayons with other substances, on albumenised, glutenised, and gelatinised paper, surfaces suitable for photographic prints. The effects are rapidly, cheaply, and easily produced, and at a great saving of time and skill, the method being especially adapted to the finishing and beautifying of portrait and figure photographs, as the effects are thoroughly harmonious with their exquisite texture and delicate gradations and tones. It is well known that the surface of albumenised as well as other papers, while apparently flat, consists of prominences and indentations. Artists have observed that dry colour applied to these prominences and indentations alike gives the appearance of opaqueness and absence of atmospheric effect, and they have aimed to apply dry colour so as to touch only these prominences, leaving the tints in the indentations to shine through, so to speak, and thus secure the retiring atmospheric effect so desirable.

Mr. Vander Weyde's method gives the appearance of a very elaborate finish, such as could be attained in an approximate degree only by great labour, artistic skill, and patience. Chiaroscuro effects can by this process be produced with great rapidity by means of the luminous stippled half or middle tint which is first produced, as this tint is capable of being rapidly and readily lightened or darkened without destroying its quality, and because the size or grain of the stipple is to a certain extent under control. By this process a large surface can be treated almost as rapidly as a small one, and the process, when applied to photographic portraits or figures, has the effect of softening, subduing, and retiring the background accessories and hard outlines, and thus enhancing by contrast the solidity, brilliancy, and crispness of the head and figure belonging to an albumenised print, the character or likeness remaining unaltered.

By this process the background and drapery of a portrait photograph may be made to resemble the mezzotint effect in engraving, but with a higher degree of atmospheric effect (in any tint or colour, and with what is technically known as great breadth and freedom of touch, and a luminous quality. The effects obtained by previous attempts in this direction are not harmonious with the delicate gradations of the albumenised photograph, the chalky, raw effect, even when a stipple was obtained, being suited only to crayon drawings or rough sketches. Indian ink and water colours have also been applied with a brush, one stroke or stipple at a time. They have also been applied in the form of spray, but the effect is blotchy and inartistic. Various other methods by printing from negatives have also been used for producing stipples, but with indifferent results.

In applying the invention to a portrait photograph to be finished in monochrome, Mr. Vander Weyde prefers a comparatively fresh print, as age sometimes injuriously affects the albumen, of which the paper should have received one coat only, for if the albumen be too thick, it detracts from the artistic advantage found in the texture of the paper surface, and makes it too much like glass. The picture should be printed in vignette, the drapery fading away gradually, the background having been well masked, and the ground around the head and figure tinted very slightly by exposure to light, this tint flowing into the head and figure evenly, and the print should be as vigorous, and its tone as brilliant, as possible. It should be mounted, before drying, on a stiff, flat backing of cardboard—care having been taken to use paste or mucilage free from lumps and grit—and rolled on a steel plate before it is thoroughly dried or quite hard, using only sufficient pressure to flatten down any irregularities, though greater pressure is needed on small pictures where a fine stipple is required. The old method of rolling it on a lithographic stone of a fine grain may be used with advantage, if the surface be very smooth or glassy. The picture thus prepared, when fixed on a drawing-board, is ready for the application of the invention. About two parts of powdered pumice-stone, of a medium grade of fineness, and one part of finely crushed black crayon or pastel, preferably the softest French (though not what is known as stumping sauce) are sprinkled separately or mixed together over the surface to be treated, adding sufficient dry colour or crayon of a warm tint—such as crimson lake—to match the tone of the photograph. Then with the fingers or flat part of the hand, or a soft pad, rub this mixture over the parts to be treated, avoiding the face and all high lights not desirable to be toned down. There should be enough of the mixture used to prevent contact of the hand with the bare surface, and the rubbing should be with a slight pressure, with an even, steady, circular motion, avoiding a jerky, angular motion, and too much rubbing in one place; but all the parts should be rubbed equally and evenly as far as possible. Where a large or cross grained stipple is desired, as towards the edges of the picture, the motion should be broad and gliding, or skimming over the surface; while to obtain a fine stipple—as, for instance, immediately round the head and figure, where an increased receding effect is desirable—a quicker, closer movement is required. It is preferable to rub a little over the edges of the head and figure than to avoid them. Rub thus over all the parts to be treated several times, adding a little more crayon as it frees itself from the mixture and adheres to the surface, and occasionally blowing off the mixture to observe the effect, ceasing to rub wherever the colour has well adhered to the surface. Blow or dust off the loose mixture, when a dark, and seemingly dirty, smudgy surface appears; with the fingers apply a little of the mixture to darken any light spots or patches, then take a little powdered pumice-stone, rubbing it slightly over the whole, which has the effect of partially loosening the mixture ingrained in the surface, and further blending it. It will be observed that the effect of the pumice-stone is practically to dilute or attenuate and minutely separate the particles of the crayon, thus giving them a transparent quality which alone they do not possess; the powdered pumice-stone, or other material, being employed in a manner analogous to the oil or water used to thin or dilute the colours in oil or water-colour painting, but with this difference, that, without laboured skilful manipulations, a continuous flat tint only is obtained in oil or water-colours, however much the colour may be diluted, whereas by the use of pumice-stone with dry colour the transparent atmospheric stippled effect above mentioned may be obtained.

The effect produced up to this stage of the process can be produced also, but not so well, by first applying and rubbing the crayon on to the surface, afterwards adding and mingling the pumice-stone with it, and proceeding to rub as before, then sprinkle over all the parts treated a small portion of finely crushed, light gray, soft crayon, mixing sufficient warm colour, such as crimson lake, to match the tone of the picture, and rub this firmly over all, with the fingers, until the surface becomes quite smooth, and an atmospheric stipple appears. For the lower parts of the picture the inventor uses a crayon of a darker gray. Should the tone of the background not be in harmony with the picture, or should it be desired to darken any part of it, it may be changed by rubbing in with the finger any colour or crayon, with or without a little pumice-stone. To produce very delicate stippled effects on the white parts of the picture, such as the shirt front, or as shown in flesh when printed from hard or dense negatives, he rubs in with a piece of chamois or kid skin a mixture of gray crayon and pumice with a little colour, using plenty of pumice and great pressure. For the purpose of removing patches and obtaining an even surface, or lighting up any part desirable, pure pumice-stone may be applied with the finger, touching or lightly rubbing the parts, and thus further attenuating or reducing the depth, of colour. A little Naples yellow rubbed all over will increase the luminous effect.

Other materials may be substituted for pumice-stone, such as flour of glass, pulverised cuttle fish, and emery powder, when a brown colour is required. Dry colours also, other than crayons, may be used when combined with pumice-stone, but the crayons are best, because of their pasty cohesive nature, the Parisian softest pastels or crayons possessing these qualities in the highest degree. For the production of the above described effects in colours substitute crayons of the colour desired, in the place of black and gray crayons.

In carrying out this process the following directions for further finishing the picture and enhancing the effects may with advantage be attended to:—Wipe off the head and figure with clean chamois skin, and when lightening or darkening any part of the background relieve the shaded side of the head and figure by a light background gradually darkening towards the edge of the picture, and conversely for the light side of the head and figure. A vigorous cast shadow will always relieve the head and figure, and it should commence suddenly and boldly (yet not with hardness) on the light background next the shady side of the head, just under the shoulder of a three-quarter figure, and just over the shoulder if a head and bust. Here soft crayon sauce, warmed to match shadows of the picture, will be found more vigorous than black crayon. This part of the background should present the strongest contrast of light and shade. Ink-eraser and vulcanised india-rubber may be used with advantage to remove small patches or lines, and to put in edge lights to the cast shadow, as well as to clear up any part of the head or figure, and for high lights. The hair, eyes, eyebrows, and all strong drapery shadows in the centre of the figure, should be treated with prepared gum-water. For increasing high lights in white drapery, or linen, or jewellery, mix a little orange-chrome with thick Chinese white, to avoid a chalky effect.

MECHANISM.*

(Continued from p. 555.)

HITHERTO the communication of motion from one piece to another in mechanism has been considered as taking place only by direct contact of the pieces. The laws which govern the ratio of the velocities of the driver and follower were either obviously impressed upon the driver, as in the case of circular wheels rotating about fixed shafts, or of cams acting upon simple rollers, or sometimes, but less frequently, the law was impressed upon the combined action of the driver and the follower, as in the case of elliptical and lobe wheels, and sometimes cams acting upon cams. Whatever might be the law, the driver and follower must, in accordance with the principles before announced, be placed in communication by means of rigid bodies moving about centres or sliding in grooves. Such communication necessarily narrows the range of primary motion. The space within which rigid bodies alone can act thus, places a very great restriction on facilities for the transference of motion. Suppose it was requisite (and the case is a very common one) to convey a fractional part of an existing primary motion to one place, leaving a large amount of unutilised motion remaining. There must then be called into play a truly perplexing array of wheels, cams, and bars, rolling, oscillating, and sliding, in order beneficially to employ the remaining surplus motion.

Valuable to mechanics and engineers as may have been the deductions of the mechanician and mathematician in relation to the communication of motion by contact, the field of their operations must have been seriously contracted, from a simple incompetency to employ the heavy cumbersome means by which alone this mode could be utilised. Let any one enter a workshop or factory, where steam or water is a source of motion, and those things which first arrest his attention are not wheels, cams, and rods—they are not the rolling and sliding of material substances, each in mechanical contact with the other—but they are the straps, the chords, and the chains which are united in what is usually called wrapping gear. Take, for example, the sheds or rooms in which the weaving of cloth is carried on. They are generally on the basement floor, in consequence of the heavy weight of the number of looms placed close to each other. Curious as are other sights which varying manufacturing processes present, it may be questioned whether anything in the manufacturing line is more perplexingly curious than the strap-gearing, the, to the eye, endlessness of interlacing by which, in these sheds, motion is transferred from a supply-shaft to the recipient shafts of the respective looms. Speaking generally, there are from one hundred to two hundred, or more, of these looms in the same shed, so closely packed that those who attend to them have but narrow space in which to move. To give motion to the parts of these looms with which the mechanician is concerned, there are apparently from two hundred to four hundred straps coming from shafts generally near the ceiling. All straps are in rapid motion, and the labyrinth of these moving bands is so bewildering, and the hopelessness of penetrating with the eye through this labyrinth to the end of the sheds in which the looms are placed is so very great that there arises in the mind of an unaccustomed spectator a sense of fear rather than of respect for the skill which, from apparent chaos, brings perfect order. And further, in this same shed there is a whirr of wheels, a click of gathering ratchets, a din of beams, and sharp raps at brief intervals, now driving and now stopping the shuttles. There are material elements of varied forms seemingly endowed with life and action, each in its own sphere, disporting itself as though chaos and order were for once agreed. In the midst of these sounds and scenes the uninitiated is lost in wonder; the moving straps which cause this babel of mechanic tongues are themselves perfectly silent. Each strap is doing—what England expects every man to do—its allotted duty in its appointed way, too busy to meddle with its neighbour's concerns; and from straps such as these, thus simply constructed and sufficient for the purpose, mechanicians can now obtain from one moving shaft, without the cumbersome mechanism and contrivance which motions by contacts require, as great a variety of motions as plants obtain of flowers and fruits from the same garden soil.

For example, through the agency of straps, or of those wrapping connectors which partake somewhat of the character of straps, motion can be accelerated, as in spindles, lathes, and circular saws. It can be retarded, as in the descent of clock weights; it can cause tools to advance, as in planing and shaping machinery, or retrograde, as in empty kibbles descending mine shafts; it may be made to pause, as in punching and shearing machinery; it can remain at rest, as in the striking mechanism of a clock which remains at rest for an hour; or it may cause a combination of reciprocation, acceleration, and retardation, as in mule-spinning.

It is not only by means of straps and bands that we can communicate motion to a distance. There are many cases in which that can be done by the aid of physical and chemical laws, just in the same way as sliding contact was, by the mechanician's ingenuity and contrivance, brought to assist rolling contact, which it seemed entirely to destroy. On these aids from physical and chemical laws the mechanician is dependent for distinct motions. For example, in the relays of telegraphs and blocking of railways, electricity and magnetism are employed. In the delivery of parcels by the Pneumatic Company, blasts of wind are used; in the motion of ships, steam is employed; in the motion of project tiles, gunpowder and gun-cotton are used; in the semaphore, light is employed; and in the conveyance of sound, air is employed.

Interesting as it is to follow the ingenuities by which the contriving minds of thoughtful men have put in harness such mighty powers, and made them obedient to their will, yet duty requires that these must not now engage attention. One brief sentence at parting with some of the noblest triumphs of the human mind over the visible and invisible colossal powers of nature.

'Twas a sight not to be forgotten when Mr. James Nasmyth, with a delicacy of touch that would barely crush a soap-bubble, caused his newly invented steam hammer to gently tap an egg in a wine glass; to drive fine needles into wood, and then come down with a blow that shivered a block of oak, as though torn into splinters by a lightning flash; and all this within the space of one minute, and without any really personal effort.

Wrapping connectors are of various forms and different materials, and within limited distances are the most convenient mode for transferring motion. The purpose for which each is to be employed determines the material of the wrapper used. Stated generally—and the statement, though general, admits of but few exceptions—where the object is the transmission of motion with a view to obtain power, flat straps are used, and when that motion is very slow then flat chains may be employed. Where the object is to communicate velocity or to work up to velocity, then round bands or cords may take the place of flat straps or chains. The mode in which these straps are generally used is by means of what are called pulleys—not pulleys as we commonly understand the word. It is to be regretted that in mechanism, as in other departments, the same name is given to articles of very different character. Pulleys are really, as we are now speaking of them, simply wheels with or without rims. There are specimens on the diagram lettered A, B, C, D, E, and F. These, of which sections are given in Fig. 24, have all at one time or other been employed; they are but a selection from a very numerous class. It is really extraordinary to note how

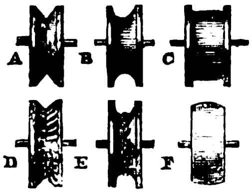
* By the Rev. Arthur Rigg, M.A., being the Cantor Lectures delivered before the Society of Arts.

prejudice or profit prompts opinions, for in pulleys the less satisfactory forms have sometimes displaced the more satisfactory ones. The selected six contain some peculiarities worth studying, for amongst them are to be found features which were once thought valuable, but would not now be employed.

A and B are smooth-grooved pulleys.

Sometimes the groove is sharp or pointed, as at A. At other times the sloping sides are rounded into each other, as at B. Those who were present at a former lecture may remember that attention was directed to the form of the sides of a large grooved pulley from the works at Crewe. The form of that groove, and the angle of inclination of the sloping sides in relation to the diameter of the rope, and the purpose for which the system was used, were then pointed out. Such a pulley would convey an amount of power, for the object of a pulley thus formed in the groove is to enable the cord which presses into the groove to drive the shaft to which the pulley is keyed. By the wedging of the cord between the sloping sides this is accomplished, and for this reason the slope of the sides and the diameter of the cord should be related. Other pulleys are arranged merely to guide the cord, and are not keyed on any shaft which must necessarily be driven by it. The groove in that case is formed as at B.*

FIG. 24



In the case of A (Fig. 24), it is essential that the cord should assume, by the force of tension and compression in the groove, something of an angular character, although only momentarily. The elasticity of the cord prevents it retaining the angular form, which is impressed upon it that the wheel may be driven. It was once thought essential, in order that a pulley might be driven by a cord, that the pulley should be roughened, or have spikes put in, as at E. The object was that the rope might lay hold of these, and so drag the pulley round. Many can remember the day when it was generally believed that railway trains could never run on smooth rails, and some of you may know that rails were laid down which were either adapted for toothed wheels, or roughened by some other means. So here it was thought that a cord could never drive a shaft through the agency of a pulley without some means of holding. Sometimes the pulley was grooved or serrated, as at D (Fig. 24), the rope laying hold on the serrated groove dragged the pulley round. Sometimes Y-shaped iron projections were fastened on the pulley, thus presenting lodgments for the links of chains, by means of which the pulley could be dragged round. Other plans for holding the chain links were also used.

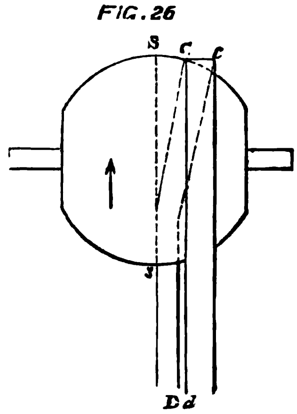
C and F (Fig. 24) are types of pulleys now in use. Those hitherto considered have been used with cords or chains. C and F are forms intended for straps. Until recent years all straps were formed of leather, latterly straps formed of gutta-percha and canvas have been introduced. Although it was found that the adhesion of the strap to the pulley gave sufficient driving-power, and so enabled mechanics to dispense with the contrivances previously named, yet it was considered that unless plans were adopted to hold the strap on the pulley it would not remain; and at the time referred to pulleys were supposed to retain the driving-band by such artificial means. Therefore pulleys, similar to C, with high edges or deep rims, were used, and the band was supposed to run between the edges or rims. Very serious difficulties encompassed this apparently simple and necessary appendage. Any mechanic who attempts it will find, that although he thus provides a way and a guide for the strap, yet the strap may be said to have "a will and a way of its own." He may persevere, and he may answer as one did when told that all facts were against a novel theory he had broached—"Then so much the worse for the facts." So here. Perseverance in a wrong opinion, however plausibly supported, cannot convert "wrong" into "right." The strap will rise up and run on these upper edges, or fray itself to pieces in the corners by attempting to rise, and so be destroyed.

Mechanics lost both time and temper in trying to keep that band in its place. It would not stop. Yet if we let the band alone it will stop where we want it to stop. It will not obey our dictation if we say you shall stop, but if we give it liberty to run off it never does. Off that plain pulley, F (Fig. 24), it never goes at all, but between those two walls on C it will not and cannot be bound. If anybody wants to destroy their bands, let them put guides upon such pulleys as this; the destruction will soon be complete.

*Many such formed pulleys are seen along the railways, guiding the cord or wire from the signal-post to the semaphore.

There is a peculiar and unexpected requirement here. A band always seeks the highest point upon the wheel, and those who take up mechanism or who take up physical science, or who take up any branch of Nature's laws, will find it their wisest plan to learn what Nature says should be done, and to seek to impress that upon what they wish to be done. We may just as well attempt to make water run up a hill as attempt to make a band run on a flat between confined walls. The proper method is to observe how a band behaves itself, and you will find it always trys to get to the highest point, in that respect imitating some of ourselves. Here (referring to a model) is a band running over a double cone, and about 6ft. lower down it runs over a cylindrical drum by which it is driven. On turning the lower drum the strap rises to the highest point of the cone. Why is that? You see it is now positively running on the edge formed by a junction of the bases of the two cones. There is no provision made to keep it there; indeed, the provision rather is that it should go down the hill, which we might think would be the easier to do; but it prefers going up and stopping at the top. The reason (now that we know the fact) is very simple—like many other facts that are easily explained when we know them. It was not so easy to anticipate it. The explanation may be given with the aid of this diagram. Fig. 25 is a rounded or coned pulley, very much distorted, in order to make the cause of the phenomenon more distinct. When a band is stretched between two pulleys, if there is any irregularity, however small it be, in the pulley or in the density of the band—we will assume it here to be in the pulley—then the line of the strap at C (Fig. 25) is clearly moving, owing to its position on the pulley, at a higher velocity than the line at c, and not only is it moving at a higher velocity, but that edge alone is conveying the power that is to be conveyed. The driving power is transmitted simply along the edge C D, because that edge is stretched and the edge (c d) is not stretched. The consequence is that the edge C D of the band touches the pulley, and the edge c d does not. Therefore, touching the pulley, it drives it, and the band being there most stretched is taken into the position shewn by the dotted lines; hence this portion of the band falls upon the larger diameter of the pulley, and is carried in a plane at right angles to the rotating shaft. A few revolutions of the shaft thus causes the edge of the band C to reach the upper or larger diameter as at S. Ultimately, the middle of the band transmits the pressure. It may not be the mathematical middle, but it is the middle, as regards density and elasticity; and although it may oscillate to one side or the other of the upper line, S, it is again driven back. It oscillates about the middle, owing entirely to the difference between the degree on which the outside and inside edges are stretched. Therefore, we have no need whatever to do anything to keep bands in their places, except give them a high point in the pulley to ride upon, and there they always stop.

FIG. 26



Another point about these bands is their great rigidity. Hence a question of some consequence arises, namely, that the pulleys should be of large diameters, and not too near each other. Nothing is more injurious to the band itself, and nothing involves a greater loss of power, than attempting to bend a rigid band round a small pulley.

So far, then, for bands and cords. Chains, however, are also used for these purposes. Chains, bands, and cords, as generally used, transfer a motion not regularly, that is to say, they do not transmit it with a definite and decided law, because there is a certain amount of sliding and slipping, and it becomes a very serious question if it is possible to arrange a flexible connector between a moving shaft and one to be moved, which shall transmit a velocity ratio identical with that which can be transferred by rolling and sliding contact. There are wheels with what may be called teeth upon them, not teeth in the sense of toothed-wheels driving other toothed-wheels, but teeth for a particular purpose, and chains made with links of a particular character, so that each link of the chain is held by a tooth of the wheel. The consequence is, that supposing another similar wheel engaged in driving this one, then the velocity ratio of those wheels would be preserved throughout the whole of the course. Thus the chain becomes, in fact, a flexible wheel with internal teeth, driving another wheel in the same direction, as it would if it was a circular wheel with internal teeth. There are other chains which hook upon hooks similar to those on the flanged pulley E, Fig. 24. A contrivance like this was used in the first mowing machine. Here are other forms of driving chains, this is one used in watches, chronometers and clocks—chains that may be bent in one direction but not in any other.

(*To be continued.*)

BRITISH ASSOCIATION.—ADDRESS OF THE PRESIDENT.

AT the recent meeting of the British Association, at Brighton, William B. Carpenter, M.D., LL.D., F.R.S., President, delivered the following address:—

Thirty-six years have now elapsed since at the first and (I regret to say) the only meeting of this Association held in Bristol—which ancient city followed immediately upon our national universities in giving it a welcome—I enjoyed the privilege which I hold it one of the most valuable functions of these annual assemblages to bestow; that of coming into personal relation with those distinguished men whose names are to every cultivator of science as "household words," and the light of whose brilliant example, and the warmth of whose cordial encouragement are the most precious influences by which his own aspirations can be fostered and directed. Under the Presidency of the Marquis of Lansdowne, with Conybeare and Prichard as Vice-Presidents, with Vernon Harcourt as General Secretary, and John Phillips as Assistant Secretary, were gathered together Whewell and Peacock, James Forbes and Sir W. Rowan Hamilton, Murchison and Sedgwick, Buckland and De la Beche, Henslow and Daubeny, Roget, Richardson, and Edward Forbes, with many others, perhaps not less distinguished, of whom my own recollection is less vivid.

In his honoured old age, Sedgwick still retains, in the academic home of his life, all his pristine interest in whatever bears on the advance of the science he has adorned as well as enriched; and Phillips still cultivates with all his old enthusiasm the congenial soil to which he has been transplanted. But the rest—our fathers and elder brothers—"Where are they?" It is for us of the present generation to show that they live in our lives; to carry forward the work which they commenced; and to transmit the influence of their example to our own successors.

There is one of these great men, whose departure from among us since last we met claims a special notice, and whose life—full as it was of years and honours—we should have all desired to see prolonged for a few months, could its feebleness have been unattended with suffering. For we should all then have sympathised with Murchison, in the delight with which he would have received the intelligence of the safety of the friend in whose scientific labours and personal welfare he felt to the last the keenest interest. That this intelligence, which our own expedition for the relief of Livingstone would have obtained (we will hope) a few months later, should have been brought to us through the generosity of one, and the enterprising ability—may I not use our peculiarly English word, the "pluck"—of another of our American brethren, cannot but be a matter of national regret to us. But let us bury that regret in the common joy which both nations feel in the result; and while we give a cordial welcome to Mr. Stanley, let us glory in the prospect now opening, that England and America will co-operate in that noble object which—far more than the discovery of the sources of the Nile—our great traveller has set before himself as his true mission, the extinction of the slave trade.

Government Aid to Science.

At the last meeting of this Association, I had the pleasure of being able to announce that I had received from the First Lord of the Admiralty a favourable reply to a representation I had ventured to make to him, as to the importance of prosecuting on a more extended scale the course of inquiry into the physical and biological conditions of the deep sea, on which, with my colleagues Professor Wyville Thomson and Mr. J. Gwyn Jeffreys, I had been engaged for the three preceding years. That for which I had asked was a circumnavigating expedition of at least three years' duration, provided with an adequate scientific staff, and with the most complete equipment that our experience could devise. The Council of the Royal Society having been led by the encouraging tenor of the answer I had received to make a formal application to this effect, the liberal arrangements of the Government have been carried out under the advice of a scientific committee which included representatives of this Association. H.M.S. *Challenger*, a vessel in every way suitable for the purpose, is now being fitted out at Sheerness; the command of the expedition is intrusted to Captain Nares, an officer of whose high qualifications I have myself the fullest assurance, while the scientific charge of it will be taken by my excellent friend Professor Wyville Thomson, at whose suggestion it was that these investigations were originally commenced, and whose zeal for the efficient prosecution of them is shown by his relinquishment for a time of the important academic position he at present fills. It is anticipated that the expedition will sail in November next; and I feel sure that the good wishes of all of you will go along with it.

The confident anticipation expressed by my predecessor, that for the utilisation of the total eclipse of the sun then impending, our Government would "exercise the same wise liberality as heretofore in the interests of science," has been amply fulfilled. An eclipse-expedition to India was organised at the charge of the Home Government, and placed under the direction of Mr. Lockyer; the Indian Government contributed its quota to the work; and a most valuable body of results was obtained, of which, with those of the previous year, a report is now being prepared under the direction of the Council of the Astronomical Society.

Man as the Interpreter of Nature.

It has been customary with successive occupants of this chair, distinguished as leaders in their several divisions of the noble army of science, to open the proceedings of the meetings over which they respectively presided, with a discourse on some aspect of Nature in her relation to man. But I am not aware that any one of them has taken up the other side of the inquiry—that which concerns man as the "interpreter of Nature;" and I have therefore thought it not inappropriate to lead you to the consideration of the mental processes by which are formed those fundamental conceptions of matter and force, of cause and effect, of law and order, which furnish the basis of all scientific reasoning, and constitute the *Philosophia prima* of Bacon. There is a great deal of what I cannot but regard as fallacious and misleading philosophy—"oppositions of science falsely so called"—abroad in the world at the present time. And I hope to satisfy you, that those who set up *their own conceptions* of the orderly sequence which they discern in the phenomena of nature, as fixed and determinate *laws*, by which those phenomena not only *are* within all human experience, but always *have been*, and always *must be*, invariably governed, are really guilty of the intellectual arrogance they condemn in the systems of the ancients, and place themselves in diametrical antagonism to those real philosophers, by whose comprehensive grasp and penetrating insight that order has been so far disclosed. For what love of the truth as it is in nature was ever more conspicuous than that which Kepler displayed, in his abandonment of each of the ingenious conceptions of the planetary system which his fertile imagination had successively devised, so soon as it proved to be inconsistent with the facts disclosed by observation? In that almost admiring description of the way in which his enemy Mars, "whom he had left at home a despised captive," had "burst all the chains of the equations, and broke forth from the prisons of the tables," who does not recognise the justice of Schiller's definition of the real philosopher, as one who always loves truth better than his system? And when at last he had gained the full assurance of a success so complete that (as he says) he thought he must be dreaming, or that he had been reasoning in a circle, who does not feel the almost sublimity of the self-abnegation with which, after attaining what was in his own estimation such a glorious reward of his life of toil, disappointment, and self-sacrifice, he abstains from claiming the applause of his contemporaries, but leaves his fame to after ages in these noble words: "The book is written; to be read either now or by posterity, I care not which. It may well wait a century for a reader, as God has waited six thousand years for an observer."

And when a yet greater than Kepler was bringing to its final issue that grandest of all scientific conceptions, long pondered over by his almost superhuman intellect—which linked together the heavens and the earth, the planets and the sun, the primaries and their satellites, and included even the vagrant comets, in the *nexus* of a universal attraction—establishing for all time the truth for whose utterance Galileo had been condemned, and giving to Kepler's laws a significance of which their author had never dreamed—what was the meaning of that agitation which prevented the philosopher from completing his computation, and compelled him to hand it over to his friend? That it was not the thought of his own greatness, but the glimpse of the grand universal order thus revealed to his mental vision, which shook the serene and massive soul of Newton to its foundations, we have the proof in that beautiful comparison in which he likened himself to a child picking up shells on the shore of the vast ocean of truth; a comparison which will be evidence to all time at once of his true philosophy and his profound humility.

Though it is with the intellectual representation of nature which we call *science* that we are primarily concerned, it will not be without its use to cast a glance in the first instance at the other two principal characters under which man acts as her interpreter—those, namely, of the artist and of the poet.

The artist serves as the interpreter of nature, not when he works as the mere copyist, delineating that which he sees with his bodily eyes, and which we could see as well for ourselves; but when he endeavours to awaken within us the perception of those beauties and harmonies which his own trained sense has recognised, and thus impart to us the pleasure he has himself derived from their contemplation. As no two artists agree in the original constitution and acquired habits of their minds, all look at nature with different (mental) eyes; so that to each, *Nature is what he individually sees in her.*

The poet, again, serves as the interpreter of nature, not so much when by skilful word-painting (whether in prose or verse) he calls up before our mental vision the picture of some actual or ideal scene, however beautiful; as when, by rendering into appropriate forms those deeper impressions made by the nature around him on the moral and emotional part of his own nature, he transfers these impressions to the corresponding part of ours. For it is the attribute of the true poet to penetrate the secret of those mysterious influences which we all unknowingly experience; and having discovered this to himself, to bring others, by the power he thus wields, into the like sympathetic relation with nature—evoking with skilful touch the varied response of the soul's finest chords, heightening its joys, assuaging its griefs, and elevating its aspirations. Whilst, then, the artist aims to picture what he *sees* in nature, it is the object of the poet to represent what he *feels* in nature; and to each true poet, *Nature is what he individually finds in her.*

The philosopher's interpretation of nature *seems* less individual than that of the artist or the poet, because it is based on facts which any one may verify and is elaborated by reasoning processes of which all admit the validity. He looks at the universe as a vast book lying open before him, of which he has in the first place to learn the characters, then to master the language, and finally to apprehend the ideas which that language conveys. In that book there are many chapters, treating of different subjects; and as life is too short for any one man to grasp the whole, the scientific interpretation of this book comes to be the work of many intellects, differing not merely in the range but also in the character of their powers. But whilst there are "diversities of gifts," there is "the same spirit." While each takes his special direction, the general method of study is the same for all. And it is a testimony alike to the truth of that method and to the unity of Nature, that there is an ever-increasing tendency towards agreement among those who use it aright;—temporary differences of interpretation being removed, sometimes by a more complete mastery of her language, sometimes by a better apprehension of her ideas;—and lines of pursuit which had seemed entirely distinct or even widely divergent, being found to lead at last to one common goal. And it is this agreement which gives rise to the general belief—in many, to the confident assurance—that the scientific interpretation of Nature represents her not merely as she *seems*, but as she *really is*.

The Scientific Interpretation of Nature.

When, however, we carefully examine the foundation of that assurance, we find reason to distrust its security; for it can be shown to be no less true of the scientific conception of Nature, than it is of the artistic or the poetic, that it is *a representation framed by the mind itself* out of the materials supplied by the impressions which external objects make upon the senses; so that to each man of science, *Nature is what he individually believes her to be.* And that belief will rest on very different bases, and will have very unequal values, in different departments of science. Thus in what are commonly known as the "exact" sciences, of which astronomy may be taken as the type, the data afforded by precise methods of observation can be made the basis of reasoning, in every step of which the mathematician feels the fullest assurance of certainty; and the final deduction is justified either by its conformity to known or ascertainable facts—as when Kepler determined the elliptic orbit of Mars; or by the fulfilment of the predictions it has sanctioned—as in the occurrence of an eclipse or an occultation at the precise moment specified many years previously; or, still more emphatically, by the actual discovery of phenomena till then unrecognised—as when the pertubations of the planets shown by Newton to be the necessary results of their mutual attraction, were proved by observation to have a real existence; or as when the unknown disturber of Uranus was found in the place assigned to him by the computations of Adams and Le Verrier.

We are accustomed, and I think most rightly, to speak of these achievements as triumphs of the human intellect. But the very phase implies that the work is done by mental agency; and the coincidence of its results with the facts of observation is far from proving the intellectual process to have been correct, for we learn from the honest confessions of Kepler that he was led to the discovery of the elliptic orbit of Mars by a series of happy accidents, which turned his erroneous guesses into the right direction; and to that of the passage of the radius vector over *equal areas in equal times*, by the notion of a whirling force emanating from the Sun, which we now regard as an entirely wrong conception of the cause of orbital revolution.* It should always be remembered, moreover, that the Ptolemaic system of astronomy, with all its cumbrous ideal mechanism of "centric and excentric, cycle and epicycle, orb in orb," did intellectually represent all that the astronomer, prior to the invention of the telescope, could see from his actual standpoint, the earth, with an accuracy which was proved by the fulfilment of his anticipations. And in that last and most memorable prediction which has given an imperishable fame to our two illustrious contemporaries, the inadequacy of the basis afforded by actual observation of the perturbations of Uranus required that it should be supplemented by an assumption of the probable distance of the disturbing planet beyond, which has been shown by subsequent observation to have been only an approximation to the truth.

Even in this most exact of sciences, therefore, we cannot proceed a step without translating the actual phenomena of nature into intellectual representations of those phenomena; and it is because the Newtonian conception is not only the most simple, but is also, up to the extent of our present knowledge, *universal* in its conformity to the facts of observation, that we accept it as the only scheme of the universe yet promulgated, which satisfies our intellectual requirements.

When, under the reign of the Ptolemaic system any new inequality was discovered in the motion of a planet, a new wheel had to be added to the ideal mechanism, as Ptolemy said, "to save appearances." If it should prove, a century hence, that the motion of Neptune himself is disturbed by some other attraction than that exerted by the interior planets, we should confidently expect that not an *ideal* but a *real* cause for that disturbance will be found in the existence of another planet beyond. But I trust that I have now made it evident to you that this confident expectation is not justified by any absolute necessity of Nature, but arises entirely out of *our belief* in her uniformity; and into the grounds of this and other primary beliefs, which serve as the foundation of all scientific reasoning, we shall presently inquire.

There is another class of cases, in which an equal certainty is generally claimed for conclusions that seem to flow immediately from observed facts, though really evolved by intellectual processes; the apparent simplicity and directness of those processes either causing them to be entirely overlooked, or veiling the assumptions on which they are based. Thus Mr. Lockyer speaks as confidently of the sun's chromosphere of incandescent hydrogen, and of the local outbursts which cause it to send forth projections tens of thousands of miles high, as if he had been able to capture a flask of this gas, and had generated water by causing it to unite with oxygen. Yet this confidence is entirely based on the assumption that a certain line which is seen in the spectrum of a hydrogen flame, *means* hydrogen also when seen in the spectrum of the sun's chromosphere; and high as is the probability of that assumption, it cannot be regarded as a demonstrated certainty, since it is by no means inconceivable that the same line might be produced by *some other* substance at present unknown. And so when Dr. Huggins deduces from the different relative positions of certain lines in the spectra of different stars, that these stars are moving from or towards us in space, his admirable train of reasoning is based on the assumption that these lines have *the same meaning*—that is, that they *represent the same elements*—in every luminary. That assumption, like the preceding, may be regarded as possessing a sufficiently high probability to justify the reasoning based upon it; more especially since, by the other researches of that excellent observer, the same chemical elements have been detected as vapours in those filmy cloudlets which seem to be stars in an early stage of consolidation. But when Frankland and Lockyer, seeing in the spectrum of the yellow solar prominences a certain bright line not identifiable with that of any known terrestrial flame, attribute this to a hypothetical new substance which they propose to call Helium, it is obvious that their assumption rests on a far less secure foundation; until it shall have received that verification, which, in the case of Mr. Crookes's researches on Thallium, was afforded by the actual discovery of the new metal, whose presence had been indicated to him by a line in the spectrum not attributable to any substance then known.

Common Sense.

In a large number of other cases, moreover, our scientific interpretations are clearly matters of *judgment*; and this is eminently a *personal act*, the value of its results depending in each case upon the qualifications of the *individual* for arriving at a correct decision. The surest of such judgments are those dictated by what we term "common sense,"

* See Drinkwater's "Life of Kepler," in the Library of Useful Knowledge, pp. 26—35.

as to matters on which there seems no room for difference of opinion, because every sane person comes to the same conclusion, although he may be able to give no other reason for it than that it appears to him "self-evident." Thus, while philosophers have raised a thick cloud of dust in the discussion of the basis of our belief in the existence of a world external to ourselves—of the Non Ego, as distinct from the Ego—and while every logician claims to have found some flaw in the proof advanced by every other—the common sense of mankind has arrived at a decision that is practically worth all the arguments of all the philosophers who have fought again and again over this battle-ground. And I think it can be shown that the trustworthiness of this common sense decision arises from its dependence, not on any one set of experiences, but upon *our unconscious co-ordination of the whole aggregate of our experiences*—not only on the conclusiveness of any one train of reasoning, but on *the convergence of all our lines of thought towards this one centre.*

Now, this "common sense," disciplined and enlarged by appropriate culture, becomes one of our most valuable instruments of scientific inquiry; affording in many instances the best, and sometimes the only, basis for a rational conclusion. Let us take as a typical case, in which no special knowledge is required, what we are accustomed to call the "flint implements" of the Abbeville and Amiens gravel-beds. No logical proof can be adduced that the peculiar shapes of these flints were given to them by human hands; but does any unprejudiced person now doubt it? The evidence of *design*, to which, after an examination of one or two such specimens, we should only be justified in attaching a probable value, derives an irresistible cogency from accumulation. On the other hand, the *im*probability that these flints acquired their peculiar shape by *accident* becomes to our minds greater and greater as more and more such specimens are found; until at last this hypothesis, although it cannot be directly disproved, is felt to be almost inconceivable, except by minds previously "possessed" by the "dominant idea" of the modern origin of man. And thus, what was in the first instance a matter of discussion, has now become one of those "self-evident" propositions, which claim the unhesitating assent of all whose opinion on the subject is entitled to the least weight.

Necessity of Special Knowledge.

We proceed, upwards, however, from such questions as the common sense of mankind generally is competent to decide, to those in which special knowledge is required to give value to the judgment; and thus the interpretation of Nature by the use of that faculty comes to be more and more *individual;* things being perfectly "self-evident" to men of special culture, which ordinary men, or men whose training has lain in a different direction, do not apprehend as such. Of all departments of science, geology seems to me to be the one that most depends on this specially-trained "common sense;" which brings as it were into one focus the light afforded by a great variety of studies, physical and chemical, geographical and biological, and throws it on the pages of that great stone book, on which the past history of our globe is recorded. And whilst astronomy is of all sciences that which may be considered as most nearly representing Nature as she really is, geology is that which most completely represents her as seen through the medium of the interpreting mind; the meaning of the phenomena that constitute its data being in almost every instance open to question, and the judgments passed upon the same facts being often different, according to the qualifications of the several judges. No one who has even a general acquaintance with the history of this department of science, can fail to see that the geology of each epoch has been the reflection of the minds by which its study was then directed; and that its true progress dates from the time when that "common sense" method of interpretation came to be *generally* adopted, which consists in seeking the explanation of past changes in the forces at present in operation, instead of invoking the aid of extraordinary and mysterious agencies, as the older geologists were wont to do, whenever they wanted—like the Ptolemaic astronomers—"to save appearances." The whole tendency of the ever-widening range of modern geological inquiry has been to show how little reliance can be placed upon the so-called "laws" of stratigraphical and paleontological succession, and how much allowance has to be made for local conditions. So that while the astronomer is constantly enabled to point to the fulfilment of his predictions as an evidence of the correctness of his method, the geologist is almost entirely destitute of any such means of verification. For the value of any prediction that he may hazard —as in regard to the existence or non-existence of coal in any given area—depends not only upon the [illegible] of the general doctrines of geology in regard [illegible] succession of stratified deposits, but still upon the detailed knowledge which he may [illegible]uired of the distribution of those deposits [illegible]articular locality. Hence no reasonably-[illegible]an would discredit either the general doctrines or the methods of geology, because the prediction proves untrue in such a case as that now about to be brought in this neighbourhood to the trial of experience.

Origin of Primary Beliefs.

We have thus considered man's function as the scientific interpreter of Nature in two departments of natural knowledge; one of which affords an example of the strictest, and the other of the freest method, which man can employ in constructing his intellectual representation of the universe. And as it would be found that in the study of all other departments the same methods are used, either separately or in combination, we may pass at once to the other side of our inquiry—namely, the origin of those primary beliefs which constitute the groundwork of all scientific reasoning.

The whole fabric of geometry rests upon certain axioms which every one accepts as true, but of which it is necessary that the truth should be *assumed*, because they are incapable of demonstration. So, too, the deliverances of our "common sense" derive their trustworthiness from what we consider the "self-evidence" of the propositions affirmed.

This inquiry brings us face to face with one of the great philosophical problems of our day, which has been discussed by logicians and metaphysicians of the very highest ability as leaders of opposing schools, with the one result of showing how much can be said on each side. By the *intuitionalists* it is asserted that the tendency to form these primary beliefs is inborn in man, an original part of his mental organisation; so that they grow up spontaneously in his mind as its faculties are gradually unfolded and developed, requiring no other experience for their genesis than that which suffices to call these faculties into exercise. But by the advocates of the doctrine which regards *experience* as the basis of all our knowledge, it is maintained that the primary beliefs of each individual are nothing else than generalisations which he forms of such experiences as he has either himself acquired or has consciously learned from others; and they deny that there is any original or intuitive tendency to the formation of such beliefs, beyond that which consists in the power of retaining and generalising experiences.

I have not introduced this subject with any idea of placing before you even a summary of the ingenious arguments by which these opposing doctrines have been respectively supported; nor should I have touched on the question at all, if I did not believe that a means of reconcilement between them can be found in the idea that *the intellectual intuitions of any one generation are the embodied experiences of the previous race.* For, as it appears to me, there has been a progressive improvement in the *thinking power* of man; every product of the culture which has preceded serving to prepare the soil for yet more abundant harvests in the future.

Now, as there can be no doubt of the hereditary transmission in man of acquired constitutional peculiarities, which manifest themselves alike in tendencies to bodily and to mental disease, so it seems equally certain that *acquired mental habitudes* often impress themselves on his organisation, with sufficient force and permanence to occasion their transmission to the offspring as *tendencies to similar modes of thought.* And thus, while all admit that *knowledge* cannot thus descend from one generation to another, an increased *aptitude* for the acquirement, either of knowledge generally, or of some particular kind of it, may be thus inherited. These tendencies and aptitudes will acquire additional strength, expansion, and permanence, in each new generation, from their habitual exercise upon the materials supplied by a continually enlarged experience; and thus the *acquired* habitudes produced by the intellectual culture of ages will become "a second nature" to every one who inherits them.*

We have an illustration of this progress in the fact of continual occurrence, that conceptions which prove inadmissible to the minds of one generation, in consequence either of their want of intellectual power to apprehend them or of their preoccupation by older habits of thought, subsequently find a universal acceptance, and even come to be approved as "self-evident." Thus the first law of motion, divined by the genius of Newton, though opposed by many philosophers of his time as contrary to all experience, is now accepted by common consent, not merely as a legitimate inference from experiment, but as the expression of a necessary and universal truth, and the same axiomatic value is extended to the still more general doctrine, that energy of any kind, whether manifested in the "molar" motion of masses, or consisting in the "molecular" motion of atoms, *must* continue under some form or other without abatement or decay; what all admit in regard to the indestructibility of matter being accepted as no less true of force—namely, that as *ex nihilo nil fit*, so *nil fit ad nihilum.**

But, it may be urged, the very conception of these and similar great truths is in itself a typical example of intuition. The men who divined and enunciated them stand out above their fellows, as possessed of a genius which could not only combine but create, of an insight which could clearly discern what reason could but dimly shadow forth. Granting this freely, I think it may be shown that the intuitions of individual genius are but specially exalted forms of endowments which are the general property of the race at the time, and which have come to be so in virtue of its whole previous culture. Who, for example, could refuse to the marvellous aptitude for perceiving the relations of numbers, which displayed itself in the untutored boyhood of George Bidder and Zerah Colburn, the title of an intuitive gift? But who, on the other hand, can believe that a Bidder or a Colburn could suddenly arise in a race of savages who cannot count beyond five? Or, again, in the history of the very earliest years of Mozart, who can fail to recognise the dawn of that glorious genius, whose brilliant but brief career left its imperishable impress on the art it enriched? But who would be bold enough to affirm that an infant Mozart could be born amongst a tribe, whose only musical instrument is a tom-tom, whose only song is a monotonous chant?

Again, by tracing the gradual *genesis* of some of those ideas which we now accept as "self-evident" —such, for example, as that of the "uniformity of Nature"—we are able to recognise them as the expressions of certain intellectual tendencies, which have progressively augmented in force in successive generations, and now manifest themselves as mental instincts that penetrate and direct our ordinary course of thought. Such instincts constitute a precious heritage, which has been transmitted to us with ever-increasing value through the long succession of preceding generations; and which it is for us to transmit to those who shall come after us, with all that further increase which our higher culture and wider range of knowledge can impart.

Matter and Force.

And now, having studied the working action of the human intellect in the scientific interpretation of Nature, we shall examine the general character of its products; and the first of these with which we shall deal is our conception of *matter* and of its relation to *force.*

The psychologist of the present day views matter entirely through the light of his own consciousness: his idea of matter in the abstract being that it is a "something" which has a permanent power of exciting sensations; his idea of any "property" of matter being the mental representation of some kind of sensory impression he has received from it; and his idea of any particular kind of matter being the representation of the whole aggregate of the sense-perceptions which its presence has called up in his mind. Thus when I press my hand against this table, I recognise its unyieldingness through the conjoint medium of my sense of touch, my muscular sense, and my mental sense of effort, to which it will be convenient to give the general designation of the tactile sense; and I attribute to that table a *hardness* which resists the effort I make to press my hand into its substance, whilst I also recognise the fact that the force I have employed is not sufficient to move its mass. But I press my hand against a lump of dough; and finding that its substance yields under my pressure, I call it *soft.* Or again, I press my hand against this desk; and I find that although I do not thereby change its *form*, I change its *place*; and so I get the tactile idea of *motion.* Again, by the impressions received through the same sensorial apparatus, when I lift this book in my hand, I am led to attach to it the notion of *weight* or ponderosity; and by lifting different solids of about the same size, I am enabled, by the different degrees of exertion I find myself obliged to make in order to sustain them, to distinguish some of them as *light* and others as *heavy.* Through the medium of another set of sense perceptions which some regard as belonging to a different category, we distinguish between bodies that *feel* "hot" and those that *feel* "cold;" and in this manner we arrive at the notion of differences of temperature. And it is through the medium of our tactile sense, without any aid from vision, that we

---

* I am glad to be able to append the following extract from a letter which Mr. John Mill, the great Master of the Experiential School, was good enough to write to me a few months since, with reference to the attempt I had made to place "common sense" upon this basis (*Contemporary Review*, Feb. 1872):—"When states of mind in no respect innate or instinctive have been frequently repeated, the mind acquires, as is proved by the power of habit, a greatly increased facility of passing into those states; and this increased facility must be owing to some change of a physical character in the organic action of the brain. There is also considerable evidence that such acquired facilities of passing into certain modes of cerebral action can in many cases be transmitted, more or less completely, by inheritance. The limits of this power of transmission, and the conditions on which it depends, are a subject now fairly before the scientific world; and we shall, doubtless, in time know much more about them than we do now. But so far as my imperfect knowledge of the subject qualifies me to have an opinion, I take much the same view of it that you do, at least in principle."

* This is the form in which the doctrine now known as that of the "Conservation of Energy" was enunciated by Dr. Mayer, in the very remarkable essay published by him in 1845, entitled "Die organische Bewegung in ihrem Zusammenhange mit dem Stoffwechsel."

first gain the idea of *solid form*, or the three dimensions of space.

Again, by the extension of our tactile experiences, we acquire the notion of *liquids*, as forms of matter yielding readily to pressure, but possessing a sensible weight which may equal that of solids: and of *air*, whose resisting power is much slighter, and whose weight is so small that it can only be made sensible by artificial means. Thus, then, we arrive at the notions of *resistance* and of *weight* as properties common to all forms of matter; and now that we have got rid of that idea of light and heat, electricity and magnetism, as "imponderable fluids," which used to vex our souls in our scientific childhood, and of which the popular term "electric fluid" is a "survival," we accept these properties as affording the practical distinction between the "material" and the "immaterial."

Turning, now, to that other great portal of sensation, the sight, through which we receive most of the messages sent to us from the universe around, we recognise the same truth. Thus it is agreed alike by physicists and physiologists, that *colour* does not exist as *such* in the object itself; which has merely the power of reflecting or transmitting a certain number of millions of undulations in a second; and these only produce that affection of our conciousness which we call colour, when they fall upon the retina of the living percipient. And if there be that defect either in the retina or in the apparatus behind it, which we call "colour blindness" or Daltonism, some particular hues cannot be distinguished, or there may even be no power of distinguishing any colour whatever. If we were all like Dalton, we should see no difference, except in form, between ripe cherries hanging on a tree, and the green leaves around them: if we were all affected with the severest form of colour blindness, the fair face of nature would be seen by us as in the chiar'oscuro of an engraving of one of Turner's landscapes, not as in the glowing hues of the wondrous picture itself. And in regard to our visual conceptions it may be stated with perfect certainty, as the result of very numerous observations made upon persons who have acquired sight for the first time, that these do *not* serve for the recognition even of those objects with which the individual had become most familiar through the touch, until the two sets of sense-perceptions have been co-ordinated by experience.*

When once this co-ordination has been effected, however, the composite perception of form which we derive from the visual sense alone is so complete that we seldom require to fall back upon the touch for any further information respecting that quality of the object. So, again, while it is from the coordination of the two dissimilar pictures formed by any solid or projecting object upon our two retinæ that (as Sir Charles Wheatstone's admirable investigations have shown) we ordinarily derive through the sight alone a correct notion of its *solid* form, there is adequate evidence that this notion, also, is a mental *judgment* based on the experience we have acquired in early infancy by the consentaneous exercise of the visual and tactile senses.

Take, again, the case of those wonderful instruments by which our visual range is extended almost into the infinity of space, or into the infinity of minuteness. It is the mental, not the bodily, eye, that takes cognisance of what the telescope and the microscope reveal to us. For we should have no well-grounded confidence in their revelations as to the *unknown*, if we had not first acquired experience in distinguishing the true from the false by applying them to *known* objects; and every interpretation of what we see through their instrumentality is a *mental judgment* as to the probable form, size, and movement of bodies removed by either their distance or their minuteness from being cognosced by our sense of touch.

The case is still stronger in regard to that last addition to our scientific *armamentum*, which promises to be not inferior in value either to the telescope or the microscope; for it may be truly said of the spectroscope, that it has not merely extended the range of our vision, but has almost given us a new sense, by enabling us to recognise distinctive properties in the chemical elements which were previously quite unknown. And who shall now say that we know all that is to be known as to any form of matter; or that the science of the *fourth* quarter of this century may not furnish us with as great an enlargement of our knowledge of its properties, and of our power of recognising them as that of its *third* has done?

But, it may be said, is not this view of the material universe open to the imputation that it is "evolved out of the depths of our own conciousness"—a projection of our own intellect into what surrounds us—an *ideal* rather than a *real* world? If all we know of matter be an "intellectual conception," how are we to distinguish this from such as we form in our dreams?—for these, as our laureate no less happily than philosophically expresses it, are "true while they last." Here our "common sense" comes to the rescue. We "awake, and behold it was a dream." Every healthy mind is conscious of the difference between his waking and his dreaming experiences; or, if he is now and then puzzled to answer the question "Did this really happen, or did I dream it?" the perplexity arises from the conciousness that it *might* have happened. And every healthy mind, finding its own experiences of its waking state not only self-consistent, but consistent with the experiences of others, accepts them as the basis of his beliefs, in preference to even the most vivid recollections of his dreams.

The lunatic pauper who regards himself as a king, the asylum in which he is confined as a palace of regal splendour, and his keepers as obsequious attendants, is so "possessed" by the conception framed by his disordered intellect, that he *does* project it out of himself into his surroundings; his refusal to admit the corrective teaching of common sense being the very essence of his malady. And there are not a few persons abroad in the world, who equally resist the teachings of educated common sense, whenever they run counter to their own preconceptions; and who may be regarded as—in so far—affected with what I once heard Mr. Carlyle pithily characterise as a "diluted insanity."

It has been asserted, over and over again, of late years, by a class of men who claim to be the only true interpreters of Nature, that we know nothing but matter and the laws of matter, and that force is a mere fiction of the imagination. May it not be affirmed, on the other hand, that while our notion of *matter* is a conception of the intellect, *force* is that of which we have the *most* direct—perhaps even the *only* direct—cognisance? As I have already shown you, the knowledge of resistance and of weight which we gain through our tactile sense is derived from our own perception of *exertion;* and in vision, as in hearing, it is the force with which the undulations strike the sensitive surface, that affects our consciousness with sights or sounds. True it is that in our visual and auditory sensations, we do not, as in our tactile, *directly* cognosce the force which produces them; but the physicist has no difficulty in making sensible to us indirectly the undulations by which sound is propagated, and in proving to our intellect that the force concerned in the transmission of light is really enormous.*

It seems strange that those who make the loudest appeal to experience as the basis of all knowledge, should thus disregard the most constant, the most fundamental, the most direct of all experiences; as to which the common sense of mankind affords a guiding light much clearer than any that can be seen through the dust of philosophical discussion. For, as Sir John Herschel most truly remarked, the universal consciousness of mankind is as much in accord in regard to the existence of a real and intimate connection between cause and effect, as it is in regard to the existence of an external world; and that consciousness arises to every one out of his own sense of *personal* exertion in the origination of changes by his individual agency.

Now, while fully accepting the logical definition of cause as the "antecedent or concurrence of antecedents on which the effect is invariably and unconditionally consequent," we can always single out one *dynamical* antecedent—the power which does the work—from the aggregate of *material conditions* under which that power may be distributed and applied. No doubt the term cause is very loosely employed in popular phraseology; often (as Mr. Mill has shown) to designate the occurrence that immediately preceded the effect; as when it is said that the spark which falls into a barrel of gunpowder is the cause of its explosion, or that the slipping of a man's foot off the rung of a ladder is the cause of his fall. But even a very slightly trained intelligence can distinguish the power which acts in each case, from the conditions under which it acts. The force which produces the explosion is locked up (as it were) in the powder; and ignition merely liberates it, by bringing about new chemical combinations. The fall of the man from the ladder is due to the gravity which was equally pulling him down while he rested on it; and the loss of support, either by the slipping of his foot, or by the breaking of the rung, is merely that change in the material conditions which gives the power a new action.

Many of you have doubtless viewed with admiring interest that truly wonderful work of human design, the Walter printing machine. You first examine it at rest; presently comes a man who simply pulls a handle towards him; and the whole inert mechanism becomes instinct with life—the blank paper continuously rolling off the cylinder at one end, being delivered at the other, without any intermediate human agency, as large sheets of print, at the rate of 15,000 in an hour. Now what is the *cause* of this most marvellous effect? Surely it lies essentially in the power or force which the pulling of the handle brought to bear on the machine from some extraneous source of power—which we in this instance know to be a steam-engine on the other side of the wall. This force it is, which, distributed through the various parts of the mechanism, really performs the action of which each is the instrument; *they* only supply the vehicle for its transmission and application. The man comes again, pushes the handle in the opposite direction, detaches the machine from the steam-engine, and the whole comes to a stand; and so it remains like an inanimate corpse, until recalled to activity by the renewal of its moving power.

But, say the reasoners who deny that force is anything else than a fiction of the imagination, the revolving shaft of the steam-engine is "matter in motion;" and when the connection is established between that shaft and the one that drives the machine, the *motion* is communicated from the former to the latter, and thence distributed to the several parts of the mechanism. This account of the operation is just what an observer might give, who had looked on with entire ignorance of everything but what his *eyes* could *see*; the moment he puts his *hand* upon any part of the machinery, and tries to stop its motion, he takes as direct cognisance, through his sense of the effort required to resist it, of the *force* which produces that motion, as he does through his *eye* of the motion itself.

Now, since it is universally admitted that our notion of the external world would be not only incomplete, but erroneous, if our visual perceptions were not supplemented by our tactile, so, as it seems to me, our interpretation of the phenomena of the universe must be very inadequate, if we do not mentally co-ordinate the idea of force with that of motion, and recognise it as the "efficient cause" of those phenomena—the "material conditions" constituting (to use the old scholastic term) only "their formal cause." And I lay the greater stress on this point, because the mechanical philosophy of the present day tends more and more to express itself in terms of *motion* rather than in terms of *force;* to become *kinetics* instead of *dynamics.*

Thus from whatever side we look at this question, whether the common sense of mankind, the logical analysis of the relation between cause and effect, or the study of the working of our own intellects in the interpretation of nature, we seem led to the same conclusion; that the notion of *force* is one of those elementary forms of thought with which we can no more dispense, than we can with the notion of space or of succession. And I shall now, in the last place, endeavour to show you that it is the substitution of the dynamical for the mere phenomenal idea, which gives their highest value to our conceptions of that order of nature, which is worshipped as itself a God by the class of interpreters whose doctrine I call in question.

"Laws," and the Power which gives Effect to them.

The most illustrative as well as the most illustrious example of the difference between the mere generalisation of phenomena and the dynamical conception that applies to them, is furnished by the contrast between the so-called laws of planetary motion discovered by the persevering ingenuity of Kepler, and the interpretation of that motion given us by the profound insight of Newton. Kepler's three laws were nothing more than comprehensive statements of certain groups of phenomena determined by observation. The *first*, that of the revolution of the planets in elliptical orbits, was based on the study of the observed places of Mars alone; it might or might not be true of the other planets; for so far as Kepler knew, there was no reason why the orbits of some of them might not be the excentric circles which he had first supposed that of Mars to be. So Kepler's *second* law of the passage of the radius vector over equal areas in equal times, so long as it was simply a generalisation of facts in the case of that one planet, carried with it no *reason* for its applicability to other cases, except that which it might derive from his erroneous conception of a whirling force. And his *third* law was in like manner simply an expression of a certain harmonic relation which he had discovered between the times and the distances of the planets, having no more *rational* value than any other of his numerous hypotheses.

Now, the Newtonian "laws" are often spoken of as if they were merely *higher generalisations* in which Kepler's are included; to me they seem to possess an altogether different character. For starting with the conception of two *forces*, one of them tending to produce continuous uniform motion in a straight line, the other tending to produce a uniformly accelerated motion towards a fixed point, Newton's wonderful mastery of geometrical reasoning enabled him to show that, if these *dynamical* assumptions be granted, Kepler's *phenomenal* "laws," being necessary consequences of them, must be *universally* true. And

* Thus, in a recently recorded case in which sight was imparted by operation to a young woman who had been blind from birth, but who had nevertheless learned to work well with her needle, when the pair of scissors she had been accustomed to use was placed before her, though she described their shape, colour, and glistening metallic character, she was utterly unable to recognise them *as scissors* until she put her finger on them, when she at once named them, laughing at her own stupidity (as she called it) in not having made them out before.

* See Sir John Herschel's Familiar Lectures on Scientific Subjects.

while that demonstration would have been alone sufficient to give him an imperishable renown, it was his still greater glory to divine that the fall of the moon towards the earth—that is, the deflection of her path from a tangential line to an ellipse—*is a phenomenon of the same order* as the fall of a stone to the ground; and thus to show the applicability to the entire universe, of those simple dynamical conceptions which constitute the basis of the geometry of the principia.

Thus, then, whilst no "law" which is simply a *generalisation of phenomena* can be considered as having any *coercive* action, we may assign that value to laws which express *the universal conditions of the action of a force*, the existence of which we learn from the testimony of our own consciousness. The assurance we feel that the attraction of gravitation *must* act under all circumstances according to its one simple law, is of a very different order from that which we have in regard (for example) to the laws of chemical attraction, which are as yet only generalisations of phenomena. And yet even in that strong assurance, we are required by our examination of the basis on which it rests, to admit a *reserve* of the *possibility* of something different; a reserve which we may well believe that Newton himself must have entertained.

A most valuable lesson as to the allowance we ought always to make for the unknown "possibilities of nature," is taught us by an exceptional phenomenon so familiar that it does not attract the notice it has a right to claim. Next to the law of the universal attraction of masses of matter, there is none that has a wider range than that of the *expansion of bodies by heat*. Excluding water and one or two other substances, the fact of such expansion might be said to be *invariable*; and, as regards bodies whose gaseous condition is known, the law of expansion can be stated in a form no less simple and definite than the law of gravitation. Supposing those exceptions, then, to be unknown the law would be *universal* in its range. But it comes to be discovered that water, whilst conforming to it in its expansion from 39¼° *upwards* to its boiling-point, as also, when it passes into steam, to the special law of expansion of vapours, is exceptional in its *expansion* also from 39¼° *downwards* to its freezing point; and of this failure in the universality of the law, no rationale can be given. Still more strange is it, that by dissolving a little *salt* in water, we should remove this exceptional peculiarity; for *sea*-water continues to contract from 39¼° downwards to its freezing-point 12° or 14° lower, just as it does with reduction of temperature at higher ranges.

Thus from our study of the mode in which we arrive at those conceptions of the orderly sequence observable in the phenomena of Nature which we call "laws," we are led to the conclusion that they are human conceptions, subject to human fallibility; and that they *may* or *may not* express the ideas of the great author of Nature. To set up these laws as self-acting, and as either excluding or rendering unnecessary the power which alone can give them effect, appears to me as arrogant as it is unphilosophical. To speak of *any* law as "regulating" or "governing" phenomena, is only permissible on the assumption that the law is the expression of the *modus operandi* of a governing power. I was once in a great city which for two days was in the hands of a lawless mob. Magisterial authority was suspended by timidity and doubt; the force at its command was paralysed by want of resolute direction. The "laws" were on the statute book, but there was no power to enforce them. And so the powers of evil did their terrible work; and fire and rapine continued to destroy life and property without check, until new power came in, when the reign of law was restored.

And thus we are led to the culminating point of man's intellectual interpretation of nature—his recognition of the unity of the power, of which her phenomena are the diversified manifestations. Towards this point all scientific inquiry now tends. The convertibility of the physical forces, the correlation of these with the vital, and the intimacy of that *nexus* between mental and bodily activity, which, explain it as we may, cannot be denied, all lead upward towards one and the same conclusion; and the pyramid of which that philosophical conclusion is the apex has its foundation in the primitive instincts of humanity.

By our own remote progenitors, as by the untutored savage of the present day, every change in which human agency was not apparent was referred to a particular animating intelligence. And thus they attributed not only the movements of the heavenly bodies, but all the phenomena of Nature, each to its own deity. These deities were invested with more than human power; but they were also supposed capable of human passions, and subject to human capriciousness. As the uniformities of nature came to be more distinctly recognised, some of these deities were invested with a dominant control, while others were supposed to be their subordinate ministers. A serene majesty was attributed to the greater gods ...sit above the clouds; whilst their inferiors ...come down to earth in the likeness of men." ...growth of the scientific study of Nature, the conception of its harmony and unity gained ever-increasing strength. And so among the most enlightened of the Greek and Roman philosophers, we find a distinct recognition of the idea of the unity of the directing mind from which the order of nature proceeds; for they obviously believed that, as our modern poet has expressed it—

> All are but parts of one stupendous whole,
> Whose body Nature is, and God the Soul.

The science of modern times, however, has taken a more special direction. Fixing its attention exclusively on the *order* of nature, it has separated itself wholly from theology, whose function it is to seek after its *cause*. In this, science is fully justified, alike by the entire independence of its objects, and by the historical fact that it has been continually hampered and impeded in its search for the truth as it is in nature, by the restraints which theologians have attempted to impose upon its inquiries. But when science, passing beyond its own limits, assumes to take the place of theology, and sets up its own conception of the *order* of nature as a sufficient account of its *cause*, it is invading a province of thought to which it has no claim, and not unreasonably provokes the hostility of those who ought to be its best friends.

For whilst the deep-seated instincts of humanity and the profoundest researches of philosophy, alike point to mind as the one and only source of power it is the high perogative of science to demonstrate the *unity* of the power which is operating through the limitless extent and variety of the universe, and to trace its *continuity* through the vast series of ages that have been occupied in its evolution.

USEFUL AND SCIENTIFIC NOTES.

A New Rock Drill.—Many descriptions of rock drilling machines have been designed within the past ten years or so with more or less satisfactory results; and although perfection in this kind of boring apparatus is possibly not yet attained, a good step in this direction has been taken by Mr. McKean, who for the last six years has been experimenting, and has at length constructed a machine which, for simplicity, facility of manipulation and application in any position, combined with strength, is believed to be unrivalled. It is driven by either steam or compressed air, and can be adapted for open cutting or tunnelling. A machine weighing 150lb., driven by 75lb. steam, drills a 2¼in. hole to a depth of 13in. per minute in Aberdeen granite. This is a maximum, but an average duty of from 6in. to 9in. may be relied on. It makes from 500 to 1,000 strokes a minute, free from shock to the machine, as the piston cushions against steam or air, and the feed is either automatic or by hand as desired. One of these drills can be seen working daily in granite at 42, Borough-road.

The Oxyhydric Light.—In relation to the oxygen light of Tessié du Motay, of which we have made mention, it may be stated that M. P. Thomas, acting under instructions from the Paris Society of Civil Engineers, has recently presented to this body a report upon the process. This report simply treats of technical advantages and disadvantages, leaving out of sight the economical question, which is somewhat to be regretted in view of the indistinct statement of the causes which have led to its removal from some of the streets of Paris where it had been introduced. The conclusions arrived at are the following:—(1) Theoretically, the combustion of oxygen does not increase the illuminating power of a given volume of gas. (2) Practically, however, it enables a burner to consume four times the quantity of gas that can be burned in air, without detriment to the utilisation of the light which may be developed. In particular, it utilises the entire luminous capacity of the gases, however rich, and in almost any quantity. Consequently, it would be disadvantageous to employ it for ordinary street-lighting, on account of the limited quantity of gas consumed by the burners, the only advantage gained being the beauty of the light, provided the gas is very rich. (Here, unquestionably, would come in the objection of expense from the complication of the apparatus.) But it is very advantageous, and the more so in direct proportion to the richness of the gases employed—for great centres of light (sun-burners, &c.), where a large volume of gas is to be consumed without loss.

Fuel in Italy.—While the scarcity of coal is alarming the inhabitants of our island, the Italians are making great efforts to utilise their own products in a way that will render them independent of the present coal crisis. Lignite is procured from the mines of Monte Rufoli, which is being more and more widely used in the Peninsula. It burns well in fireplaces without making any noise, and experiments have been made which have proved it not very inferior to the most expensive Newcastle coal, one quintal of the former being equal to three-quarters of a quintal of the English coal. This material is already being used in distilleries, and it is likely to be employed in the fusion of the iron of Elba, as it contains no element injurious to that mineral. It will be all the easier for Italy to be independent of our coal, as the inhabitants consume charcoal in their kitchens in a very economical manner, their expenditure being about one-tenth of that of an English culinary establishment.

LETTERS TO THE EDITOR.

[We do not hold ourselves responsible for the opinions of our correspondents. The Editor respectfully requests that all communications should be drawn up as briefly as possible.]

All communications should be addressed to the Editor of the ENGLISH MECHANIC, 81, *Tavistock-street, Covent Garden, W.C.*

All Cheques and Post Office Orders to be made payable to J. PASSMORE EDWARDS.

"I would have every one write what he knows, and as much as he knows, but no more; and that not in this only, but in all other subjects: For such a person may have some particular knowledge and experience of the nature of such a person or such a fountain, that as to other things, knows no more than what everybody does, and yet to keep a clutter with this little pittance of his, will undertake to write the whole body of physicks: a vice from whence great inconveniences derive their original."—*Montaigne's Essays.*

MR. PROCTOR'S GULF STREAM MAP.

[4755.]—As this map was solely intended to give true areas, "E. L. G.'s" criticism (let. 4731, p. 566) is misapplied so far as his comparison between the equal surface and stereographic projection is concerned. (Surely he does not suppose there is anything new in his remarks beginning "there is another projection quite as easy," &c. The stereographic projection is probably the oldest in existence. Its properties were perfectly well known to me. They are considered and demonstated in a simple way in my "Handbook of the Stars," published more than six years ago. They are employed in the index-maps of my smaller atlas; both of which, by the way, show much more than a complete hemisphere. I have also suggested the use of the projection, applied so as to show nearly the whole sphere as the best possible contrivance for enabling nautical men to readily plot down "great circle" courses.) The difference ("barely a third larger superficial measure") which "E. L. G." considers "truly immaterial" seems to me simply monstrous. Does he consider it a matter of indifference if an area of 3,000,000 square miles is apparently increased by 1,000,000 square miles? But he is mistaken as to the limits of my map. It includes the *whole* of the Arctic Ocean, and the whole coast line of Asia. This was essential for my reasoning. "E. L. G." will find that if the stereographic projection were applied to such a range of our earth's surface, a change of superficial scale far greater even than his immaterial (though monstrous) change would accrue.

I had no occasion whatever to illustrate forms in my article on the Gulf Stream; though I fully recognise the interest of Mr. J. Wilson's communication, relative to the direction of the currents which impinge on the shores of the British Isles. Nor could I have opened out the meridians as "E. L. G." suggests, without carrying the boundaries of the Atlantic much too far away from each other, between South America and Africa, to be included in any map of reasonable dimensions.

I venture to think that I have had a much wider practical experience of all modes of projection than "E. L. G.," having constructed more than a thousand maps on different projections; and I will undertake to say that the purposes I had in view in constructing the map "E. L. G." speaks of can be fulfilled *by no other plan* than that which I have adopted, at least, not *on any definite projection*. A mixed construction would have served somewhat better; and I began the preparation of a map on such a plan; but I found it would take much more time than I could spare.

RICHARD A. PROCTOR.

OCEANIC CIRCULATION.—CARPENTER *v.* MUHRY.

[4756.]—IN answer to "J. B." (let. 4745, p. 567), I may remark that I had his letter and some other communications in view in saying that "in the year 1869, Dr. Carpenter was first led to *advocate* the theory" in question. If I had intended to imply that Dr. Carpenter was the original inventor, I should have substituted the words "put forward" for "advocate." A student of science cannot rightly be said to advocate a theory if he is the inventor of it. At least, Webster defines "advocate" as "one who pleads for another." But as my remark seems open to misconception, I am much obliged to "J. B." for setting the matter right.

I thank "J. B." for the very gratifying way in which he speaks of my essay. I ought to remark, however, that I have no settled convictions as to oceanic circulation. The subject is one which requires an abundance of research and observation before it can be regarded as in a position for safe theorising.

I am not aware that there is the slightest evidence to prove that the Gulf of Guinea is the place whence the Atlantic circulation has its origin, as suggested by "Popularis" in letter 4746, p. 567. If I could have included the South Atlantic in my map, the Gulf of Guinea would not have appeared to be in any sense distinguished from any other part of the surface circulation. It appears to me that the main (not the *sole*) cause of the oceanic circulation is the continual withdrawal of millions of tons of water from the tropical seas through evaporation. As far as I can judge, no other cause is comparable in energy with this tremendous process of solar suction.

R. A. PROCTOR.

ENGLISH MECHANIC TURNERS' SOCIETY.

[4757.]—I AM afraid the above has fallen through again. I was in hopes Samuel Smither would have given it a start, but nothing seems to have come of it.

FABER.

SETTING MOTHS.

[4758.]—ALLOW me to mention a method of setting these which is, in my opinion, superior to those already named. After securing the insects in position with needles, an operation which will be assisted by ruling guide lines across the stretcher, wind some fine glazed thread over the wings from end to end of the setting-board, securing it from slipping by notches in the board. Three threads across each wing are enough for the largest. A slight twirl given to the needles on pulling them out will prevent them dragging up the wing.

FABER.

THE ORGAN (EXPRESSION *A LA MAIN*).

[4759.]—I AM afraid our friend "The Harmonious Blacksmith" has proposed a practical impossibility, although theoretically it is possible: all these things are possible to an organ builder who has a good enough golden glass to look through. But before looking at the uses of this expression, and some of the difficulties to overcome, let us see what is the intended use of it. If I remember rightly "expression *à la main*" was introduced into harmoniums about the year 1850, principally to allow the treble note of an air to be heard more distinctly, although it also equally allowed any other note to be strengthened, or even a single chord or a whole passage could be so strengthened, yet the idea was to allow the tune to be more distinctly heard than it usually is in harmoniums, where all the notes blend together so much as to give the idea of one rich note rather than a musical combination of various notes (in passing, I may mention Dawe's melody attachment, which is another attempt to overcome the same defect, but does it by softening every note except the highest, so that the melody or air of the tune is distinctly heard). Such being the use of the expression, *à la main*, and the difficulty to be overcome, is there anything in the tone of the organ which wants improving in a similar manner, and what difficulties are there in the way of producing such an expression? To my mind, such an alteration would be no improvement; if it is required to give the melody more distinctly than usual it can already be done by playing it on a loud stop on one row of keys and the accompaniment on another row. I do not quite understand whether "The Harmonious Blacksmith" proposes to inclose each pipe of only one stop in a swell, or to have a swell to inclose the corresponding pipes of each stop, so if the organ has 54 notes there would be 54 swell boxes, each box inclosing the pipes belonging to the same key, the latter, I presume, is his meaning. To do so the pipes would require to be planted in a single line on the soundboard instead of a double one as at present, and that would require a windchest of something like ten feet from side to side, as space would have to be allowed for the side of the swell between each pipe. Now, to my mind, expression *à la main* could only be useful—if at all—in small organs with one row of keys, in fact, only in chamber organs, and an organ ten feet wide without a case would be rather too big for most people who are content with one row organs. There is, however, a serious defect to overcome also, if the swell shuts closely, and it ought to do so; the boxes being so small, if all the stops were drawn and a note played without opening the box the pressure of wind would very quickly increase to such a degree as considerably to flatten the tone, and what would our "Harmonious" friend say then? And last of all, it does not appear to me to be required, for unless a number of mutation stops are used, the tones belonging to each key are so distinct that every note in the fullest chord is readily distinguished.

J. D.

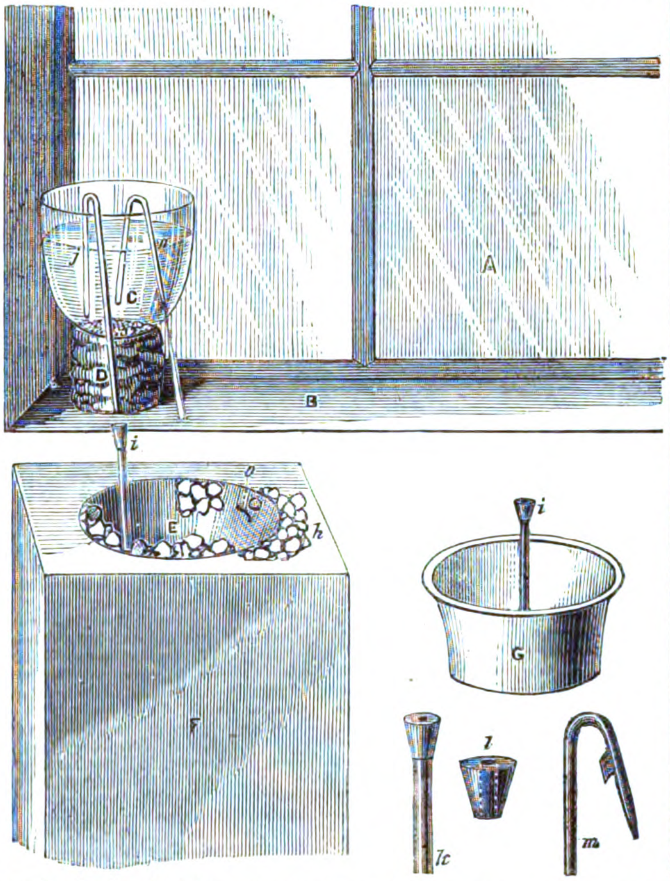
ECONOMY IN USING COAL.

[4760.]—IT is well known that most of our grates are very badly constructed, and the greater portion of the heat goes up the chimney. The sides of the grate should make an angle of 135°, with the back to reflect out the heat. Other faults are mentioned by Count Rumford.

PHILANTHROPIST.

MARINE AQUARIUM.

[4761.]—HAVING been rather successful with a marine aquarium (or rather a rock pool), I thought it likely that the readers of the ENGLISH MECHANIC would like to follow my plan, which seems to me to be good as well as cheap. On a window-sill place a moderate-sized glass globe aquarium of fresh water (see C); in this have two siphons, one short like *n*, and one long like *j*; bring a large earthenware pan about 2ft. in diameter and 9in. or 10in. deep; cover the inside of this with stones and rockwork, using pumice-stone, pebbles, gravel, and sand; in cementing the stones, &c., to the side of the pan use a cement made of two parts resin, one part beeswax; fix the pan in a rough deal table or stand, the top of which also ornament with rough rockwork (see *h*); in the crevices of the rocks plant seaweeds (sea-grass is the best); fix and cement to the pan a glass tube, reaching to the bottom (see *i*); this tube must have a cone-shaped cork (bored through the centre) fixed into it (see *k* and *l*); *m* is the shorter glass siphon, having a cork-rest fixed to it, so that it may rest on the edge of the globe when not in action. When the seaweeds have been planted in the rockwork of the pan fill up with sea-water, until a marked point is gained (see *o*). When the sea-water evaporates put the siphon of fresh water, *n*, in action, until the original level is gained; then stop the flow of the water. In some cases it is better to add the fresh water from the bottom of the pan, in which case fix the siphon *j* into the cork of the tube *i*, when the water will rise from the bottom and freshen the lower plants, &c. These rock pools may be made very cheaply, and if nicely done will afford quite as much instruction and amusement as the more expensive square glass aquariums.



A, window; B, window-sill; C, glass globe aquarium (fresh water); D, rustic stand for globe; E, large earthenware pan; F, rough deal table or stand; G, large earthenware pan before placed in the stand; *h*, rough rockwork; *i*, tube leading to the bottom of the earthenware pan to carry fresh water; *j*, siphon tube to be fixed to *i* tube; *k*, same as *i* tube, only drawn larger; *l*, cone-shaped cork, to fit into *i* tube. This cork to be bored through the centre; *m* siphon, with a cork-rest cement to it. *n*, same siphon in action.

CUPRUM.

SCREW CUTTING.

[4762.]—WITH the consciousness that I might prove of service to some of my young brother turners, I forward the following hints upon screw-cutting. I generally find that shopmates are jealous of another knowing the "tips" they have in screw-cutting, and if a beginner does not chance to be "well in" with some one who can screw-cut, he not unfrequently blunders, notwithstanding his knowledge in calculating wheels. I have not had much experience myself, but (as you would have us do) I write what I know, and no more. It is unnecessary for me to give any rules for finding wheels, as books already exist containing all the information required. My intention is to write such things about screw-cutting as I have not been able to find in books. My experience has been upon a lathe with the leading screw of 2 threads to the inch. Therefore, my remarks will only apply (practically) to that, as I have to write what I know, and no more:—If you are chasing a screw with an even number of threads in the inch, such as 2, 4, 6, &c., with the lathe screw of 2 threads per inch, you find the wheels required. Fix the tool in the box tight, then put the nut into gear with the leading screw, and set the lathe on. When it has travelled the length of the screw to be cut, you may either stop it or keep it going; take off the cut and the nut out of gear. But before doing this, put a mark on the boss of the hand-wheel fastened to the screw for working the cutter box, also on the fixing against which the boss of the hand-wheel goes, so that when you take off the cut, you can screw it to the same place again, and put whatever cut on you wish. If you have stopped the lathe, wind back the saddle a little way past the beginning of the screw; turn the hand-wheel until the marks are together again, and then put the cut on you wish to take; put the nut into gear with the leading screw, and start the lathe. Repeat this until the screw is cut. There is, however, no necessity for stopping the lathe if, as I have said before, you are cutting an even pitch; you may keep it running. When the saddle has travelled the length of the screw required, take off the cut (after marking the hand-wheel as before described) and the nut out of gear; wind back the saddle; put on another cut, then the nut into gear. There is no fear of your getting across the thread, if you put the nut properly into gear.

In cutting odd pitches, it is different, but I have found no difficulty by doing as follows:—If you are cutting (say, for example) 3 threads per inch with the leading screw of 2 per inch, and you only want the screw to be cut to be 1½in. long, if you can work the saddle farther than the length required, you may do so; thus, after making your tool and the thing you are going to cut ready, you put the screw into gear; turn the lathe round until you feel the saddle move; then put a mark behind the saddle on the lathe-bed; start the lathe; cut the 1½in.; then take the cut off, and let the lathe run another ½in., and put a mark at the other end of the saddle. The saddle has thus worked 2in.; bring it back, and do likewise. If it is not convenient for you to work the saddle farther than the length required, you may allow ½in. at the starting point. You will easily see that by letting the saddle work ½in. farther, we make the ratio between the screw to be cut and the leading screw of 6 to 4 an even pitch. One example will suffice, and I think this matter will be sufficiently understood. But should it not be convenient to work the saddle a greater distance than the length of the screw required, proceed as follows:—Put the saddle into gear with the leading screw, turn the lathe with your hand until you feel it move, then put a mark at the end of the saddle on the lathe-bed, one on the lathe-spindle and the fast headstock, just behind the face-plate, and another on the leading screw and the fixing that holds it in its place; then set the lathe on, and travel the length of the screw required. Stop the lathe, wind back the saddle to the starting mark, and then turn the lathe round until the marks on the lathe-spindle and headstock are together, and the marks on the leading screw and fixing are together; then put the nut into gear with the leading screw; start the lathe, and proceed in this manner until the screw is cut.

APPRENTICE TURNER.

NEW SOUTH WALES AND ITS METALS.

[4763.]—SINCE my last letter to you a new era has dawned on us. The golden age has been revived here, and an age of copper and tin is opening new treasures to our view. The mining mania here is now at fever heat. I will send you by this mail a copy of the *Sydney Morning Herald*, which will give you some idea of what is taking place in New South Wales at present, but it will not inform you of all that has been done in mining matters for the last few months. Since the commencement of the year to the 1st of May—a period of four months—upwards of 200 companies have been floated for the production of gold, copper, and tin, involving a nominal capital of some four millions sterling, and the floating of new companies is still in progress. Before this reaches you I have no doubt that the mineral richness of this colony will be known in England, as large shipments of metals and ores have been made for several months.

It has just occurred to me that the ENGLISH MECHANIC might be of great use in assisting the development of our resources by occasional articles on the extraction of metals from their ores. We have abundant supplies of coal and iron of the best quality, and gold and copper have for years been articles of export from these colonies, but tin is a recent discovery here, and is found in rich abundance imbedded in primitive rocks, or disseminated along the beds and banks of rivers and creeks in alluvial deposits, which are richer and purer than that obtained from mines, as by exposure to the atmosphere the pyrites originally associated with the tin is oxidised and disappears. Some of this stream tin is very rich in gold, the gold in some cases being as valuable as the tin. Now, as tin is a new product here, we want the advice of our English friends how to turn it to best advantage, and you would be conferring a great favour—which, I doubt not, would be appreciated by the colony—if some of your contributors were to publish from time to time the most approved methods of crushing, washing, and smelting the ore, and more particularly of separating the gold from the tin.

I merely throw out these hints as the mail is leaving, and you may make such use of them as you think advisable.

Sydney, N.S.W., June 15, 1872. JOHN RAE.

BEE MANAGEMENT.—DRIVING AND TRANSFERRING.

[4764.]—When it is necessary to transfer the contents of an ordinary straw skip, or box hive, to a bar frame hive, it involves the necessity of driving or drumming; names given to the operation by which bees are made to leave their combs and hive, and ascend to the hive placed above them for their reception. Given, then, a common straw skip full of combs and bees, to transfer to a bar frame hive. The first operation will be driving or drumming, henceforth by me called driving. In passing, I may say that the same process is that by which artificial swarms are made, and the presence of queens ascertained, and the queens themselves extracted if required.

Driving should be performed in the middle of the day, when the majority of the working bees are away in the fields, for reasons the most obvious—to wit, there will be fewer bees to deal with in driving, and the majority will be uninfluenced by the operation, whatever means be used, and consequently robbing need not be apprehended, as the said majority will quite be able to deal with all marauders.

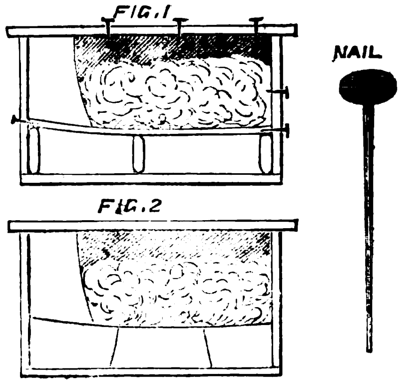
Driving is performed as follows: In the middle of the day blow a little smoke into the hive, a very little will do, and to do this the only apparatus required is a common pipe of any kind, but timid people may use a long clay. Put a small bit of tobacco in the bowl, put a lighted fuzee into the tobacco, wrap one or two thicknesses of handkerchief over the bowl, and apply the mouth to the bowl, blowing the smoke out of the waxed end of the pipe into the hive. A very little smoke must be used, or the bees will not come out with all the drumming you can give them, and if they are made drunk, they will stick in the combs as if entangled together. The reason for this is, that smoke frightens them, and their first impulse is to gorge themselves with honey as if determined to save all they possibly can of the sweets they think endangered. In that condition they are perfectly good tempered and controllable; but if too much smoke be given they become sick and drunk, and vomit their honey among themselves until they become a sticky, immovable mass.

After smoking (gently), the hive should be prised off its floor-board, and kept up, say an inch, so that the bees may be the more alarmed, and after about five minutes the hive may safely be carried from its stand; inverted, and set, if a round topped one, in a pail, if a flat topped one, on an inverted pail a few yards from the stand. An empty hive of the same size (or larger) should be set on it and another empty hive should be placed on the stand where the full hive was removed from. The empty hive is for the purpose of "amusing" the bees which return from the fields while the drumming goes on, and their astonishment at finding it there instead of the full one prevents the robbing and excitement one reads so much of. The empty hive having been fairly set on the inverted full one, a round towel should be bound tightly round their place of junction; and as a rule it will be found that the towel will go twice round, and may be secured by putting a stick in the loose fold and twisting it up tight. Then begins the drumming, so called because two sticks are used, one in each hand, to beat the sides of the lower hive. In this care should be taken not to drum too hard on the sides of the hive to which the ends of the combs are attached, for fear of causing a collapse of the whole, and it will be found that in about a quarter of an hour nearly all the bees will have ascended to the top hive. The real object of the drumming is to cause a slight jarring of the combs, a sort of miniature earthquake, which terrifies the bees and drives them out, unless they have had too much smoke.

The bees having ascended to the top hive it should be removed and set on its own stand instead of the empty one placed there, the pseudo empty one being turned over anywhere to cause the bees therein to join the main swarm, which they will readily do.

If it is required to get rid of the few remaining bees from the inverted hive—and it cannot be done with a feather—scrape a hole in the ground in front of the original stand, put the round towel into it, pour on about an ounce of chloroform, and set the hive over it for a few minutes, when it will be found quite free of bees, and it will also be found that those operated on are too full of honey and too tired to make any demonstration, all that has been written to the contrary notwithstanding. The cause of mischief is in cutting the honeycombs and filling the air with the aroma therefrom, which the bees from other hives scenting afar off come in thousands to partake of. Imperfect observers think they are the bees which have been operated on, but they, poor things, are already overcharged with honey or pollen, and have nowhere to deposit it, so why should they, or how could they be robbers? I have driven hundreds of swarms under all circumstances, and I most distinctly assert, without reservation, that a driven swarm is invariably cowed and helpless, and never volunteers a marauding attack. Transferring the combs after the bees have been got rid of is simply a mechanical operation; but had better be performed by an amateur in a room to which the bees have no access, for if they be allowed to taste the honey within doors, they will speedily and for several days become a nuisance to the household. The tools which will be necessary are a sharp carving knife, a large dish, a few strips of thin deal just a trifle longer than the frames are from front to rear, inside, a few wine corks, a fine awl, a few strong pins or nails, and little wooden rack or grating similar to a small hurdle. Lay the grating on the dish, and the frame on the grating, cut the hive containing the combs slick through between the two centre combs, and then cut out comb cleanly, and lay it in the frame. If it comes out of a flat-topped hive it will fit close along the upper bar of frame; but, if from a round-topped hive, it will require cutting to fit. Remember the comb must always be attached to the top bar of frame, and to one or both sides if possible. If it is too large or wide for the frame, cut away the parts containing honey, and let them fall through the grating into the dish, and crowd the comb into the frame with the knife, and if it fills the frame, a few pins or nails through the frame will hold it in its place until the bees have time to fix it permanently—hence the necessity for an awl, to bore the holes through the frames. Flat-headed slate nails will answer admirably for the purpose, they are about 1¼in. long, fine, straight, and clean, and are cheap. In fixing the comb by them they should not be thrust into the centre of the combs, but just a little on either side alternately, for the centre or foundation of the comb is much stronger than the cells, and if the pins are on both sides of it it cannot fall out. If the combs are too small, and will not fit or fill the frames, the best plan is to fit it to the corner of the frame, as in Fig. 1. Place one of the deal strips under it, and press it up tight with two or three of the corks, pin it in as shown, and raise it up to a perpendicular by raising up the grating so as not to cause any strain on the comb or fixings. The corks act capitally as blocks to keep up the strip at bottom of comb, and standing solid are not likely to turn or fall. The comb is now ready to put into the hive, and being a centre comb should be put into the centre of it. The other combs should be treated in a similar way, taking care that the combs are put into the new hive in the same order they were in the old hive, so as to keep all the brood together, and as soon as completed the whole should be taken to the original stand, and the bees smartly shaken into it.

It seldom happens that the contents of a straw skip will fill all the frames of a bar frame hive, but as it is much better to have six full frames than ten partly filled, I recommend my readers to fit in only such combs as contain brood, at the first operation, for a second operation is always necessary to remove the nails and strips, or wires, or whatever may have been used, for it is pretty certain that almost everybody will adopt some improvements of his own. To remove the *impedimenta* give the bees a little smoke as before, lift out one of the combs, brush all the bees off it, and carry it into the operating room—keep it perpendicular as it hung in hive, place the grating behind it, and lay it down on the dish, then draw all the nails, and remove the corks and wood, leaving the frame as in Fig. 2, the vacancies of which may be filled up with the reserved combs as suggested by the dotted marks.



This will be found a much better plan than attempting to fill up the whole frame at once with several pieces of comb, as is generally recommended, and will suggest to many persons who keep bees on the old plan an easy method by which the lives of their bees may be saved, and the portions of comb which contain brood and pollen, and which have generally been thrown away may be utilised. Any one with three or four stocks of bees which they wish "to take" may by this means save such a tremendous stock for next year as will make him wonder how he could have been for so long what Mr. Langstroth calls an "Old fogey bee-keeper."

Let me add a word of caution to my bee brethren. If you have any weak stocks to unite do it now; if any to feed, do it now, and give the bees a chance of evaporating the moisture out of it and out of the hive before the cold weather sets in. Cold and dry will never hurt bees, but cold and damp mean dysentery and death.

C. N. Abbott.

SOLUBLE GLASS.

[4765.]—As I have often seen inquiries about soluble glass in your columns I send the following, which may interest several of your readers. Soluble glass is simply a variety of purely alkaline glass in which the alkali is in excess. Ordinary window glass is a compound of silica with potash or soda, and in some cases lime; oxide of lead added to the compound of silica and potash or soda, gives flint glass; Bohemian glass is a compound of silica, soda, and lime; and the coarse glass used for bottles contains much iron and some alumina, which is the base of clay. According to the quantity of alkali employed, the glass will be soluble or insoluble, it being understood that all glass is soluble to a certain extent. Old window panes that have been exposed to the elements for years are in general so corroded that their surfaces are no longer perfectly transparent; and common flint glass, when finely powdered, dissolves in water to such an extent that its presence can be detected by the least delicate reagents. But when the proportion of alkali is largely increased, and especially when the compound consists of pure alkali and pure silica, we obtain a glass which dissolves entirely in water, and which may be applied as an incombustible varnish to wooden articles, or used as a cement, or as a coating for brick and stone. Soluble glass was first brought into practical use by Prof. Fuchs, of Munich, in Bavaria, in the year 1828, and hence is frequently known as Fuchs' soluble glass. At first it was prepared by fusing ten parts of pearlashes, fifteen parts of powdered quartz, and one part of charcoal together, and pulverising the mass, which was then added in small portions at a time to boiling water until the whole was dissolved. The solution was then evaporated to a jelly-like consistency, when it was ready for market. More recently it has been found that certain varieties of silica are soluble in a boiling solution of caustic soda; and also that, when the temperature of an alkaline solution is greatly increased, which may be done by boiling it in a close vessel under great pressure, flints and other hard varieties of silica dissolve rapidly. It is in this way, we believe, that Ransome prepares the soluble glass used in the manufacture of his famous artificial stone. It is therefore obvious, from a consideration of these methods, that soluble glass is readily prepared; and, as the materials are comparatively cheap, there is no reason why it should not come into very extensive use, provided it should prove really valuable in the arts.

The first notable application of soluble glass was to the theatre of Munich, where it was used for the purpose of preventing the recurrence of a fearful disaster by fire. Before trusting to its protecting qualities, however, a test was made of its powers, and a small building coated with soluble glass was erected in one of the public squares, and attempts made to fire it at several points, by placing small heaps of light wood in contact with it and setting these heaps on fire. Of course, where the flames came in contact with the building, the wood of which it was made was charred, and to a certain extent destroyed. But in no case did the building itself take fire or burn; and the test was deemed so satisfactory that the theatre was immediately coated in such a way as to be made fireproof. Since that time, it has been applied in many cases, and always with success when the application was made with a moderate amount of skill. That it might be used extensively for preventing fires, and for adding to the durability of all wooden structures, is unquestionable; and therefore a few hints as to the best methods of using it may not be out of place. These hints we are enabled to give more readily, since the whole subject was carefully investigated by the celebrated French chemist Dumas, who has, in his "Traité de Chimie appliqué aux Arts," detailed very fully the results at which he arrived. He found that, although soluble glass is of itself a good preservative from fire, it fulfils the object better when it is mixed with another incombustible body in powder. Clay, whiting, calcined bones, powdered glass, &c., may all be employed for the purpose, though it is difficult to decide which of them is the best. A mixture of clay and whiting appears to be better than either used separately. Flint glass, and the crude soluble glass as it comes from the furnace, are excellent additions. The powdered soluble glass ought to be exposed to the air until it has attracted some moisture; after which, if it be mixed with the solution and applied to any body whatever, it will in a short time form a coating as hard as stone, which, if the glass be of good quality, is unalterable by exposure, and resists fire admirably. When soluble glass is used for rendering wood fire-proof or indestructible, it is always well to apply, in the first place, a coating of the pure glass. The pores are in this way filled up; while, if we use a thick and paint-like mixture of the solution with some powder, the liquid does not penetrate beneath the surface, and much of the effect is lost. When properly prepared, soluble glass, after being dried by exposure to the air, suffers a change which renders it incapable of being washed off. The alkali not being completely neutralised in this form of glass, it is difficult to apply oil paint to woodwork that has been treated with it; but this objection might be remedied by treating the prepared surface, when dry, with a weak solution of acid.

G. J. H.

ATOMIC PROPORTIONED ALLOYS.

[4766.]—In the report of Mr. Laird's lecture on "Cast Iron," p. 534, the composition of speculum metal is given as "about two of tin to one of copper," which would be nearly that of their atomic weights. But are not the proportions here reversed? In Mr. E. B. Denison on Bells ("Lectures on Church Building," p. 283) he says "Lord Rosse adopted *multiples* of the chemical equivalents, or atomic proportions for combination, of copper and tin for his great 6ft. speculum. They are copper 32, tin 59, very nearly; and for speculum metal 4 equivalents of copper to 1 of tin give nearly the usual ratio of 2 to 1 in weight. For bell-metal 6 equivalents of copper to 1 of tin will give very nearly 15 to 4" (an error for 13 to 4), "which would probably be produced by putting the metals in the proportion of 2 to 7, as before recommended. It is impossible and useless to be very precise, because the waste of the tin in melting is not uniform, but is greater the longer it has to be kept hot."

With the latest values for the equivalents, the above atoms for speculum metal would give copper 13 to tin 6 very nearly; which might result from mixing 2 and 1, if the loss of tin by evaporation be about 8 per cent. I cannot anywhere find the reverse proportion stated; and the only case I have seen of an alloy directed to be made in what are now known to be the single atomic weights or near them, is the alloy of silver 2 and antimony 1, for penetrating glass with the red orange stain referred to in reply 12108, p. 544. In connection with this subject, can your chemical contributors tell us of any alloy having its more fusible component in excess? It seems to me as if the opposite rule, the less fusible metal to prevail in quantity, had the force of a law in useful alloys. E. L. G.

A NEW MATERIAL IN ORGAN BUILDING.

[4767.]—"SUCRAM" may rest satisfied that his suggestion, if not a new one, is of a practicable and useful character. Some years since I made a small bird-organ of pipes formed of waxed cartridge-paper, whose performance was "very tidy." It was only of 3 octaves compass, tuned in the key of C natural. It convinced me that the thing was feasible, and, in better hands, would, for amateur attempts, prove often convenient and satisfactory. From want of experience, I cannot say whether paper would answer well for larger pipes. I should think it would not for large ones. I found the tone was modified by the thickness and homogeneity, as also the solidity, of the walls of the pipe. I also made a paper flute, the tone of which was satisfactory, although, from my clumsiness and inexperience, it was not of much use, being considerably out of tune. Has "Sucram" tried guttapercha for small pipes? Pipes made of it give out a very sweet tone. A friend of mine devoted much time to making a guttapercha cornopean. Many were his failures before he succeeded in producing a satisfactory one, but the results amply rewarded him, as an amateur, for the time and labour he spent on it. The guttapercha, for this purpose, must be of the best quality and commercially pure; indeed, quite equal in quality to that used for insulating the copper wire of submarine telegraphs. The pipes must be made slightly longer than required, and, after being thoroughly seasoned, tuned and varnished.

AROTES.

[4768.]—I HAVE read Dr. Ussher's note in answer to mine upon a new material in organ-building, let. 4637, and am rather surprised at one or two remarks, which most likely he would not have made had he taken a little more time for consideration. I thank him for the little credit he awards me for my enthusiasm; but I certainly shall be sorry to find any of our amateurs running off on a wrong track, who, I think, cannot possibly do so, because those who enter upon the task of building an organ for themselves (it being to such I address myself principally), would certainly not run far before taking that consideration necessary for such an undertaking, and so try an experiment or two by way of proof to prevent the useless cruelty I am charged with. Knowing as I do that professionals, as a rule, will not teach others any more than they can possibly help, true it is that metal-pipe making must be learned at the bench; but these are things which a great many amateurs cannot get at, and are obliged to do without them, at the same time they must have an organ and build it themselves entirely. Dr. Ussher will find that I have not said, nor even hinted, that I recommend paper instead of metal, far from it; but I do say that paper may be turned to some account in organ-pipe making, in addition to the rest of materials, and so introduce means of producing tones of a character different from those brought out by the present range of materials. Dr. Ussher seems to forget that if an organ of (say) eight stops (four wood and four metal) were put up in a cottage and played full, it would drive everybody out of the house, and this entirely on account of the metal, whereas if the stops were four wood, three paper, and one metal (if metal must be used), it will be much softer and give the same variety. And as to the tuning and voicing, I must say there would be no difficulty, because it is only the cylinder I would have made of paper, so that the parts of a pipe concerned in the voicing would be made of wood like all wood pipes, and open to the same means as usual for that purpose, and as to tuning that would be simple enough. It does not follow that because the cone is used to metal that it must be used to paper; the means for tuning would suggest itself to any mind of moderate contrivance. He says, "Another medium may be got as good as wood, but would it be worth the trouble." I say name the medium, and some of us will try it, as I want some one to try mine, and as to the cat and king, I think one is as good as the other, when both are made of paper, neither of which will help us either in or out of a difficulty, but paper I feel sure, would, with the assistance of wood and metal. Perhaps I had better say before closing my remarks what I know to have been done by way of experiment. A cylinder was made of paper entirely, 9ft. in length, tapering from 1in. inside diameter at the bottom to 8in. at top; it was very hard, straight, and varnished inside and outside, and put upright and allowed to fall on to a stone floor for the purpose of trying its stability, which was found to be quite as good as before. Then it was slipped into a short tube made to receive it, the same tube containing a large striking reed similar to those used in a trumpet-stop, then it was blown by means of a small wind-chest and feeder made for the purpose of trying experiments. And now for the evidence obtained at the trial. A young man who has had some years of experience in an organ factory was brought into the adjoining room so that he might not see it before hearing it, and so give his candid opinion on it, and after expressing himself satisfied with its tone, he was taken into the room where it was, and there expressed his surprise at the result from such material, saying it was very good indeed, and that the pipe had been far more severely tried than it would be under usual circumstances. The reed was 4in. long, $\frac{3}{4}$in. wide, and rather thicker than usual, requiring very little wind. SUCRAM.

PIANOFORTE CONSTRUCTION.

[4769.]—"ONE WHO DESIRES TO BE INSTRUCTED" (let. 4665, p. 539) cannot see that the bridge in a pianoforte is the lever with which the string sets the soundboard in vibration. He thinks the string rises and lowers the soundboard bodily. I am pleased to think that I can show now more clearly than I have done before that the lever moves in a radius whose centre is according to the construction of the soundboard, in the bar, or soundboard, or if no bars are behind the soundboard may be within the lever itself. For economy's sake I avail myself of the opportunity to show the vibration of the breast of a violin at the same time. Fig. 1 is a section of a violin, and if at rest we may suppose the breast and back waveless, but when the bow is drawn across the string the latter will stick for a small interval of time to the bow, and consequently will be drawn out of its straight line, and that will increase its tension, press heavier on the bridge, and make an impression on the breast. At the same time it will pull on the neck and nut, which form levers to the back, which will be drawn towards a straight line; but that can only be done when the soundpost is making an impression underneath the breast. Leaving it in that position for a moment, I must say that if the breast is $\frac{1}{8}$in. thick, the soundpost should be $\frac{1}{4}$in. away from the bridge, to allow the two opposite pressures to create a full half wave, as seen in Fig. 1. Now, the string releases itself from the bow and springs back in a straight line, and the extra pressure is gone and the breast is waveless again. Of course the number of waves so created in a second depend upon the tension of the string. Fig. 2 is the same as Fig. 1, with the exception of the soundpost, and it will be clearly seen that if we go through the same experiment as before, the breast and back will move bodily in the dotted line and back again at each deflection of the string. Fig. 3 is a section of a piano, but before I describe its meaning I must cite a practical experiment of the brothers Weber, the description of which will be found in "Wellenlehre," p. 1, table 1, Fig. 1. If a rope or a string is struck with a hammer near one of its ends, it makes an impression on it, or as we will call it, a wave. This wave, when the hammer is drawn back quickly, will run along the string until it is checked on

FIG. 2

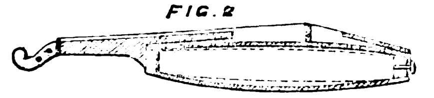


FIG. 1

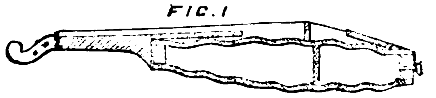

FIG. 3

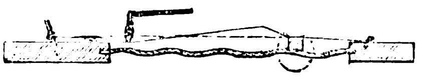

FIG. 4

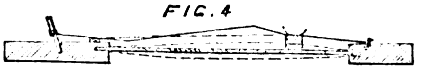


the other end, then it will spring up to the opposite direction in which it came and return, spring in its original position, run along again, and so on, 1 2, 1 2, until it comes to rest again. Now, in Fig. 3, we see a hammer creating a wave on the string which, as above stated, will run along the string, and before it meets the lever will give it a turn towards the soundboard, then the wave will spring up in the position in which it returns and draw the lever back, and besides this the longitudinal vibrations of the string cannot act otherwise on the lever, but move it in a radius (see dotted line). Fig. 4 simply shows the transversal or bodily vibration of the soundboard, as in the violin without the post (see dotted lines in Figs. 2 and 4). Before I describe the different characters or timbre of the sound so produced I beg to cite Pellison. His opinion is derived from practical experiments. Pellison found that that construction of a soundboard is the best which prevents its vibration transversely or moving as a whole. However, such construction should not destroy its inner elasticity. See Dr. Oscar Paul's "Geschicte des Claviers," p. 15. "One who Desires to be Instructed" refers to an experiment made by Dr. Tyndall with a rod put vertically on a tray or box, the description of which will be found in his book on "Sound," p. 80, which I beg to say shows nothing in this respect, for Dr. Tyndall did not construct the box in such a form as to produce the loudest or clearest tone, but simply shows the transmission of the vibration of a tuning-fork through a long rod to the box. If the soundboard of a pianoforte is constructed so loose that it can vibrate transversely, the timbre of the tone is what "The Harmonious Blacksmith" properly calls "harpy;" but the tone of a harp can be produced by fastening a string on a common door panel or any unscientifically-constructed box or board. Many people think it a very sweet tone, but it is not the tone which highly-educated musicians patronise, for it is the least clear, or, if I may say so, the unclearest tone produced; vocally speaking, it borders on hoarseness. And besides this, I dare to say no instrument produces more than two or three octaves of this so-called sweet tone; the treble as well as the bass must always be wretched. The tone we want must be clear, no matter what peculiar character it has derived from the instrument by which it is produced. If we hear the voice of a good singer, we cannot fail to detect a delicate beating or pulse in it. The meaning of this is most highly valued by "The Harmonious Blacksmith's" friends, the pianofortetuners. Next after the human voice is the musical-box, the concertina, the harmonium, and organ.

J. H. SCHUCHT.

PIANOFORTE TUNING-KEY.

[4770.]—IN reply to "Bedca" (let. 4672), I designed two or three years ago, and with the assistance of a clockmaker, constructed a pianoforte tuning-key exactly on the same principle as the one illustrated on p. 540, with this difference; mine consists of two eight-leaved pinions and two forty-eight toothed wheels. If "Bedca" carries out his idea he will find that the spindle E F should not be fitted into a square hole in the handle G H, because it has the effect of making it work like an ordinary tuning-key, on account of the fulcrum and lever being moved together. The frame-plate should be held steady, and the spindle turned by another key. JAS. OULTON.

BLINKERS REMOVABLE.

[4771.]—IT was a learned man who once wrote that "early prejudice is stronger than the power of reason," and I think it is conceded that all unbiased minds have accepted the assertion as well founded. Being very unlearned (not all my own fault), I will not make a similar assertion, but offer an opinion that fashion exercises a greater power over the million than does reason, and that a vast amount of suffering both to the million and to the million's animals is the result.

Now, in East Kent it is the fashion for all farm horses to wear blinkers when drawing carts or waggons; in the fields, at plough, harrow, roll, or in Suffolk drill they are never used, as what is called the plough harness is not furnished with them, but the cart-harness is. If a farmer of that district purchased a horse from any of the adjoining counties where they are worn at field work, he would not for a moment think of sending him to plough in blinkers—it would not be the fashion, and the animal would not run away from his companions, at least, I never heard of such a case. I could mention instances of horses running away from another cause, but space forbids.

OLD PLOUGHMAN.

THE "FALLACIES OF DARWINISM."

[4772.]—NOTHING can more clearly show the *animus* which pervades the mind of the reviewer of my book than the paltry nature of his criticism and its misrepresentations. I will give an instance of each.

1. The paragraph about the two lines of religion and science is, I admit, unfortunate, but it had already been altered for future use. Instead of running "parallel," if your critic had simply told us it ought to have been "opposite," a good deal of ill-nature might have been spared.

2. The reviewer has misrepresented me to have said, "Speaking of the vivid colours of birds, Dr. Bree says they are produced by striæ of pigments which decompose the light, and enable the feathers to absorb the most brilliant rays."

What I did say was the following:—"To make a certain colour in a bird's plumage, either colour pigment is deposited in appropriate cells, or the little barbules are striated so as to decompose the light, or both of these means may be found in the same feather. But to make this colour, it may require 10,000 gradations either in the pigment or in the length or depth of the microscopical striæ on the barbules. Dark pigment here and lighter there—striæ which will decompose the light, and enable the feathers to absorb the most brilliant rays, and so commingle them as to produce the most vivid, the most varied, the most beautiful colouring in the world." (Page 230.)

Colchester. C. R. BREE.

[It is unnecessary for me to deny that any "*animus* pervaded my mind" when reviewing Dr. Bree's book. Whether the criticism is of a paltry nature, and guilty of misrepresentation, are questions that readers are evidently better able to decide than Dr. Bree. The word "parallel" is, no doubt, "unfortunate;" it is also very unfortunate that it should be attributed to Mr. Spencer—at least for Dr. Bree; because it is one of those mistakes which cause a writer's statements to be regarded with suspicion. Now, with respect to the "misrepresentation," Dr. Bree has apparently overlooked the meaning of the italicised word—"absorb," and has omitted the concluding part of the sentence; but this is immaterial, as he supplies the whole passage from his book, and many of his readers will doubtless wonder how feathers can produce the "most beautiful colouring in the world" by *absorbing* the "most brilliant rays" of the spectrum. Truly, this is a "misrepresentation"—of the theory of light and colour. I may here mention two errors which do appear in my review: "striæ of pigments" should be "striæ *or* pigments;" and the reply to M. Flourens by Professor Huxley was originally published in the *Natural History Review*, and is reprinted in his "Lay Sermons."—THE REVIEWER.]

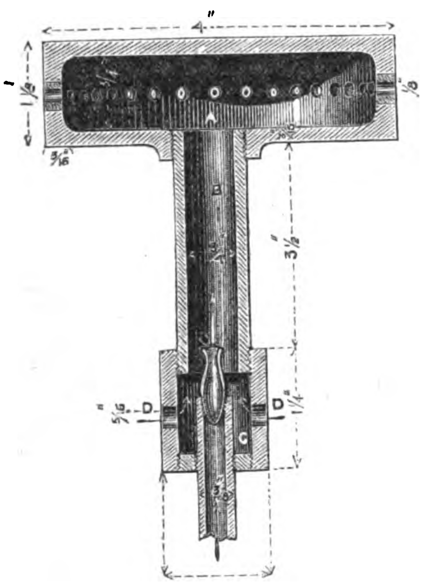
TESTS FOR TELESCOPES.

[4773.]—OF "F.R.A.S.'s" tests, the following are the results, taken from my observatory book:—τ Aquilæ, pretty well divided, well seen at times; λ Ophiuchi, well separated, colours yellowish and bluish; 73 Ophiuchi, not well seen, like an hour-glass. (In these observations the air was unsteady.) ζ Boötis, elongated pear-shaped; ϵ Equulii, well elongated. The rest I have not had the opportunity of looking at. Σ 2873 Pegasi I cannot find in Proctor's large atlas.

J. W DURRAD.

WARMING GREENHOUSES.

[4774.]—Seeing in last week's English Mechanic a letter on the construction of a moderate-priced greenhouse, and in view of the fact that some of your readers may wish to heat by gas either directly or indirectly, it has occurred to me that a few hints from one who has had some experience in greenhouse heating might be acceptable. Suggestions from practical readers of the Mechanic would also doubtless be very apropos at the present time, when the price of coals is rising so frightfully. I have experimented pretty largely with burners, and have at last designed one which will compete with any I have seen on the score of cheapness and economy. I inclose a sketch of one I made of cast iron principally, but the material is non-essential. The burner proper (A in sketch) consisted of a disc 4in. in diameter, cored out inside so as to leave $^3/_{16}$in. thickness of metal all round; the core being supported in the mould by a stalk which formed the central hole, and by which the ventilation was insured, and the core cleaned out. This hole was tapped with 1in. thread, and a piece of ⅜in. gas-pipe 3¼in. long, screwed in. This piece of ⅜in. pipe was also screwed for ½in. at its lower extremity, and on to this a 1in. gas coupling screwed up. In this coupling were drilled four $^5/_{16}$in. holes on opposite sides. The bottom of the coupling was filled by a piece of hard wood driven in tight, and through this was screwed the piece of ⅜in. brass piping, which carried the burner. In the sketch B is the ⅜in. pipe, and C the coupling; so far the means of supplying and mixing the gas and air. Now for the burning. The disc A being 4in. in diameter, the circumference will be 12½in., and round the circumference 25 holes ⅛in. diameter were drilled, not exactly on the centre of the edge, but near the bottom; they were just ½in. centre to centre. The gas being turned on rushes through a No. 2 burner up the pipe B, and an induced current of air enters the holes D drilled in the coupling C, mixing with the gas both in the pipe and the head of the burner. After a few moments a light is applied



to the rim, and the mixture ignites, running all round, the holes being near enough for the purpose. The flame is pale blue, with a slight tinge of white at the tip, perfect mixture of gas and air, and perfect combustion being insured by the construction of the burner. The results are intense heat and no smell. A friend of mine, a young doctor, begged this burner from me last summer, and fixed it in his dressing-room, merely covering it with a sheet iron dome to prevent any accidental conflagration. The room is about 14ft. by 6ft. by 8ft. high, and was kept during the whole of last winter at an even temperature of 70° to 75°. The extreme consumption of gas would be 3ft. per hour, but the burner was working half power, 16 hours in 24. I also made a 8in. diameter burner, and one 12in., supplied with two No. 3 gas burners, this last generated a prodigious amount of heat, sufficient to keep a greenhouse 14ft. by 8ft. 6ft. by 6ft. average height, at a temperature of 65° throughout the winter. I shall be happy to give information touching these or any other type of atmospheric burner.

Atmospheric Burner.

HINTS ON THE CONSTRUCTION OF GREENHOUSES.

[4775.]—I was glad to see in "our" Mechanic so able a letter (4662) from our worthy correspondent, of whom we hear so often, upon greenhouses, &c., and the best adapted for the amateur, as I was myself under the same impulse to break the ice, as it were, in this matter, for the benefit and profit, I trust, of our numerous readers. Well, as our friend solicits criticism, may I be allowed to say his plan in general is very good; but shall we find all our mechanics good enough at joiner's work as to be able to put up a house after this sort, and if so, I fancy we shall not all get bricks and cartage at £1 per 1000, nor quite so easy a bargain as our friend offers for £5 in the prospectus issued, may I say.

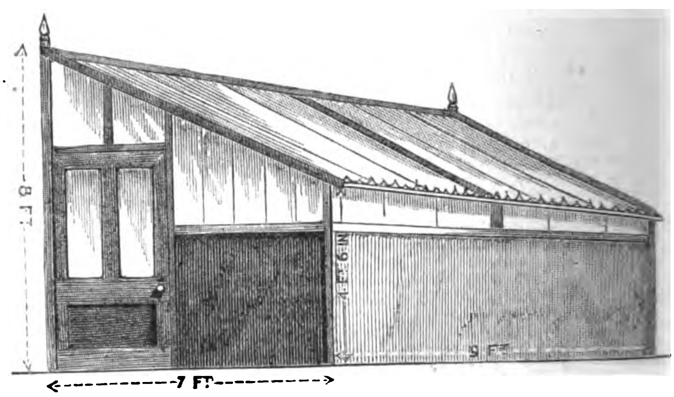
Now, would it not be better, provided it could be done, to get a building fitted complete, with bars, &c., all made into sashes or lights, ready fitted, door hung in frame, and the glass supplied us; the woodwork once or twice painted, &c., and then for us only to have the mere putting of the same together? Now, I have hinted the same to a friend of mine, and he has taken great interest in the affair in endeavouring to bring about the desired end. Thus, he will make a greenhouse for sale, say, 8ft. × 8ft., or 12ft. × 6ft., or, I think, better still, 9ft. × 7ft., as it gives one more room in front of him, and seems in better shape and form, after the following manner and costs. Two lights for roof, each 9ft. × 4ft. 6in.; two lights in front to swing as ventilators; two lights for the ends of same building, and a door hung in frame, all of which can be put up by a man and a lad in three hours complete. The glass to be all cut to a uniform size.

Thus we gain much in time and labour—a great feature to most of us, and have only to supply ourselves with a few rough boards, old packing-cases will do, or a concrete front or brick wall, as the case may be; but only reducing the same to a minimum, and one which all of us can easily manage, and erect to the satisfaction of our own minds and pleasure to our numerous friends. Thus the cost of same would come thus:—

	£	s.	d.
Six lights, fitted and framed together, to compose a house 9ft. × 7ft., with one door and frame hung complete	2	17	6
Glass for ditto, at 3d.	1	10	0
Painting for same	0	10	0
	£4	17	6

I find 16oz. glass to suit admirably, as my own house is glazed with same, and I have been within the same when heavy storms have poured down upon it with hail in abundance; but it merely gave way by bending before the storm, and did not show a flaw or crack anywhere afterwards.

I inclose a sketch of house, and trust it will be the means of moving our young friends to try their hands at this pleasurable pastime. Now, as regards heating the same. I shall be glad to hear what our friend states upon that, and then, if agreeable, I will also bring out my idea, as I have one, which will heat from 150ft. to 200ft. of 2in. hot-water pipe at the small cost of 4d. per day and night, and will go for eight or ten hours without attention, and, I think, will not cost more than another £5 to complete the whole affair, or at least enough to warm the above-sized house. As soon as I can get my electros done I shall offer them in the advertisement sheets of "our" paper, and trust they will prove the means of satisfying our long and much-desired wish of a cheap greenhouse heated sufficiently but economically. Should the same meet with approval, and



that, too, of our worthy editor, I shall only be too pleased to name it the "English Mechanic Greenhouse." As I know it has been a source of great concern how to secure our stock of bedding stuff from Jack Frost, for how many of us have had choice and valuable assortments of plants, &c., and have had the mortification to see them wither and die?

However, I think if we only endeavour to help one another, we shall overcome this difficulty as we have done many others, by the help of this our friend the Mechanic. I trust our friend "Saul Rymea" will continue to lay before us things both new and old, and enlighten us as as far as he is able.

Bro. Sam.

[4776.]—In continuation of my letter (4662, p. 538), I have now to deal with the method of heating the greenhouse, or rather of keeping out the frost, for this is all that is supposed to be attempted in greenhouses, which are thus distinguished from the stove, or hothouse proper. For very many plants just sufficient warmth to prevent the inmates of the house being frozen is all that is required, and to achieve this result two or three of the small benzoline lamps will be found to yield quite enough heat to prevent any disastrous effects from the coldest night, if they are supplemented by coverings of mats, old sail-cloth, carpets, or other non-conducting material capable of keeping the heat in. But with the half-hardy and tender plants at present used in "bedding out" it is necessary to do something more than merely preserve them from being killed outright; for if fine specimens are desired capable of yielding a tolerably long season of bloom, it is requisite that cuttings should not only be taken early, but that they should be kept steadily growing on. Once the element of artificial heat is introduced, however, the greenhouse will require all the attention the amateur gardener can bestow; for too high a temperature or a too long continuance of it will be found to cause as much ruin as will frost in its absence. With the changeable weather of spring in this climate (for instance, that of the present year) fire heat must never be allowed to meet sun-heat—indeed, this should never happen under any circumstances; and while the warmth of February induces the belief that the fire may be dispensed with, the cold, biting nights of April and even May will often disappoint the hopes of the floriculturist, and administer a check to the plants that they will not speedily recover. Again, fires once resorted to, the artificial heat must be kept up, and I have frequently known one night's neglect to result in the death of a whole house of plants, which would probably have survived the winter if artificial heat had never been given at all. I think, therefore, that, unless the amateur can devote sufficient attention to his pets to guard against the vicissitudes of the weather, that "heating" had better be left alone.

But heating being determined on, in a greenhouse of the proposed dimensions (12ft. by 6ft.) we have choice of only two methods, for, on the score of economy, hot water is said to be out of the question, and the alternative lies between an iron and a brick stove burning ordinary fuel, with a chimney carried directly through the roof or a flue running along the path. Gas has been tried, as your readers are aware, both for heating water and in what I may term the dry state, but the results, so far as have yet come under my personal knowledge, have not been of a very satisfactory nature. Nevertheless, I believe that with appropriate apparatus very satisfactory, though not, I think, economical results might be attained with it. But it must be remembered that any defect in the apparatus permitting the escape of the fumes would end in the destruction of the plants. I speak, however, with diffidence as far as concerns hot water and gas; for it by no means follows that because a method of employing either of these economically is not widely known, that it does not exist or cannot be invented. But your readers will scarcely misunderstand me. I shall have made a great mistake and certainly be much disappointed if the discussion on this subject in these columns does not lead to great improvement in the heating of greenhouses.

Between the choice of an iron stove or a brick I cannot personally hesitate. Iron is not a suitable medium for radiating heat and warming air breathed by plants, and this applies even when the stove is lined with firebrick, or a space of 3in. is left between the iron case and the bricks inclosing the fire. Therefore, I recommend what I believe to be the best and most economical, as well as neatest, arrangement—viz., a brick stove with a flue running along the pathway. To construct this flue a trench must be dug in the centre of the pathway about a foot or fifteen inches wide and about eight inches deep. This trench should have the bottom made tolerably firm, and a layer of cinder ash or fine gravel 2in. thick put in and levelled. On this the bottom tiles are laid, and bricks on edge at either side, so as to leave a passage 5in. wide and 3in. deep. The covering tiles one inch thick are then laid on, and the sides closed in with gravel or cinder ash, so that the tiles form the path. It is decidedly best to mortar all the joints closely, but it is not absolutely necessary, for if the stove and flue are properly arranged very little smoke or gas will escape into the house. The brick stove should be built entirely in the greenhouse, and should be constructed at the same time as the foundation wall is erected, so that the front of the stove may serve as part of the wall. It will be necessary to dig a hole at least 2ft. 6in. deep, for the firegrate should be at least 18in. below the level of the flue, and this must be left for ash-pit. The hole should be 2ft. square on plan, and be lined with 4½in. brickwork, the bottom courses being laid a full brick thick to form the ash-pit and to afford support to the fire-bars. The fire-place should be about 7in. wide by 7in. deep, formed of clay lumps or fire-bricks, which should entirely surround the fuel. An opening for the feeding-door will have to be left in the front or external wall above the top of the fireplace, and a hole about 2ft. 6in. deep corresponding to that in the interior, and of a breadth and width sufficient to allow of convenient "stoking," must be dug out on the outside. The feeding-door should be double, fitting very close, and the ashpit must either be provided with an equally close fitting door containing a valve to admit more or less air, or an iron plate must be made to slide in grooves just under the fire-bars, so that the supply of air can be shut off entirely or regulated to a nicety. This latter plan I certainly prefer.

In many of this description of stoves a bar of fire-clay is placed about 3in. in front of the opening to the flue, and extending about 2in. on either side of it, the object being to keep the heat in the stove and prevent a too rapid exit of the heated gas by way of the flue. This is the secret of all heating by stoves: to retain the heat at one radiating point, and to prevent it as much as possible from escaping by the chimney

The bottom of the flue as before mentioned should be not less than 18in. above the grate; and the brickwork need not be carried up more than 6in. or 8in. above the floor of the house; but I think it advisable to carry it up nearly level with the staging, and utilise the upper part as a kind of miniature forcing-pit, for raising tender seeds, striking cuttings, &c. This is easily accomplished by placing an iron plate over, so as to receive the heat of the fuel beneath, building a shell of bricks on this, and filling up with sand and compost, or sand alone if it is to be used for plunging pots. The stove would, of course, be at one end of the house, preferably the door end, and the chimney at the other, built against the wall of the garden, and connected by a short rising flue with the main flue, at the end of which (the point of connection) a tightly fitting door is to be placed to enable the soot to be removed. I believe it to be perfectly immaterial where the stove or the chimney is placed; the former might be placed in the middle of the front with a chimney rising directly from the top through the roof, or with a flue running diagonally to one of the back corners, or with a flue running all round and the chimney taken out just over the stove. I have also seen very serviceable heating arrangements in which 5in. drain pipes formed the flue, but these require careful joining, and are not more economical than the brick and tile flue. Again, the flue need not be sunk in the pathway, but may be carried along under the staging on the ground level, which will also, of course, reduce the depth necessary for the stoke-hole. And then again, it is quite possible that some one can suggest something better than what I have done. Still, I think a brick stove is not only cheaper but more advantageous and suitable than an iron one, although some very useful and portable articles of this latter description have been introduced of late years, and of course this portability is one of the principal desiderata in the greenhouse and its appurtenances I am endeavouring to arrive at. As to the management of the house when obtained, it is scarcely worth while entering into that here; let us get our hare and we will soon cook it. But I may point out that a stove of the construction indicated, and with the arrangements detailed, will consume but little fuel. The object is, of course, to get the heat up to a certain degree, and then by regulating the combustion by means of the sliding door under the firebars, a fireplace of the dimensions given will contain enough fuel to last all night, and even if it should go out towards daylight, the bricks will still radiate sufficient heat to prevent Jack Frost from doing harm. Small coke, coal, cinders damped, coal and coke dust with sawdust, peat, leaves, hedge clippings, anything almost can be utilised as fuel. For very many plants it will be sufficient to start a good fire in the evening and let it burn out; but if you want things to grow, the temperature must never be less than 40° Fahr., so that a thermometer is a sine-quâ-non. I have just read the plan of Mr. Taylor (let. 4710, p. 569). I can only say that it is rank "heresy," but not, therefore, necessarily incorrect or useless. It is against all the "doctors of heating," but it seems feasible, and is certainly convenient.

Saul Rymea.

ANOTHER REMEDY FOR THE POTATO DISEASE.

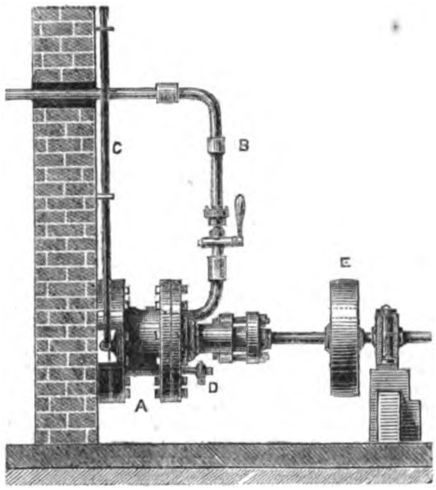
[4777.]—As I see from various reports that the potato disease is showing itself in many parts, and as every suggestion is possibly worth trial in the general absence of any radical means of prevention or cure, I send you the following cutting from the *Glasgow Herald*, the author being a "correspondent:"—"I am satisfied, from the little experience and the few experiments I have made, that the potato disease arises from a superabundance of alkaline matter, absorbed by the plant from moisture and heat. Any one may test this for himself for a halfpenny. Cut off the shaws [haulm ?], and water the ground with a watering-can, taking ½oz. of sulphuric acid diluted with 1½ to 2 gallons of water. If it has rained, examine in twenty-four hours; if not, wet the ground with plain water to carry down the solution to the tubers, and examine in another twenty-four hours, when it will be found that the disease has been arrested, and the part affected returned to its natural state, the acid counteracting the superfluity of alkaline matter absorbed. If our chemical friends would analyse the sound and unsound potato, and bring out something practical from this hint, they would confer a great boon on the human family."

I cannot understand, from this, how it is ascertained that the "part affected has *returned* to its natural state;" for unless the tubers are taken up and examined previously, I think it would be impossible to know what parts were affected, and consequently what parts had "returned" to the natural state. It seems to me that the cutting off of the haulm is the secret of this method; but the writer does not say how long after the disease is noticed in the leaves his remedy has been found effectual. Can he dig sound tubers when the haulm is black to the ground?

Saul Rymea.

NON-PACKING AND VALVELESS ENGINE.

[4778.]—The diagrams inclosed represent a unique little engine, well tested for its capability at Mr. Tyroll's factory, Deptford. It is used to drive the blowing machines, which that gentleman states requires 4 horse-power, and this it performs with such energy as to leave no doubt it possesses not only the force requisite, but something more. Fig. 2 is a transverse section through the middle of the cylinder and piston. These are 5in. deep; the piston moves on a crank, the centre of which is compelled to move round the middle circle, thus communicating a rotary motion to the pulley as marked E, Fig. 1. The steam is admitted by a pipe into the steam chest, the opening into the working part of the cylinder being covered with a plate of metal, to which the piston is firmly secured, the centre of each revolving round the middle circle before referred to. Through this plate on one side of nearly the extremity of each arm of the piston are holes to admit the steam into the cells, and so arranged as to be opened and shut by the surface of the cylinder over which it passes in its eccentric revolution with the piston. The exhaustion is effected from the bottom of the cylinder, and the escape is at the side marked D, Fig. 1. The action of the steam in giving motion to the piston A will be understood by referring to the same diagram. The cylinder and piston are perfectly steam tight; the exquisite form and workmanship

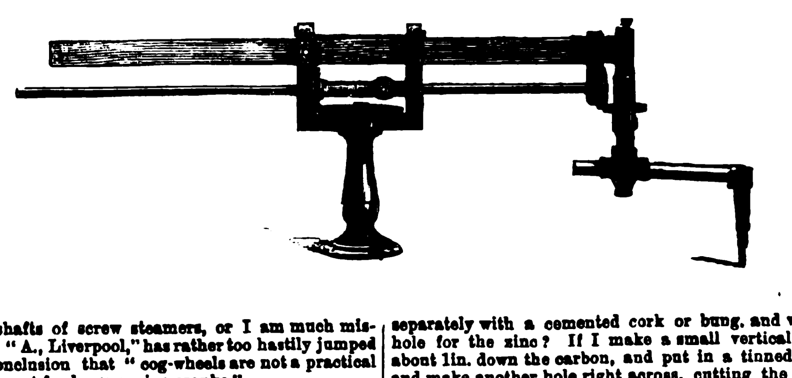


renders them so, the supply being at the top, at the bottom the exhaust, at the side the escape. This double action is continued uniformly during every revolution of the crank, and each cell continues to be steam-tight in every position of the piston. Outside diameter, 18in.; depth, 5in.; A, cylinder; B, steam pipe; C, escape; D, exhaust; E, driving pulley. This is a non-packing and valveless engine.

Joseph William Fennell.

CHANGING RECIPROCATING INTO ROTARY MOTION—ELLIPSOGRAPH.

[4779.]—The writer begs to inform "A., Liverpool," that the plan in letter 4578, p. 484, is not a modification of the one "A., Liverpool," saw working in Lincoln, but quite a different thing. There may possibly be a great backlash when cog-wheels are worked inside a circular hoop with teeth on inside rim, and all consequently converging towards a centre; but, as is shown in Rev. Arthur Rigg's article on "Mechanism," p. 533, No. 385, with well made and well fixed wheels as ordinarily used, backlash may be reduced to a minimum. As for "A.'s" idea that toothed wheels would be decidedly objectionable for use in sea-going vessels, I think, considering that in most cases where heavy work with constant and sudden variations of resistance is done by the steam-engine (such as an iron rolling, punching, and shearing mill, for instance), the power is all applied through the medium of cog-wheels, and that there is no substitute for them, what great objection can there be to their use in marine engines; indeed, they have been used to give motion



to the shafts of screw steamers, or I am much mistaken. "A., Liverpool," has rather too hastily jumped to the conclusion that "cog-wheels are not a practical arrangement for large engine cranks."

John H. Kidd is no nearer the mark than "A., Liverpool." He says the plan is fifty years old. Let him compare the poor, clumsy instrument for drawing ellipses, which he used in 1848, with its balance, its two teeth short, and its miserable show of deficiency in inventiveness (the paper having to be placed in a vertical position), with the plan of one shown on page 281, December 1, 1871, of "ours"; besides, the truth must be told, his instrument would *not* describe ellipses, *nor* straight lines: he would have to give back the two teeth he has robbed the wheels of, and then it might do its work.

Herewith I send photograph of my best instrument for describing ellipses. After over thirteen years of study in this particular matter I cannot make or find a better; if any one of "ours" knows of one he would confer a great favour by letting me have a slight description of it, or by saying where it might be seen. The drawing will explain itself to those interested in the subject, if they will take the trouble to read description of small instrument, page 281, December 1st, 1871. This instrument will describe circles and ellipses of any given diameters that the length of the main sliding bar and rod allows of; said bar and rod regulating the mean diameter of ellipses, and the small bar with pencil attached giving the difference between the mean and the major and minor axes. This instrument can also, by change of position of one wheel, and

by using wheels with different numbers of teeth as substitutes for said wheel, be made to describe a number of beautiful curves similar to those produced by Suardi's pen. (For a description of this pen see Knight's "Penny Cyclopædia.")

G. Pinnington.

BATTERIES.—To "Sigma."

[4780.]—Will this correspondent kindly give me some hints about setting up some manganese cells on the principle lately described by him in his excellent articles on "Electro-metallurgy"? Let me premise that the cells are for working electric house-bells. I propose using stone-ware jars, 4½in. diam. × 5¾in. deep, which I propose filling up within about ¾in. or ½in. of the top. I propose having the porous cell of this same height, and placing it in the centre. On one side I shall place a carbon about 6½in. long. I shall pack all round the cell with pieces of carbon about the size of a hazel nut, and a mixture of manganese and powdered carbon equal parts. A disc of cardboard soaked in paraffin will cover all, with holes for a zinc rod placed in the porous cell and for the graphite to pass through. On the cardboard will be poured melted cement. The head of the graphite will be soaked in paraffin, and a tinned copper wire will be cast into the zinc. If "Sigma" sees anything wrong about the above will he kindly correct it? Now for a few direct queries—What size should the graphite, the porous cell, and the zinc rod be? Will a few ⅛in. holes in the porous cell be an advantage? Would it be better if the porous cell came through the cardboard, and was closed separately with a cemented cork or bung, and with a hole for the zinc? If I make a small vertical hole about 1in. down the carbon, and put in a tinned wire and make another hole right across, cutting the first, and run them both full of lead, shall I have a reliable connection? Is sulphate of ammonia or chloride of ammonium best, and should I put some crystals, and should the solution be saturated or not? If not, what strength? Lastly, what does "Sigma" think of Geo. Fox's plan of graphite porous cells made with tar and pounded gas carbon and burnt?

I hope he will pardon this long list of queries, but opinions on some of the points vary so much, and others, I think, want explaining. I want a battery that will go the longest possible time with the least possible attention.

H. H. G.

FUEL FOR THE WINTER.

[4781.]—With reference to this subject, concerning which "Philo" makes some remarks (let. 4656), let me suggest that if any of your correspondents have had practical personal experience in making up coal dust into cakes for fuel they could scarcely do better service than by publishing in your columns a full description of some of the methods which are available for private families. I was in Wales last year, and intended to have taken some steps to ascertain how the Welsh go to work, but was prevented by circumstances. I satisfied myself, however, that coal dust can be formed into most valuable fuel. The points upon which information should be given for the use of English readers seem to me chiefly the following:—What are the proportions in which the clay and coal are to be mixed? What is the best agent that can be employed for binding them together? Is it necessary to intermingle with the main mass any inflammable material such as bitumen to facilitate combustion; and what is the condition into which the clay must be brought in order to make the admixture easy of performance? Some particulars as regards the manipulation generally would also be desirable. I make this last remark chiefly because I notice such a great want of detailed practical information in many of the answers sent by correspondents of the English Mechanic; they write rather as if they were performing on the spot as well as explaining, and so suppress petty details which although petty are none the less essential to be known by persons seeking at a distance to carry out as tyros the recommendations made to them. Reverting again to the coal question, I would say that my belief is that many small families could save during the winter many pounds sterling if they knew how properly to use up fuel refuse, and acted on their knowledge. Certainly, with coal at its present price, and with the prices in prospect during the next six months, every householder belonging to the upper and middle classes owes it as a duty to society to do all he can to show ~~strike-loving democrats~~ that Capital is not, and does not intend to be, at the mercy of Labour if it can help it.

G. F. Chambers.

TAR PAVEMENT.

[4782.]—A new process for making serviceable tar pavements has been recently patented in America. The purpose of this invention is to furnish a new and improved composition, whereof to make side-walks and the like, which shall be free from objectionable odours, not liable to injury from rains falling on it soon after it is put down, and which, it is claimed, has other incidental advantages. It is made principally of equal parts of coal-tar, pitch made from coal-tar, and asphalte, to which is added gum camphor, in the proportion of 3lb. to each barrel of coal-tar. The coal-tar and pitch are melted together, and the camphor added thereto. The asphalte is melted separately, and then mixed with the other melted ingredients. In laying down the pavement a substructure of about 2in. of small cobble-stones is laid, ranging in size from about the size of a goose's egg to the size of a robin's egg, and previously coated with coal-tar by pouring the tar over them and raking them about. This is rolled down first with a roller about 22in. long, weighing about 500lb., and afterwards with a roller about 24in. long, weighing about 800lb. Screened sand is next mixed with melted tar, pitch, asphalte, and camphor, till the whole forms a stiff paste, which paste is put upon the substructure sufficiently to cover it when subsequently rolled, first with the light roll and then with the heavy one, to about an inch in depth. When well rolled the surface is sprinkled with water-lime to the depth of about one-sixteenth of an inch, which is rolled into the paste with a light roll. The inventor claims that the combination of the tar, pitch, and asphalte makes the most durable composition for this purpose yet known. The proportions given will best fulfil the conditions required; but they will approach this result in any combination. The camphor deprives the whole mass of bad odours from the first. The water-lime forms a thin scale over the walk impervious to water, which will not wear away till the walk is sufficiently hardened to resist all action of the rain without this protection. These "tar" paths make excellent substitutes for gravel, and are being extensively used in one form or another for various public works.

Tages.

AXES OF THE PLANETS.

[4783.]—In let. 4449, p. 406, Mr. Proctor wishes to be informed as to the inclination of Mercury's equator to the plane of his orbit. "W. T. R." has supplied the information in let. 4536, p. 460, saying that "Schröter estimated the angle which the equator of Mercury makes with the plane of his orbit at about 20°." Schröter's determination was, I think, something more than an "estimate," for from twenty-seven drawings made May 18 to July 4, 1801, or within the space of forty-seven days, he deduced the position of Mercury's equator by a graphical process, the principles of which he details at some length. See "Hermographische Fragmente zweyter Theil, nebst den Beobachtungur des Planeten Vesta, von Dr. J. H. Schröter, Göttingen, 1816."

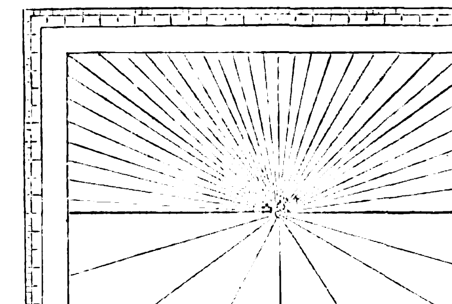
A further deduction may be made from Schröter's observations, for, as he says (p. 126), during the whole of the time from May 18 to July 4 the markings on the surface of the planet, as shown in the drawings, maintained the same invariable angle of rotation, or nearly so; whence it follows that the earth must have been all that time in the neighbourhood of one of the equinoxes of the planet. That this was the vernal equinox follows from the fact that the position of the axis of rotation was about 20° less than that of the terminator, and also that Mercury was in superior conjunction about the 3rd of June. Again, on the 10th of June, or about the middle of the series of observations, Mercury would follow the sun by about 6°, so that his longitude was about 85°, therefore the earth's longitude seen from Mercury would be 265°, and his north pole would consequently lie in longitude 355° or thereabouts. This is, of course, merely the rudest approximation; but, as Schröter himself says, when giving the inclination of the axis, it is better to know something of this element than nothing (indessen ist es doch besser, von der Schiefe der Mercurs-ecliptic etwas, als gar nichts zu wissen).

As I have seen the telescope with which Schröter mostly observed the inferior planets, it may be a valuable hint to some of your readers to know that although it was 10ft. in length its aperture was only about 3in. The powers he used were 82, 126, 206, 242, and 291.

R. C.

PERSPECTIVE.

[4784.]—I by no means lay any claim for pretensions to high art, yet, if allowed to say a few words on the subject of perspective, I will simply say that the laws as defined in most of our schools often perplex the student. I myself find the most simple means the most efficacious. I will quote the opinion expressed in the *Athenæum*:—"Perspective Simplified.—A picture in perspective is simply a plane parallel to the plane of the eye intersecting the rays that come from the surface of the objects represented. The points of these rays, at the places of their several intersections, combine to form the true perspective representations. Now, without much semi-scientific pedantry, the whole science may be understood by balancing a half-crown on the top of the forefinger of your right hand; hold it up so that its broad plane is parallel to the eye's plane, put it nearer or farther, and it seems to increase or diminish in size; turn it obliquely, and it appears an oval; put the edge on a line with the eye, and it appears a mere thin straight line. A sphere is the only geometric form that undergoes no perspective changes. The eye is able to take in any given space set at an angle of under 60 degrees. When both eyes view a scene, instead of the circle one eye sees we have an ellipse, formed by the continuation of the two circles of vision, the point of sight being opposite the centre of the space between the two eyes."



I inclose my simple plan of measuring and finding the given point in perspective, being a frame scaled out, with fine threads diverging from a given centre; the horizontal line is distinctly marked.

Joseph William Fennell.

[4785.]—With reference to letter 4654, p. 536, I beg to be allowed to state that my experiments with a plumb line and with vertical lines on a window pane are fallacious, because these lines must converge towards the zenith as well as the sides of the tower. As I feel quite sure the sides of the houses I observed were not parallel with the lines, I conclude they are not exactly vertical. The only way to test the difference between A B and C D is therefore by angular measurement. But nobody appears to deny that A B is optically narrower than C D. Therefore on the stock "pane of glass" A B must be narrower than C D. Now, as it is perfectly true that on paper or canvas we need not notice this convergency, yet as it appears on the glass two things are evident—first, that Sir David was right in stating that a photo. would show convergency; second, that I was right in stating that the pane of glass mentioned in books of perspective will not guide us to the perspective of a picture. With respect to my "cookery," I would remind "E. L. G." that pictures are very rarely viewed from the proper place, and, therefore, as according to his own showing, the perspective must be thrown out, I think we may indulge in a little departure from its rules, if we can by so doing produce some desirable effect. As "E. L. G." permits me to cook in some instances, why not in others? His observation as to the curved images on the retina seems to indicate that he supposes we see them instead of by them. Sir David knew better than that. If "E. L. G." had to paint architecture on the inner surface of a "Great Globe," he would have to paint his tower converging. I beg to say that I do not put myself forward as possessing any depth of knowledge of the matters we are discussing, far from it.

M. Paris.

NEW DOUBLE STARS.—To Mr. Bird.

[4786.]—I was glad to see your observations and notes of some of the new double stars, and I cannot but feel encouraged and gratified by the interest abroad you have mentioned. I am not surprised at your failure to see the close pair near ξ Boötis (let. 4376), even with a moderately large aperture, unless the night was a fine one, for with my instrument it is excessively difficult, and requires very favourable conditions; but then I see it perfectly. I find I have been anticipated in the discovery of this pair. Mr. Alvan Clark informs me that a year or two ago his son, Alvan G. Clark, found it with a 12in. object-glass, but that the fact had never been published. It does not seem to have been measured by any one.

Speaking of doubles in the same fields with conspicuous and well-known stars, there is a pretty but very faint pair in the field with γ Aquilæ, only 8′ south of it. I have perhaps called attention to this before. The components are nearly equal, of 10 or 11 mag., and separated perhaps 2″ or a little more, the position angle being about 40°. There is a third star a short distance preceding.

I have not been able to identify the double you have found in the neighbourhood of the pair near ξ Boötis, but perhaps I have not looked in the right direction. How far from the star marked 1 in the sketch (let. 4258) is it? It is certainly new if in the same field with any power, and I shall be glad to look it up, although it is getting rather late now. The nearest catalogued double is OΣ 288 (about which I put a query in let. 4258); but that is nearly 3½° from ξ in the direction of your star. Did you observe star 3 in reference to its present brightness?

The double star you mention as not being in the *Mens. Mic.* appears to be OΣ 261 (18h. 4m. 57s.: + 32° 53′, mags. 7, 7·8, D = 0·5″). The distance (estimated) is somewhat less, but the identity is sufficiently established. Not having an equatorial mounting, I have not been able to look it up. I may say, in passing, that my object-glass, and its tube, and everything else belonging to it except the eyepieces and finder, are about a thousand miles apart. The substitute for the tube which I am using consists of two pieces of board about 4in. wide, nailed together at the edges at right angles, the object-glass being fastened to one end in a frame and the eyepiece to the other. Though excessively unsteady, and the object-glass difficult to keep in adjustment when the instrument is reversed, (the movement is equatorial), its performance is good enough for almost any object, however difficult. The identification of doubles, when found, is laborious and troublesome, but it can be done with the aid of star maps.

You should procure, if possible, a copy of Otto Struve's catalogue of 514 double and multiple stars. The objects in this are far more interesting than those in *Mens. Mic.*, from the equal pairs being generally very close, and a very great difference in the magnitudes of the wider ones; in fact, there are very few easy stars. In this catalogue 167 pairs range in distance from 0·3″ to 1″, and more than 200 are as faint, or fainter, than the 10m. of Struve's scale. The original was published in 1843, and a revised edition in 1850, with the addition of 16 new stars. The number has since been increased to 539 by other discoveries, which will be found in *Monthly Notices*, Vol. XX., p. 8.

I would call attention to the so-called 16m. companion to α^2 Capricorni, and would like you and others to examine it with apertures of 6in. or 7in. Either this star is becoming easier, or its difficulty has been greatly overrated. Herschel, in his third catalogue of double stars, observed with the 20ft. reflector, rates it as 18 magnitude, and in the introduction to the paper says, "It is one of the most beautiful and delicate objects in the heavens, and could not be expected to be seen double in the 5ft. equatoreal, or indeed with any telescope of inferior light to that with which I observed it [20ft. reflector], unless, indeed (which I partly suspect may be the case), a very perfect destruction of aberration, by bringing the whole light to bear rigorously on a single point of the retina, and destroying all loose light in the field of view, may not in some measure compensate for a defect of quantity. But this has obviously its limits." (Mem. R.A.S., Vol. III.).

In his fourth catalogue he gave the magnitude of the companion as 15·16, and in a note says, "The small star is brighter than 18 mag., as set down in my former catalogue. The position differs greatly from my former estimation; but this is satisfactorily accounted for by the proper motion of the large star." The distance he gives now as 6″, and position as 134·8° (Mem. R.A.S., Vol. IV.). I always see it steadily in good weather, and even when a good way from the meridian, with my 6in. refractor, and could not call it a severe test for that aperture. I should rate the magnitude of the small star now as about 13, or 14 at the most, and the distance perhaps a little more than Herschel's second estimate. When it is remembered that the companion itself is a pretty close double, this object cannot be considered other than one of the most interesting. The duplicity of the companion I detected some two years ago with the Chicago glass of 18in., but afterwards learned from Mr. Alvan Clark that he had observed it with the same instrument while the glass was in his possession. He states that he can see traces of its duplicity with an aperture of 12in.

Have you seen the companion to β Aquilæ (OΣ 532)? and if so, what aperture is necessary to show it? This is one of the very few double stars I have not thus far been able to see with my instrument. I would like to inquire if ϵ^1 and ϵ^2 Cygni are regarded as forming a naked eye test. It is a more difficult object than any wide similar pair I now recall, but is very readily seen nevertheless. In this connection I may state that I can in any ordinary weather clearly divide ε Lyræ with the unassisted eye.

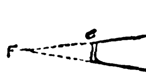
I have just been very fortunate in being able to make my double star literature almost, if not quite, complete. Prof. Young, Director of the Dartmouth College Observatory, very kindly placed his astronomical library at my service, and I have made copies of everything to be found in this department, embracing all the various catalogues in a complete set of the "Memoirs of the R.A.S.," new objects in Herschel's and South's catalogue, various objects noted from time to time in the *Monthly Notices*, *Astronomische Nachrichten*, &c. I also obtained recently a copy of Herschel's "Results of Astronomical Observations at the Cape of Good Hope," which contains a good many northern stars. So far as I know, my collection of known double stars is substantially complete. In all of these lists I find but two of my objects—one, 12 Scorpii, and another a double star in Hydra, communicated some time since—two of the easiest I have noted as new.

July 29. S. W. BURNHAM.

NEW DOUBLE STARS.—CORRECTION.—In let. 4549, p. 462, communicating the discovery of several new double stars, the description in reference to the second double should read, "About 1° from 33 Vulpeculæ," the number being omitted by the printer. The distance of that pair given as 2" is rather over-rated, I think. It is a very pretty pair, and not at all difficult.—S. W. BURNHAM, Aug. 5.

ON THE DISREGARD OF THEORY FREQUENTLY SHOWN IN THE CONSTRUCTION OF THE OPERA OR FIELD-GLASS.

[4787.]—THE opera or field-glass is an instrument of general use, yet there are numerous examples of inconsistent construction to be met with to which I would direct attention. It is a recognised fact to the initiated in optics that the limit of effective aperture of an object-glass is reached when the diameter of the glass bears to the diameter of the pupil of the eye the same ratio as the magnifying power to unity, any excess of aperture beyond this limit being useless, for the simple reason that the diameter of the cone or pencil of rays formed by the glass (where it enters the pupil) then begins to exceed the diameter of the pupil or aperture of the eye itself. Hence the cone of rays from an object-glass, whose diameter exceeded this limit, would merely cast a useless glare upon the part of the eye surrounding the pupil. An absolutely definite size cannot be given for the pupil of the eye, since it is capable of dilation within certain limits, but it may be stated with accuracy that the diameter is rarely less than ⅛in., and very seldom exceeds ¼in.; the mean diameter may be probably taken at about three-sixteenths of an inch. In the case of an opera-glass a magnifying power of two is very common, and this is in general quite sufficient for the purposes of this instrument. For this power the concave lens *e* is placed exactly half way between the virtual focus F of the cone of rays proceeding from the object-glass and the object-glass itself, as shown in the accompanying diagram.



The pupil of the eye being placed immediately behind the eye-lens *e*, it is obvious that the diameter of the pencil of rays where it enters the pupil is in this case one-half that of the object-glass itself. It need scarcely be remarked that the rays on passing through the eye-lens are rendered approximately parallel. It is clear from the above considerations that for a magnifying power of two the effective diameter of the object-glass is exactly twice that of the pupil, *i.e.*, a seven-sixteenths to half-inch object-glass would be amply large enough for this power; any larger diameter would only have the effect of casting a glare of useless light outside the boundary of the pupil, at the same time increasing the spherical and chromatic aberration of the object-glass, besides other disadvantages.

Now, opera-glasses having a magnifying power of two, with object-glasses of 1in. diameter up to even 1½in., if not beyond, are to be met with; the unsophisticated public supposing probably that increased light is thus obtained, whereas a detrimental glare which plays uselessly over the non-sensitive parts of the eye is the only result, to say nothing of the increased optical errors due to increased diameter of glass. If, on the other hand, the diameter of the object-glass were no greater than that which was efficient—say seven-sixteenths to half an inch—for a magnifying power of two, then the focal length of the object-glass might be proportionately reduced—the whole instrument would be much more portable and convenient. Instead of the clumsy affair at present too common the whole instrument would almost go into the waistcoat pocket, and its use would become more frequent. The dimensions of the lenses of some of these instruments, the focal lengths and powers of which any one may measure and judge of for himself, are, without exaggeration, utterly preposterous, and would remind one much of using a telescope of 2ft. aperture for a power of 20.

Many are no doubt deterred from using this convenient adjunct to a play or concert from the inconvenience due to its absurd size. A compact instrument, with object-glasses not exceeding ½in. in diameter, and whose length when shut up need scarcely exceed an inch, would no doubt find its way into more general use. S. T. P.

CALCULATING WAGES.

[4788.]—I BEG to send you the following observations on calculating wages:—Let a be the number of hours in a full week's work, s the shillings to be paid for it, h the number of hours actually worked; then, supposing the payment A to be in proportion to the hours worked, we have $A = \frac{h}{a} \times s$. It must be observed, however, that this formula is not suited for overtime—that is, h must not be greater than a, although it may be equal to it or less than it; overtime is, of course, as it ought to be, paid for at a higher rate. Taking a full week's work at 54 hours, and putting this value for a, we get $A = \frac{h}{54} s$. Now, the usual means of tabulating such tables is by products; this method makes the tables very long—for example, a table of products of numbers up to 50 would give 2,500 products (all not necessarily different numbers), or more than half of 2,500, if the same number was not repeated.

Now, a table of squares up to 100 requires only 200 numbers—viz., the numbers themselves 100, and their squares 100. To adapt the formula $A = \frac{h}{54} \times s$ to such a table, $A = \frac{hs}{54} = \frac{4\ hs}{216} = \frac{(h+s)^2 - (h-s)^2}{216} = \frac{(h+s)^2}{216} - \frac{(h-s)^2}{216}$. Let the squares of the numbers 1, 2, 3, &c., up to 100 or more be calculated, and, dividing each square by 216, and expressing the quotient as shillings, the fractional parts being reduced to pence, we obtain the accompanying table, calculated up to 54 hours, and wages up to 50s. a week. To illustrate its use, suppose 47 hours are wrought, and the wages for 54 hours is 38s., how much is to be paid? Adding 47 and 38 together we get 85, opposite this sum in the table is 33s. 5½d. Take the difference of 38 and 47 (no matter whether hours or shillings per week are greatest), we get 9; opposite 9 in the table is 4½d. Subtract the latter result from the former and we get 33s. 1d., correct to the nearest penny—the table is calculated to the nearest halfpenny; but if one result was nearly ¼d. too much, and the other nearly ¼d. too little, there would be an error of less than ½d. The table could readily be extended, and calculated for quarters of hours, and for every 3d. of weekly wages, instead of for every shilling. A similar table could be adapted for a week of full work, of more or less than 54 hours. The table is very compendious, and saves the trouble of turning over leaves, or finding the intersection of lines and columns. The principle might be applied to other tables.

PHILANTHROPIST.

A GIANT PLANET.

[4789.]—"G. F. H." (let. 4687) seems to be in error, the freezing point of water is 32° Fahrenheit, and 0° Centigrade. The boiling point of water is 212° F., 100° C., therefore 212 − 32 = 180° of Fahrenheit's scale = 100° of the Centigrade scale. 1200 F. is 1168 F. above freezing, or $\frac{5}{9} \times 1168$ C. above freezing = 760 Centigrade. Also $1\frac{11}{135}$ Centigrade is not equal to 1·95 Fahrenheit, but = 32° + 1·96 = nearly 34° F.

PHILANTHROPIST.

ERRATA.—In letter 4725, p. 565, "mixing and slacking" should be "mixing and stacking;" "the month's supply for three fires" should be "three months' supply for three fires."—INLAND.

REPLIES TO QUERIES.

*** *In their answers, Correspondents are respectfully requested to mention, in each instance, the title and number of the query asked.*

[11589.]—**Dry Steam.**—I do not think it likely any experiment proving so simple a result of the third law of motion as "Philo" asks for, on p. 554, can have been specially recorded. Of course a stiffly moving piston might have such friction as to be driven only to the place of exact equilibrium between the pressures, and there stick fast; but with a large cylinder and high pressure, I should barely believe my own eyes on seeing such a movement. Now, whatever the steam expands to with the largest and most freely moving piston to drive, it surely would expand farther with no piston at all.—E. L. G.

[11887.]—**Hair Dye.**—The lotion of hydrosulphate of soda, lately discovered accidentally by Dr. M'Call Anderson to be a hair-dye, promises, it is said, to be the most perfect black one yet seen. It stains neither skin nor clothing. I have never seen it applied, and cannot tell whether it is or is not injurious to the skin or hair, but perhaps some reader of the ENGLISH MECHANIC will kindly give "Gray-Beard" this and other desirable information.—BLACK-BEARD.

[12191.]—**Surgery Abroad** (**U.Q.**).—I should have replied to this query sooner but I thought some of ours could have answered it better. I met a colonel last year who had resided many years in Adelaide, he said there was a good opening there for a surgeon, but Australia is very fluctuating, and the surgeons who go out with emigrant vessels often remain, so that openings are uncertain, and may be soon filled up. As to Canada, there are about 20 doctors in London, Ontario, to a population of less than 20,000, and besides this there is more equality in the colonies than here, and of course the professional man has not so good a position as in England. The M.D. is easier got in America, particularly in the United States, than here, and this overstocks the profession. Still, I think a doctor might do well in the States, or in Australia.—PHILANTHROPIST.

[12291.]—**Nature Printed Leaves** (**U.Q.**).—I inclose a cutting from one of the photographic journals which, I think, will be useful to "Robo" and others. I can, if required, give a more minute account of the entire process, but I should advise "Robo" to do as I did and take a lesson or two. The only skill that is required is manipulative, so that the process is best learnt by seeing it done. The Autotype Company, of Rathbone-place, Oxford-street, give instructions gratis once a week. At least they used to do so, and I suppose they do still. I should also advise that the carbon-paper be purchased ready prepared, and sensitised of the required tint, but only a small quantity must be purchased at a time, as it does not keep in working condition for more than three weeks. "The basis of the process is the action of light on bichromate of potash in contact with organic matter. Coat a paper with a mixture of this bichromate and gelatine; expose it to the light, under a photographic negative, in a common photographic printing-frame. Where the light reaches the coated paper freely — *i.e.*, in the high lights of the negative, which are the extreme darks of the picture to be printed—the bichromatised gelatine becomes insoluble. Where the light is entirely shut out from the coated paper—*i.e.*, in the deepest darks of the negative, which are the brightest lights of the picture to be printed—the bichromatised gelatine remains perfectly soluble, and may be entirely washed away. In the half tones—to be reversed, be it remembered, for negative and picture, by reading half light in negative for half dark in picture, and *vice versâ*—insolubility is attained, or solubility preserved, in proportion to the degree in which light is shut out from or let in to the coating of bichromatised gelatine. Now mix a pigment with your gelatine, and your lights, darks, and half-tones, are at once translated into gradations of that pigment, be it red or black chalk, sepia, Indian ink, common ink, bistre, or what you will. The practical difficulty in this process was to preserve the half-tones of the printed picture till they could be fixed on some durable support. They were floated away in the washing process necessary to get rid of the soluble parts of the print—its lights. It was Mr. Joseph Swan, an inventive chemist of Newcastle-upon-Tyne, who so far overcame this difficulty as to make the process commercially workable; but it was rendered practically and generally available by the patents of Mr. J. R. Johnson, the Chemical Director of the Autotype Company. Mr. Johnson has devised a new and highly-improved pigment paper; has discovered that when an autotype print is impressed on this paper it may be attached to a permanent backing, or support, without any cement. If this backing (a plate of zinc, glass, porcelain, &c.) be coated with a fatty substance (infusible at the temperature of the water used for washing away the soluble coating, but fusible at a somewhat higher point), the picture film may be readily detached from the backing. All that is necessary is, that it should be mounted on properly prepared paper by any of the many colloids that may be used for the purpose."—QUERCUS.

[12378.]—**Bat-making.**—A spokeshave is used to finish off, and they are pressed in a machine to make them hard. Scotch glue is the best.—E. M.

[12398.]—**Silver and Gilt Articles.**—"Spero" will find all he wants in back numbers. Oxidising silver is explained on pp. 311, 336, 361, Vol. XIV.; cleaning silver on pp. 394, 419, 463, 617, Vol. XIII. See indices of last four volumes.—TAGES.

[12495.]—**Watch Making.**—I regret the delay in answering this query, illness having been the cause. The horizontal escape-wheel will be included in the article which follows the next one, and, as I am unable yet to write for any length of time without rest, I hope to claim his indulgence. I am hopeful of treating his subject, "Trains," soon. I cannot find the No. of ENGLISH MECHANIC which contains his query thereon, but will order one.—SECONDS' PRACTICAL WATCHMAKER.

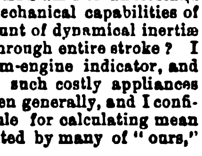
[12496.]—**Stained Scarlet Tunic.**—Scour the part with strong soap and water, in which some pearlash has been dissolved, then sponge it well with weak solution of sulphuric acid, say one teaspoonful to a pint of water.—BALCAIRN.

[12504.] — **Sketching from Nature.** — "Old Boots" gives a very nice plan on prepared glass, simple and easily got up, but is not clear in his description. What sketch is the glass to be laid over, and how is the second glass to be prepared to trace the reverse way—trace what? Explain, please.—JULIA.

[12506.]—**Power of Engine.**—If G. Valentine (p. 548) will kindly explain the following, he will confer an obligation on myself, and perhaps many others. By what arithmetical or other process does he get his 26·666 mean elastic force throughout the whole stroke? May I suggest that 26·666 looks ominously like $\frac{2}{3}$ of the 40lb. boiler pressure which is cut off at $\frac{2}{3}$ of stroke, and ask what becomes of the expansive force of the steam already in the cylinder when the supply is cut off? And am I to understand by effective horse-power the mechanical capabilities of the engine entire; or the amount of dynamical inertiæ expended against the piston through entire stroke? I understand the use of the steam-engine indicator, and the brake dynamometer, but such costly appliances are out of the reach of workmen generally, and I confidently assert that a simple rule for calculating mean effective pressure is much wanted by many of "ours," including—J. TONKES.

[12506.]—**Power of Engine.**—G. Valentine is in error when he states that the mean pressure of steam in a cylinder, cutting off at $\frac{2}{3}$, with an initial pressure of 40lb., is 26·666lb. Now, the way to find the mean pressure of steam on the piston throughout the stroke is, divide the initial pressure by the ratio of expansion, and multiply the number by its hyperbolic logarithm, plus one. In the example given it will be $\frac{40}{1\cdot5} \times (\cdot405 + 1) = 26\cdot6 \times 1\cdot405 = 37\cdot37$lb., and not 26·666lb., as stated by G. Valentine. The nominal horse-power is a name given in commerce, and is useless, as an engine is sometimes worked to six times its nominal horse-power. The indicated horse-power will be 106·7.—K.

[12537.]—**Compressing Air.**—To solve this question with perfect accuracy might be impossible; for, if we consider the fact that a quantity of air compressed into one-half its volume has its pressure more than doubled on account of the additional pressure caused by the increase of temperature. As to the temperature part of the question, I have no tables, and cannot reply to it. As to the work, I will give a reply, neglecting temperature, which does not affect its accuracy much; and, indeed, considering temperature even, if we have the requisite data, which is doubtful, it would probably give us an expression which we could not integrate, and therefore we should be forced to neglect it, or approximate to it by a series. Take rectangular axes Ox, Oy. Let the curve represent the pressure of the steam in the following manner:—The pressure varying inversely as the expansion, if B F be 1ft., and L F the initial pressure, and the piston drawn up to P, then B F × L F = P N × P M. Let P M = x, P N = y. F B = 1ft. F L = a pounds on the inch. Atmospheric pressure a known pressure. Then $xy = a$, which is the equation to a hyperbola, to a particular kind of hyperbola, the equi-angular hyperbola. The equation is generally written in the form $xy = c^2$. Now, $y = \frac{a}{x}$, and the area of the curve between the limits x = M P and x = L F will give the work done in compressing the air. To consider the case of expansion—



$$\int_{MP}^{LF} \frac{a}{x}\,dx = a \log. LF - a \log. MP,$$
$$= a \log. (\text{pressure of atmosphere}) - a \log. x,$$

giving x its value at the point P. If the air be expanded to twice its bulk, and the atmospheric pressure be 15lb. to the inch, we get work given out by expansion of the air = area of piston in square inches × (a log. 15 − a log. $7\frac{1}{2}$). Against this we have 15 (P N − 1) × area of piston for pressure of atmosphere. So, on the whole, in this case, we lose by expansion, as the pressure of the air in the cylinder is low.—PHILANTHROPIST.

[12541.]—**Fish Culture.**—Dace are not worth much for the table, being soft and flabby. They never grow to a large size, being when full grown only a few inches in length. "Green Drake" may conveniently cultivate dace for his young ducks by sinking a deep hole at the side or in the bed of the river. The fish are not fond of clear deep streams of running water like the trout, but prefer ponds and pools of rather turbid water. In this respect they are like the roach and eel, but do not wriggle through the mud or make their haunts in holes as the latter does. They feed on insects, water-worms, and shells, and may be caught with gentles, paste, moths, insects, and worms as baits.—RAT-TAT.

[12542.]—**Luminous Tubes.**—Sulphuric acid is said to have a similar effect when agitated in a glass tube in a darkened chamber, but its luminousness is intermittent and inconsiderable. Most probably, if a sufficient supply of rarefied air could be supplied at intervals to the inclosed mercury, a constant and steady light could be maintained; but "Pegasus" does not say whether the mercury is charred or rendered impure by the operation. To support the light something must be burned or decomposed, perhaps the inner surface of the glass, and if the products of combustion mingle with the mercury it would soon be rendered useless for illuminating purposes.—RAT-TAT.

[12546.]—**Protection for Steam Boilers.**—Either wood, hay, or straw, or vulcanised indiarubber can be used. The last is best, as it is a non-conductor of heat and electricity. As boilers when jacketed look unsightly and out of proportion, a thick covering as a protection ought not to be employed. Perhaps very thin laths surrounded by a light sheet-iron case, and inclosing a thin layer of air around the boiler, might be the best protection.—RAT-TAT.

[12548.]—**Flexible Black Varnish.**—This query has been answered very often in back numbers. Different proportions of rubber, boiled linseed oil, turps, lamp-black, ivory black, spirits of wine, coal-tar, naphtha, and such things, are recommended. Camphor, as a preservative, also enters the mixtures.—RAT-TAT.

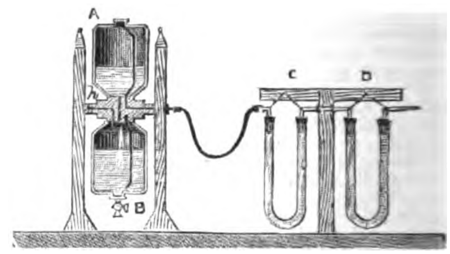
[12551.]—**Picture Framing.**—Lay the ends of the laths forming the sides of the frame over each other, and with a tenon-saw cut from the inside across the right angle formed. When the sides are cut apply a little glue with a brush to the ends intended to be joined. Join and drive a short tack through the ends near the angle from the top. Of course the sides must be planed and rabbeted beforehand, or "Jim" may glue on the face pieces cut with the others with the tenon saw.—RAT-TAT.

[12555.] — **Packfong, or Chinese White Copper.**—The Chinese packfong, tutenay, German silver, and electrum, owe their whiteness to the presence of the metal nickel, and like brass, the proportions of their ingredients—viz., copper, nickel, zinc, with occasionally a little lead or iron—are variable. Thus, the packfong contains $13\frac{1}{2}$ per cent of nickel, whilst the ordinary "German silver" contains from 20 to 25 per cent.—M. F. P.

[12566.]—**Bees.**—It would be illegal to retain the bees on the owner making application with a properly witnessed declaration that the bees which had taken possession of the empty hive were his, and that he traced them to the place. Bees can be recovered by the owner like other stray property, as cattle or sheep. —RAT-TAT.

[12571.] — **Break for Bicycle with Indiarubber Tires.**—In reply to E. B. Shaw, I know nothing with regard to the wooden block or the roller, but I think a good brake is still a desideratum; the system at present in use is simply rapid destruction of the indiarubber tire of the back-wheel. I have had a Phantom bicycle in constant use for the last twelve months, and I am much pleased with the very soft rubber which is supplied by the makers of that machine, but on the back-wheel I find that it wears away very fast. It seems to tear off in short strips: possibly a harder variety might wear better; that is, might grind away in the form of a powder. In any case, it seems to me that if you only put on the brake so as to check the wheel (but not stop it) while going down hill, the tire must grind at two points, at the part in contact with the brake, and at the part in contact with the ground; if, however, the brake is put on vigorously so as to stop the hind wheel from turning at all, then the destruction is only at the one point at the part in contact with the road. Practically, I believe the best plan would be to have very soft rubber on the front wheel, and a much harder kind on the hind one. The rubber tire on the front wheel should be as soft as possible to neutralise the irregularities of the road, which are felt by the rider almost entirely through the medium of the front wheel, to which the handle and treadles are attached; and, except for abolishing the noise, I can see no reason (as far as comfort is concerned) for an indiarubber tire on the hind wheel. I had a front wheel in use for many months over between 2,000 and 3,000 miles of all sorts of roads, and the soft indiarubber tire was as good as ever; it was cut in many places, but in consequence of the construction of the "Phantom" tires, it could not gape at the cuts, and was, therefore, practically uninjured; it gave way through an accidental fracture of the felloe. It is obvious that the brake should be applied to the hind wheel, because any check to the front wheel will cause the rider to turn a somersault over the steering-handle; but I think this might be arranged so as to make the hind wheel turn stiffly in its bearings; I can see a way of doing this after the fashion of a friction-brake without applying the skid directly to the tire of the wheel. By this means the machine might be controlled so as to run steadily at a moderate pace down a hill without grinding the tire to pieces. With the present system, the only way to save the tire of the hind wheel is to control the machine with the feet on the treadles down the steep hills until you reach a part where you can let it run at full speed, and if in good order, this will very soon be nearly twenty miles an hour when once let loose.—A. WOOLSEY BLACKLOCK, M.D.

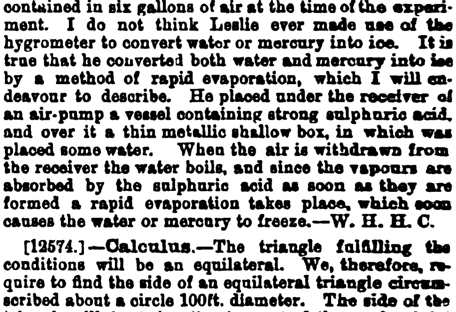
[12573.]—**Hygrometer.**—A hygrometer is an instrument for measuring the degree of saturation of the atmosphere. There are several kinds of hygrometers, one of which I will describe, called the chemical hygrometer. In this hygrometer a given volume of air is made to pass through chloride of calcium, or very strong sulphuric acid which has been previously weighed. The increase of weight shows the amount of moisture in the volume of air. Two brass reservoirs of the same construction, and holding a gallon each, are fixed on the same axis, but on opposite sides, as in the appended figure, and made to turn about it. The interior of each vessel is connected by a central tubulure, and the lower one is always in connection with the air outside by means of tubes running through the axis, while the upper one is connected by means of guttapercha tubes to the tubes C and D, which are filled with chloride of calcium or some porous substance saturated with sulphuric acid. The tube C prevents any vapour from escaping from the reservoirs to D, and D absorbs the vapour of the air which passes through it. The lower reservoir B being filled with water is inverted so that the water running slowly from it expelled the air in A through the tubulure h which con-



nects it with the air outside. The vacuum now formed in A causes a draught of air through the bent calcium tubes C and D, and the calcium absorbs the moisture in the air which passes through it. When all the water has run into B, the reservoirs are again inverted, and the same process commences again. If the reservoirs have been turned six times, it is evident that six gallons of air have passed through the tubes C and D, and have been deprived of the moisture in them. The contents of the tubes C and D are then weighed, and the increase of weight gives the amount of vapour contained in six gallons of air at the time of the experiment. I do not think Leslie ever made use of the hygrometer to convert water or mercury into ice. It is true that he converted both water and mercury into ice by a method of rapid evaporation, which I will endeavour to describe. He placed under the receiver of an air-pump a vessel containing strong sulphuric acid, and over it a thin metallic shallow box, in which was placed some water. When the air is withdrawn from the receiver the water boils, and since the vapours are absorbed by the sulphuric acid as soon as they are formed a rapid evaporation takes place, which soon causes the water or mercury to freeze.—W. H. H. C.

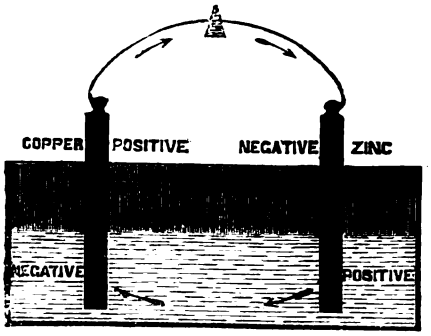
[12574.]—**Calculus.**—The triangle fulfilling the conditions will be an equilateral. We, therefore, require to find the side of an equilateral triangle circumscribed about a circle 100ft. diameter. The side of the triangle will be twice the tangent of the angle of 60° in a triangle whose cosine (the radius of the circle) = 50ft. Under these conditions the tangent will be found to equal 86·6025ft., and the side of the required equilateral triangle being equal to twice this tangent will be 173·205ft.—EXCELSIOR.

[12577.]—**The Iris or Rainbow.**—I think M. Ganot's explanation of the cause of the rainbow will suit "A Young Astronomer." M. Ganot says:—The phenomenon of the rainbow is produced by the decomposition of the white light of the sun when it passes into the drops, and by its reflection from their inside face. In fact, the same phenomenon is witnessed in dewdrops and in jets of water; in short, wherever solar light passes into drops of water under a certain angle. The appearance and the extent of the rainbow depend on the position of the observer and on the height of the sun above the horizon; hence only some of the rays refracted by the raindrops and reflected in their concavity to the eye of the spectator are adapted to produce the phenomenon. Those which



do so are called effective rays. To get a general idea of this let us refer to the figure, in which two raindrops a and c are represented extremely magnified as compared with the arc of which they formed part. The pencil of white light which falls upon a is refracted on entrance into the droplet and decomposed, giving rise to seven rays, red, orange, yellow, green, blue, indigo, and violet. At the point a, on the posterior face of this droplet, a portion of the refracted light escapes, and is dispersed in the atmosphere without giving rise to any particular phenomenon; the light which has not emerged from the droplet is collected at a, returns and emerges in being a second time refracted, and reaches the observer's eye as represented in the figure. A second droplet, *c*, placed below the preceding one, produces just the same effect, yet it does not send the same colour to the spectator. For as the different colours are unequally refrangible the coloured rays which emerge from the same raindrop diverge, and therefore are not propagated together, whence it follows that each drop sends only one kind of colour towards the observer. But from the degree of refrangibility of each ray the droplets on the outside of the arc send only red rays towards the eye and those on the inside violet rays. The other colours arise from intermediate droplets. In short, the rainbow is the circumference of the base of a cone, the apex of which is the observer's eye, and the surface of this cone is found from the outside to the inside of seven successive envelopes, red, orange, yellow, &c., corresponding to each of the bands of the spectrum. The nearer the sun is to the horizon the larger is the visible part of the rainbow; but as the sun rises the arc diminishes, and entirely disappears when the sun is 42 degrees above the horizon; hence the rainbow is never seen except morning and evening.—M. F. P.

[12578.]—**Medical Coil.**—"S. A. Z." is quite right when he connects the zinc of one cell to the silver—or what I presume to be the platinised silver—of the other cell; this would, of course, leave the terminals or poles as positive and negative ends. "S. A. Z." says, "The binding screw on the coil which connects the wire coming from the extreme silver is marked N, which I take for negative, &c." This is correct. N for negative, P for positive; but why "the wire coming from the silver" should apparently of necessity be connected with the binding screw marked N, as if there were no other alternative, I am at a loss to understand. Unfortunately, this is the first stumbling-block, and, consequently, is the cause of much confusion. The wire from the silver should be connected with the screw marked P, not N. "S. A. Z." continues to say, "Now what I want to know is if the electricity flows first from the zinc through the fluid to the copper, and from the copper to the zinc through the connecting wire above, how is it that the copper extreme is the negative?" Now, permit me to say that the copper extreme is the positive, and not negative; of course, I presume by "extremes" is meant the ends of plates not immersed. The platinised silver plate may be called a negative metal, but it, nevertheless, constitutes a positive pole, and the zinc may also be called a positive metal, yet it is a negative pole. Let me refer to the following diagram:



I think it will be evident from the above diagram that the current of electricity passes from the zinc in the fluid to the copper, and from the copper to the zinc out of the fluid, each plate assuming a positive and negative end; and here it is where a mistake is made of great importance, when it is assumed that a negative or positive plate would be the same throughout its entire length both in and out of the fluid; that, for instance, a negative plate in the fluid would also be negative out of it. It is important to recollect that such is not the case, but that each plate assumes polarity, and is, in fact, the reverse in the liquid to what it is outside of same: hence, a copper or platinised silver plate would be negative in the fluid and positive out. And, further, that "the electricity in the battery is given off into the coil," not from the zinc, but from the copper or positive pole, and this is the "extreme" which should be put into connection with the screw marked P. As to using a current of electricity from a coil for rheumatism, I would advise "S. A. Z." to put his feet, also the negative pole, into warm water, and apply the positive pole to the part affected under a strong power once a day for about twenty minutes; and, further, twice a day as opportunity offers to take the negative pole in his hand on that side which is affected, and apply the positive pole to the place where the pain exists, taking care to insulate the handle, and having within it a damp sponge. Having used electricity in many cases of rheumatism, neuralgia, debility, toothache, &c., I can testify as to its efficacy and value, if properly applied. Should "S. A. Z." require any further information, I shall be most happy to give it, so far as lies in my power.—E. O. SIMMONDS.

[12579.]—**Counting Envelopes.**—I should think a machine for counting envelopes would be almost a superfluity. If "Philanthropist" will take a packet of envelopes by the right hand bottom corner between the finger and thumb of the right hand, and hold them up, they will spread out like a fan, and count them with the two first fingers of the left, a little practice will enable him to keep pace with any machine yet invented.—A MAKER.

[12579.]—**Counting Envelopes.**—There is a machine at present in use—a babe from Yankeedom, I understand—for counting leather envelopes, *alias* boot-tops, which are cut like paper envelopes, on a block of wood upon which is made to descend a steam hammer with the cutting edges of hard steel set in suitable form on its lower face. There is one erected in a large shop in Newcastle-on-Tyne. A mechanic from the United States had to be brought over to set what we may call the counting apparatus in working order. I don't know the principle of this portion of the machine, as I have not seen it, but I suspect that the hammer or die, acting as a pendulum, touches a small cog-wheel, and at each blow passes a tooth in the wheel which sets in motion a train of wheels, one indicating by means of a clock-hand on a figured dial the number of envelopes cut. Soles are cut and the number indicated in the same way. An overseer is not necessary with this machine for looking after the workmen, as it shows at once whether they have idled by the number cut. An improvement is also in contemplation to indicate the time since starting, like an engine clock. A very light and simple modification of this machine would do for cutting and counting paper envelopes, as suggested by "Philanthropist."—RAT-TAT.

[12581.]—**Tests for Flour.**—The most reliable test for rice is the microscopic appearance of rice-starch, which is quite peculiar and characteristic. China clay, if present in the biscuits, would be left behind on ignition. Wheat flour never leaves more than 1 per cent. of ash, anything above this proportion may be regarded as mineral additions.—ALFRED H. ALLEN.

[12582.]—**Paper Clothes.**—The doorways of the galleries near the Indian Court in the International Exhibition are hung with paper curtains which have some resemblance to chintz. The fabric is the invention of Mr. Eugene Pretto, and is something like Japanese paper. In its manufacture various animal and vegetable substances are used, such, for instance, as buffalo skins, the intestines of animals, the fibres produced from the various nettles and grasses, barks of trees, and from flax, hemp, and cotton. These substances, mixed together in varying proportions, are treated much the same as the materials for paper are treated, that is to say, disintegrated, purified, bleached, rolled, pressed, and finally printed upon. The fabric produced differs, however, from ordinary paper in this, that it is not readily torn, is somewhat elastic, and soft enough to fall readily into graceful folds. The inventor claims for it, further, that it will resist the action of the weather and sun, and that damp does nothing more than make it more soft and yielding to the touch. The fabric at present has been principally applied to window curtains, roller-blinds, bed-curtains, and for the covering of walls, not so much in the way of ordinary paper-hangings, but more as chintzes or tapestries are used. The patterns are an imitation of the brocaded silks of Lyons, chintzes, and cretonnes. The inventor, however, has in view the production of a material that shall go much farther in superseding woven fabrics, in the shape of coverings for chairs, and even as carpets for floors. The colours are less liable to fade than in chintzes, as they are printed principally in body colours, and will keep clean the longer, as dust is not absorbed, but can be brushed off. The prices of the curtains vary from 5s. to 30s. per pair, complete; the material may also be bought in the piece. This application of paper is practically new so far as this country is concerned, though the Japanese have long ago found out that it could be applied to such purposes as what we call drapery is used for. Possibly this material may be utilised at no distant date in the direction intimated in "Kappa's" query.—TOPSY.

[12584.]—**Bee Keeping.**—"Phan" has not given sufficient information to enable one to give a sound opinion as to whether it is proper to put on new supers when the bees have killed their drones. A great deal depends on the size of hive and super already filled, for if they be of small sizes the chances of further surplus are very small indeed, but if the stock be large and powerful the bees may yet fill a small super if partly filled with empty comb, but will rarely take to a second one if empty. Killing the drones does not always imply that the honey season is over, but sometimes in strong stocks it is the reverse, for having nowhere else to store a glut of honey the bees turn out the drone brood and use those cells for the purpose, and having begun with the brood they finish with the destruction of the drones themselves. It is not to be wondered at that cottagers have prejudices in bee-keeping and prefer their own ignorant blindness to the blind leading of others. Let any one try "Rat-Tat's" advice to "W. T. L.," July 26, p. 494, "late in the evening, which is considered the best time," and after that say if the cottagers have not some ground for their prejudices. The cottagers' prejudice against supers is the best argument against their own system, for they practically acknowledge that the super system, or as it is called, the depriving system, leaves the stocks so strong that those saved from the brimstone pit are unable to hold their own. When a large super is removed from a strong stock of bees it must be evident that the stock hive becomes more crowded, consequently greater heat is engendered, and the bees are more robust than those left in hives which, as cottagers say, are not fit "to take," forgetting that what are not fit to take are not fit to leave. Cottagers should learn by experience, and adopt the system which gives the best results. Why, even "Pettigrew" advocates the super, although at the same time he defends the sulphur pit, and considers it no more cruel to suffocate bees for honey than to cut a sheep's throat for mutton, but if there were any other way of attaining the mutton that process, like bee-burning, would be most wanton cruelty. The cottagers' folly does not consist in charging deprived bees with robbing, for it is a fact that strong stocks will plunder their weaker neighbours without mercy, really carrying out the good old plan—"That they shall take who have the power, and they shall keep who can." It is undoubtedly a provision of nature that weak stocks should be absorbed by stronger ones, and in one's own apiary such unions are beneficial rather than otherwise, but when a cottager's bees are absorbed by another person's strong stocks the cottager ought to learn the lesson inculcated, and have strong stocks too. "The way to preserve peace is to be prepared for war," and if all are "fit" for aggression, all are prepared to resist it. The cottager's folly consists in destroying all his strong stocks, and so placing his apiary in jeopardy. My advice to all bee-keepers is—notwithstanding all that has been said about equalising stocks for winter—equalise if you can—*i.e.*, make all strong, but never weaken a stock to do so; better unite three or four than weaken one to aid another. This is, perhaps, gratuitous, but none the less valuable.—C. N. ABBOTT.

[12586.]—**Magnetine or Improved Skeuasma.**—There are three magnetic belts in the field—the skeuasma, patented by Messrs. P. W. Seymour and F. W. Darlow, in November, 1866; the amynterion, patented by Mr. P. W. Seymour, in January, 1872. In the form of the magnetic blocks it is superior to those of the skeuasma, being lighter and more flexible. Since then the magnetine has been published. The date of its patent I do not know. As to the principle of action of all these belts or appliances, I am quite in the dark. They profess to alleviate and cure by wearing magnetic iron on the body. The skeuasma is made by fusing magnetic iron filings with indiarubber; this, in small blocks, is placed at equal distances in a belt or other contrivance, inclosed within flannel on the one side and a kind of jean on the other. As these blocks are somewhat stout, I presume that in the improved skeuasma they are cut up into minute needle-like strips, so as to be more pliable, and then fastened over the whole inner surface of the belt or other appliance. I gather this from Mr. Darlow's advertisement. I may add, in conclusion, that whatever may be the principle that governs the magnetic appliances, I have fairly tried the amynterion according to the directions given me for over two months, carefully watching for symptoms daily, but felt no improvement whatever in my health, no tingling sensation, and no other difference except warmth such as an ordinary flannel belt would give. Yet the amynterion influences the needle of the pocket compass.—A WORKING B.

[12588.]—**Railway Metals.**—As the earth moves from west to east it would cause a train moving from north to south to swerve a little to the west side, which would throw a little more weight on the west rail, and more weight means more wear, the swerving would not occur in a train running east to west, or *vice versâ*, as it would then be moving in near the same direction as the earth.—STADACONA.

[12588.]—**Railway Metals.**—The earth's rotation is from west to east, and is more rapid at the equator than towards the poles, thus a train proceeding northwards has a tendency to wear the eastern rail, for in order that it may keep on the rails its velocity of rotation becomes gradually a little less, being always the same as that of the part of the earth it is passing over, but as it proceeded southwards the western rail would be more worn.—PHILANTHROPIST.

[12588.]—**Railway Metals.**—It has also been asserted that the wearing of river banks is for the same reason influenced according to their direction with regard to that in which the earth rotates.—M. PARIS.

[12589.]—**Lapidary's Wheel.**—About 10 or 12 inches diameter, from 400 to 1000 revolutions per minute. Runs horizontal.—JACK OF ALL TRADES.

[12590.]—**Glues.**—I should recommend "A Country Bookbinder," when he has melted his glue, to stir a tallow candle in it for about one minute. He will find that his glue will work better. When I was in the trade I have made hundreds of cloth cases with the glue thus served.—C. COLEBY.

[12592.]—**Silk Solvents.**—If "The Harmonious Blacksmith" wishes to find out how to dissolve silk, let him put one of his better half's old silk dresses into a basin of muriatic acid, when, if it be a pure silk dress, he will find that it has entirely disappeared. If he could manage to precipitate the silk from the above solution, and make it into threads, he could send it to the factory and get it woven, which would be a very good "spec." indeed. However, joking aside, I have found that a thick solution of silk makes a very good cement for glass plates, and when pure is entirely transparent. Perhaps some chemical correspondent can give a solution to the query of how to precipitate it.—OPALINE.

[12593.]—**Lightning and Thunder.**—Sheet lightning occurs without thunder in very warm weather. I have seen a portion of the sky beautifully lit up at intervals with sheet lightning on warm nights in Canada.—PHILANTHROPIST.

[12593.]—**Lightning and Thunder.**—As far as my reading enables me to answer I should say not. Summer lightning, as observed by "Seneca," is merely the reflection of a distant storm. Lightning without the thunder being heard may be noticed in the clouds about waterspouts.—M. PARIS.

[12593.]—**Lightning and Thunder.**—Lightning is seldom, if ever, accompanied by thunder at sea; the reason for this is that the surface of the sea does not present obstacles, like hills and other irregularities on land, to intercept the passage of the waves of air caused by the lightning.—R. D. D. M.

[12593.]—**Lightning and Thunder.**—Lightning never occurs without being accompanied by thunder. Sometimes, however, the reflection of lightning a long way off is seen, and then, of course, the thunder cannot be heard. When this summer lightning occurs, it is often followed some hours after by a real thunder-storm, as was the case at Weston-Super-Mare on the evening of July 25th, when summer lightning was observable, and at 2 a.m. on the 26th when a *bonâ fide* thunder-storm occurred.—E. Johnson.

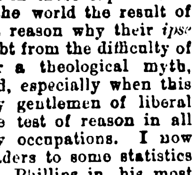
[12593.]—**Lightning and Thunder.**—We might safely pronounce, I think, a concession like any electric discharge, in air within four miles of the ground, to be impossible without noise. There is a good riddle. What is it that always starts with the train, goes and stops when the train does, is of not the slightest use to the train, but no train can go without it? By night we may plainly see either the light of lightning or the flashes themselves beyond 100 miles, and shall then suppose them unaccompanied with thunder; because I have never found, by counting seconds, that any thunder was audible quite 24 miles. One very still evening, by the coast, with a storm of lightning retiring out to sea, the last thunder I could hear was like a faint moan of not half a second duration, 119 seconds after its flash, which was a great and vivid one between cloud and sea, the wind being favourable. I doubt if thunder is ever heard much farther than this; especially as the shortness of the sound proved it to arrive from all parts of the flash almost simultaneously. Had one part been a mile nearer than another, so as to spread the sound's arrival over 5 seconds, it would certainly have been inaudible.—E. L. G.

[12593.]—**Lightning and Thunder.**—Professor Thomson, in his "Outlines of the Source of Heat and Electricity," after describing the nature and appearances of thunder and lightning, says that when no noise is heard, it is distance alone which prevents it; for there can be no lightning without thunder, any more than we can take a spark from an electric machine without a snapping noise.—Alastor.

[12594.]—**Varnish Cells.**—If "Alf." uses good copal varnish with his Brunswick black instead of gold size, I believe that he will get over his difficulty.—Jack of All Trades.

[12596.]—**Canoe.**—If "Paddler" values his life he will go by train with his canoe from Hull to Scarborough. It is just possible that the trip might be safely accomplished by sea provided you possess a thorough knowledge of the tides, and the weather is fine, and the water smooth. But how can you insure the latter conditions? The wind might rise, and the water roughen when you were rounding Sperm Point, or when you were passing Flambro' Head (where, by the way, you would find it impossible to land); and you would then speedily wish yourself on firm earth again. Begin by sailing about in the bay at Scarborough when the weather is fine. A canoe will ride safely on a good deal of swell provided the waves do not "break." Nothing materially smaller than the *Rob Roy* canoe is fit for the sea. Full dimensions are given in "1,000 Miles in the Rob Roy Canoe," both of craft and sails, &c.—W.

[12597.]—**Water-wheel Floats.**—Poncelet's undershot wheel is the best; the buckets are curved so that when the impulse of the water is expended it gives further power by running down the floats, and there is less shock in the meeting of the current with the wheel as the water runs up the float a little. I do not know the exact form of the curve; it is concave towards the stream.—Philanthropist.



[12598.]—**Age of Trees.**—The age of trees being now positively determined by the number of zones or rings in the fibre of the wood, it settles the question into one of veracity and honour in those explorers of botanical science who afford the world the result of their observations. The great reason why their *ipse dixit* is impugned arises no doubt from the difficulty of substituting a visible fact for a theological myth, which is greatly to be regretted, especially when this myth is steadily adhered to by gentlemen of liberal education, and who apply the test of reason in all matters concerning their daily occupations. I now beg to refer your intelligent readers to some statistics carefully compiled by Sir Rd. Phillips in his most useful work, "A Million of Facts," furnished to him by Mr. Don, Secretary Linnean Society: The baobab, of Senegal, 5,150 years; deciduous cypress, 6,000; yew, 3,000; olive, 2,500 years; dragon blood, 4,000. I have no doubt that the very gigantic trees of California will yield upon examination an antiquity far exceeding these above quoted. I should be grateful to any of your numerous correspondents if they could add other facts of extraordinary longevity of trees.—A Believer that One Fact is Worth a Million Myths.

[12598.]—**Age of Trees.**—Judging from the concentric rings supposed to indicate the annual growth, some of the gigantic Californian trees must have been growing when Father Abraham was a boy.—M. A. B.

[12599.]—**Dimensions of Mail Boats.**—The following are the principal dimensions of the Holyhead mail boats (they are all very much alike):—Length, 350ft.; breadth, 35ft.; depth, 20ft.; draught, I think, about 13ft.; tonnage, 2,000 tons; engines, diameter of cylinders, 90in.; stroke of ditto, 7ft.; nominal horse-power, 750; indicated horse-power, full speed, 4,300.—No. 170.

[12599.]—**Dimensions of Mail Boats.**—The dimensions of *Leinster* are—length, 360ft: breadth, 35ft.; mean draught, 12ft. 9in.; area of midship immersed section, 330 square feet; engines, 720 nominal horse-power; cylinders, 98in.; stroke, 6¼ft.; boilers, eight; with 40 furnaces; with 4,176 tubes; and 16,800 square feet of heating surface. The working pressure is 20lb. per square inch. The boilers are not fitted with superheating apparatus, nor are the engines fitted with an expansive gear, but steam is cut off by the slide valves at five-eighths of the stroke. The paddles are on the feathering principle, float boards 12ft. long. 5ft. deep.—J. B. Clay.

[12600.]—**Hydraulic Explosions.**—I have often met with explosions when preparing hydrogen by the action of sodium on water, but they have never been so violent as those described by "Dabbler," though sufficiently so to break the receiver. I never tried to fill a quart jar by the above method, but only prepared a few ounces of hydrogen. I have always attributed the explosion to a layer of sodic hydrate being formed round the metal and kept by the intense heat from contact with the water by an intermediate layer of steam (just like water on hot iron). On condensation of the steam, the water comes in contact with the hot metal and hydrate (or possibly oxide), producing suddenly a large quantity of steam and hydrogen, and thus causing an explosion. I do not feel sure, though, that the effect is not due to some impurity in the sodium used. I cannot see how oxygen could possibly be liberated in the presence of sodium, and "Dabbler" must remember that the heat required to decompose water is the same as is generated by its synthesis, so that no extra heat could in that way be evolved.—Alfred H. Allen.

[12601.]—**Tuning Æolian Harp.**—"Opaline" must tune the strings of his harp in unison to what note he wishes.—Horatio.

[12602.]—**Extinction of Fires.**—A gas for extinguishing a fire should be without smell, which neither chlorine, hydrochloric acid, nor sulphur dioxide are. Sulphuretted hydrogen is not a supporter of combustion, but is itself combustible. Carbonic acid satisfies the necessary conditions, and is used in the apparatus called the "Extincteur," which is very useful for small fires, being equivalent to so much soda-water.—Alfred H. Allen.

[12604.]—**Quill Pen-Making.**—Cut the point considerably longer than you intend to use it, then reduce it to a comparatively broad point previous to splitting. To make a good split, insert the point of your knife very gently in the broad point to start it, and then press your thumb-nail against it until you have led it sufficiently far up. This plan I have always found answers well. You can then reduce the size of the point in the ordinary manner.—Alastor.

[12604.] — **Quill Pen-Making.** — I am not an adept at making quill pens, but I have made them. The way I slit mine was this: I cut a piece of hard wood to fit the end of the quill as far as I wanted to cut, then I fixed it nice and handy to get at, then slit them with a sharp penknife, beginning at the broad part and finishing at the point.—Sting.

[12605.]—**Organ.**—If "E. J. D." purposes building an organ of four stops and one manual he can with safety begin his soundboard and bellows; they will take him some little time to make, and by the time he has them finished I shall have described, in "The Organ Built," the action he inquires about, as I intend to show a fan frame action to the great organ. The length of middle C in the clarabella is 2ft. on a scale of 1¾ × 1⅜. Why make a wooden dulciana? anything like a true tone cannot be obtained from it, for it would only be a soft clarabella without the singing tone it should have; if, however, you are inclined for it use the same scale as for the stopped diapason, making the pipes, of course, twice as long.—J. D.

[12606.]—**Submerged Forests.**—Though I know of no special work on this subject, "J. G. W. R." may like to know that he may see remains of submerged woods among other places on the coast of Sussex, between Eastbourne and Hastings. I lately visited one of these woods near Bexhill. It is extraordinary how little is known in the neighbourhood about such a natural curiosity. I found it by walking along the sands from Bexhill towards Pevensey at low water. A coastguardsman about 200 yards from the spot where the remains of the forest are knew nothing whatever about the matter. The old trees are to be found a few yards east of Martello Tower No. 52. There are few large roots and stumps left, though there are plenty of roots of bushes cropping out of the shingle. The largest stump I found was about 8in. in diameter, and about 6in. out of the sand. There is a description of the forest in the "Handbook for Eastbourne," by Mr. G. F. Chambers, F.R.A.S. (Stanford and Co., Charing-cross), with an extract from an article which appeared in the *Gentleman's Magazine* in 1814 on the subject. Since the time the article was written, however, the forest must have dwindled terribly in its proportions, probably at the hands of too inquisitive geologists. I believe there is another forest of the same nature nearer Hastings. I read in the *Morning Post* of the 6th instant, in the account of the opening of the new pier there, that submerged trees had been removed when the foundations of the pier were being laid, and that an oak had been placed by the pier authorities in S. Andrew's Gardens.—V. B.

[12606.]—**Submerged Forests.**—A great many submerged oak and other trees can be seen in the Bog of Allen in Ireland. Turf or peat is a good preservative, and the timber of the trees is as sound as before submerged. The wood is carved into bog-oak ornaments, &c., and from its hardness it can be exquisitely carved and polished. Forests of trees may be also found submerged on the west coast of Portugal, Japan, and Chili.—Rat-Tat.

[12608.]—**Bookbinder's Press.**—Substitute brass or steel male and female screws.—Rat-Tat.

[12609.] — **Packing Grapes.** — Pack between layers of their own leaves in willow baskets to preserve the bloom.—Rat-Tat.

[12609.]—**Packing Grapes.**—Pack in dry sawdust.—Excelsior.

[12609.]—**Packing Grapes.**—Let "A. B." pack his grapes in sawdust or bran, preferably bran, take the box, cover bottom with bran, then a layer of grapes, cover with bran, being very careful to fill up spaces between grapes, stalks, and everywhere; then repeat, leaving a good layer of bran on top, and nail down the lid. Do not press the grapes, but use them like little babies, very tenderly, and the bloom will stay on.—Sting.

[12611.]—**Moth in Pianoforte.**—Pack in case as air-tight as possible, and fill it with the vapour of ether, spirits of wine, tobacco smoke, fumes of sulphur, carbolic acid gas, or burnt camphor, with a blowing apparatus, and the moths will be destroyed.—Rat-Tat.

[12611.]—**Moth in Pianoforte.**—Touch the dampers with spirit of camphor.—Excelsior.

[12612.]—**Action of Oil on Waves.**—The only explanation of this which occurs to me is that oil being more viscous than water requires greater surface agitation before it is lashed into waves. To illustrate this, take a tumbler, and having about half filled it with water, rest it on a level table. A very slight blast from the mouth will cause wavelets to be formed on its surface Now add oil to the depth of 1 centimetre (⅜in.). Considerably greater force must be exerted to form similar waves on the surface of the oil. But it seems highly improbable that a similar action would take place in a storm such as Graham Young describes.—Alastor.

[12612.]—**Action of Oil on Waves.**—It prevents the ruffling by friction of the wind, but does not stop undulations propagated. You can throw a little into a breezy pond and see how the oil smooths the surface. I cannot think its effect would be very decided in a gale on shore.—M. Paris.

[12613.]—**Drying by Steam.**—If the rubber is vulcanised, anything short of a burning heat will not destroy it.—Rat-Tat.

[12614.]—**Corpulence.**—Fat, sugar, gum, starch, farinaceous food, milk, and the like, and articles of diet abounding in them, are favourable to the production of fat in the body of animals, man included. Mild ale, beer, and porter, for like reason, has the same tendency. Much exercise or labour acts in a contrary direction. Indeed, quiet and repose tend greatly to the production of both fat and flesh, but the latter is not then of a muscular character, as witnessed in feeding domestic animals. Leanness is generally caused by defective digestion or action of the stomach or bowels; often both. Cod-liver oil (the best now pale Newfoundland) has a wonderful power of increasing the weight and fleshiness of the body.—Arotes.

[12614.]—**Corpulence.**—There are some people on whom all the food they could eat would never put fat. I never saw a jolly, good-humoured, kind-hearted person, who took pleasure in making others happy, who was one of Pharaoh's lean kine, unless through disease. A selfish, uncharitable, cantankerous, nagging skinflint is always thin. Look at the late Mark Lemon and his prototype Falstaff. Compare (as the commentators say) with Pecksniff and Uriah Heep. Believe me, the proper sugar to make you fat is a sweet temper, and the milk that of human kindness. Any greasy or oily substance tends to be stored up in the system; but Wilkie Collins was wrong when he drew the silky villain Fosco as a fat man.—M. A. B.

[12614.]—**Corpulence.**—Diet is the thing for "Anti-Banting," but not inactivity. Bread and milk, cocoa, &c., for breakfast. Mutton chop, port wine and rice-milk pudding at lunch (or, if he dines late, then); bread, with Devonshire cream or thick butter at tea. Porridge may be substituted for bread and milk.—E. Johnson.

[12614.]—**Corpulence.**—"Anti-Banting" asks how a thin person may be made fat, and a fat one made lean. He little thinks, probably, how wide a subject his question opens out. We often hear people vaguely talking about getting fat and getting lean, or fattening or leaning upon this or that kind of food, but they don't know what they say. Even some of our learned (?) medicists and chemists talk about food as if a person had only to subsist upon starch, sugar, albumen, fat, &c., in different quantities, to become of the dimensions of the "Claimant," or a mere "rickle of bones," as Dr. Livingstone describes himself when Mr. Stanley found him. It is almost purely a question of *temperament*, and involves more a knowledge of this science than of dietetics or chemistry. A man's shape, form, squareness, roundness, tallness, shortness, fatness, or leanness are all dependent upon his temperament, as inherited from and impressed by his parentage and ancestry. They have little, *very little* to do with his food. To answer "Anti-Banting's" question, as regards his own case, no one could answer it truthfully unless he knew his temperament, and the different degrees in which he had the several temperaments blended in his own person. Along with this the shape of the brain has much to do with it, for certain types of brain do to a certain extent accompany certain types of temperament, or form and strength of body. The vital or lymphatic temperament is, under all circumstances, and with *any* kind of food, the most likely to become fat. Such temperaments like plenty of food, and that good, but as it exists amongst all ranks, so it gets all kinds of food, from that which an epicure might revel in to that of the poorest of the poor; both would be fat, though not, perhaps, equally so. These persons have a predominance of the vital powers, of the digestive apparatus, and their nerves are not too active, so as to become great waste producers. They are easy and content, hence get fat. A person with a pure, or even highly predominant nervous temperament, never gets fat. The most prominent and active part of his body is the nervous system; he is all alive; all nervous action; his mind is ever awake; he can't get fat, no matter what he eats, or how much. "Anti-Banting" may remember that the less motive, or bony and muscular, and nervous system there is, and the more lymphatic, the more favourable for getting fat. The less vital, and the nervous or mental high, the less likely to get fat. Cardinal Wiseman, Spurgeon, Macleod, Punshon, the "Claimant," Mark Lemon, and men of that class, have the vital temperament high, and the osseous and muscular systems less developed. In many cases the brain is large and active, yet at times lazy: such men do love their stomachs, and altogether have the natures for getting fat, and they make the best of them generally. Small, limber, clean, neatly made men, like J. S. Mill, Archbishop Manning, Mr. Gladstone, Professor Tyndall, C. Dickens, and others, have the mental or nervous temperament highest, hence their cleverness; such men are not usually thin through poverty, yet who ever sees them fat? it is not their nature, and their systems mould and modify their food, rather than their food moulding and controlling their systems. The inherent power and quality of food is much, but the inherent power of an organised animal over its food is more. Before a pig, an ox, or a horse, can become a prize for fatness, it must possess a certain blending of temperament, and this is given to it by the process of "breeding." Men like Lincoln, Wellington, Clyde, Shaftesbury, Disraeli, and others, are of another type: the bilious or motive; they don't get fat; they are too active, too industrious, both mentally and bodily; all their surplus nutrition is worked off. The lymphatic are the lazy, mentally and bodily, in different degrees, of course. The nervous are pre-eminently the active minded; the bilious the active minded and bodied; the last gives the most power of mind, as mind; the lymphatic or vital the least. In what degrees are the various temperaments possessed by "Anti-Banting"? This known, he has a greater chance of knowing his chances for fatness or leanness than all the writings ever penned upon dietetics or medicine can tell him.—GEORGE DAWSON, Sheffield.

[12618.]—**Excessive Perspiration.**—Constant ablution with sponge and cold water, especially where perspiration lodges or excoriations exist. Dry perfectly after, and dust part with prepared fuller's earth. It is put up for nursery use, and is a great boon to stout people in India.—M. A. B.

[12618.]—**Excessive Perspiration.**—In training for athletic sports, the usual mode of preventing perspiration is to leave off taking butter, potatoes, &c., and I see no other course for "A." to pursue.—R. D. D. M.

[12618.]—**Excessive Perspiration.**—Take a hot bath from 90° to 100°, and dress down either with cold dash, shower, or cold water and towel.—JACK OF ALL TRADES.

[12618.]—**Excessive Perspiration.**—Let "A." rest satisfied with his present condition and rejoice, rather than complain, that he perspires freely, or even excessively, in hot weather. Let me strongly advise him not to attempt in any way to interfere with the natural efforts of his system to compensate for the effects of immersion in an atmosphere of unusually high temperature. All he should do is to be temperate in eating and drinking, keep the bowels regular, avoid all debilitating habits, avoid the use of ices and cold drinks, and exposure to draughts of air, and indulge in daily ablutions or baths of warm or tepid water. Evaporation causes cold. Witness the effect of wrapping a wet cloth round a bottle of wine, or of the porous earthenware bottle on its contained water. The skin, moistened with perspiration, offers an immense surface for evaporation, and the consequent cooling action on the body is very considerable, and is, further, often the salvation of those who complain of it. I myself perspire excessively when I take brisk exercise in the sun, or even the shade, in hot weather, but I never feel oppressively or even unpleasantly hot, although the perspiration trickling down my face and head, and falling on my dress, often annoys me. The chief cause of the so-called "sunstroke" or summer apoplexy, is insufficient perspiration, and consequently an unnatural increase of the temperature of the body, particularly of the brain and heart, and the blood passing through them. When living under the almost vertical sun of the tropics I never felt oppressively hot, because I perspired very freely, whilst those around me who did not do so, bitterly complained that they "felt suffocated, nearly burnt up," and that their heads "felt bursting." Of the numbers of Europeans then around me who died of sunstroke, I found nearly all (most likely all) belonged to the latter class—viz., persons with dry skin, or skin scarcely moistened with perspiration. Of course the cold sweats of phthisis and other diseases of debility is another thing.—AROTES.

[12618.]—**Excessive Perspiration.**—Bathe in warm water, or apply an infusion of senna leaves.—RAT-TAT.

[12618.]—**Excessive Perspiration.**—Try 10 to 15 drops of diluted phosphoric acid in water twice a day I have used this with great benefit, and think it worth a trial.—OPALINE.

[12619.]—**Bad Water.**—Most probably the water "Inquirer" speaks of contains a trace of iron. Has not his pump an iron barrel or pipe. There may be iron in the strata the water of the well passes through; but this is very rarely the case. A mere trace of iron in his water would produce all the effects he speaks of. It is a common consequence where iron pumps or pipes are employed, and not much water drawn through them.—AROTES.

[12621.]—**Black Dye for Leather.**—Make a strong decoction of elder bark and dress with it. Treat afterwards with a strong decoction of nut-gall and a small portion of logwood, and lastly with acetate of iron.—JACK OF ALL TRADES.

[12621.]—**Black Dye for Leather.**—Nitrate of silver, or green copperas and common black ink.—RAT-TAT.

[12624.]—**Stuffing Reptiles.**—The skin of the boa constrictor must be damped to soften it, and then filled with tow. You can then, after neatly sewing up the aperture, place it in any position you choose. When quite dry the skin must be sized and varnished in the following manner. The best size is made of parchment cuttings, about a good handful boiled for an hour in a pint of water is about the proportion. The size is required in order to preserve the colour and beauty of his majesty. Apply with a dry brush three or four thin coats of size, allowing each to dry well before putting on another. When the last is dry coats of crystal varnish must be applied in like manner. This varnish may be purchased of an oilman or colourseller in any quantity. Fasten in the eyes with putty, and then your snake may be placed in a case, which should be decorated with mosses and reeds.—HORATIO.

[12625.]—**Heat Bumps.**—Take the child off flesh meat, allow it plenty of fresh sound vegetables, and sound ripe fruit. Bathe the spots with cold vinegar and water, and do not stuff the child with sweets and cakes.—JACK OF ALL TRADES.

[12625.]—**Heat Bumps.**—Give your child at bedtime 2½ grains of Dover's powder mixed in a little preserve. In the morning as much citrate of magnesia as will lie on a shilling in half a wine-glass of water. A hot bath for fifteen minutes at eleven, to be followed by warm beef-tea or mutton broth. In three days it will be well. No cold drinks or wine at present.—A. J. DAYMAN.

[12625.]—**Heat Bumps.**—Get 3oz. or 4oz. of concentrated fluid extract of sarsaparilla from a good wholesale chemist, give a teaspoonful two or three times a day in a wine-glass of water. This will also generally cure all forms of eruptions on children.—EXONIAN.

[12627.]—**Carbolic Acid as a Hair Dye.**—Carbolic acid is not a hair-dye, nor have I ever noticed that it has the slightest effect on the colour of the hair. Its use (highly diluted) as a hair-wash is now very popular. It acts by constringing and stimulating the skin, and thus tends to slightly thicken the scalp. Gradual attenuation of the scalp is one of the most common causes of failing hair and baldness. I have for many years used a wash of carbolic acid (1 part acid, dissolved in 40 parts hot water), but my hair is as silvery as ever.—AROTES.

[12628.]—**Rusty Iron Castings.**—Take 1 part sulphuric acid to 12 or 20 of water, and place your castings in this until the rust disappears; well wash and dry them; you can then treat them either to a coat of boiled oil or paint.—JACK OF ALL TRADES.

[12628.]—**Rusty Iron Castings.**—Acid is rather dear to use for such heavy work. It wouldn't pay to use it. Heat the castings, and file off the rust.—RAT-TAT.

[12629.]—**Skeleton Flowers.**—These are prepared by the old and simple, but tedious, process of "retting," the resulting skeletons being subsequently bleached and mounted, or set up. The art requires considerable patience, and some degree of taste and delicacy of touch in those who adopt it. These pretty objects can be purchased cheaper than an amateur can make them. My friend, the late Prof. Lindley, and myself, at one time devoted much attention to the subject, but we found that there was very little improvement to be made on the old methods of procedure.—AROTES.

[12629.]—**Skeleton Flowers.**—Flowers are very difficult to treat, being far more delicate in texture than leaves. They may be gathered and placed in a dry cellar for some time, then the petals or flowers are taken out and pressed between the leaves of a book prepared for the purpose. After that they are dipped in dilute hydrochloric acid, and the fibres are left behind. Leaves only require to be left in stagnant water till their substance is partly decomposed.—RAT-TAT.

[12629.]—**Skeleton Flowers.**—To obtain skeleton leaves, place the selected specimen in a plate just covered with water, and leave it in a place where it will not be disturbed until decomposition sets in, which generally takes place in about three weeks. Then carefully take the leaf out, and after placing it on a flat surface pour water on it from a watering-can, and if that does not wash away the green parts, dab the leaf gently with a clothes-brush, which will separate the particles which adhere more closely to the stem and veins.—C. N. W.

[12630.]—**Magnetism.**—If the machine is made to give shocks, like an induction coil, I see no reason why "D." should not work a vacuum tube with it. I have never heard of its being done, but I see no reason against it.—R. D. D. M.

[12631.]—**Fixing the Bloom of Scarlet Runners.**—I have some scarlet runners, and the bloom was falling off without the beans forming. I was advised to try liquid manure or sulphate of ammonia. I applied the latter in solution in water at the rate of half an ounce of the sulphate to one gallon of water. The beans have now set, and I am going to have an abundant crop.—G. W., Leeds.

[12631.]—**Fixing the Bloom of Scarlet Runners.**—I have likewise been disappointed by the falling off of the bloom of scarlet runners, and consulted the head gardener at a large garden close by, and he assured me it was caused by the heat, and that shading them would prevent it, or on the other hand if the weather became cloudy they would "set," which has actually taken place this week or ten days past, and the beans are setting and growing beautifully. My beans are planted under a high wall in a very hot situation.—OPTICAL BRICKLAYER.

[12631.]—**Fixing the Bloom of Scarlet Runners.**—If planted in drift that can be collected off the roadside, this never occurs. Draw a trench along both sides now, and put some in, or some old decayed hot bed, and well water. Cover up, and you may yet have a good sample. Nothing better for peas and beans or carrots than the drift off a turnpike road.—JACK OF ALL TRADES.

[12633.]—**Dried Yeast.**—Brewery or distillery yeast after proper purification and compressing will dry rapidly of itself. The dried yeast coming from Holland, at present, is in many cases too dry, owing to a good portion of farina or potato starch being mixed with it, partly to prevent its becoming soft on the voyage, and also a greed of extra profit. I am in possession of the entire process of manufacture of German dried yeast, and would have much pleasure in opening a correspondence with "H. W. T." if he will advertise his address.—GEO. A. DAVISON.

[12633.]—**Dried Yeast.**—If mixed with barley meal or pea meal very stiff and air dried, it can be kept any length of time if kept dry and cool.—JACK OF ALL TRADES.

[12633.]—**Dried Yeast.**—Let the yeast be kept in a dry cool place, and when pressed put it in bags at once. If at all moist sprinkle it over with a little rice flour, and it will keep firm and good.—EXONIAN.

[12633.]—**Dried Yeast.**—If "H. W. T." will wash his yeast twice in tepid (not warm) water, that has been previously boiled and cooled, before pressing it, I think he will find it will keep better. I have taken yeast, thus prepared, on several long voyages in hot climates, and found it good after six months. It should be kept as dry and cool, nevertheless, as circumstances will allow. The addition of chemicals always injures the quality of the yeast. The only thing I found that might safely be used was the addition of a little, a *very little*, common salt to the washing water. The best Dutch and German yeast is generally treated in this way. The admixture of dried pipe-clay, often adopted, injures the fermenting quality of the yeast, as well as that of the bread, &c., made with it, is unhealthy, and punishable by law.—AROTES.

[12635.]—**Transferring Pencil Drawings on Paper to other Paper.**—Take a piece of unglazed paper and treat it to one of these processes—1st, rub with a piece of cloth and lard, and after rubbing it well in smoke it over a candle or lamp; 2nd, rub the back of picture or one side of a sheet of unglazed paper with a solid block of black lead; by placing the prepared paper between the picture and paper, the prepared face upon that upon which you wish to make the transfer, and tracing the lines of the picture with an ivory style or nicely-rounded point of a steel knitting-needle, upon taking the paper off you will find a copy of it upon the paper required. This looks simple enough, but it requires great practice and care to get anything accurate and satisfactory.—JACK OF ALL TRADES.

[12635.]—**Transferring Pencil Drawing on Paper to other Paper.**—Any kind of reasonably fine paper, either thick or thin, serves to receive the copy. You simply lay it upon the drawing board, then upon the face of the drawing paper lay the transfer paper, and upon the top of the lot lay the drawing, pencil marks upwards, fasten the whole three sheets together, and to the board, by four drawing pins, one at each corner, then proceed to run over the pencil marks with a fine but dull pointed instrument. I have used for the purpose a stocking darning needle with a handle, and the point ground off, run over the marks in the same way as with a transparent slate. If the drawing is not too thick, and the carbon paper good, you may get a good copy with care and practice. I have seen copies taken by first perforating the picture with small holes along the marked lines with a needle, then afterwards laying it on the face of another sheet of paper, and rubbing it over with powdered black lead; the black lead goes through the holes and leaves a dotted outline beneath. A pencil is afterwards run over the marks, and a fair copy is produced, which can be quickly multiplied. I cannot promise instructions for taking copies of engravings as "T. H." asks for. I should be glad to hear of a method to do so. I know of none.—JOHN HOPKINS.

[12635.]—**Transferring Pencil Drawing on Paper to other Paper.**—The following, copied verbatim from an old book on "Philosophical Recreations," may, perhaps, contain some useful hints for "T. H.'s" purpose:—"A perfect copy of any print or other picture may be obtained by taking a sheet of the finest white paper, and wetting it over with clean linseed oil on one side completely. Wipe off the oil as clean as possible. Let it stand to dry a few days, otherwise it will spoil the picture: laying several sheets aside will be equally effectual to prevent this accident and render them more smoothly transparent. Lay a sheet of this prepared tracing paper on the picture to be copied, keeping it firmly down by means of weights on the corners and elsewhere; and then with a soft blacklead pencil copy over all the leading outlines of the figures, filling up the shades as may suit your fancy or be consistent with the subsequent genius to be evinced in this part of the affair. This being done, lay the tracing paper face downwards upon the paper, or other substance that is to receive the picture, when the pencil marks are to be transferred from the transparent tracing paper to this new substance. Pressure does this, and a pair of smooth boards in a common press will effect it, and is to be preferred when the copy is meant to be worked out in oil colours, for the greasy nature of the oiled paper may probably come off at the same time, a circumstance which then signifies very little. But for water colours or pencil copies, a stump made of a skewer, or a sharp pointed tracer, very smooth, is to be used, going over your former strokes of the outlines, &c., and you shall have the same very neatly and exactly copied." There is also a transferring fluid sold by a stationer in Chancery-lane. I bought a bottle; and although it brings off impressions of wood-cuts and printed matter, yet so faintly as hardly to be of any real practical service. The principal ingredient appears to be spirits of turpentine; but whether there is anything else mixed with it I cannot say; I merely go by the strong smell of turps it gives off. The directions are to saturate the picture, place it on a sheet of writing-paper, then place between the leaves of an old book and well beat with a mallet.—Hy. Taylor.

[12637.]—**Optics.**—Let x be the required distance. Then, if A be the angle the mark 8in. square subtends at 200 yards, $A = \dfrac{8 \text{ inches}}{200 \text{ yards}} = \dfrac{\frac{1}{4}\text{in.}}{x}$ nearly in circular measure. That is, $x \times 8\text{in.} = \frac{1}{4}\text{in.} \times 200$ yards. $x \times 32 = 200$. $x = \dfrac{200}{32} = 6\frac{1}{4}$ yards.

—Philanthropist.

[12637.]—**Optics.**—The apparent size of an object depends on the acuteness of the angle formed by two lines drawn from the eye to the two extremities. The angle included varies inversely with the distance of the object—that is, an object at a distance of 200 yards has its apparent height and breadth doubled at half the distance, and so on. A square having its sides 8in. is thirty-two times as high and broad as a square only ¼in. in the side. For the two to appear equal in size, the smaller must therefore be placed thirty-two times nearer than the larger. Therefore, $\dfrac{200}{32} = 6\frac{1}{4}$ yards for the distance; the ¼in. square must be placed to appear of the same size as a mark 8in. square, at the distance of 200 yards.—Alfred H. Allen.

[12637.]—**Optics.**—A simple rule of three sum. As 8in. is to 7200in. (or 200 yards), so is ¼in. to the answer required. Answer, 6¼ yards.—Quercus.

[12638.]—**Fleas in Dogs.**—Quite harmless at the proposed dilution.—Opaline.

[12639.]—**Worms in Pony.**—Get some smoking tobacco, and dry it before the fire, rub finely into dust; a teaspoonful given with the first feed in the morning will have the desired effect.—N. O.

[12639.]—**Worms in Pony.**—Give 60gr. of calomel at night, and 6oz. of castor-oil in warm gruel in the morning; you can mix the calomel with his food, giving a dose once or twice a week; don't give him much work to do when under treatment.—Opaline.

[12639.]—**Worms in Pony.**—Take green broom and male fern green, and chop small; give him a handful to eat occasionally with his food, first thing in the morning best.—Jack of All Trades.

[12640.]—**Ice.**—I believe that the cheapest freezing powders are made of two parts of common soda, and one part sal-ammoniac. The cost for freezing a gallon of water I cannot say.—Jack of All Trades.

UNANSWERED QUERIES.

The numbers and titles of queries which remain unanswered for five weeks are inserted in this list. We trust our readers will look over the list, and send what information they can for the benefit of their fellow contributors.

Since our last "Philanthropist" has answered, 12191; "Quercus," 12291.

12359 Sulphurous Smell after Thunderstorms, p. 443
12364 Hoist, 443
12370 Liquid Rosin, 444
12383 Electrical, p. 444

QUERIES.

[12702.]—**Photographic Enlargements.**—Will some correspondent kindly give us details of the best method of making enlargements by development?—G. N.

[12703.]—**Fuchsias.**—I should be glad to learn the reason and the remedy, if any, for the buds and blossoms of fuchsias bought at greenhouses or from the street barrows, falling off soon after they appear. I have tried a good and a scanty supply of water, indoors and out, but with the same result. I have one which has shown twenty or thirty buds the last fortnight, and now every one has dropped.—Fuchsia.

[12704.]—**Maple Veneers.**—Having a lot of sawn maple veneers in which the saw marks are very deep, I wish to know the easiest way to work them up into picture frames. Also, if there is any way of making them pliable. Any suggestion will be received by—Old Hatter.

[12705.]—**Extracting Vegetable Colouring Matter.**—Can some one inform me how to extract colouring matters from leaves or roots of plants, *e.g.*, the yellow dye in roots of *Angelica sylvestris*?—P. R. C. P.

[12706.]—**Laboratory Purification.**—An amateur chemist experiences a difficulty in removing from his laboratory unpleasant gases and smells. Passing a current of air through the room only serves to impregnate the whole house with the obnoxious vapours. Will some one kindly inform him of the usual and best methods of removing them?—Alastor.

[12707.]—**Geometrical Query.**—The following question was proposed in a recent honours' paper of the Government examinations in plane and solid geometry, and to which I should be glad to obtain the answer:—"What must be the position of a circle in regard to the picture plane in order that its perspective projection may be a parabola?" And further, I wish to know, what is the projection of a circle, oblique to the picture plane? It is certainly not an ellipse.—W. E. C.

[12708.]—**Liquid Resin for Violin.**—Will some one give an opinion on the liquid resin or colophony said to be superior to the ordinary resin?—Corelli.

[12709.]—**Soundboard Varnish.**—Will "The Harmonious Blacksmith" or any of "our" readers inform me how to make a varnish for pianoforte soundboards, &c.?—Yorkshire Amateur.

[12710.]—**Ginger Beer.**—In making aërated ginger-beer I use the essence or tincture of ginger extracted from the root by spirit, but as this makes the water quite milky and spoils the sale, I shall be glad to know if I can make a suitable essence in any other way. I have seen a dark red stuff called gingerine, prepared, I believe, from the green root. Would this do, and if so, how prepared? The aërated ginger beer sold in London is quite clear and has a cream on it, but I am at a loss to know what is used in the preparation. Any information how to get rid of the cloudy appearance will oblige.—Sodawater.

[12711.]—**Height of Mountain.**—Can any one inform me how to calculate the height of a mountain whose base is inaccessible, and the distance therefrom unknown?—Quercus.

[12712.]—**Linseed Oil.**—Can any reader tell me what can be best used to keep tin clean and bright where linseed oil is used about it? It sticks very fast to the tin, and in cleaning brings the tinning off with it.—J. G.

[12713.]—**Thermometer in the Shade.**—Thanks for inserting queries 12373, 12374, and 12375, p. 444; a slight correction is required in the first and second. For "a deep well" read "dip well," and in the second query, "with a diameter of 14ft. 4in.," should be diameter of 14in. Will some of your obliging correspondents assist me with their opinion to decide the term of shady place wherein to hang a thermometer? The definition has a wide range. In my opinion, inside a garden summer-house the readings would be higher than in the hall of a brick or stone built house, while both positions would be in the shade.—Gillem, Ontario.

[12714.]—**Echo of Sound on Water.**—A curious phenomenon was produced here on the 1st July, during the festivities to celebrate the anniversary of Dominion Day. Barrie is built at the end of Kempenfeldt Bay, an arm of Lake Simcoe, five miles long; on the above day a salute was fired from guns in Barrie, causing a momentary sound which died away, but revived again after a lapse of five or six seconds, then re-echoed as distant thunder away over the waters of Lake Simcoe; no sound whatever being heard during the interval of five seconds. How is this to be accounted for? Was the sound conveyed by air or water; if the latter, why was it not heard in the interval?—Gillem, Ontario.

[12715.]—**Ladies' Fans.**—Will some reader oblige the ladies with instructions how to make those pretty paper fans, which have little or no decoration about them, but are yet so elegant and attractive at fancy fairs?—Ada.

[12716.]—**Electrical Clocks.**—Some time back Dr. Grabham and Mr. Fox gave particulars of their electric clocks. Will either of these gentlemen kindly say what is the usual going or losing rate of one of these clocks?—No. 170.

[12717.]—**Watch Drills.**—Will any correspondent be so good as to inform me how to make watch drills small enough for pivots and hard enough for steel?—Daniel B.

[12718.]—**Potato Stains.**—Can any of your readers kindly inform me of anything that will take out the stain from the fingers caused by peeling or rasping potatoes? It seems to be a powerful acid in the skins that does so.—Anti-Acid.

[12719.]—**Medical Coil.**—I have two pint and one quart Daniell cells. Will either or all of these do for use with a coil for rheumatism, &c., or will it be preferable to abandon them, and get a quart bichromate cell for this purpose? If unsuitable for a coil, how will the above Daniell cells do to work a clock instead of Leclanché cells?—No. 170.

[12720.]—**Medical Coil.**—I shall be obliged to some of our electrical or medical correspondents if they will kindly inform me in what cases the usual interrupted current of a coil is most suitable, and in what cases a steady continuous current is to be preferred. I suppose the continuous current will be obtained by setting up the screw of the contact-breaker and not allowing the contact to be broken. If not, what will be the best way to use the coil with this current?—No. 170.

[12721.]—**Hydraulic Machine for Blowing an Organ.**—Can any one give me a description of a hydraulic machine for blowing an organ, and explain the principle on which it works? Is it on the same principle as a steam-engine, the motive power being a column of water, and what is the cost of one for a small organ?—W. B.

[12722.]—**Coal Getting.**—Having seen a little now and again relative to coal and coal getting, will some of our subscribers be kind enough to tell me the best system of getting it at the present time by machinery? I have seen a sketch of a sawing-machine, with boring-bar and cutters, working, with crank and two cylinders, by compressed air, the said bar radiating while revolving, and taking a sweeping cut. This is called Davis's, I believe. Another one was a Mattock fixed at the shaft end by a joint, and worked mid-way up the shaft by cylinder, &c., after the style of a man hewing it. These were in use some years ago; what have we now?—Inquisitive.

[12723.]—**Compressed Air.**—Having seen in the English Mechanic that compressed air is used for driving coal-getting machinery and rock-boring machinery for quarrying and tunnelling, what is the best method for getting this compressed air for the purpose?—Inquisitive.

[12724.]—**Tobacco Culture.**—Wanted to know all about the cultivation of tobacco and manufacture of cigars, Cuban principle preferred, by an old sailor, who, by wear and tear of a sailor's life, was compelled to settle on this island two years ago, and having been considerably benefited by this fine climate and God's blessing, is now desirous of earning an honest penny in the above line.—Will Watch, Jamaica.

[12725.]—**Fused Chloride of Silver.**—Can any of "our" able readers kindly inform me as to the method of making the above, to be used in conjunction with zinc plates for "Gaiffes'" battery? I have precipitated the chloride from the nitrate, in the usual manner, but have signally failed in the operation of fusing it. My fused cake presents the appearance of a gray, hard, and gritty substance; that supplied with the battery is of a brown and somewhat soft and transparent form. I should feel greatly obliged if some one can kindly show me where my error lies.—Argentum.

[12726.]—**Motion of a Sailing Boat.**—Would any of "our" correspondents kindly explain the following: When a boat is sailing as near "the wind's eye" as possible, the force (the wind) which is causing it to move is being applied in nearly an opposite direction to that in which the boat is sailing. Why, then, does the boat sail as it does—why not in an opposite direction? Also, when any thin, flat body (a slate, for example) is placed evenly on the surface of water, and allowed to sink, it does so in a zig-zag manner, and not straight down, though the attraction of gravity and (apparently) the resistance of the fluid are equal at all parts of its surface.—Tub.

[12727.]—**Circulating Library.**—Is there in London a circulating library for scientific and technical works?—Faber.

[12728.]—**Wave Pattern.**—I should be much obliged by an explanation of the wave form for ships.—Faber.

[12729.]—**Breech-Loaders.**—Would some fellow reader, who is well "up" in arms, give us some drawings similar to those of the "Berdan" in No. 326 of the more celebrated breech-loading systems now in use, both for heavy guns and small arms? I should more particularly like to see the Westley-Richards and the Prussian system for heavy guns.—Faber.

[12730.]—**Weir's Sewing Machine.**—I should feel obliged to "Jack of All Trades" if he would explain the way to set a Weir sewing machine. We have one of these machines (which, according to the advertisement, cannot get out of order), which will work pretty well for a few stitches, then either cut the cotton or drop stitches.—H. E.

[12731.]—**Hand Pad.**—Would some fellow reader be kind enough to explain the manner in which hand pads or tool handles are made for holding tools with tangs of the customary form, as I wish to make a set of tools to fit into the same handle?—H. E.

[12732.]—**Glass Paper.**—Can any practical maker give me any information as to the material used to fasten on the glass to paper for the use of cabinet makers, &c.; how it is applied; and also the cost of a machine for grinding the glass for the purpose? An answer will greatly oblige.—Stadacona.

[12733.]—**Measuring a Cob Thatching.**—Will some reader kindly inform me where are the proper places to take the measures for measuring the thatching of a round stack commonly called a cob?—W. Bull.

[12734.]—**Cement for Greasy Strapping.**—I have heard of a cement for the above which adheres quick and is ready for use in a few minutes without the aid of stitching. Would some kind reader give me the recipe?—T. T. M.

[12735.]—**Barometer and Clock Rate.**—I saw somewhere a notice of the new clock at Greenwich, in which it was stated that the influence of varying pressure on the rate could be easily allowed for. Can "F.R.A.S.," or some one connected with the National Observatory, supply the scale by which this correction is applied?—Rho.

[12736.]—**Cement on Postage Stamps.**—What is it?—Rho.

[12737.]—**Size of Globe and Speed Rate of Rotation.**—Will some of your readers be so kind as to set me right (if I am wrong) in the following? One revolution of globe in 24 hours gives 8 hours diameter; to give 8 hours diameter must travel 1,000 miles an hour, 24,000 miles in 24 hours. It makes 365 revolutions to form four seasons—spring, summer, autumn, winter—one year. It follows that the globe travels 8,7— miles a year. Circumference of globe, 24,000 miles; diameter, 8,000 miles; speed rate of rotation, 1,0— —

an hour. Circular course of globe 365 times larger than itself, being one revolution in 24 hours, gives distance 8,760,000 miles to make four seasons.—BALCAIRN.

[12738.]—**Graphite Cells.**—To GEO. FOX.—Will this correspondent tell us if his graphite cells answered his expectations of a year since?—H. H. G.

[12739.]—**Geometrical Theorem.**—Point (1) is the intersection of A D and F C in Problem XLVII. of Euclid, Book 1; point (2) the intersection of F C, B K, A L; point (3) the intersection of A E, B K; point (A) is the 4th point. Show that a circle may be described through the 4 points (A), (1), (2), (3).—THETAMU, Horsham.

[12740.]—**Lever Escapement.**—I have a rack lever and wish to detach it. It has a small escape-wheel. Would it be better to put a new escapement to it, or merely put a new fork and roller? Would any brother be kind enough to give me proper depths?—NO SOFT SOLDER.

[12741.]—**Leather Machine.**—I experience great difficulty in getting leather of one uniform thickness for covering pianoforte levers, &c. Can any of our readers give me a design or suggestion how to make a small machine for the purpose?—PIANOFORTE REPAIRER.

[12742.]—**Portsmouth Harbour Steam Bridge.**—Can any reader give me a description of the steam bridge that runs across Portsmouth Harbour?—CONSTANT SUBSCRIBER.

[12743.]—**Essence of Wood Smoke.**—Would any of my fellow readers furnish me with the recipe for making essence of wood smoke, such as is used in curing bacon, hams, &c., instead of the usual unsatisfactory way of sending them to the carpenters, &c., to be hung in their chimneys? An answer to the above through the medium of the ENGLISH MECHANIC would greatly oblige—AN ANXIOUS ONE.

[12744.]—**Martini Rifle.**—Would "Artillery Captain," or some one acquainted with the working of the Martini or Westley Richards, explain the action of the extractor, and the manner in which it pitches out the empty cartridge case? Also state whether it especially requires the bottle-neck cartridge, or could it be used with the ordinary Boxer cartridge, similar to that used in the Snider?—A. L.

[12745.]—**Hen Keeping.**—Will much feeding with dry Indian corn have any bad effect upon hens? Will it cause them to lose the use of their legs?—H. K.

[12746.]—**Screws for Woodwork.**—Will some one give me a description of the best way now in use of cutting screws for wood, metal screws, but for wood work? and the best means of making the cutters for the same?—WILLING TO LEARN.

[12747.]—**Roasting Jacks.**—Can any one give me full details how to make and fit in the spring same as in meat jacks, so as to work easily but with the greatest strength? Also if there are any other means used than the spring for the working of jacks?—WILLING TO LEARN.

[12748.]—**Transparent Cement.**—Can any one tell me of the best compound or chemical to be used as a liquid first, and afterwards to set as a hard substance; but after setting to have the appearance of water?—WILLING TO LEARN.

[12749.]—**Punching Holes in Sheet Brass.**—I wish to punch out some small circular pieces of sheet brass by hand. Which will be the best means of doing it so as to leave the pieces as clean on the edges as I can?—WILLING TO LEARN.

[12750.]—**Steam Yacht.**—I possess the only attempt at a steam yacht in the port of Melbourne. She is 28ft. long by 6ft. 4in. beam, propelled by a one-horse inverted cylinder engine (screw) bore 4in., stroke, 4½in.; propeller, 18in. diameter; 18in. pitch; pressure, 85lb.; speed, 5 knots. Boat and engine both my own (amateur) build. The boiler is of copper, and is made by a tradesman—it is 3ft. high, with rounded dome, and 2ft. diameter, vertical flue, outside of copper, 5lb. to square foot. Firebox of 6lb., crossed by two Galloway tubes. I should like to hear some comments from some of my home brothers, especially as to the pressure I may carry with safety. Would 50lb. or 60lb. be safe, and if so, what pressure of cold water would be a sufficient test?—FIRE-FLY.

[12751.]—**Improved Æolian Harp.**—Will Mr. E. B. Fennessy be good enough to answer the following queries?—What thickness is the sounding-board? What is the inside height of box above the strings? What is the distance between strings? Does one bridge at each end carry all strings, or has each string two separate bridges? Are they ordinary small fiddle-strings?—A. T. HASWELL.

[12752.]—**Nervous Excitement.**—"T. L. V." in his article on "Constipation," in last week's number, alluded to "a remedy which has the power of allaying nervous excitement and strengthening the great nervous centres." Could the writer of the article just mentioned, or any of your readers, give a professional gentleman a definite idea of the means to overcome this terrible detractor of his efforts in public as an instrumentalist?—TREMOLO.

[12753.]—**The Moon.**—I have been much puzzled to ascertain the laws regulating the moon's motions in declination, and with your permission will see if any of your astronomical readers can assist me. I have searched at least half-a-dozen books on astronomy, but fail to get from any of them an adequate explanation. If I take a *Nautical Almanac* for one year I find the declination is, say 18° north and south; if another, 25° north and south, what is the cause of this variation, and does it occur in a cycle coming to the same number of degrees north and south in a certain number of years? Is there any cycle in which the moon returns to the same position in the heavens with regard to the earth on the same day in the same month, and being also at the same time in apogee or perigee, or at the same distance. I should very much like to know whether there is any period in which the cycles of the moon's motions and positions will return to precisely the same place on the same day after a certain number of years, so that there is an exact repetition of these positions with the apogee and perigee of the moon and her positions in declination. I do not know whether I have made my meaning sufficiently plain, but perhaps some of your readers will understand my difficulty. The motions of the moon are doubtless very easy to understand to those who know all about it, but to the tyro in astronomy they are very puzzling, and the way that the so-called "popular" books set about to explain or half explain the subject, only makes what is already a confusing subject "worse confounded."—W. L. BROWN.

[12754.]—**Cheap Firewood.**—We shall feel obliged if any of your numerous readers would give us information about a cheap firewood made inflammable by the addition of rosin. We have saw mills in a very poor neighbourhood, and now that coal is twice the price it was last year, we fear the coming winter will be a very trying one. Every year coal tickets are distributed, but what is very much wanted is a firewood that would enable a poor person to boil a kettle without keeping up a fire all day. Any hints as to the mode of making such will much oblige.—OLDEN AND GIBBS.

[12755.]—**To "Jack of All Trades."**—Will "Jack of All Trades" please look at q. 11964, p. 312, and tell me why the curd soap acts quite the contrary to what he said?—J. B. SHARPLEY.

CHESS.

ALL communications intended for this department to be addressed to J. W. ABBOTT, 7, Claremont-place, Loughborough-road, Brixton, S.W.

The great Earl of Chatham, upon being complimented on one of his finest strokes in politics, is reported to have said that "he deserved little praise, for his success arose only from having been checkmated by discovery, the day before, at chess. And in his speech in the House of Lords, on the 20th January, 1775, relative to the affairs of America, he said, "The hour of danger must arrive in all its horrors, and then these boastful ministers, spite of all their confidence, and all their manœuvres, shall be forced to hide their heads. They shall be forced to a disgraceful abandonment of their present measures and principles; principles which they avow, but cannot defend; measures which they presume to attempt, but cannot hope to effectuate. They cannot, my Lords, they cannot stir a step; they have not a move left; they are checkmated."—From "Game of Chess," by P. PRATT, published 1817.

ENIGMA I.—BY F. HEALEY.

White.

K on Q 2; Q on K Kt 2; B on Q B 7; Kt on Q 4; P on Q B 3.

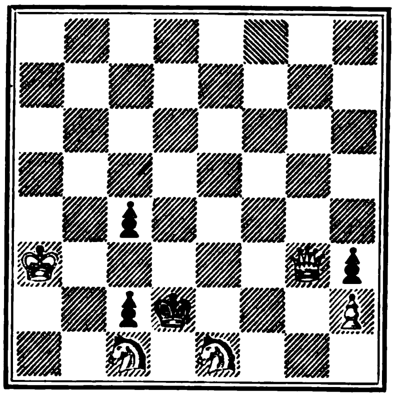
K on Q B 5; Kt on Q B 4; B on Q R 2; P on K B 2.

White to play and mate in two moves.

PROBLEM XII.—BY C. W. (Sunbury).

Black.



White.

White to play and mate in two moves.

SOLUTION TO PROBLEM X.

White.	*Black.*
1. R to Q 8.	1. Anything.
2. Kt or Q mates, acc.	

J. L. B. (Liverpool).—You cannot castle when your King is in check, and checking your adversary's King does not interfere with his privilege of castling. In reply to your other questions, we advise you to get Lowenthal's or Staunton's works, either of which will afford you ample course of study.

W. NASH.—The idea is somewhat similar, but the positions are not identical. Scores of problems admit of the same coincidence. For instance, how many times has the Indian Problem been served up, and by some of the best composers, too?

F. C. COLLINS.—The problem appears to be perfectly correct and very good.

A. W. COOPER.—The last two problems are neatly constructed, but rather easy; they are, however, marked for insertion.

M. L. MARKS (Swansea).—Wrong in both instances.

G. J. SLATER (Bolton).—Your problem (No. 27) admits of a solution in three moves—

(1) $\frac{\text{Kt to Kt 7}}{\text{K moves}}$ (2) $\frac{\text{Kt to Q 8}}{\text{K moves}}$ (3) Kt to B 6, mate.

The other is correct and good, and it shall shortly appear.

CORRECT solutions to Problem X. have been received from S. M. Barker (Kensington); A. R. Moll son (Swansea); G. C. Heywood (Great Torrington); E. T. Grays; R. L. Conderford; J. E. Lines; R. J. Pearce; James Harrison; W. Nash (S. Neot's); Aleph (Bedford); Argo (Yarmouth); A. W. Cooper; H. Cherry; W. Airey (Worsley); F. C. Collins; A. G. (Islington). All others are wrong.

ANSWERS TO CORRESPONDENTS.

*** *All communications should be addressed to the* EDITOR *of the* ENGLISH MECHANIC, 31, *Tavistock-street, Covent Garden, W.C.*

HINTS TO CORRESPONDENTS.

1. Write on one side of the paper only, and put drawings for illustration on separate pieces of paper. 2. Put titles to queries, and when answering queries put the numbers as well as the titles of the queries to which the replies refer. 3. No charge is made for inserting letters, queries, or replies. 4. Commercial letters, or queries, or replies, are not inserted. 5. No question asking for educational or scientific information is answered through the post. 6. Letters sent to correspondents, under cover to the Editor, are not forwarded; and the names of correspondents are not given to inquirers.

The following are the initials, &c., of letters to hand up to Tuesday morning, August 20, and unacknowledged elsewhere:—

G. C. Price.—Wm. Fryer.—J. Gadsby.—P. W. Spencer.—Bernard Davis.—W. H. Collins.—J. W. Stuchberg.—Wonder.—E. L. Daniel.—E. J. Rowley.—W. Davenport.—R. G.—F. R. Leyden.—G. Burland.—James Dine.—J. W. Willis.—John Finch.—Rimington Wilson.—Frederick Carre.—J. M. Rimington.—J. W. B.—Clotilde.—Rev. F. Salmon.—R. A. Proctor.—Tub.—Zealous.—J. R., jun.—West Cornwall.—Glasgow Artisan.—J. B. Q.—E. H.—Joe.—Kendal Saddler.—Outgenious Whitesmith.—C. M. M. B.—C. Gaudibert.—A Librarian.—E. Ward Jackson.—E. J. W.—Rev. J. M. Taylor.—R. Terret.—John Hopkins.—Tapper.—R. S.—W. D. T.—An Old Blue.—Alfred S.—W. H. H. C.—Camera.—R. C. T.—E. W. Pullen.—Harry Macpherson.—South Devon.—P. France.—Thos. Hackett.—A Country Smith.—J. Wareham.—H. J. W.—J. F. E.—J. D.—J. K. P.—Dr. Carpenter.—Cervus.—E. W. Burnham.—J. D. H.—Old Chips.—R. L. F.—R. J. B.—Optical Bricklayer.—Hants Farmer.—Athol Jack.—J. S. M.—Loach.—An Athlete.—Apiarian.—M. A.—W. M. Colles.—Linea.—S. Selwyn.—Zeta.—Alfred Thos. Jenkins.—Philo.—M. Paris.—Nitrogen.—W. Welden.—D. A. Adams.—Hugh.—A Constant Reader.—Balcairn.—Herbert.—F. Stewart.—A. J. Jarman.—Etna.—Analyst.—Stump.—One of the Edinburgh Branch.—T. Tebeck.—Spirit.—S. K. S. T.—Practical Grainer.—C. Bethell.—John Watson.—Jannifred.—R. L. S.—A., Liverpool.—Photo. Bristoliensis.—Vircas.—Levatt.—Mutual Tom.—M. P.—A. B. C.—C. B. Shaw.—Chester.—An English Mechanic.—A. Jote.—Proved.—Senecio.—John Hunt.—W. Bright.—P. L. Simmonds.—Bobo.—The Harmonious Blacksmith.—Hyrab Sen.—California.—Emigrant.—M. A. B.—A Poor Irishman.—F.W.—Clinchey.—G. E. L. S.—S. Bottone.—H. H.—H. B. E.—Science and Art.—Sigma.—Centrifugal Force.—Boctus.—Nemo.—Q. Yorke.—Associate.—V. Cambridge.—J. Snellgrove.—Fulcrum.—James Tresize.—E. R. Johns.—James Bellows.—Ramsgate Subscriber.—G. H. G.—C. H. W. Biggs.—Comus.—Jasper.—E. M. J.—R. Cuthbert.—Thos. R. B. Blindley.—Wm. Wray.—W. H. M.—Hy. Northcote.—Doubtful.—C. Lucern.—Mechanic.—Canny Scott.—A. G. Boyd.—Fred. Walton.—M. & S. Mason.—John.—W. H. F.—Philanthropist.—Salvator.—E. J. Wilson.—E. L. G.

A. B. W.—Quite impracticable, so far as we are concerned.

H. B.—Yes. Consult a solicitor.

YANKEE.—Put your question more plainly. What plates do you mean?

OUTGENIOUS WHITESMITH.—Could not say without seeing the drawings. The furnace sent this week is in principle too much a repetition of the other to be worth inserting. Kindly take a *little* more care with your sketches. The last inaccuracy was due to your indistinct drawing.

A STUDENT.—See review of Mr. Collins's book on "Perspective," on p. 527.

DESIGNER.—L. Gwilt's "Encyclopædia." 2. See back vols.

ONE THAT TRIES.—Cannot appear as a query.

H. WASHINGTON.—Write Bennett Woodcroft, Government Patent Office, Southampton Buildings, London. Your local bookseller should change his agent; there is great neglect somewhere.

H. R.—We cannot be everybody's lawyer. We should expect, if we complied with your wish, requests from subscribers to draw up their wills for them, which we could only do on condition of being allowed to insert a handsome legacy to ourselves.

SUBSCRIBER (Bristol), A. L. (Hindley), and J. Pugh, are referred to back vols.

INQUIRER.—For information on mushroom culture see letter 65, p. 400, Vol. XI.

TIM.—For description of instruments for describing ellipses see pp. 502, 548, 595, and 618, Vol. XI.

INQUIRER (Hartlepool).—Ask at any chemist's.

JAMES HURTE.—For information on ferns see reply 2417, p. 93, Vol. XI.; also indices to other back vols.

RITUALIST.—The incense used in the services of the Church is benzoin. You cannot "make" it.

APPRENTICE TURNER.—Write Lockwood and Co. or Longmans for a catalogue.

J. W. DURRAD.—Thanks for your sketches. Mr. Proctor has, however, in a contribution which appeared in our last, treated on the subject, giving illustrations of spots of a later date.

TOM-TIT.—If you will define what you mean by "point of time" in contradistinction to the time indicated by the hands of the clock, we will endeavour to answer your very hazy question.

G. W. LEEDS.—Directions for making picric acid are given in replies 4504, pp. 578 and 596, Vol. XI.

C NATURAL.—Ask a plain question embodying what you want to know about the dulcimer.

DANIEL B.—For information on six and twelve lens opera glasses see reply 4999, p. 91, Vol. XII.

D. P. L.—For information on the construction of the metronome see p. 161. Vol. XI.

John Rae (Sydney).—Vol. XI. is out of print. We have sent you for your friend Vols. XII., XIII. and XIV., and three blank cases. The cost of these, deducted from the sum remitted leaves enough to pay Mr T.'s subscription up to April 11, 1873. Vols. and cases sent to firm named in your letter on Aug. 15.

Careful, Bertha, David Long, and G. S. are referred to indices to back vols.

C. H. W. Biggs thinks that "a mathematical column would be an estimable boon to many." He says, "I am supposing that such a column should not degenerate into mere puzzle pages and catch questions, but that the questions and solutions should be valuable to the many, not the few." "If no better one, like to Mr. Proctor or 'E. L. G.' would undertake the responsibility, I offer my services. I know I cannot compete with these gentlemen, yet I think I know what would be valuable to the student, both theoretical and practical."

Hyrab Sen.—The reason mentioned was not the only one that stood in the way of the insertion of your letter. A love of truth, for its own sake, independent of personal considerations of any kind, should be the primary and prevailing consideration in scientific controversy. We cannot comply with your request as you do not give your address.

Johan.—You were referred, as you are now, to indices of back volumes.

Guinevere, J. Wallis, Ibid, Hannibal, Wm. Millard, W. Hindley, Publican, W. B. M., your queries are advertisements. See Hints to Correspondents.

W. Millard.—Your query is rather beyond our line.

Ed. H. M.—First query not in our way. Second query, Sheridan was the author of "School for Scandal."

J. T. H.—Pray consult a medical gentleman.

A. G.—The Metropolitan Institution for Diseases of the Ear, 32, Sackville-street, London.

Next Week.—We have an unusually large number of contributions standing over for next week from many of our esteemed correspondents, including F. R. A. S., Sigma, Mr. Proctor, E. L. G., J. K. P., Saul Rymea, The Harmonious Blacksmith, W. R. Birt, S. Bottone, Jack of All Trades, and dozens of others.

Anti-Flattite.—We do not intend to permit another discussion with those who believe that the earth or the moon is flat and not round. We believe Charles Rabache has some theory of the moon being egg-shaped, or something of the kind.

Ch. Rabache.—Your letter (both for its matter and its manner) on the moon is unsuited to our columns, and, in our opinion, to the columns of any scientific paper. The same remark applies to your letter on centrifugal force.

THE INVENTOR.

APPLICATIONS FOR LETTERS PATENT DURING THE WEEK ENDING AUGUST 13, 1872.

2266 R. Milburn, Whitechapel, and H. Jackson, Leeds, for improvements in apparatus for drying or pulverising, or for drying and pulverising sewage deposit, manure, cement, chemicals, grain, malt, and some other matters or materials.

2267 T. Bean, Liverpool, for improvements applicable to folding machines for perforating, puncturing, indenting, separating, or dividing newspapers and other like sheets during the process of being folded.

2268 W. Morgan-Brown, Southampton-buildings, for improvements in apparatus for raising water. A communication.

2269 H. S. Flood, San Francisco, U.S., for an improved corset.

2270 C. Dreyfus, Radcliffe, Lancashire, for improvements in dyeing and printing textile fabrics.

2271 A. Friedmann, London-wall, City, for improvements in injectors for feeding steam boilers, and for raising and forcing fluids.

2272 F. Jackson, Whinlatter, Cumberland, for improvements in slide valves for steam engines.

2273 F. Jackson, Whinlatter, Cumberland, for improvements in slide valves for steam engines.

2274 G. Rydill, Dewsbury, for improvements in machinery and apparatus for dyeing or staining animal and vegetable substances, also suitable for drying the same, and for bleaching purposes.

2275 R. Hutton, Whitby, Yorkshire, for improvements in the construction of stove pipes for blast and other furnaces.

2276 W. B. G. Bennett, Nichols-square, Hackney-road, and J. C. Watt, Lancaster-road, Notting hill, for improvements in the preparation of asphalte, and in the application thereof to the construction of roads and footpaths, and other purposes.

2277 E. P. H. Vaughan, F.C.S., Chancery lane, for improvements in the treatment of phosphates of lime. A communication.

2278 J. F. Meakin, Baker-street, Portman-square, for an improved method of readily and effectually securing to sliding window sashes platted line or other material now in partial use, and which he calls a tubular sash-line holder.

2279 I. Brown, Edinburgh, for improvements in the treatment of sewage and in the manufacturing of manures.

2280 J. H. Johnson, Lincoln's Inn-fields, for improvements in water meters. A communication.

2281 A. M. Clark, Chancery-lane, for improvements in breech-loading fire arms. A communication.

2282 G. Haseltine, Southampton-buildings, for an improved process of converting cast iron into steel. A communication.

2283 B. J. B. Mills, Southampton-buildings, for improvements in rotary engines and pumps. A communication.

2284 W. H. Dilnutt, Old Kent-road, for an improved construction of furnace fire bar.

2285 T. Whitehead, Holbeck, Leeds, for improvements in machinery for combing wool, cotton, flax, and other fibrous substances.

2286 A. Browne, Gracechurch-street, City, for improvements and modifications in the treatment of phosphate in general, and in the production and purification of phosphoric acid and its combinations. A communication.

2287 P. A. Dormoy and F. A. Paget, Seymour-chambers, Adelphi, for improvements in puddling furnaces.

2288 T. Laycock, Skipton-in-Craven, Yorkshire, for improvements in the construction of sewing machines.

2289 C. Levey, Sussex-road, Holloway, for improvements in steam-engines.

2290 A. Crowther, Lockwood, Yorkshire, for an improved means or apparatus for the drying of yarns, which improved means or apparatus are also applicable in the use of tentering machines.

2291 B. J. B. Mills, Southampton-buildings, for improvements in the manufacture of match and other boxes of paper, pasteboard, thin wood, or other flexible material, and in machinery for manufacturing the same, and in apparatus for sanding match boxes. A communication.

2292 A. Tylor, Newgate-street, City, for improvements in apparatus and arrangements for the water supply of water-closets and baths, and preventing waste, applicable also in whole or in part for controlling, regulating, and arresting the flow of liquids and fluids, and preventing waste.

2293 J. Young, Kelly, Renfrewshire, for improvements in obtaining motive power.

2294 A. Pringle, Bessbrook, Ireland, for improvements in the treatment of flax and other fibrous substances.

2295 W. S. Hudson, New Jersey, U.S., for improvements in locomotive engines.

2296 G. Haseltine, Southampton-buildings, for improvements in machines for the manufacture of gas. A communication.

2297 J. Fletcher, Ashton-under-Lyne, and S. Fletcher, Tailsworth Lancashire, for improvements in indicators or yarn-counters for mules and actuated by the cam shaft of mules.

2298 G. F. James, Salford, Lancashire, for improvements in the manufacture of fuses, and in the machinery employed therein.

2299 A. C. MacLeod, Cumberland, for improvements in the means of imparting motion to drills churns, and other machines where a rapid alternating rotary motion is required.

2300 E. Norman, Bayswater, for an improved sewing machine.

2301 J. Fielding, Manchester, for improvements in apparatus for conveying signals from one person to another in railway trains.

2302 D. Greig and T. Gillott, Leeds, for improvements in coal-cutting machines.

2303 E. G. Banner, Billiter-square, City, for improvements in traps for preventing the passage noxious gasses from sewers or drains through pipes communicating therewith.

2304 W. A. Boyden, Harrisburg, U.S., for an improvement in axle-boxes for railway bars.

2305 H. E. Towle, Budge-row, Cannon-street, City, for improvements in machines for turning screws, bolts, and blanks for wire or rods. A communication.

2306 A. H. Hart, Gresham-street, City, for improvements in the manufacture of fasteners for binding papers and other materials, and machinery for the same.

2307 E. T. Hughes, Chancery-lane, for improvements in bed bottoms. A communication.

2308 C. F. Galand, Paris, for an improved revolving pistol, which may be dismounted without tools.

2309 C. Richardson, Gracechurch-street, City, for improvements in looms for weaving.

2310 J. Douglas and J. Scott, Sunderland, for adjusting compasses, correcting the same, and taking bearings by day and night.

2311 D. Whittemore, Boston, U.S., for improvements in machinery for pegging boots and shoes. A communication.

2312 G. G. André, Dorking, Surrey, for improvements in raising or forcing water from mines, wells, or other places, and in apparatus therefor.

2313 N. Thomas, Glasgow, for improvements in motive-power engines.

2314 N. Thomas, Glasgow, for improvements in heating feed-water supplied to steam-boilers and in generating steam.

2315 W. Husband, Hayle, Cornwall, for improvements in steam hammers and stampers.

2316 A. L. Fyfe, Noble-street, City, for an improved scarf box or holder.

2317 W. Brown, Gray's Inn-road, for an improved apparatus for tilting casks and barrels

2318 J. Henderson, Glasgow, for improvements in converting cast iron into steel and wrought iron, and purifying cast iron for foundry and other purposes.

2319 H. C. Lobnitz, Renfrewshire, N.B., for improvements in generating steam and in the apparatus employed therefor, which improvements are also applicable for heating fluids and for heating or evaporating liquids.

2320 E. Russ, Winchester, for an improved package box or receptacle for keeping or holding wines, spirits, or other liquids during transport or otherwise.

2321 G. Haseltine, Southampton-buildings, for improvements in reed organs. A communication.

2322 W. E. Gedge, Wellington-street, Strand, for a new or improved manufacture of cordage and of woven fabrics from the textile material of the hop plant. A communication.

2323 J. C. Michelet, Dieppe, France, for a new system for converting a slow alternate circular motion into a rapid continuous circular motion.

2324 W. E. Gedge, Wellington-street, Strand, for an improved portable pump. A communication.

2325 E. T. Hughes, Chancery-lane, for improvements in machinery or apparatus for dressing lithographic stones. A communication.

2326 C. Catlow and W. Overton, Lancashire, for improvements in looms for weaving.

2327 E. A. Calahan, Southampton-buildings, for improvements in telegraphic printing instruments, and in apparatus connected therewith.

2328 E. Packard, jun., Ipswich, for improvements in the manufacture of superphosphate of lime and artificial manure.

2329 G. Haseltine, Southampton-buildings, for improvements in machinery for manufacturing cigars. A communication.

2330 G. De Lara, Fleet-street, for an improvement in the manufacture of all descriptions of blotting articles, and the utilisation of blotting paper.

2331 C. M. T. du Motay, Paris, for an improved mechanical and chemical method of epurating the cast irons in order to allow the same to be directly or indirectly tranformed into iron or steel.

2332 J. Deere, Glamorganshire, for improvements in the manufacture of artificial fuel.

2333 T. Wrightson, South Stockton-on-Tees, for improvements in hydraulic hoists.

PATENTS SEALED.

350 J. C. Calvert and J. Taylor, for improvements in apparatus for heating water, steam, or other fluid.

361 J. G. Cunningham and J. Corbin, for an improved agent to be used in the preparation or production of baths.

362 A. G. Bell, for an improved galvanic belt.

364 A. Oldroyd, for improvements in the manufacture of india-rubber and other tobacco pouches and purses.

368 E. Seyd, for an improved method of casting bars or plates of silver and gold, and the moulds for such purpose, also an improved method of rolling such said bars to reduce them to the proper thickness for manufacturing into coins and medals.

374 J. Edwards, for improvements in locks.

377 G. W. Lamb, for improvements in the manufacture of boots and shoes, and machinery or apparatus to be used therein.

384 J. Phillips, for improvements in ships' signal lamps.

385 W. S. Sutherland, for improvements in welding or uniting plates, tubes, and other forms of iron or steel, and in means or apparatus employed therein.

395 G. Smith, for an improved instrument for clipping hair or wool from horses or other animals.

400 E. Jones, for an improved construction of military spade or shovel.

403 W. Willoughby, J. Willoughby, S. Willoughby, for improvements in steam stamping machines for ores and other hard substances.

407 T. Gibb and C. Gelstharp, for improvements in the construction of furnaces for carbonating or drying alkaline salts and other substances, and in the method of working the same.

416 A. Cresswell, for improvements in apparatus for straining or filtering liquids.

446 T. McM. Wilson, for improvements in the mode of and apparatus for refining or purifying oils.

475 R. Edwards and T. Robinson, for improvements in the construction of furnaces for heating, puddling, or melting iron steel, or other metals.

519 W. F. Heshuysen, for an automatic water or other fluid regulator.

531 S. Nuttall, for improvements in shuttles for looms.

559 W. J. Murphy, for an improved system or method of "rifling" applicable to fire-arms and ordnance.

631 C. H. E. Brandauer, for improvements in metallic pens.

1141 F. Alekan and I. Alekan, for improvements in screw studs for shirts, cuffs, and similar purposes.

1270 W. Morgan-Brown, for improvements in steam generators.

1350 W. Morgan-Brown, for improvements in centrifugal machines.

1508 J. Imray, for improvements in apparatus for working brakes in railway trains.

1512 J. A. Turner and G. Davies, for improvements in the manufacture of waterproof packing material.

1611 A. C. Hobbs and J. M. Hart, for improvements in safes and other depositories for property and other articles of value, and in door for such and other places, and in locks or fastenings for the same, part of which improvements is applicable to other structures.

1695 J. Stevenson, T. Carlile, and J. Stevenson, for improvements in the manufacture of bichromates of soda and potash.

1710 W. Morgan Brown, for improvements in dyeing animal or vegetable textile fabrics or yarns aniline black, or other fast colours derived from coal tar.

415 J. Kiloh, for improvements in manufacturing groats, and in apparatus therefor.

418 C. Hodgson, for improvements in apparatus or appliances to be used in connection with wire tramways.

425 R. F. Smith, for improvements in obtaining yellow and red prussiates.

431 J. Hastie, for improvements in ship-steering apparatus.

433 W. E. Gedge, for an improved horizontal boiler.

412 T. J. Smith, for improved means of and apparatus for dividing the fleece in carding engines.

497 G. Williamson and W. H. Williamson, for improvements in the construction of the travelling wheels of traction engines, road rollers, steam carriages, or other traction vehicles, and in the construction of wheels, pulleys, or drums for transmitting power in connection with such vehicles, or where power is required to be transmitted by means of cords, ropes, or belts.

529 B. Hunt, for improvements in leather or other stiffenings for boots and shoes.

625 F. W. Lawson, for improvements in batching jute.

648 G. G. Tandy and J. A. Dryden, for improvements in lamps.

704 E. W. Elmslie, for improvements in the manufacture of hermetically-closed cases, and the opening thereof.

721 W. Gray, for improvements in rotary engines and pumps.

744 W. Gray, for improvements in steam-boilers.

752 E. Watteau, for improvements in explosive compounds.

950 W. Morgan-Brown, for improvements in the manufacture of horse-shoe nails, and in the machinery for that purpose, applicable also to other articles.

968 W. R. Lake, for improvements in paper-rag engines.

1018 J. H. Johnson, for improvements in heating and in apparatus employed therefor.

1064 W. R. Lake, for improvements in the manufacture of sieves.

1080 J. J. Bodmer, for improvements in the manufacture of iron and steel.

1122 P. Jensen, for improvements in the construction of ovens, in the utilisation of the waste heat therefrom for the manufacture of refined salt and in the apparatus therefor.

1271 J. S. Richard, for improvements applicable to warping or beaming machines and to other machines in which excess or slackness, breaking, or exhaustion of a thread, other than a warp thread, necessitates the stopping of such machines, and also to cases where an expanding comb is required.

1310 R. Coddington, for improvements in printing presses, partly applicable to other machines.

1355 J. E. Walker and J. W. Cole, for improvements in apparatus for screening coals.

1409 J. H. Johnson, for improvements in the treatment of ores, more particularly iron ore, for the manufacture of cast iron, wrought iron, and steel therefrom, and in the apparatus to be employed therein.

1470 J. H. Johnson, for improvements in the manufacture of shoes, and in machinery and apparatus connected therewith.

1537 E. A. Calahan, for improvements in electric telegraph signal or alarm apparatus.

1555 W. Lockwood, for improvements in safety valves for steam boilers.

1617 J. Pickup, for improvements in grate bars.

1554 C. Turner, for improvements in machinery for scudding or puri[illegible] skins or hides.

16[illegible] E. R. Hollands, W. Maker, and C. H. Jefferies, for improvements in meters for measuring water and other fluids.

1735 H. P. Holt, for improvements in machinery and locomotive engines for driving tram cars and other road vehicles, parts of which improvements are applicable to other steam-engines.

1776 T. A. Weston, for improvements in differential pulleys, portions of which are applicable to other chain wheels.

1799 J. H. Johnson, for improvements in the manufacture of iron.

1801 G. Haseltine, for improvements in the manufacture of iron and steel, and in apparatus employed therefor.

1818 W. Campion, for improvements in the mode of securing stitching together the seams of looped or knitted fabrics, and machinery or apparatus to be employed for such purpose.

1837 T. Hampton, for improvements in the manufacture of Bessemer steel ingots.

The English Mechanic

ARTICLES.

OCEANIC CIRCULATION.

By Richard A. Proctor, B.A., Hon. Sec. R.A.S.

Author of "The Sun," Light Science," "Essays on Astronomy," &c.

IT is impossible but that on a subject so difficult and complicated as that of oceanic circulation, different views should be entertained by students of science. And it is clear that in the present stage of the inquiry no useful purpose could be fulfilled by making the problem a matter for controversy. Dr. Carpenter himself has shown that much more is to be gained by observation than by reasoning on imperfect knowledge. If I venture to remark that his deep-sea researches have led to the most important contribution which has been added for many years to our information respecting oceanic circulation, he will not, I trust, consider that I am passing beyond the bounds of controversial courtesy. But I am, indeed, not anxious to treat the matter as one for controversy in any sense. It will be perceived by those who have read my remarks on the subject, that I have rather put them forward as suggestions than as indicating theories which can be maintained with any degree of assurance, far less with conviction. Nor does it seem to me likely that one explanation can suffice to account for all the phenomena recognised in oceanic circulation. This is a case, if ever such case were, in which more causes are in operation than one; so that it may very well happen that excellent arguments can be adduced in maintenance of different views. If, therefore, I enter on the defence of what I have already written on this subject, it is not with the wish to show that one particular explanation of oceanic circulation is correct, and all others erroneous. If I am desirous of dealing with the considerations urged by Dr. Carpenter, it is not because they seem to him to militate against the views I have to some extent advocated. What I wish to show is that I have not addressed your readers on the subject of oceanic circulation without making myself familiar with the facts which bear upon that subject, and at the very least, with those comparatively fundamental facts to which attention has been invited.

And here I would remark that one who writes so much and so often as I have had occasion to do on this and kindred subjects, is placed to some degree at a disadvantage. He cannot on the one hand assume that the readers of any particular essay have also read all that he has written on the subject; yet, on the other, he cannot assume that none have done so, and that he is therefore free to repeat (in a more or less modified form) much that he has formerly urged. I was, perhaps, somewhat too careful in writing for your pages to avoid touching at any length on any parts of the subject which I had more particularly dealt with elsewhere; and accordingly I have laid myself open to a method of attack, which in reality involves the suggestion that I have written without due consideration even of the elements of my subject. I have no doubt that Dr. Carpenter has no wish to imply this directly, yet indirectly it is implied in every paragraph of his reply. I shall be able to show, however, that every one of the points touched on by Dr. Carpenter had been fully considered by me—and, for the most part, several months before he had turned his attention to this subject.

First there is the remark that I have left out of view the circumstance that if there is excess of evaporation in the intertropical area, the excess ought to show itself, as in the Mediterranean, in an *increase* of specific gravity, whereas the specific gravity of the equatorial water is *lower* than that of tropical water. Now, it is unquestionably true that the effect of evaporation is to increase the specific gravity of sea water; but it is equally true that the effect of the heat which causes the evaporation is to diminish the specific gravity. The point is considered in my essay entitled "Is the Gulf Stream a Myth?" which forms part of my "Light Science for Leisure Hours." "We recognise," I there say, "two contrary effects as the immediate results of the sun's action. In the first place, by warming the equatorial waters it tends to make them lighter; in the second place, by causing evaporation it renders them salter, and so tends to make them heavier." And I proceed to inquire which cause is likely to be the more effective; arriving at the conclusion that the water is made lighter. The case, indeed, appears to me to be altogether different from that of the Mediterranean Sea cited by Dr. Carpenter. In the Mediterranean we have the same heating action as on the Atlantic in the same latitudes, but not the same relatively enormous quantity of water freely communicating with the region so heated. We have, then, in the Mediterranean evaporation as everywhere else, and evaporation to the same degree, appreciably, as elsewhere in similar latitudes; but evaporation *not* compensated as in the open Atlantic by the effects of free communication with surrounding water. Hence we have in the Mediterranean an increase of saltness; in other words, an increase of specific gravity. And precisely because this increase takes place in the Mediterranean, whereas the water of the Atlantic in the same latitudes, exposed to the same average degree of heat, is not rendered heavier, it may be maintained not unreasonably that the water of the equatorial Atlantic being unconfined will in like manner not be rendered heavier by evaporation. It seems to me that we have here a positive argument of great weight in *favour* of my views. But independently of this I would ask whether it can be questioned that enormous evaporation *does* take place over the equatorial area. This is what I contend for, and I should have imagined that few would undertake to deny the proposition.

In passing, I must remark that I do not adopt the distinction between equatorial and tropical water which Dr. Carpenter appears to recognise. I have in view the evaporation over an enormously larger area than he considers—no less an area, in fact, than the whole ocean between latitudes 40° north and south of the equator (at the equinoxes, and varying according to the season). It by no means follows that because the equatorial current does not cover this enormous area, that therefore the relation which I have suggested as the mainspring of oceanic circulation has not that extent. On the contrary, while it is on the one hand certain that there is an excess of heat over this enormous area, it is on the other almost a necessity of my theory that the resulting current should be found running along the middle only of the great region of evaporation.

This brings me to Dr. Carpenter's second objection, that if the removal of equatorial water draws in polar water from the *bottom*, the whole intermediate stratum should first rise towards the surface. I do not hold the view thus demolished, but simply that the inflow is from below. The question whether the inflow would be from above or below was dealt with by me in a paper on "Oceanic Circulation" in the *Student* for July, 1868. I do not urge this as a proof that Dr. Carpenter's objection is invalid. My reasoning may admit of being refuted. But I wish to show that the objection is not a new one to me. The inflow may be from below without being from the bottom. If it were from the bottom it would not have the effects I have ascribed to it, that is, it would not result in a westwardly-flowing current. What I conceive is that since the whole tropical and equatorial area is a region of excessive evaporation (as surely no physicist will deny), there is over the whole region a depression of the ocean level. This depression may be, or rather must be, exceedingly minute; but the total quantity of water thus, as it were, wanting, must be enormous. The difference must by the laws of fluid equilibrium be supplied, and though the immediate supply in equatorial regions may come from tropical regions, the actual source of the total supply must be sought for in higher latitudes. That the water drawn in under these circumstances would traverse the surface of the Atlantic, is by no means proved by the fact that the eminent mathematicians cited by Dr. Carpenter consider that an in-draught to replace water "swept off from the surface," by trade wind action would be a surface current. The two cases are wholly dissimilar. I must, however, admit that *my* case is one of extreme difficulty regarded as a problem in hydrodynamics. It is so difficult that I do not believe it can be solved even after the very imperfect fashion in which hydrodynamical problems have hitherto perforce been dealt with. When the physics of hydrodynamics have been treated by mathematicians like the physics of astronomy—or rather when they *can* be so treated, it may be possible to deal with this problem. Unless I greatly mistake, however, in such a *then* we shall find a *never*.

I do not see how the action of the cause I have considered is affected by the circumstance that the equatorial heat does not show any effects below 200 fathoms; for the cause is in its very nature a surface one. But I would remark that so far as continuity of action is concerned, the equatorial heat seems at least on a par with the polar cold. For as the aqueous vapour rises it finds its way to regions where the atmospheric circulation is at work to carry it away (it is only the surplus quantity which is condensed into clouds, and even these are in great part carried away); and thus the process of evaporation can hardly be exhausted. Even at night, though in a modified manner, the evaporation must continue. But the action of the polar cold, though it is continuous in the sense that the increase of cold extends to great depths, yet has this great difficulty to contend with that the descending water must perforce wait until room is made for it by the slow removal, the *creeping away*, as it were, of that which it replaces. That this cause, *per se*, can ever become one of sufficient activity* to generate a complete system of vertical oceanic circulation seems at the least open to grave question. It appears to me also that when applied to the North Pacific this theory fails. Very little water can pass through Behring's Straits, and beyond Behring's Straits there is an island-locked and shallow sea of enormous area, altogether unlike the deep North Atlantic.

I would further point out that the interesting fact above mentioned, namely that the equatorial heat exerts no perceptible effect at a depth exceeding 200 fathoms, is in reality almost a necessity for my theory. For if the whole of the equatorial ocean were heated, and, therefore, of reduced specific gravity, the water arriving from higher latitudes would flow to the bottom, and so have to force up the intervening strata, in order to produce the observed effects; and this may be regarded as impossible. As it is, such colder and heavier water would be in dynamical equilibrium within a very short distance of the surface.

Next, as to the question of rainfall. Dr. Carpenter considers that I have overlooked the considerations (1) that the rainfall of Europe and North America may be accounted for by the evaporation in the Mid-Atlantic, beyond the region of the trade winds, say between 20° and 40° north latitude; and (2) that there is an enormous rainfall in the region of equatorial calms, which Sir John Herschel attributes to the deposit of waters taken up by the N.E. and S.E. trades. To this I must reply that in my essay on Rain in the "Intellectual Observer" for December, 1867, I have weighed the whole question of rainfall at least with great care, and with constant reference to the best sources of information. One circumstance I there note which seems at a first view (or rather viewed as Dr. Carpenter appears to consider the matter) much more fatal as an objection to my theory than either of those noted by Dr. Carpenter; viz., that according to the observations of Humboldt and others, the annual rainfall is at a maximum at the equator, and diminishes with increase of latitude. But the whole question is, where does all this rain come from? If it comes from tropical and equatorial evaporation it will surely not be argued that what falls in or near the place of evaporation itself, represents the total amount of such evaporation. It is unquestionable, I conceive, that the rainfall is only the excess of the aqueous vapour poured so copiously into the air from the whole of this region. It is the quantity which the air, as it were, rejects. It is a matter of little importance where the rainfall of higher latitudes comes from, though it should be noticed that the views of Dové, Kaemtz, and other leading meteorologists respecting the winds and rains of high and low latitudes, support my remark about the great rivers.

Now we have in the phenomena of the zone of calms a crucial test of Sir J. Herschel's theory as to the origin of the equatorial rains. It appears to me that this test altogether negatives Herschel's theory. If the moisture to which these equatorial rains are due came from the trade-wind regions, we should certainly not expect the fall of these rains to be associated in any

* In passing I may notice that I did not suppose Sir J. Herschel to be humorous in reference to the intensity of the polar action, but in his use of the word "emphasis." I should not have touched on the point did I not thoroughly sympathise with the emphatic utterance of speculative or theoretical opinions.

marked degree with the progress of the equatorial day; or, if at all, then the cooler parts of the day, when the point of saturation is lower, would be the time of precipitation. With the mid-day heat would come a cessation of precipitations. As a matter of fact the contrary is the case. The sun (we are told by Dové, Kaemtz, Humboldt, Maury, Buchan, and many more) rises commonly in a clear sky in equatorial regions. As the day proceeds clouds form, and towards mid-day they grow dense. It is at noon that heavy showers fall, and towards evening the skies again become clear. Now, any one who has noticed what happens on calm summer days in any well-watered region can see that the equatorial phenomena represent the same processes on a greatly enlarged scale. On a summer's day in such regions we see how scattered cumulus clouds begin to form in early morning, become larger and more numerous as the day proceeds, and in the afternoon begin to be transformed into cumulo-stratus. The explanation is simple. The sun's heat has caused aqueous vapour to rise into the air, until there is so much that not very far above the earth's level the saturation point is reached. The further rise of the vapour is followed by the process of condensation into clouds, much heat being given out in the process, causing the air to expand in the neighbourhood of the clouds so formed, and thus giving to these clouds their peculiar rounded tops. (At least this feature seems better explained thus than by De Saussure's theory.) Now suppose the conditions changed to those existing at the equator. The supply of vapour is very much greater, the saturation point is very much higher near the sea-surface, and the contrast between the conditions prevailing there and in the region where condensation begins is very much more marked. The air above the equatorial and tropical seas contains, in the form of invisible aqueous vapour, an enormous quantity of water; this vapour rises and extends itself, its place being continually supplied by fresh evaporation. What must happen when the process has continued for several hours, but precisely what is observed to happen? There is an overflow, so to speak, resembling, only much more marked, that which causes the formation of our summer clouds. Enormous cloud-masses are formed, which cannot be carried away by the atmospheric circulation (very high above the calm zone), so fast as they are formed. Hence follows excessive accumulation, presently resulting in precipitation, accompanied by remarkable electrical phenomena.

But to suppose that the whole quantity of water evaporated at the equator, and in tropical regions, is precipitated *there* in the form of rain, corresponds to such a supposition as that the water overflowing a dam includes all that has risen to the level of the dam.

I should not be greatly concerned if the result of the experiments I spoke of should not accord with my prediction. But merely to put ice in water capable of melting it, is not in any sense to represent the conditions of the actual case. The addition of water from the ice as it melts is not in accordance with these conditions. It cannot surely be maintained that the oceanic circulation depends on the addition of water from the melting of ice; and yet I apprehend that the melting of ice is no unimportant feature of Dr. Carpenter's experiment. At any rate, the ice does melt, and the movement comes to an end when all the ice has melted away. Let the ice be packed outside the arctic end of the canal, so as merely to produce a refrigeration corresponding to what actually takes place with water carried into arctic latitudes, and I conceive that a very feeble circulation would result. Under the actual circumstances, the melting of the ice produces effects much more nearly corresponding to those due to rainfall than to the mere effects of arctic cold. The very activity of the circulation shows that the water which moves towards the ice does not undergo refrigeration. Water does not cool quite so quickly. It is the melted ice-water which descends; and nothing takes place in the arctic regions which corresponds to this continual addition of water to that already circulating. Otherwise, the arctic ice would be continually diminishing, which, of course, is not the case.

It will be gathered that I agree entirely with the opinion which Sir W. Thomson expressed, as to the reason why heat is necessary for Dr. Carpenter's experiment. Heat is necessary, because the ice *must* be melted to make the experiment succeed. But comparing the effects of heat and refrigeration (*not* of heat and the continual inflow of ice-cold water), I conceive that heat would be found altogether the more effective.

Lastly, as to the wind theory of the Gulf Stream, Dr. Carpenter remarks that, so far as he knows, I am "the only man of science in this country agreeing with Captain Maury in attributing the Gulf Stream to some other cause than the impelling force of the trade winds." He must be aware that there are not half a dozen students of science in this country who have expressed definite opinions on the subject after a thorough and independent inquiry into the evidence. Amongst those who maintain the wind theory there is not one, so far as I know, with whom Dr. Carpenter is in agreement. Mr. Laughton disputes the very principle of Dr. Carpenter's reasoning, holding that the change of temperature from equator to poles proceeds too slowly mile for mile to produce the effects which Dr. Carpenter indicates. Mr. Croll, in like manner, has expressed his complete dissent from Dr. Carpenter's reasoning. So also has Mr. Findlay. I believe these gentlemen to be mistaken, and I conceive that I have been able to put my finger on the precise point where their respective lines of reasoning fail. But, if Dr. Carpenter is to take general consent as an argument, and to maintain that I am wrong because he knows of no one who agrees with me, I may as well point out that he is entering into a very questionable alliance so far as his special views are concerned. So far as I know, all the continental students of science who share our common views as to vertical circulation, reject the wind theory as *solely* sufficing to account for the Gulf Stream. Again, he sets Sir J. Herschel's opinion (30 years ago) that "the Gulf Stream is *entirely* due to the trade winds" as almost conclusive against me. It is, at least, not new to me, since it is cited in every paper I have written on the subject. But is there no evidence to show that Sir J. Herschel abandoned the view he formerly entertained? I would ask what Sir John Herschel implies when, in his letter to Dr. Carpenter, he writes "The action of the trade and counter-trade winds, in like manner, cannot be ignored; and henceforward the question of ocean currents will have to be considered under a twofold point of view." The word "henceforward" implies very distinctly that Sir J. Herschel was entertaining a new opinion—that is, an opinion new to him; and I think Dr. Carpenter would find it difficult to demonstrate that this new opinion would not have enforced the omission of the word *entirely* from the sentence quoted by Dr. Carpenter.

I need hardly say that I do *not* agree with Captain Maury, whose theory of oceanic circulation appears to me to be wholly untenable. Nor do I for a moment assert that the winds play no part in producing oceanic circulation. I may have been mistaken in attaching so much weight as I have to Maury's evidence as to the trade wind zones, though it is known that science owes more to him than to any man for our present knowledge of the winds prevalent in certain regions; and when I first wrote on the Gulf Stream there was no evidence on the subject even approaching Maury's (or that collected by Maury) in accuracy and completeness. But there is one argument which those who have adopted the trade winds as the primary cause of the Gulf Stream appear to me to have overlooked, and it is on this argument that my own view has been chiefly based. The trade wind zone of the northern hemisphere is not constant in position; but travels northwards and southwards with the northerly and southerly motion of the sun in declination. The change in the position of the zone of calms is not, indeed, so great as is stated in Buchan's meteorology, where it is said to travel from 25° north to 25° south of the equator; but it is considerably greater than was supposed by Dové, Kaemtz, and others. If we set the extreme shift of the northern trade-zone at ten degrees we are certainly not over-rating it. Now, taking this zone as extending in spring or autumn from 10° to 25° north latitude, we should have it in winter extending from 5° to 20°, and in summer from 15° to 30°, the only part common to these two ranges being that from 15° to 20°—that is to say, the northern five degrees of the winter zone, and the southern five degrees of the summer zone, each zone being 15° wide. Now, if any one will mark these zones on the North Atlantic, he will find that while the zone of winter trades would produce a current flowing into the southern half of the Gulf of Mexico, the zone of summer trades would produce a current flowing into the northern half. The former would produce a current flowing as the Gulf Stream actually flows; the latter would produce a current flowing precisely in the opposite direction. This being the case, I do not find the evidence for the trade winds as the sole or even the main cause of the Gulf Stream altogether convincing. The case does not, for instance, seem quite "as clear as the rotation of the earth." It seems, also, not undesirable to mention that the equatorial current and the Gulf Stream are not mere drift-currents, and that on a careful estimation of the frictional action of such winds as the trades on the surface of the ocean, the action will be found quite unequal to the propulsion of so vast a body of water as is actually carried westwards (not, by the way, *before* these winds). Until difficulties such as these have been removed from the trade wind theory *as solely sufficient* to account for the Gulf Stream, I think I would rather be the only student of science opposing that theory, than one of a phalanx, however large, maintaining it. There is, however, no such phalanx; the subject being regarded by nearly all students of science as a very open one.

NOTES OF COMMUNICATIONS TO THE ACADEMY OF SCIENCES, PARIS.*

PHYSICS.—OPTICAL PHENOMENON OBSERVED AT GRAND CHARTREUSE.—The description of the phenomenon observed in the balloon by M. Tissandier† recalls to mind an identical circumstance observed by me four years ago. On the 3rd September, 1868, towards 5 p.m., I was, with several other persons, upon the narrow platform which terminates the Grand Som (2,033 metres high), and of which the walls form themselves into a peak at the Grand Chartreuse. Clouds enveloped us each instant; the sun, nearly setting, cast our shadow, and that of the cross planted upon the summit, upon them, somewhat enlarged, surrounded by a rainbow-coloured circle. We could distinctly see our movements reproduced by the shadow; it appeared to be distant a hundred paces, and a little below us; a circle presenting all the colours of the spectrum, violet on the interior, red on the outside, completely surrounded it. The phenomenon appears to be analagous to that known under the name of the Spectre of the Brocken. I have not observed the white rainbow, or circle of Ulloa, beyond the irridescent circle which formed the frame of the picture.—M. J. GAY.

THE PRIMARY SPECTRUM OF IODINE.†—The emission of red light by the vapour of iodine strongly heated appeared to me to present sufficient interest to engage me in studying yet closer the spectrum of that metalloid. MM. Plücker and Hittorf have not succeeded in producing with iodine, by help of the Geissler tubes, a spectrum of the first order that would correspond with the spectrum of absorption; I have been more happy in employing a sheathed tube, and have been able at will, and in the same apparatus, entirely constructed of glass, to obtain a spectrum of lines described by Plücker, and a new spectrum of which the least refrangible part reproduces, so to speak, the negative proof of the beautiful spectrum of absorption, so well studied by M. Thalén; it is accompanied by bands excessively diffused at the commencement of the blue and the extremity of the indigo; these bands become more luminous on increasing the tension of the vapour, but then the lines of the secondary spectrum will appear. The light of the tube is of a bronze-yellow with cold; it becomes a violet-blue with heat. To obtain the new spectrum it is necessary to employ a source of electricity having little tension, as the bobbin of induction with a jar; it is but little luminous, unless one employs a particular artifice to observe it, presenting only to the spectroscope the section of the narrow tube. Each bright band, on being brought under the reticle of the glass, is replaced by a black band when the vapour is illuminated from behind. We perceive in this a new example of multiple spectra. One cannot suppose that the body which furnishes the new spectrum is a compound of iodine, for this would be the compound that gives the well-known bands of the spectrum of absorption; in other words, the characteristic coloration of iodine, from which it derives its name, would be due to an impurity. It seems to me, then, proved that the same elementary body may have two spectra, as it can have two allotropic states, which is the old opinion of Plücker. It became interesting to know whether the continuous spectrum of iodine heated to redness would present signs of the primary bands, as the theory of the proportionality of emissive and

† ENGLISH MECHANIC, 2nd August, 1872, p. 507.

absorbing powers demands. With better conditions and by employing strong dispersion I have succeeded, in fact, in recognising the principal of them.—M. G. SALET.

ON A NEW ELECTRIC PILE OF ECONOMIC CONSTRUCTION.—[The object of the author was to construct a pile of common materials in every-day use, that might be made anywhere, without the intervention of special workmen, and which should possess the essential quality, constancy in effect.] The pair which I have adopted, after some trials, recalls in its form that of Calland, employed some years since on telegraph lines; but its elements are different. It is composed of a vessel in which is plunged a sheet of lead and another of zinc; that of lead descends to the bottom of the vessel; that of tin is one half shorter; the bottom of the vessel is occupied by a bed of minium; the exciting liquid is water mixed with chlorhydrate of ammonia in proportions 10 to 100. The electro-motive force of this pile is about one-third of that of Bunsen; its interior resistance is weak and varies little, and the resultant compound does not materially change the conductibility of the exciting liquid; its constancy is great, and the expenditure is almost nothing when the circuit is open.—M. GAIFFE.

JOHN J. LAKE.

ASTRONOMICAL NOTES FOR SEPTEMBER.

BY A FELLOW OF THE ROYAL ASTRONOMICAL SOCIETY.

THE right ascension of the Sun at Greenwich mean noon on September 1st is 10h. 43m. 32·22s., and his declination north 8° 5' 15·6", so that he will be found in the constellation Leo, almost close to the small double star 179 Piazzi X. He rises in London on the 1st at 5h. 15m. a.m. and sets at 6h. 44m. p.m., thus being obviously 13 hours and 29 minutes above the horizon, and only 10 hours and 31 minutes below it. He is, however, travelling rapidly down towards the equator, which he crosses at 5h. 53m. on the afternoon of the 22nd. At this instant he is technically said to enter Libra, and autumn commences. He is really at the time in the constellation Virgo, a little to the south of a line joining β and η, and rather nearer to the latter. The time of his crossing, or being *on* the equator, is very evidently that of the equinox, but the nearest practical approach to the equality of day and night will be on the 25th, when he will rise at 5h. 53m. a.m., and set at 5h. 52m. p.m. Subsequently to this the nights will gradually become longer than the days, and on the 30th sunrise will happen in London at 6h. 1m. a.m. and sunset at 5h. 39m. p.m. The equation of time is subtractive during the whole of September, and increases very rapidly from only 0m. 17·12s. on the 1st o the 30th, when 10m. 10·73s. must be taken from the instant of apparent noon to give the time which a properly regulated chronometer should indicate. The semi-diameter of the Sun at the instant of his crossing the Greenwich meridian on the 1st is 15' 53·7", and this occupies 1m. 4·38s. of sidereal time (convertible into mean time by the subtraction of 0·18s.) in its transit. The semi-diameter increases to 16' 1·2" by the 30th, and this occupies 1m. 4·33s. of sidereal time (convertible as above) in its transit. The sidereal time at Greenwich mean noon on September 1 is 10h. 43m. 49·35s., and on the 30th 12h. 38m. 9·39s.; the mean time at sidereal noon, or mean time of transit of the first point of Aries, being 13h. 14m. 0·22s. and 11h. 19m. 58·9s. on those days respectively. An abnormal number of spots continue to diversify the solar disc.

The Moon will be new at 53·5 minutes after midnight on the 2nd; enter her first quarter at 2h. 8·3m. in the afternoon of the 10th; be full at 5h. 4·7m. a.m. on the 17th; and enter her last quarter at 1h. 21·5m. p.m. on the 24th. She is 28·1 days old at noon on the 1st, and 29·1 days at the same hour on the 2nd. On the 3rd, at Greenwich mean noon her age will be 0·5 days; and so increasing by one day *de die in diem* until the end of the month, will, on the noon of the 30th, be evidently 27·5 days. At 5 a.m. on September 8 libration will bring an additional portion of her S.E. quadrant into view; while more of her S.W. quadrant will be perceptible at 11 o'clock on the night of the 20th. The south-eastern libration will very evidently occur when the Moon is beneath our horizon. The Moon will be in conjunction with Mercury at 7h. 58m. a.m. on the 2nd; with Venus at 2h. 39m. a.m. on the 4th; with Saturn at 10h. 42m. a.m. on the 12th; with Uranus at 6h. 43m. a.m. on the 27th; with Jupiter at 5h. 38m. in the afternoon of the 28th; and, lastly, with Mars at 11h. 54m. on the same night.

There will be seven occultations of fixed stars by the Moon during the months of September. Firstly, at 8h. 27m. on the night of the 14th, B.A.C. 7550 will disappear at the Moon's dark limb, reappearing at the bright limb at 9h. 21m. Then on the 15th, ι^1 Aquarii will disappear at the dark limb at 11h. 29m., to reappear at the bright one 33 minutes after midnight. Subsequently, at 12h. 46m., ι^2 Aquarii will disappear at the dark limb, reappearing at the bright limb at 1h. 50m. At 1h. 33m. a.m. on the 20th, B.A.C. 728 will be occulted by the bright limb, and will emerge from behind the dark limb at 2h. 46m. On the night of the 23rd 132 Tauri will be occulted by the bright limb at 11h. 45m. This star will reappear at the dark limb exactly one hour afterwards, or 45 minutes after midnight. ϵ Geminorum will be occulted by the bright limb of the Moon 27 minutes after midnight on the 24th, and curiously (as is the case of the star previously named) reappear exactly one hour afterwards at the opposite one. Lastly, at 4h. 45m. in the early morning of the 26th, κ Geminorum will be occulted by the bright limb to reappear at the dark limb at 5h. 33m.

Mercury is a morning star during September, and may be caught before sunrise towards the middle of the month. At 16 minutes after midnight on the 15th he attains his greatest western elongation, 17° 52' from the sun. At this date he appears above the horizon in the morning nearly an hour and three quarters before the sun. The beginning of the month, however, will be preferable for viewing him should the observer possess an equatorially mounted telescope, inasmuch as his apparent diameter is now decreasing daily. He continues in the constellation Leo until the end of the month, when he passes into Virgo. On the 15th, at Greenwich mean noon, he will be close to ρ Leonis and slightly to the north-east of that star, while at 6 23 a.m. on the 24th he will be in conjunction with σ in the same constellation. His conjunction with the Moon at 7h. 53m. in the morning of the 2nd has been before spoken of.

Venus is an evening star in the sense of setting after the sun, but she is much too close to him to be favourably observed. Moreover, her apparent diameter is exceedingly small, and she is very nearly round. She is travelling through Virgo during the whole of September, but never passes near any conspicuous star. Her conjunction with the Moon at 2h. 39m. a.m. on the 4th has been previously noticed.

Mars is a morning star too, but is such a wretched little object as assuredly not to repay the trouble involved in pointing a telescope at him; his diameter never subtending an angle of 5" during the entire month. He rises soon after 2 o'clock in the morning at the beginning of September, and a little earlier at the end of it. He is moving across the face of the heavens from Virgo into Leo, and at the end of the month will be pretty near to Regulus. α Leonis is not a pure white star, but it will be seen to contrast markedly with the sullen red of Mars, small as the planet now appears. Mars will be in conjunction with Jupiter at 4h. 36m. in the afternoon of the 21st, but both planets will be close to their setting in bright sunlight. We have mentioned his conjunction with the Moon at 11h. 54m. on the night of the 28th under another heading.

Jupiter is a morning star, rising about 3h. 7m. a.m. on the 1st, and about 1h. 46m. a.m. on the 30th. This planet is travelling across a barren part of the constellation Leo, and will be pretty close to that very curious variable star ψ Leonis at the end of the month. His apparent diameter continues very slowly to increase, subtending an angle of 32" at the beginning, and one of 33" during the latter part of the month. The conjunction of Jupiter with Mars at 4h. 36m. p.m. on the 21st, and his conjunction with the Moon at 5h. 38m. on that of the 28th have been adverted to before.

Of the phenomena presented by Jupiter's satellites, some few will be visible during September, but many of them will occur at times when the low altitude of the planet, or the brightness of the twilight, will render their observation problematical. Firstly, during the early morning of the 2nd, the eclipse of satellite 3 may possibly be witnessed at 4h. 27m. 6s. So again may the reappearance of satellite 2 from occultation at 3h. 40m. a.m. on the 5th. The ingress of the shadow of satellite 1 will be visible at 3h. 51m. a.m. on the 8th, and that of the satellite itself afterwards at 4h. 26m. The same satellite (1) will reappear from occultation at 4h. 8m. in the early morning of the 9th. During that of the 13th the egress of satellite 3 will happen at 4h. 30m. It is possible that the eclipse of satellite 1 may be witnessed at 3h. 7m. 50s. on the 16th; as also the egress of the shadow and that of the same satellite at 2h. 34m. and 3h. 16m. respectively, on the 17th. An eclipse of satellite 2 will be visible at 4h. 51m. 27s. on the early morning of the 19th; while at 5h. 11m. on the next, satellite 3 may just possibly be detected in its entrance on Jupiter's limb. The egress of the shadow of satellite 2 may, perchance, be seen at 2h. 53m. a.m. on the 21st.; that of the satellite casting it will be visible at 4h. 26m. An eclipse of satellite 1 can also be seen at 5h. 1m. 32s. a.m. on the 23rd. Before sunrise on the 24th the ingress of the shadow of satellite 1 will happen at 2h. 7m., followed by that of satellite 1 itself at 2h. 56m. Then at 3h. 34m. satellite 4 will enter on to Jupiter's disc. After this the shadow of satellite 1 will leave the planet's opposite limb at 4h. 27m.; as will the satellite which casts it at 5h. 16m. Perhaps satellite 1 may be detected as it reappears from occultation at 2h. 37m. a.m. on the 25th. The ingress of the shadow of satellite 2 will begin at 2h. 32m. a.m. on the 28th, the satellite itself not following its shadow until 4h. 16m. The egress of the shadow may possibly be perceived at 5h. 28m. Finally, although pertaining (according to civil reckoning) to the early morning of October 1, we may, astronomically speaking, consider the reappearance from occultation of satellite 3, at 3h. 36m.; the ingress of the shadow of satellite 1 at 4h. 1m., and that of the satellite itself at 4h. 55m. as belonging to this month.

Saturn may still be seen during the early part of the night, but is just as wretchedly placed as ever for observation. He is still in Sagittarius, and during the whole of it just to the south-east of π in that constellation. He rises on the 1st about 4h. 21m. in the afternoon, souths at 8h. 19·3m., and sets about 17 minutes after midnight. On the 30th his rising, southing, and setting occur at 2h. 27m. p.m., 6h. 25m. in the evening, and 10h. 23m. at night respectively. We have mentioned his conjunction with the Moon at 10h. 42m. a.m. on the 12th (of course beneath our horizon) above.

Uranus is a morning star, is situated in Cancer, and is gradually coming into a more favourable position for the observer. He rises on the 1st about 50 minutes past 1 a.m., souths at 9h. 41·4m. (of course in bright sunlight), and sets at 5h. 34m. in the afternoon. Then, at the end of the month, he rises about 4 minutes after midnight of the 29th, souths at 7h. 53m. the next morning, and sets in the afternoon of the 30th about 3h. 43m. He is in a somewhat barren part of the heavens. His diameter increases from 3·6" at the beginning of the month to 4" at the end of it. His conjunction with the Moon at 6h. 43m. a.m. on the 27th has been previously spoken of.

Neptune must also be called a morning star, in so far as he is not on the meridian until nearly 3 a.m. at the beginning of September, and about 1 o'clock in the morning at the end of it; but he rises about 7 minutes past 8 in the evening on the 1st, and about 6.15 on that of the 38th, so that he is fairly visible during the working hours of the night. He is situated in the constellation Pisces, close to the 5th magnitude star o, and will be almost due south of it, and in the same field of a high-power eyepiece, upon the nights between the 5th and the 9th. The planet will require considerable magnification to demonstrate its nature satisfactorily. His apparent diameter is very slightly increasing.

Showers of shooting stars have been suspected at the beginning of September, and between the 18th and 25th of the month; but there is no definite confirmation of this. Observers may look out, though, as such confirmation would possess a considerable degree of interest.

INFLUENCE OF LIGHT ON ANIMAL LIFE.

IN a paper in the *Revue des Deux Mondes*, M. Papillon communicates the following facts:—Certain Infusoria, in stagnant water, receive carbonic acid from the liquid and give out oxygen (like the green parts of plants). The oxygenation thus produced varies throughout the day, having a minimum at sunrise and a maximum about four p.m. It takes place by night as well as by day, but with less intensity; and in clear weather it is greater than in cloudy. Light accelerates the vital movements in animals, especially those of nutrition. Fowl and cattle are fattened in partially darkened chambers. In these vital action takes place more slowly, and the nutritive matters are more readily deposited in the organs. Continued absence of light sometimes kills animals, sometimes produces a marked change in their organisation. There are, in some subterranean caves of the Basse-Carniole, certain curious reptiles resembling salamanders. They are nearly white, and have only rudimentary eyes. When exposed to light they seem to suffer, and their skin colours. It is probable these animals have not always lived in the darkness, and that their skin and vision have been affected by the absence of light. The appearance of animals in such conditions presents a striking analogy to the case of etiolation in plants.

Edwards, in 1820, studied the influence of light on animal development. Frog's eggs and tadpoles, exposed to light, developed regularly, while growth was retarded or hindered in the case of others kept in darkness. M. Moleschott, 30 years later, found the carbonic acid gas expelled by frogs in the light was a fourth more than the volume expelled in darkness; also that the production of carbonic acid was proportional to the intensity of light. He thinks the action of light on batrachians is transmitted partly by the skin, partly by the eyes.

M. Beclard has more recently studied the effects of glass receivers of various colours on flies' eggs contained in them. Maggots were produced in each case, but, in four or five days there were perceptible differences of growth; those in the violet and blue rays had developed most, those in the green much less, while red, yellow, and white rays had an intermediate effect. He examined, also, the quantity of carbonic acid produced by birds and mice in the various coloured rays, but found no difference; the hair or feather covering, possibly, obscuring the effect. Frogs, similarly treated, produced more carbonic acid in the green than in the red rays. The difference is generally about a third or a fourth. When the skin is removed, the effect is reversed. The cutaneous exhalation of water vapour in frogs was found a half less in darkness than in light, and in violet rays it was nearly the same as in white light.

M. Bert has made some curious experiments on the predilection of animals for various coloured rays. He put a number of *Daphnia* (a minute fresh water crustacean), in a glass vessel placed in the dark. When the spectral colours were thrown on it, the little creatures, which were dispersed throughout the vessel, grouped themselves, chiefly in the yellow and green rays, and in diminishing quantity towards the more refrangible end. On interposing a screen they were again dispersed. The more luminous parts of the spectrum appeared the most agreeable to them. M. Bert thinks also that, like ourselves, they have no ocular perception of ultra-red or ultra-violet rays.

The change of colour in the chameleon has been variously explained. M. Brucke's recent researches show that it is due to varying dispersion of solar light in the coloured cells; a phenomenon of the same kind with that observed in soap-bubbles and thin plates. The tint of the animal passes from orange to yellow, from green to blue, by a series of shades dependent on the state of the diurnal radiation. M. Brucke thinks temperature has no influence on the phenomenon.

The hair and feathers of animals are of a darker colour on the back than on the belly and breast. Their colours are also more intense in summer than in winter. Butterflies of the night never have the brilliant tints of those which appear by day, and of the latter those of spring are much brighter coloured than those of autumn, showing a congruity with other colouring in nature. Night birds also have a darker plumage and a softer tegument than day birds. We have, again, a striking difference of colouring between the animals of cold regions and those of the torrid zone. The influence of light on organic forms, as well as colour, is also seen in the gradually increasing abundance and variety and beauty, from pole to equator.

The influence of light on the human system presents many interesting points. An infant instinctively seeks the light, turning in the direction whence it comes. The organ most affected by light is the eye, and the excitability of the retina is very variable. Prisoners in dark dungeons have been known to acquire a wonderful distinctness of vision in the dark. The eyes of such also become sensible of very slight changes in intensity of light. Lavoisier, in 1766, wishing to acquire a greater delicacy in perceiving the relative intensities of certain flames, shut himself in the dark for six weeks. Dionysius the Tyrant constructed an inclosure with bright illuminated chalk walls, into which he introduced prisoners who had been kept long in darkness, whereupon they became blind. Travellers to polar regions speak of the injurious effect which the reflection of light from the snow has on vision. When the impression of light on the eye is powerful and instantaneous, the retina suffers most. If less energetic and more prolonged, the humours of the eye are altered. The phenomena of sunstroke arise from the action of light, not from elevation of temperature. A very intense artificial light (such as the electric) may produce it. The rays causing it appear to be the violet and ultra-violet, and those studying the electric light often employ glass screens which absorb these rays.

The skin is evidently affected by light. The hands and other uncovered parts have a darker colour than the covered. Country people are browner than those in the town. In latitudes little distant from each other are to be found variations in colour of skin corresponding to solar luminous intensity. In Europe several varieties are perceptible; but the same phenomenon may be observed among darker peoples. For example, the Hindus of the Himalayas are nearly blind; those of Malabar and Ceylon are darker than some of the negro tribes. The Egyptians present an ascending chromatic scale as you advance from the mouths of the Nile towards its sources. Again, the women of certain coloured races, being kept constantly under cover, become whiter, so do the Esquimaux in their long winter. And many other facts might be given. Doubtless, many other influences co-operate in such effects, but the effect of luminous radiation is incontestable.

All the organic functions benefit by light. Darkness seems to favour the preponderance of the lymphatic system, the susceptibility of the mucous membranes to catarrhal affections; the flacidity of the soft parts, swellings, irregularities in the osseous system, &c. Miners and others are subject to these disadvantages.

Certain spectral rays influence animal life as darkness does. M. Bert found the orange rays hinder the development of Batrachians. Now, these same rays are favourable to plant growth; and, on the other hand, green light, which is hurtful to plants, is very favourable for animals. M. Dubrunfaut hence divides the rays of the spectrum into two complementary groups, a green and an orange, manifesting antagonistic qualities in nature. Green light being a powerful stimulant of the animal functions, makes the spring time specially enjoyable.

The relation between perfection of form and exposure to light is also seen in the case of human beings. Light tends to develop the different parts of the body in harmonious proportion. Deformities are most rare among the coloured races. Men who live naked have all their parts bathed in light, whence arises regularity of functions and development. It might further be shown how the functions of the mind are affected by light. A mind that has been dull and sluggish throughout the day, in a sombre room, will in the evening become lively and active in the brilliantly lit hall or drawing-room. And every one is familiar with the opposite effects of a cloudy and a bright day upon the spirits. A. B. M.

MEASUREMENT OF WAVES.

A PAPER on this subject was read at the meeting of the British Association, by Mr. C. W. Merrifield, F.R.S., Principal of the Royal School of Naval Architecture. The author was induced to look into this matter in consequence of a question put to him by Mr. Francis Galton as to whether it was possible to arrive at any definite estimate of the "roughness of the sea," at present recorded for meteorological purposes at a very coarse guess from mere inspection. He considered it was desirable to confine the measurement to the two points of ascertaining the aggregate height of the waves and their number during measured intervals of time; and he had devised simple and compact machinery for this purpose, as well as for obtaining profiles of waves when desired. The machinery could consist of a float sliding up and down strained wires on a platform like Brighton or Scarborough piers. A line from this float could pass over a pulley, the motion of which, transmitted through its shaft, would give all the required measurements. The measurement of the aggregate height of the waves would be effected by simply connecting a ratchet wheel, pawled so as only to turn one way, with the float pulley. A projecting stud on the ratchet wheel would record the aggregate height of the waves by means of any mechanical counting arrangement. In order to count the waves it was simply necessary to record the number of times the float pulley reversed its motion. This was effected by a reciprocating frame connected with a ratchet wheel by a pawl which the wheel could reverse by lifting the reciprocating frame. The method of counting which he proposed was to make a pencil which, if undisturbed, traced a straight line on a long slip of paper, such as a Morse telegraph coil, and received a slight shake at stated numbers. Time would be marked on the same paper by a clock giving a similar shake to another pencil at stated intervals of time. In this manner a permanent and continuous record of the number of waves and aggregate height at all times would be automatically made. The machine might be perfectly boxed in, with no other communication with the external pulleys and float than a shaft passing through a stuffing box. The recording machinery would thus be secure from injury. It would, moreover, require attention only once a day. Mr. Merrifield also described an arrangement by which the same machine might be made to trace the profile of waves whenever required. But this additional apparatus would require to be specially set at work when required, the waves of the sea being far too numerous for it to be possible to take portraits of all of them. He suggested that it would be very interesting to establish such an apparatus at Brighton Pier.

Mr. Hawkshaw suggested that observations should be made with the view of ascertaining the motion of waves with special reference to force, which would be a matter of practical importance to engineers; but Mr. Merrifield explained that his experiments had been for meteorological purposes rather than to discover the character of waves in the open sea.

DEEP-SEA SOUNDING-LINES.

A PAPER was read at the British Association meeting by Sir W. Thomson, F.R.S., on "The Use of Steel Wire for Deep-sea Soundings." The great difficulty of deep-sea soundings consisted, he said, in the resistance of the water to the material used for letting down and raising the weight, and that the only way in which that difficulty had ever been overcome in very deep soundings had been by employing extremely heavy weights. When the depth of three hundred fathoms was passed, the ordinary lead line ceased to be available, or at all events convenient; and until very recently the difficulty of calling up a long line and heavy weight from considerable depths was so great that it had become the practice to leave the weight behind, simply bringing up the specimen of the bottom. The Admiralty had made great improvements in deep-sea soundings, but even with the rope now used its resistance to the water when drawn up by hand at considerable speed was so dangerous as to necessitate the use of steam power. When there was great resistance to the line, and the currents carried it away to a distance, it was difficult to know when the bottom was reached. However, he believed that with so great a weight as 3 cwt. the depth of the water might practically be perceived within a few fathoms, and although it must be difficult to stop the line all of a sudden, he did not think the error in the sounding could be considered to be serious. To many it had occurred that wire rope would be a great advantage, inasmuch as it would occupy much less space and, therefore, create less resistance to the water. The objections which had been raised to wire were that it was liable to rust, that the men could not handle it, as it would kink, and it would go down in a heap over the weight; but he believed all those difficulties might be overcome by proper care. It had been considered necessary to have a great deal of mechanism, but all that he deemed to be essential was a wheel, which would operate like a brake, and around which the wire should be twined, the wire used being No. 22 gauge, of the quality known as the homogeneous steel wire, which could be manufactured in great lengths, was ·03in. in diameter, weighed 12lb. per statute mile, and broke with a weight of 252lb. To the end of the wire was attached a piece of hemp cord, which carried the weight, and by that means the wire was prevented from touching the bottom at all. He had made an experiment in mid-ocean, at a depth of 2,700 fathoms, experiments with the apparatus and materials he had indicated, and it having been attended with the most perfect success, he was sanguine that if wire were allowed to take the place of cord in deep-sea soundings, it would be far more economical, and the calculations themselves would be more accurate. Mr. Hawkshaw thought it would be a great pity if our deep sea sounding expedition completed its labours without adopting Sir W. Thomson's recommendations; and in the discussion which ensued it was generally conceded that wire would more effectually resist water than a porous material such as rope; a doubt was, however, expressed whether any plan could be adopted to altogether remove the danger of wire breaking when the soundings were being conducted in rough weather.

DR. CARPENTER ON CHALK.

THE following is the substance of the lecture delivered by Dr. Carpenter to working men, at the close of the meeting of the British Association at Brighton. After alluding to the fact that many persons were disappointed that he had not in his opening address, as it were, "cooked up an old dinner," by referring to his own researches, the lecturer said:—

You all know what chalk is. I need not tell you Brighton men what chalk is—that is to say, I need not tell you what it looks like, but I shall have to tell you what it is. If I were to say to you, "Do you know what chalk is?" "Oh, of course we do! Don't you suppose we know a piece of chalk when we see it?" But then I think I can tell you a little about this chalk. In the first place, where do you see it? You see it forming cliffs on your coasts; you find it forming downs in your interior; you find it wherever there is a little removal of the surface grass; you find plenty of chalk pits in various parts of the ridges of your downs. Where there is an exposure of the cliff, you will see, if you observe, that there are certain indications of what we call stratification—that is, that there are regular strata or layers one above another. And these are separated more or less distinctly from each other. Sometimes by distinct lines, and sometimes by lines of flint, for example, but you will not see them always horizontal: sometimes they are inclined, and sometimes vertical, but they were all horizontal once. These are the lines which intimate the successive deposition that took place at the bottom of the deep sea; for there is no question now but that the whole of the chalk formations of this part of England (which you see at Dover and Folkestone higher than in this neighbourhood, and at Alum Bay and the Needles) were once at the bottom of the sea. Some of these layers were horizontal, and some of them tilting up; but it would carry us too far if I were to carry you to consider the causes for this tilting-up. I want you to understand that these layers of chalk one above another indicate their successive ages. What position does this chalk occupy with regard to the other strata, to the great series of stratified rocks which geologists tell you of? It is a comparatively new formation (that is comparatively). The general series of stratified rocks were first studied in England; for it happens, by a most fortunate thing for science, that in Great Britain we have a sort of comprehensive pocket edition of the great series of stratified rocks. Beginning in Scotland and Cumberland and North Wales we have the oldest of these rocks; then, in the middle of Wales, we have those rocks called the Silurian system by Sir Roderick Murchison. In the Midland counties and the west of England, in Shropshire and Devonshire, we have the Devonian and the Silurian, all of them inclined—all of them shelving towards the east. And then you have that great and most important formation, the carboniferous limestone under which the coal-basin lies. Then comes the end of the series; all these lie more or less regularly on one another; and then again we find animal forms passing from one another. This series we call the Palæozoic, which is a Greek compound meaning ancient life. We come at the end of that to a great break; and I wish you to understand that the break occurs in this country, in America, and in every part of the continent of Europe. But it does not follow that it occurs everywhere else; but we find an apparent great break in the series being marked by this in the next strata, where we find no animals at all; the fossils of the new red sandstone are rather scanty, but there is the beginning of a new set of types. It generally lies unconformably with two different degrees of slope, and that makes great changes between the mountain limestone and the magnesian limestone. We do not use the term primary now for the old period, because that applies to a still older set; but the secondary is a term still in use, and we sometimes call it the Mesozoic, or middle-life period. Then we have the lias—the formation of the middle counties, and Dorsetshire and Bristol. There is a band of lias crossing the middle of England. Then we have the oolite which gives us our Bath stone and Portland stone. Then we come to the greensand and the chalk. The chalk is the last of that strata. There is this very beautiful type of life, the Pentacrinus. Mr. Willett has a beautiful specimen in his collection, which, I am happy to hear, will henceforth belong to Brighton. It passes up from the lias into the chalk. Then there is a similar great break to that at the end of the Palæozoic series, before what are called the tertiary. These deposits generally lie unconformably upon the chalk, and the types of life are mostly new. They cannot be traced distinctly from the chalk. There seems to have been a dying out of the animals of the chalk, and we begin with a new set of the animals of the tertiary strata. It is very curious that both London and Paris are situated upon the great bases of chalk of a subsequent formation, some of them fresh water and some of them local deposit. Now, the clay in our own area in the neighbourhood of London—that stiff clay which lies immediately over the chalk—is the local representative in that area of a very different formation in the south of Europe, namely, that great limestone which makes hills and even mountains in some places, and which runs along both the south of Europe and the north of Africa, and into India. The London clay was formed where clay was plentiful. There are no means of determining whether it is nummulitic, but we know it is of the same period, because we find in it nummulites representing the great nummulitic series. It will be seen, on examining a specimen of nummulitic limestone, that it is a chambered shell, and divided into an immense number of partitions. It is of this nummulitic limestone that the pyramids of Egypt are built. I had the pleasure of visiting the pyramids last autumn, and brought home a beautiful specimen of this limestone. I will now just give a general sketch of the position of the chalk. It is the highest of the secondary series, and it is usually considered that there is a great gap between the chalk and tertiary formations. Every geologist who is interested in the progress of modern science knows that, more and more, as we examine it carefully and minutely, there are in this formation great gaps, but if we find a gap here, there is a continuity there. A gap is caused by the formation being covered by sea; it remains here for ages; and, therefore, when it sinks, a fresh deposit takes place, but this deposit represents altogether different conditions. But then, during that period, deposits take place elsewhere. In Russia, there are immense areas covered with new red sandstone. I speak under correction, because I do not profess to be a geologist, but merely a zoologist, when I say this, but I believe large areas in Russia have never been under water since the old red sandstone deposits. Supposing they were to sink, a fresh deposit would cause an enormous gap. Now, you see it is entirely a question as to whether a particular area has been above the sea or not, and I believe all the modern geologists are now coming to the conclusion that, if there is an interruption in one place there is continuity in another. Only two days ago I had the pleasure of a conversation with one of the most distinguished French geologists upon this very point, and I said, "It is my opinion that, if there is an interruption here there is continuity there." He said, "I am entirely in accordance with you," and he came to the conclusion that where the interruption seems the greatest it is bridged over by what we have found, or what we shall hereafter find, in some other part. I will give you an illustration. This is not a proved fact yet, but it will show you the kind of knowledge that we may get. I daresay many of you have heard, with great regret, that the health of Professor Huxley broke down at the beginning of the present year. He was obliged to go to Egypt to recruit it, and he went up the Nile a great deal further than I did. I asked him "Did you follow up the curious nummulitic limestone?" "Yes," he said, "and as far as I could see, it rested conformably upon the chalk." Now, in the south of Europe and here, the London clay does not lie conformably on the chalk, nor does the nummulitic limestone of the south of Europe generally. Now, we come back to the question, what is chalk? Chalk is an aggregation of either very minute shells, or the remains of very minute shells, which we call Globigerinæ. Hundreds of them would only weigh a grain. What is the nature of the animal? It is a little lump, or rather a series of lumps of jelly, with no mouth, no stomach, no nothing, except that it can send out long threads, the minuteness of which is something hardly conceivable to you. They are not the ten-thousandth of an inch in diameter. They go out in clusters; they diffuse themselves through the water, lay hold of particles still minuter than themselves, and they draw these particles back: there is a continuous restless movement. I have sometimes described these as a sort of animated spider's web. It is always sending out some of these threads and other threads are being drawn into it, and in this manner, without any distinct mouth or stomach, the nutrient particles are constantly being drawn in, and in this way the animal is supplied. Now, when I tell you that there is a greater quantity of this life at present existing than of all other kinds of life put together—you will see what an important part they play in nature. The whole bottom of the Atlantic, except where cold currents come down, is covered with these animals and masses of decayed and broken shells. There is so much in the Atlantic that I cannot pretend to form an idea of how much there can be. In dredging the Atlantic at one mile in depth, we brought up nearly half a ton at one time, and at three miles depth we brought up 1½ cwt., besides our three miles of line and a heavy dredge. I shall give you a little history of this remarkable inquiry. Some years ago, my friend Professor Williamson, of Manchester, had an opportunity of examining some mud brought up from the Levant, and he found, by the aid of the microscope, that there were a large number of these organisms there. These all belong to the same general group, and are called Foraminifera, which means many-holed; and as these shells are filled with small holes, you will see that this name is applicable to them. These holes are pores (as you see in the diagrams). All these shells are composed of carbonate of lime, and now you see why geologists believed that lime, which is found in limestone rocks, at one time or another formed parts of this animal, which has the power to draw lime from the water and then pour it out again in the form of shells. Geologists have come to the conclusion, very advisedly, that all the lime that is found in various limestones has at one time formed part of an animal. Here we have this mass of chalk, which has all formed part of these Globigerinæ, which have drawn into themselves the lime from the sea water, and exuded it from these shells, just as shrimps, or lobsters and oysters. All these have lime. Oysters form layer after layer. The lobster forms a new shell. Some of you know what are called "crab's eyes" in the stomach, which are little accumulations of lime stored up against the time when the crab wants to make a new shell. Then these disappear from the stomach. I give you this illustration to show you how lime passes from sea water into shells. We have long known that chalk was made up of this and deposited in the deep sea. There are certain minute particles which I won't speak of, because we do not know the meaning of them, but we find certain other curious particles which will afford geologists study for a good while, and these we find in our chalk mud. I have here two lumps of dried mud which we brought up from the bottom of the Atlantic, and not one of you would know these from pieces of chalk, except that they are a little grayer, and they have a little more sand. But the important point is that these coccoliths in our chalk are precisely the same as those which are found in the old chalk itself. There is, therefore, a precise correspondence between the mud which we have brought up from one mile and two and three miles from the bed of the Atlantic and the whole of those cliffs. Now, as to animal life. We have found a great number of types most distinctly characteristic of the cretaceous period. The most remarkable we met with—it was our great prize—was a wonderful sponge, of which I have a drawing. Now, I will just mention to you the fact, as I think it may interest you, that I have been knocking about the North Sea making some deep-sea explorations. Our first vessel was not suited for our purpose. It was a most antiquated steamer, being the first that was built for her Majesty's service in the year 1825. We had very rough weather, and for several days we were knocking about doing a little work now and then. But one day we had a most successful dredge, and I rather glory in it because it was done on a Sunday. I glory in it because it was a study of one of the most important and most wonderful of the works of nature and of the works of the Creator. After several days of knocking about we had a fine Sunday. I said to the captain that I was very unwilling to work the men on a Sunday, but that we must not miss the opportunity, for it was a good and a holy work to do. Reward was given us. The discovery of this sponge was, to all scientific men, one of the most remarkable that has been made. Many of you have seen the wonderful and beautiful works of Mr. Gould, the ornithologist, who went to Australia, and expended £8,000 in his visit and in the production of his work; and when he saw this specimen he said, "Dr. Carpenter, I envy you. If I had only found such an interesting specimen, it would have been a reward to me for all my toil and expense." You may suppose, therefore, if this excites such an interest among those who are not of my own line of inquiry that it must have created feelings of intense pride in my breast. This specimen is of great interest in itself, and it is one of a type of skeleton. The skeleton of the ordinary sponge is horny, and is useful because it has no flint in its composition. It has needles in it which will run into your hands, but in this particular type of sponge the skeleton is composed of flint. Now, the great interest of this is that it is a new specimen of a most remarkable group of sponges. This sponge represents the whole type of chalk fossils. Professor Huxley one day came to my house to see it; he knelt down at the table to look at it, and, turning to his wife, said, "Now, do not speak; this surpasses the love of woman." Last Saturday I was on Lewes Downs, on Mount Harry, and I was asked to say a few words about the chalk. I just adverted to this, and my friend Mr. Crosskey, a very able geologist, who was born and brought up at Lewes, at once said, "Why, the whole of this hill is full of Ventriculites. I have got them over and over again in the chalk in this hill." Now, I think you will understand what a point of extreme interest this was to us. Here we found the type of the old Ventriculites, which was supposed to be extinct, still going on in the deep sea, and not only the sponge, but a great number of other animals; and the more we have examined them the more curiously they correspond to the old chalk forms. One of the last we got was a most singular specimen of the urchin tribe. You know the globular form of the common sea-egg, but this most singular specimen, instead of being like a box shell, was like chain mail, a number of separate pieces, all flexible; and it flattened itself out when laid on the hand, and I said to my friend, Mr. Wyville Thomson, who is a little heavy sterned, "This looks as if you had sat upon it." One or two imperfect specimens had previously been found, and may be seen in the British Museum, but here we had the animal actually existing at the present time. I will not descant further upon this, but will just go, in the last place, to the general question of what this means. Now, the credit of the suggestion is entirely due to Mr. Wyville Thomson—but it devolved upon me to publish it, as I was the reporter of the expedition, and I entirely fathered it—that really there has been no cessation in the production of chalk from the old cretaceous period to the present time. Perhaps the form in which we put it out was open to a little exception. We said that we might be considered to be still living in the cretaceous epoch. Very eminent men, such as the late Sir Roderick Murchison and Sir Charles Lyell, have taken exception to that statement, and perhaps not unreasonably, but it all depends upon what you mean by the words "cretaceous epoch." Sir Charles Lyell says the meaning of the words is that period which was terminated by the disappearance of a great number of types of animal life that you do not find in that chalk. Where, he asks, are the chambered cephalopods, where are the fishes that were characteristic of the old chalk? Do you find any other? The shells of the nautilus type, the animals of the cuttle-fish kind? Well, we hide our diminished heads and say, "Certainly we do not find them, but still we think that the evidence favours the actual continuity, that there has never been a break or cessation, and the ground we go upon is this, that during the whole of the tertiary period there is no evidence in this north-western portion of Europe, nor is there any evidence on the other side on the corresponding latitude, that the bed of the Atlantic has ever gone up more than about 2,000ft." Now, what is 2 000ft. to 15,000ft.? Why it only leaves you 13,000ft. instead of 15,000ft. We find tertiary shells from 1,500ft. to 2,000ft. on Welsh mountains and elsewhere. There is evidence that the land has been lifted up 2,000ft. or near it, in the tertiary period, but there is no evidence that it has been lifted more, and, if not, the bed of the Atlantic must have been the bed of the Atlantic from the time of the commencement of the formation of the tertiary strata. We have every reason, therefore, to believe that our modern chalk formation goes back to the commencement of the formation of the tertiary strata. Now, may not we go a little farther? Mr. Darwin taught us first that there are great areas in the Pacific ocean at the present time in course of elevation and of subsidence; that there are parts where by the condition of the coral we can surely assert that the bed of the ocean is slowly, slowly sinking down, and that there are other parts in which we can as surely say that the bed of the ocean is as gradually rising. Very well: now I apply that doctrine to this formation of chalk. I believe that at the time when the area of Europe and Britain, and what was formerly chalk lying at the bottom of the deep sea, that then occupied a great part of Europe, had been formed, when the elevation gradually lifted it up above the sea, the bed of the Atlantic was going down, and that the chalk animals migrated from what was then the old chalk sea of Europe into the new chalk sea of the Atlantic; that certain species that would bear the migration went along, and others that would not bear it did not go, and died out. But now, then, comes my friend, Mr. Prestwich, who, in his presidential address to the Geological Society last year, adopts that view, and gives us the rationale, and a most beautiful rationale I think you will consider it. Mr. Prestwich, on other grounds, quite irrespective of any hypothesis of ours, believes that the old chalk sea of central Europe was a warm sea, that it did not communicate with the Polar Sea. He believes that at the end of the chalk period a communication was opened between the Polar Sea and the sea of central Europe; that that let in a great quantity of polar water; that the temperature of the old chalk sea was considerably reduced; and that the reduction of temperature killed off fishes and these higher molluscs, but left us those lower forms which could survive the reduction of temperature. I think you will say this is one of the most beautiful of geological speculations (it is no more than a speculation) ever put before the world. In the greensand, which is all silex, composed of siliceous minerals, you find these little particles. Professor Aaronberg, who is one of the greatest microscopic discoverers, has shown that the greensand which occurs in the geologic period contains abundant internal casts of Foraminifera, and I can assign each one of those on the diagrams to one or other of the order named by Professor Aaronberg. What we now know to be chalk does not always retain its present condition as chalk. In the cliffs of the Giant's Causeway, in Ireland, you will find what we know to be chalk, by the series of its strata, &c., converted into white crystallised marble, and this marble was once animal life, as chalk was; and we know it was so by the course of interpretation which geologists are accustomed to employ. There we find great masses of carboniferous limestone which forms the bed on which the coal-measures are deposited; and there we also find coral reefs, and other beds which geologists, like Phillips, have concluded to be deep sea beds. I believe it will prove that these beds were formed like chalk and converted to the condition they at present are by the subsequent process of metamorphosis. I must now speak of the newest of the limestone formations—the lowest stratified series now known as the Laurentian, which is abundantly developed in all the countries of Europe. In this series there has been found to be serpentine limestone, composed of layers of lime and serpentine. Professors Lowman and Davidson have been enabled to decide that these serpentine layers are of organic structure like that of the internal casts found in the greensand. Sir Roderick Murchison had been enabled to make out that the Laurentian series in Canada is 90,000ft. thick, and the azoic is at the bottom of that. Now when you think what that 90,000ft. represents, you will see that we naturalists and geologists do not let astronomers have it all their own way. You hear about the immense lapse of ages that must have existed before we got the light of Sirius, and that, if Sirius were extinguished now it might be some millions or billions of years before we should see it again. I believe that these inquiries carry us as far backwards in geological time, as the inquiries of the as ronomers carry them back in distance and time in their way. There is something romantic in this. You know it has been said that reason carries us where imagination scarcely dares to follow. The spectroscope is the greatest romance, and goes beyond all the beyonds, if I may use the expression. But I think those matters which have been placed before you to-night are not altogether behind them in interest, and that they will have your thoughtful consideration.

INSTINCT.

An interesting paper on this subject, interspersed with anecdotes, was read by Mr. D. A. Spalding at the meeting of the British Association. With regard to instinct we have yet to ascertain the facts. Do the animals exhibit untaught skill and innate knowledge? May not the supposed examples of instinct be after all but the results of rapid learning and imitation? The controversy on this subject has been chiefly concerning the perceptions of distance and direction by the eye and the ear. Against the instinctive character of these perceptions it is argued that, as distance means movement, locomotion, the very essence of the idea, is such as cannot be taken in by the eye or ear; that what the varying sensations of sight and hearing correspond to, must be got at by moving over the ground by experience. The results, however, of experiments on chickens were wholly in favour of the instinctive nature of these perceptions. Chickens kept in a state of blindness by various devices, from one to three days, when placed in the light under a set of carefully prepared conditions, gave conclusive evidence against the theory that the perceptions of distance and direction by the eye are the result of associations formed in the experience of each individual life. Often at the end of two minutes, they followed with their eyes the movements of crawling insects, turning their heads with all the precision of an old fowl. In from two to fifteen minutes they pecked at some object, showing not merely an instinctive perception of distance, but an original ability to measure distance with something like infallible accuracy. If beyond the reach of their necks, they walked or ran up to the object of their pursuit, and may be said to have invariably struck it, never missing by more than a hair's-breadth; this, too, when the specks at which they struck were no bigger than the smallest visible dot of *i*. To seize between the points of the mandibles at the very instant of striking seemed a more difficult operation. Though at times they seized and swallowed an insect at the first attempt, most frequently they struck five or six times, lifting once or twice before they succeeded in swallowing their first food. To take, by way of illustration, the observations on a single case a little in detail:—A chicken at the end of six minutes after having its eyes unveiled followed with its head the movements of a fly twelve inches distant; at ten minutes, the fly coming within reach of its neck, was seized and swallowed at the first stroke; at the end of twenty minutes it had not attempted to walk a step. It was then placed on rough ground within sight and call of a hen with chickens of its own age. After standing chirping for about a minute, it went straight towards the hen, displaying as keen a perception of the qualities of the outer world as it was ever likely to possess in after life. It never required to knock its head against a stone to discover that there was "no road that way." It leaped over the smaller obstacles that lay in its path, and ran round the larger, reaching the mother in as nearly a straight line as the nature of the ground would permit. Thus it would seem that, prior to experience, the eye, at least the eye of the chicken, perceives the primary qualities of the external world, all arguments of the purely analytical school of psychology to the contrary notwithstanding. Not less decisive were experiments on hearing. Chickens hatched and kept in the dark for a day or two, on being placed in the light nine or ten feet from a box in which a brooding hen was concealed, after standing chirping for a minute or two, uniformly set off straight to the box in answer to the call of the hen, which they had never seen and never before heard. This they did struggling through grass and over rough ground, when not yet able to stand steadily on their legs. Again, chickens that from the first had been denied the use of their eyes by having hoods drawn over their heads while yet in the shell, were, while thus blind, made the subject of experiment. These, when left to themselves, seldom made a forward step, their movements were round and round and backward; but when placed within five or six feet of the hen mother, they, in answer to her call, became much more lively, began to make little forward journeys, and soon followed her by sound alone, though of course blindly. Another experiment consisted in rendering chickens deaf for a time by sealing their ears with several folds of gum paper before they had escaped from the shell. These, on having their ears opened when two or three days, and being placed within call of the mother concealed in a box or on the other side of a door, after turning round a few times ran straight to the spot whence came the first sound they had ever heard. Clearly of these chickens it cannot be said that sounds were to them at first but meaningless sensations. One or two observations favourable to the opinion that animals have an instinctive knowledge of their enemies may be taken for what they are worth. When twelve days old one of my little protégés running about beside me gave the peculiar chirr whereby they announce the approach of danger. On looking up a sparrow hawk was seen hovering at a great height over head. Again, a young hawk was made to fly over a hen with her first brood of chickens, then about a week old. In the twinkling of an eye most of the chickens were hid among grass and bushes. And scarcely had the hawk touched the ground, about twelve yards from where the hen had been sitting, when she fell upon it and would soon have killed it outright. A young turkey gave even more striking evidence. When ten days old it heard the voice of the hawk for the first time, and just beside it. Like an arrow from the bow it darted off in the opposite direction, and, crouched in a corner, remained for ten minutes motionless and dumb with fear. Out of a vast number of experiments with chickens and bees, though the results were not uniform, yet in the great majority of instances the chickens gave evidence of instinctive fear of these sting-bearing insects.

NEW METHOD OF OBTAINING STEARIC AND PALMITIC ACIDS.

Mr. W. Lant Carpenter read a paper on the process of removing albumen in fats. In the International Exhibition of 1871 there were exhibited several specimens of stearic acid, &c., manufactured by Professor J. C. A. Bock, of Copenhagen. It was stated that they were produced by a new process, which possessed very many advantages over any other known method. Mr. Carpenter having twice visited Copenhagen to study the process, and having extended its application to neutral fats other than tallow, in England, thought an account of the scientific aspects of the subject might not be uninteresting. Professor Bock was led up to his invention by patient microscopical and chemical study of the properties of neutral fats, and reflection upon the reasons of the disadvantages of methods hitherto practised. These disadvantages Mr. Carpenter pointed out at some length. Hitherto, when fats were decomposed by alkali, a considerable excess of alkali above the theoretical quantity was required, unless the operation were conducted under very great pressure, when the risk of explosion was great. When they were decomposed by sulphuric (or any other strong) acid, as was usually the case in England, much of the fat was lost by being charred and burnt, and the remainder was so black that it was necessary to distil it to render it good enough in colour for manufacturing purposes. The risk of fire, and of explosion, in this operation, was considerable, and the expense great. Professor Bock had shown that most neutral fats were made up of minute globules of fat, surrounded by albuminous envelopes, which form 1 to 1·5 per cent. of the weight of the fat, and he considered that the excess of alkali, of pressure, or of heat required to decompose fats, was really used in the destruction and removal of these albuminous envelopes, which also attracted to themselves the colouring matters contained in the fat, or those produced therein during its decomposition. The existence of the albumen could be demonstrated in the laboratory by dissolving the fat in ether or benzole, and precipitating the solution by water, or by boiling the fat on a strong solution of oxalic acid. In both cases the albuminous envelopes collected at the plane of junction in the two liquids. In Professor Bock's process, the albuminous envelopes were broken and partly destroyed by the action, for a limited time, and at a given temperature, of a small quantity of strong sulphuric acid. The neutral fat then poured out from the envelopes in a state ready for decomposition by water in open tanks, an operation which required several hours for its complete performance. Its progress was judged of by microscopical examination of the crystals of the fat, or fatty acid, formed by slowly cooling a thin layer upon a glass slip. When it was completed, the glycerine, which was dissolved in the water used for the decomposition, was drawn off, purified, and concentrated for sale. The fatty acids, amounting to 84 per cent. of the original fat, were at this stage of a very brown or blackish colour. The next operation was to eliminate the albuminous envelopes, and with them most of the colouring matters. This was done by submitting the fatty acids in open tanks to the action of dilute solutions of certain exidising agents, by which the black matters were partly oxidised, and their specific gravity greatly increased, so that when the oxidation had proceeded far enough, they readily subsided to the bottom of the tank, leaving the fatty acids comparatively good in colour. After two or three washings with dilute acid and water, the fatty acids were cold pressed and hot pressed in the usual way, and the result was a stearic acid higher in melting point and greater in quantity than could be produced in any other way, and an oleic acid excellently fitted for the manufacture of soap and other purposes. One of the greatest advantages of the process was, that all operations were conducted in open tanks, with steam not exceeding 35lb. pressure. Mr. Carpenter stated that he was at present engaged in applying this process to palm oil and other vegetable fats, and he illustrated his paper with specimens of the various stages of manufacture from Copenhagen, and from the factory in which he was a partner.

MECHANISM.*

(Continued from p. 584.)

THE use of wrapping connectors is very old; it was one of the earliest modes adopted for driving machinery, and here is one of those lathes which has given the name to the tool we now have, though our present lathe bears no more resemblance to it than do substances that never were like each other. Although in a course of lectures on mechanism so universally useful a machine as a lathe could not avoid notice, yet the primitive form of the instrument seems to have been "improved out of existence."

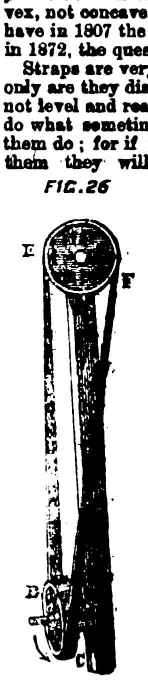
In Clerkenwell, however, the original lathe is still in use, and the construction of one is this:—A long lath, or elastic branch of a tree, is put over a beam, one end being held firm; at the other end, therefore, is an elasticity similar to that in a bow. A cord from the end of the lath passes round a piece of wood roughly shaped cylindrically with a hatchet, thence it passes to a treadle, which, in the one before you, is nailed to the floor by a piece of common shoeleather. The whole tool is thus complete, and motion is given by pressing the treadle. When the pressure is withdrawn the spring of the lath takes the cord back again, and so a backward and forward motion is obtained. Whatever may be the amount of time occupied in turning one way, there is an equal loss of time in turning backwards. Whilst so returning the workman withdraws the tool, replacing it as the work comes forward again. Therefore half the time of the man is lost, while the work goes backwards. There are two trades, and perhaps only two, in which this antiquated lath-lathe cannot be dispensed with. No mechanism has yet enabled the artisan to replace what we should call the rough-and-ready varying travel of that lathe. The two trades in which it is used are the watch-case makers and that of making brass water or steam taps. On looking at the case of a watch you will find in the rim one or two hinges. These hinges are steps to the turning tool. Hence very short arcs of circles have at times to be turned or "milled," too short and too varied to permit of special adjustments. Hence, chucks for segment-turning are not available.

No doubt mechanism might be invented, but the time lost in setting the mechanism would be more than the time now occupied in doing the work. Therefore, a man skilled at the trade—and one man told me he had been working at one of these lathes 30 years—can turn half-an-inch, or two or three inches, or not a quarter of an inch, of a circumference of 8in. or 9in.

Emerson, for whom a mechanic ought to have great respect, suggests another mode of retaining cords in pulleys, that knots should be put upon the cords in order that the pulley might be driven, and the cord instead of being smooth would be covered with knots, which would hold in the roughnesses of the pulley and so drag it round. As to the smooth pulley F, Fig. 24, (p. 584) here is Young's book, entitled "A Course of Lectures upon Natural Philosophy and the Mechanical Arts," delivered in the Royal Institution of Great Britain, and printed in 1807. Now, let us see what Young in that day wrote. He says (Vol. 2, page 183), "When a strap runs on a revolving cone, and is sufficiently tight, it advances towards the base of the cone and does not slide towards the point; for the edge of the strap nearest the base is driven more rapidly than the other; and the portion advancing towards the wheel is driven towards the base. Therefore, in order that a strap may remain on the middle of a wheel, it must consist of two portions of cones joined at their bases, and if rounded must be convex, not concave at its circumference." Thus we have in 1807 the true principal laid down, and yet, in 1872, the question is still occasionally discussed.

Straps are very peculiar in their behaviour. Not only are they disposed to stop on a pulley that is not level and reach the highest point, but they will do what sometimes mechanics try in vain to make them do; for if you observe the laws that govern them they will most willingly "drive" round corners. Nothing is more easy, and nothing is more difficult—if not done in the right way. Here is a pulley at the bottom of a shaft and one at the top, at right angles; as you see, there is no difficulty in making the strap turn this right-angled corner. There is nothing to hold it on, but it keeps its place. Yet, if the driving pulley be turned in the other direction the strap will not keep on. The principle is very simple, and applies to shafts oblique to one another as well as to shafts at right angles to one another. The mode of operation to secure the strap remaining on is this—Ascertain the point where a perpendicular to the two shafts could be drawn. Draw a line, in fact, from one shaft to another, at right angles to the two shafts. The upright, in Fig. 26, is clearly perpendicular to both shafts. Now, take from that perpendicular a distance for the top pulley equal to the radius of the lower pulley, and for the lower pulley a distance equal to the radius of the top pulley. The radii of the pulleys are the portions involved. If the distance from the perpendicular of either pulley be too great, then you will observe that the point on the pulley where the strap enters is not in the plane of the other pulley. All that is needed to retain a strap in its position is that it should leave one pulley in the plane of the pulley on which it is to travel. It must be entering in the plane of the pulley to be moved. It may leave a pulley in any plane, but it may not enter in any plane.

FIG. 26



In Fig. 26 the direction of the motion of the strap is shown by the arrows. Remembering the previous explanation, it will be noticed that the point E in the upper pulley projects or overhangs so far as to be in the plane, passing through the lower pulley D C. Therefore, when the strap is entering on the lower pulley, there is no tendency to run off. Again, the lower pulley D C is so placed that the point C is in the plane E F, and therefore the strap does not leave E F. Not only so, but a small deviation from the true planes may be permitted. For there is, as it were, a contest between the curvature or rounding, as in F, Fig. 24 (p. 584), of the pulley, and the tendency to run off. If, now, the direction of motion of the driving pulley be reversed, then the strap immediately falls off, in accordance with what the preceding reasoning led us to suspect. It is discreditable to a mechanic to hold straps or pulleys, or to use guide pulleys under many circumstances in which these are placed. Whoever does so may perhaps be a good mechanic, but he is a poor mechanician.

(To be continued.)

* By the Rev. ARTHUR RIGG, M.A., being the Cantor Lectures delivered before the Society of Arts.

CAVE EXPLORATIONS.

THE report of the Settle Cave Exploration Committee was brought up by Messrs. Boyd, Dawkins and Tiddeman. Both geologically and historically, the results of the labours of the Settle Cave Exploration Committee in the Victoria Cave during the last three years are of great importance. The cave is situated to the north of Ingleborough, and consists of several large chambers, often nearly filled up with earth and stones. Work commenced by cutting a trench through a layer of stones broken from the cliff above, which proved to be resting on a dark layer composed of burnt stones and bones, fragments of pottery, and a few Roman coins. Following the layer right into the cave several bronze gilt ornaments of Roman workmanship were found, and others, certainly not Roman, but bearing a strong resemblance in design and execution to Irish or Celtic works of art preserved in various museums. The Celtic shorthorn, the goat, horse, and pig seem to have been the principal food of the dwellers in the cave, from the great quantity of their bones which were discovered. The strange mixture of articles of luxury and ornament in so wild a place seem only accountable by the supposition that the cave was inhabited, as a place of refuge, by some well-to-do Romano-Celtic family, who carried off with them into their place of retreat many of their valuables, cattle, and other property. The date of this occupation seemed to be between the fifth century, as shown by the barbarous imitation of Roman coins, and the first quarter of the seventh century, when the kingdom of Strathclyde was conquered by the Angles. But besides this evidence was found of a much older occupation. Underneath the Romano-Celtic layer, at the entrance, pieces of chipped flints, broken bones of ox and bear, and rude bone instruments, proved that animals other than man inhabited the cave at a lower level, and therefore before the accumulation of the talus on it. A subsequent shaft being sunk, the discovery was made of a still older occupation of the cave by hyænas. Their broken bones, teeth, and coprolites showed that they must have lived there in large numbers, and the gnawed bones of rhinocerous, cave bear, mammoth, reindeer, &c., showed on what animals they preyed.

In the eighth report of the committee for the Exploration of Kent's Cavern, Torquay, for which an annual grant is made by the Association, Mr. W. Pengelly stated that, during the past year a tooth of the great cave tiger (*Machairodus latidens*) had been met with in the cavern. Flint implements, the undoubted work of man, had also been met with in a bed below the cave-earth, and the oldest stratum yet worked. On this tooth Mr. Boyd Dawkins read a short paper, affirming its true character, after which Professor Phillips stated his belief that many of these bone caverns might be preglacial. In reply, Mr. Dawkins showed that many of the animals which occupied the European area before the glacial period, returned after the cold had passed away. He thought the entire evidence of the Kent's Cavern pointed out that it was of preglacial age, and that man might have been living in Europe at that time. In this Mr. Pengelly concurred.

THE WASTE OF COAL.

THE following is the address delivered by Mr. F. J. Bramwell, President of the Mechanical Science Section of the British Association. After a few preliminary sentences, Mr. Bramwell said:—I have thought over many subjects connected with mechanical science, but I cannot discover any thing more practically important than "Coal." Very few matters are of greater real interest at all times to the nation at large, and very few are more prominently before the minds of the public at the present time; and certainly no subject can be more appropriate for a mechanical engineer, if for no other reason than this, that the steam-engine is still the very crowning glory of mechanical engineering, and that coal is the staff of life and, so to speak, the breath of the nostrils of the steam-engine. . . . . The increase of consumption and the rise in price are startling facts, and force us seriously to reflect upon the use and also upon the abuse of coal. These reflections will make us remember that whatever the known store may be, and whatever new discoveries of other beds may be made, the supply after all is but a finite quantity; that, unlike the fuel wood, which grows year by year to replace the annual consumption, the fuel coal is given to us once and for all; that we are therefore dealing with a store that knows no renewal; that if we waste it, the sin of that waste will be visited upon our children; and that it becomes us to look upon coal as a most precious, valuable, and limited deposit, of which we are the stewards and guardians, justified, no doubt, in using all that we require for legitimate purposes, but most criminal in respect of all that we waste, whether that waste arise from wilful indifference or from careless ignorance, an ignorance culpable as the indifference itself. This being so, let us see how we do deal with coal in those cases where coal must be used; how we might deal with it in such cases; and how we might in certain instances substitute other sources of power for the coal which we now consume.

Utilisation of the Power of the Tide.

And let us first of all consider this question of finding sources other than coal for our motive power. Before the steam-engine was so extensively used as it now is, the wind, the force of streams, and the force of the tide were all employed to give motive power. With respect to the power of the wind, it is to be feared it is too irregular to enable any manufacturer to rely upon it in competition with the steam-engine. With respect to the power of our streams, the altered condition of the soil, due to increased drainage and cultivation, has so materially interfered with the regularity of their flow, that their efficiency as sources of constant power is seriously diminished, while competition with them by steam has become much greater than it was when the water-mills themselves were better off. This state of things, however, might be cured, and, in fact, has been cured in certain districts by the union of a large number of mill-proprietors to form storage reservoirs, from which the water can be delivered with regularity, so as to give a uniform supply to the mills. But the third source of water-power, the tide-mill, which at one time was used to a considerable extent, is now almost wholly discontinued. The causes of this discontinuance are sufficiently obvious. The tide-mill, as formerly constructed, could work for only a limited period in each ebb; and, to obtain the full effect, it had to utilise both the night and the day tides. But while tide-mills laboured under these disadvantages, they possessed the great merit that their power, such as it was, was one that could be depended on, and one which, although it fluctuated, fluctuated regularly and within known and definite limits.

I would suggest that in those cases where there are large manufacturing districts within a few miles of the sea, and where there is a large rise and fall of the tide, coupled, in the outset at all events, with natural indentations of the coast, which might be comparatively readily dammed up for the storage of the water, there such storage should be made that the water should be put to work. Turbines of the best kind (turbines which will work with very nearly the same percentage of the total power given out by the water at any particular moment, whether they are immersed or whether they are not); that these turbines should be employed in pumping water at a high pressure into Armstrong accumulators, and that pipes should be laid on from those accumulators to the neighbouring manufacturing town, and should there deliver their power to the consumers, requiring it to be used by them in water-pressure engines. Suppose a beginning were made with the city of Bristol, which is no doubt a very favourable instance for the application of this suggestion. Here the rise and fall of the tide might safely be taken at 24ft. Half a square mile of water inclosed would, after the most lavish deductions for loss, yield in Bristol at least 5,000 horse-power, probably sufficient to replace the whole of the power of the stationary engines now at work in Bristol.

I will not detain you by further dilating upon this subject; but it does appear to me, looking at the opportunity which good turbines give of utilising the power residing in water under constantly varying conditions of head, looking at the fact that by Sir William Armstrong's arrangements this power may be transferred to an extremely small quantity of water under high pressure, and that therefore such water may be transmitted for many miles through pipes at low velocities, even although those pipes be of no great size,—looking at these facts, I say, I cannot help thinking that there is here open to the talent of the mechanical engineer a new field of enterprise, and one which, if successful, would tend to economise the fuel we so much value, and to leave more of it for consumption in metallurgical operations and in other operations requiring heat.

Before quitting the subject of finding sources of power other than steam, the Section will perhaps permit me to remind them of what has been done in the town of Schaffhausen by a public-spirited inhabitant in the way of utilising the water-power of the Rhine, and of laying it on, so to speak, to every man's door. This has been accomplished by erecting turbines, which are worked by the river, and deliver their power to endless wire ropes carried over pulleys placed alongside the Rhine, the rope extending nearly from one end of the town to the other. This rope gives off power at the end of each street abutting on the river-bank, and that power is conveyed along those streets by a shaft in a channel under the paving. Each manufacturer can make his own communication with these principal shafts, and thus obtain the power he may require. I believe that no more is charged than is just sufficient to pay for the current repairs and for depreciation.

Waste of Coal in Mines.

I will now consider the question how coal is wasted in its use; but before doing so I will say a few words upon the loss that occurs in the coal-mine itself. Happily this loss has for some years past been greatly reduced. More economic systems of working have prevailed, plans of dealing with small coal by washing away its impurities, so as to render it fit for cokeing, have been largely adopted, and thus a great deal of that coal which a few years since would have remained buried in the mine, as not justifying the expense of raising it to the surface and of paying royalty upon it, is now brought to light and is utilised. Nevertheless, we know that at ordinary prices of coal it is to the advantage of the colliery proprietor in many instances to leave a considerable percentage of the seams that are worked, rather than to endeavour to lessen that percentage by the use of a more expensive system of artificial support for the roof; and, further, that it also pays him to leave altogether unworked very thin seams of coal. Thus, in the very outset, we are wasting fuel. But the prevention of this source of waste is a question quite as much for the mining engineer and the political economist as for the mechanical engineer. I have, however, mentioned it before this Section, because the mechanical engineer may contribute to such prevention by devising new modes of extracting coal in places where hand labour would press too heavily upon the men engaged in the work, and where, therefore, their labour would be too costly.

Domestic Waste.

I now come to the question of the way in which waste occurs in the use of the coals that are brought to the surface. This use may be divided into two great branches, the domestic and the manufacturing. I will consider first the domestic use. This is a highly important branch of the subject. It is believed that out of the total of 98 or 99 millions of tons of coal which in 1869 were retained for home use, 18¼ millions of tons, about one-fifth of that quantity, were consumed for domestic purposes (about 10 millions being exported). We all of us know so intimately the way in which coals are burnt for domestic purposes, that I fear it will seem an idle waste of time to describe it. Nevertheless, I really must occupy a few moments in so doing. We put a grate immediately below and within a chimney, and as this chimney is formed of brickwork, by no possibility can more than the most minute amount of heat be communicated from the chimney to the room. On this grate we make an open fire: fire cannot burn without air, and we provide no means whatever for the air to come into the fire; this is a provision that not one architect or builder in a thousand dreams of making. The consequence is that the unhappy fire has, as it were, to struggle for existence. In a well-built house especially it has to struggle; for the doors and windows shut tightly. The result is that the fire is always smoking, or is on the verge of smoking. We breathe the noxious gases and we spoil our furniture and pictures; nevertheless, happily for us, the fire does succeed in getting supplies of air which, even although insufficient for the wants of the chimney draught, do renew the air of the room. If to satisfy the demands of the chimney and to stop its smoking, a window is left a little open or a door is set ajar, we complain of draughts, and we complain of the unhomely look caused by sitting in a room with an open door; so that there we are, with an asphyxiated fire, our smoky rooms, and our draughty rooms. Moreover, the fire being immediately below the chimney, the main part of the conducted heat inevitably goes up it and is wasted, leaving the room to be warmed principally, if not entirely, by the radiated heat; and we do and suffer all this in order that we may see the fire and be able to poke it. For myself I must confess that if there was no cure for the evils I have described other than the close stoves of the Continent, with the invisible fire and with the want of circulation of air in the room, I would rather put up with the whole of our present domestic discomforts, and even with the loss of heat, than resort to the stove as a remedy. But there are modes by which freedom from smoke, freedom from draught, efficient ventilation and utilisation of the heat may all be combined with the presence of the visible pokeable fire. Some members of this Association may recollect the paper that was read before it at the Norwich Meeting in 1868 by Captain Douglas Galton, in which he so clearly described his admirably simple invention of fire-grate.* This consisted in putting a flue to the upper part of the fire-grate, which flue passed through a brick chamber formed in the ordinary chimney, which chamber was supplied with air from the exterior of the room by a proper channel, and then the air, after being heated in contact with the flue in the chamber, escaped into the room by openings near the ceiling, so that the room was supplied with a copious volume of warm fresh air, which did away with all tendency to draughts from the doors and windows, and, moreover, furnished an ample supply for the purposes of ventilation and combustion. These fireplaces, I regret to say, have been but little used in England, from a cause I shall have to advert to hereafter, a cause which, as I believe, stands in the way of the adoption of improvement generally. The merits of these fireplaces were at once acknowledged by the French, who made the most careful and scientific investigation of their working; and they found that, with such fireplaces, three times the effect was obtained from a given weight of coal that could be got with those of the ordinary construction. No doubt there are many other plans by which the same end as that attained by Captain Galton may be arrived at, and yet we go on year after year building new houses, making no improvement, exposing ourselves to all the annoyances, and worst of all, wasting the precious fuel. Suppose that we could reduce the total consumption both in summer and in winter by 50 per cent., what an enormous boon that would be even in the one matter of a pure atmosphere.

Waste in Manufactures.

The other way in which we use coal is for purposes of manufacture; and this, again, may be divided into two branches at least, namely, the coal that is employed for obtaining power, and the coal that is employed in metallurgical and other operations not immediately connected with the production of power. To treat of these latter cases first, they are far too numerous to be dealt with in detail, and a few of the principal therefore only must be considered. Take the subject of coke-making. How much coal is heated in clamps and in kilns to be converted into coke, and in how few instances is any use made of the whole of the heat residing in the gaseous parts of the coal which are driven off. This heat frequently amounts to 30 per cent. of the whole of that which is in the coal. We come next to the smelting of iron. Take the preliminary process of calcining the ore. In those cases where the ore is "black band," the ore so common in Scotland, the calcining is done by the combustion of the carbonaceous matter mixed with the ore. Far more than the quantity of fuel requisite for the calcination is associated with this ore; but the whole of it is burnt off, and no effort whatever is made to utilise the surplus heat. Then, with regard to the blast-furnaces for smelting iron. Here still, almost universally in Scotland, that large seat of the iron manufacture, and to a considerable extent in England, the waste gases are suffered to issue from the furnace-top, illuminating the country for miles, and bearing testimony to the indifference of the owner of the furnaces to a waste of our store of fuel. Upwards of 60 years ago, viz., in 1811, the utilisation of these gases was suggested in France; but not much was done for 30 years. About 1840, however, their use became not infrequent in that country, and their manufacturers and chemists taught us that the gas thus recklessly wasted might be collected and utilised, and made to replace the fuel expended in heating the hot blast-stoves and in raising steam for the blowing-engines. But, for the cause which has been and will be alluded to, the adoption of this plan was very slow indeed in England. It has now been in use, however, for many years in our best conducted works; but, as a proof of the slowness of its introduction, the furnaces of Scotland, as I have already said, are even to this day almost universally worked upon the wickedly wasteful principle of allowing these gases to burn idly away. Take, again, the melting of steel in crucibles where the heat issues from the furnace of necessity hotter than the heat of the melted steel (for were it not so it would cool it), and of this issuing heat, as a rule, no use whatever is made. Take again the heating-furnace and puddling-furnace of our ironworks; very commonly from these heat at a greater temperature than that of welding iron escapes up the chimneys disregarded, as though it had cost nothing for its generation.

In many works, it is true, a portion of this heat is utilised for generating steam; but far more steam can be obtained than is required, even with the most unnecessary and lavish consumption of it, and thus in great ironworks boilers in which the steam is generated by the waste heat of the furnaces may be seen constantly blowing off large volumes of steam at the valves; and many furnaces are in use to which no boilers are applied, for the simple reason that they would be absolutely superfluous. This waste of heat in steel-melting and in furnaces for iron and for other metallurgical operations is by no means necessary, although it might be urged that it is; and it might be said that if a furnace is to heat a body to 3,000 degrees, you must of necessity allow the heat to escape at that temperature, or rather at something above it, or else in lieu of heating the body you will be cooling it, and that you can no more trap escaping heat than you can trap a sunbeam. But one of my predecessors in this chair, Mr. Siemens, has, as we know, shown us that you can trap the heat, and that you can so lay hold of it and store it up, that the gases as they pass into the chimney from the furnace in which there is, say, even melting steel, shall be lowered in their temperature down to that which will not char a piece of wood; and he has shown us how this stored up heat may be communicated to the separate streams of incoming air and gas of his gas-furnaces, so that they shall enter the furnace at a high temperature, that temperature to be increased by their union and combustion in the furnace. So beautifully can this trapping of heat be carried out, and so successfully can the heat be retained by very trifling attention on the part of the workmen to the apparatus, that Mr. Ramsbottom, the late Locomotive Superintendent of the London and North-Western Railway, knew he should not be applying too delicate a test when he inserted the ends of pieces of wood through openings into the outgoing flues of the steel-heating furnaces at Crewe. These pieces of wood were padlocked in their places, were taken out periodically, and if they were found to be burnt it was known that the man in charge of the furnace had been negligent in his duty of saving fuel and had misused the Siemens apparatus. But although this invention has been before the public for very many years, and although it has had the approval of Faraday and of every other distinguished scientific man who has investigated the question, and, I am glad to say, the approval of the leading minds among the users of furnaces, nevertheless, for the general reason I shall have to allude to, the progress of this invention has been by no means commensurate with its importance; and it is not too much to say that manufacturers would rather waste cheap coal than embark capital in new furnaces, and more than all, be at the trouble of instructing and of watching over their workmen.

Waste in Steam-Engines.

Next, let us consider how we are dealing with coal when we use it for obtaining motive power in our steam-engines. Steam-engines may be divided into the four great heads of marine, locomotive, portable, and fixed. Including within the term steam-engine, the boiler as well as the engine, waste may arise in a steam-engine in two ways, either in one of them or in both combined. It may

* An improved form of this fireplace was illustrated and described in the *Building News* of August 16.—Ed.

arise from an imperfect utilisation of fuel in the production of steam, that is, a waste due to the boiler and to the firing; or it may arise in an improper use by the engine of the steam provided for it by the boiler. There can be no question but that the boiler waste is, as a rule, very large indeed. A pound of fair coal is theoretically capable of evaporating from the boiling-point 13lb. of water. I do not believe that I shall overstate the case when I say that on an average not more than from one-third to one-half of this quantity is obtained from the whole of the boilers in use.

This poor result varies from a variety of causes:—1st, bad firing, which means bad combustion; 2nd, insufficient surface to absorb the heat; 3rd, an unclean condition of that surface, either from internal or external deposit, or both; 4th, a faulty proportioning of the parts of the boiler to each other and to the work to be done, which cause heated water to be carried over with the steam,—a cause of deficiency of evaporation, which, however, so far from being at a rule detected, goes to swell the apparent duty of the boiler. Bad firing may result in the fire being too thick, or too thin or irregular. If too thick, the carbonic acid that is generated by the combustion of the lower part of the fuel with which the air first comes in contact is changed in its passage through the upper part of the fuel into carbonic oxide, by absorbing from the fuel a second equivalent of carbon. If this gas, carbonic oxide, does not meet with free atmospheric air, and meet with it at a suitable temperature in the upper part of the furnace, it must remain unconsumed, and will pass through the flues or tubes of the boiler and make its escape into the air, carrying with it the valuable unconsumed carbon of the coal in a gaseous form. It is commonly said that smoke is unconsumed fuel. This is true; but it is not commonly recollected that there may be invisible smoke arising (even from a coke-fire) which shall contain the highly combustible ingredient carbonic oxide gas. When it is remembered that every pound of coal burnt into carbonic acid is capable of evaporating, as has already been said, about 13lb. of water from 212°, while a pound of coal, converted only into carbonic oxide, is capable of evaporating but 4lb., it will be seen how necessary it is that no mismanagement of the fire should cause a portion of the fuel thus to escape unburnt up the chimney. Another defect in the management of a fire (an opposite defect, as it were) by which coal may be wasted, is the admission of too much air; and this arises when the fire is too thin in relation to the chimney-draft, or when (a more common evil) it is thin in places, owing to the negligence of the firemen in keeping it properly levelled.

The way in which waste arises from these causes is, that unnecessary air is introduced into the fire at a temperature of, say, 60°, and that this air has to be heated, and then (even if the heat be abstracted from it, as far as practicable by the boiler) it will escape up the chimney at a temperature of from 200° to 800° in excess of that which it had; and the whole of this excess represents wasted coal. Thus, on the one hand, it is of importance that there should be a proper amount of air to secure the perfect conversion of the carbon into carbonic acid; and, on the other hand, it is most desirable that this amount should not be exceeded, involving the necessity of uselessly heating air not wanted for combustion. Such a happily balanced state of things it is almost impossible to secure by hand firing, almost impossible, but not absolutely impossible, though only attained at competitive trials, and when these trials are conducted by highly skilled men.

In such trials of portable engines before the judges of the Royal Agricultural Society of England, the firemen will put coals upon the fire as frequently as forty-five times in an hour, the quantity put on at each time being, as may be supposed, little more than a spoonful. Writers on the management of the steam-engine usually advise that the fire-doors should be opened as little as possible, and that the firing should take place about every quarter of an hour. Under ordinary circumstances they may be right; but when it is desired, regardless of the amount of manual labour, to obtain every particle of useful effect out of the fuel, it is then found to be remunerative to open the door, not four times an hour, but more than forty times an hour, taking care, however, that it is only opened for the fraction of a second. It is by this frequent feeding of a small quantity of coal, distributed over the fire, that the competitors are enabled to insure a uniform condition of that fire to receive the action of the air. They know precisely the amount of draught they have got, and by experience they also know what thickness of fire will exactly balance, as it were, the air that comes through, so that the combustion may be perfect, and yet there may be no free air. But in ordinary hand-firing, done at intervals of a quarter of an hour, it is obvious that the thickness of the fire at the end of such an interval must be very different from that which it was at the beginning of it, and thus if that thickness be right in relation to the draught at one time it must be wrong at another. At one time, immediately after firing, there may be a distillation of the coal, producing black smoke and carbonic oxide; this will go on till the fire burns thin and burns into holes, when there will be a passage of free air. I do not wish to be understood that I am advocating the attendance of skilled firemen to fire forty-five times in an hour. Coal must be far dearer than it now is to make it pay so to occupy a man, or rather watches of men; for no one man could submit to such continuous labour for more than from four to five hours. But my observations tend to call your attention to the subject of mechanical firing. I believe that the high evaporative duties that have been obtained by the use of liquid fuel, duties approaching very closely indeed to the theoretical power of that fuel, are largely due to the fact that the air and liquid can be injected in definite and regular proportions, insuring perfect combustion. Again, in the use of powdered fuel by Mr. Crampton, where the powder is blown into the furnace by the very air which is there to enter into combustion with it, very high evaporative results have been reached even under the disadvantageous circumstances attendant upon early experiments; and this also I believe to be due to the power of accurately adjusting the quantity of air to the fuel to be burnt.

The same power of adjustment may be obtained in those instances where the fuel is previously converted into gas, as practised by Mr. Siemens; and nearly similar control can be got with ordinary fuel by reverting to some of those systems of mechanical fire-feeding which were in use from twenty-five to thirty years ago, but which have been to a great extent abandoned in consequence of the more general adoption of internal fires and high-pressure boilers. The fires of such boilers are in furnaces of small diameter, which do not admit of the introduction of the apparatus, for which room was readily found below the bottoms of the waggon-shaped boilers formerly used for low-pressure steam. Other modes of fire-feeding, however, have been devised, and have come, to a certain extent, into use. I am perfectly certain there is hardly any subject more worthy the attention of the engineer than the replacing the stoker by some mechanical arrangement which shall afford absolute uniformity of firing, and therefore absolute uniformity of the conditions of the fire; and this is a subject not only worthy of attention on account of the saving of coal, but also on the ground of putting an end to a most laborious, exhausting, and, it is to be feared, unhealthy occupation—viz., that of the steamboat fireman, more particularly when he is working in a hot climate. If perfect combustion were obtained in the fire, I do not think there would be much difficulty in properly utilising by the boiler the heat evolved. All that is necessary to attain this end is to give a sufficient amount of surface to absorb the heat and to transmit it to the water, always bearing in mind that, above all, the form of the boiler should be a safe one, that there should be proper water-space within it, and an adequate water-surface from which the steam could escape, that it might do so with tranquillity, and so as not to give rise to the spray technically known as "priming," and that all parts of the boiler should be accessible for cleaning.

I am aware there is a temptation on the score of saving expense and of saving room to make the boiler of small size in relation to the amount of coals burnt under it, and to the quantity of steam required from it; but this is a most extravagant economy—it is a saving in the outset, but it is a perpetual source of loss in the working. Temperatures as high as 800° and even 1000° of heat have been known to exist among the products of combustion escaping from the boiler. Now, when it is recollected that every 100° of heat in the outgoing products of combustion represent $2\frac{1}{4}$ per cent. of the whole heating power of the coal, even if only the minimum amount of air to insure perfect combustion is admitted, it will be seen how necessary it is that there should be sufficient surface in the boiler to absorb the heat of the gases, and to bring them down to a few degrees above the temperature of the water in the boiler itself. I have mentioned the temptation to use boilers of inadequate size on the score of expense and on the score of room. It is this latter reason, no doubt, which induces shipowners to endeavour to diminish the size of their boilers as far as practicable, because they argue that the space occupied by the boilers and machinery is all waste room, as it cannot be filled either with coals or with cargo. With short-voyage steamers, voyages of a few hours only, this argument may be a valid one; but for the long-voyage vessels to India and elsewhere, where fuel has to be carried for from twenty to thirty days' steaming, and where on the homeward voyage the ships have to be supplied with coal that has been brought from England by sailing-vessel at a large cost for freight, the true space deducted from the cargo and passenger-carrying power of the steamship is clearly not that occupied by the engines and boilers alone, but that occupied by the engines, the boiler, and the coal for those boilers. Even supposing that if, after enlarging the boilers to diminish the consumption, the space to be given up to the engine, boilers, and coal were still the same, in consequence of the increase in the size of the boilers being equivalent to the coal-space saved, manifestly it would be to the advantage of the shipowner that that space should be occupied by the boilers rather than by the coals. The expense of the boilers is a first outlay, and has not to be repeated for years until the boilers wear out; but the expense of coal is an outlay that has to be made at every voyage, and therefore it is a short-sighted policy to restrict the amount of absorbing surface in a boiler on the plea that a boiler with full surface takes up a greater space in the ship, if by doing away with such restriction a saving can be effected in the fuel.

The beneficial results which are attained by the greater size of boiler in relation to the coal burnt and to the horse-power required, can be shown not only by calculation, but by example. In H.M.S. *Briton*, fitted with extremely economic compound engines of Mr. E. A. Cowper's design, close upon 2lb. per horse-power per hour were burnt when the ship was making thirteen knots; but on being worked at ten knots the consumption fell to $1^{3}/_{10}$lb. of coal for the lesser horse-power then used.

Good and Bad Engines.

I will now say a few words upon the engines. The locomotive engine has for many years past been doing very fair duty. This has arisen, I believe, first, from the fact that since the introduction of coal the furnaces have been to a considerable extent gas-furnaces, with a free admission of air through open fire-doors to the surface of the fuel. Second, from the fact that the boilers have large absorbing surfaces. From these causes as much as 9lb. or 10lb. of cold water are commonly evaporated per lb. of coal, while the engines working with high steam and considerable expansion make a good use of that steam.

In marine engineering there has within the last ten years been an enormous improvement. The old-fashioned engine working at 20lb. steam, and with injection condensers, is being abandoned for engines generally on the compound-cylinder principle, working at 60lb. and 70lb. steam highly expansive, and fitted with surface-condensers. The result is a reduction of the consumption of fuel in the same vessels on the same voyages, and performed in the same time, of from 40 to 50 per cent. of that which was previously burnt; but I believe that a large field for improvement in marine engines still remains, especially in the firing and in the size of the boilers.

Among the best instances of what can be done in the way of economy may be mentioned the rapidly increasing class of portable agricultural engines. These engines, like the locomotive, are, from their migratory condition, incapable of being fitted with condensers, and thus must be worked as non-condensing engines, exhausting their waste steam into the air—a most serious disadvantage. Nevertheless, so great advances have been made by the unremitting attention of the extremely skilful mechanical engineers who construct these engines, that at the late Cardiff meeting of the Royal Agricultural Society of England, one of the engines ran for five hours and one minute with 14lb. of coal per horse-power, being therefore a little under $2^{8}/_{10}$lb. of coal per horse-power per hour; and this horse was the horse-power of the dynamometer brake, and not the mere indicated horse-power by which marine engines and other engines are ordinarily judged. The indicated horse-power is, of course, in excess of that developed upon the brake, as the indicated power includes all the engine-friction and brake friction; and if this latter horse-power be taken as a standard, the best of the engines tried by the Royal Agricultural Society this year at Cardiff will offer favourable comparison with even very good condensing engines, and will be found to give a duty far beyond that which ten years ago would have been thought obtainable in any but the very best.

It may be mentioned that the Cornish pumping-engines, which used to be looked upon as the most economic of all engines, are, according to the June monthly report, doing only an average duty of $53^{3}/_{10}$ millions of lb. lifted 1ft. high for 1cwt. of coals, and that the very best of them is doing only $71^{7}/_{10}$ millions of lb., while the brake horse-power, developed by the engine at Cardiff, gave a duty of $79^{1}/_{10}$ millions of lb. This large duty was due to the great ability in the management of the fire (as has already been hinted at) and to the proper proportion of the boiler in obtaining the steam, and to its thorough cleading in preserving it in the first instance, and then to the efficient utilisation of that steam by high expansion in a cylinder steam-jacketed around its circumference and at the ends. But at the very same show there competed for the prize an engine which, to the eye of the uninstructed (the ordinary purchaser for example), was as likely an engine as the prize engine; and yet this engine burnt 10lb. of coal per horse-power per hour, or nearly four times that which was burnt by the prize engine; and, moreover, it must be remembered that this wasteful engine was one which the maker thought worthy to be sent to trial.

It may be said that hitherto my observations upon consumption in steam-engines have contained quite as much of praise as of blame, and I am glad to say that it has been so; but it will be found that these praises have referred to the engines of railways, which are under the especial charge of educated mechanical engineers who carefully watch and tabulate all their results, and who have funds at their disposal for the purchase and maintenance of good engines; that they referred to the recent improvement in marine engines, which engines, being as a whole in the hands either of powerful companies or of large capitalists, enjoy the advantages of due outlay and of proper superintendence, and that they referred to the prize engines and to the better competitive engines of the portable class, while admitting the existence of a large number of such engines which were most destructive of fuel. But there remains the great class of fixed engines used for driving manufactories, which engines are, as a rule, of the most disgraceful and scandalous character. In the first place, enormous numbers of them are non-condensing engines—as an excuse for this it is in many instances alleged that water is scarce and that there is not, therefore, the means of providing condensation. To meet such excuses it should be remembered there are appliances well known to scientific engineers—at all events that have been in use for many years—by which condensation can be effected with no more water than is required for the feed of a high-pressure engine. I allude to the ordinary cooling-ponds for injection-water, and to the surface-evaporative condenser. In every instance these may be employed; and thus, in lieu of sending steam into the atmosphere at a pound or two above atmospheric pressure, that steam might be condensed, and a pressure of 12lb. or 13lb. additional throughout the whole stroke of the piston might be obtained; moreover, the interior of the boiler would be kept clean, and thus its surface would be in the best state for transmitting heat.

But passing by this question of the repugnance to the use of condensing engines, and admitting, for the sake of argument, that non-condensing engines may be allowed, what does one ordinarily find as a type of the non-condensing engine? One finds the cylinder with a cubic capacity far too great for the work required; where steam is used throughout the stroke, one finds that this capacity is not utilised as it might be by the employment of high pressure steam and considerable expansion, and that while the steam, even in the boiler, is probably at only 40lb. above atmosphere, the governor is flying out nearly to the full width, the throttle-valve is all but closed, and there is a continuous wire drawing off the steam, so that its average pressure throughout the stroke of the cylinder is only some 15lb. or 20lb. above atmosphere. Now, when one recollects that it requires one portion of coal to get steam up to atmospheric pressure, and that this portion may be looked upon as practically constant, whatever pressure of steam above atmosphere may after be attained, and that if, therefore, steam at 15lb. above atmosphere be used, half of all the fuel is lost, while if at 30lb. above atmosphere, ⅓ only is lost, and if at 120lb. above atmosphere, one-ninth only will be lost in getting up steam to atmospheric pressure, one can understand how essential it is that in non-condensing engines the steam should be used at a really high pressure; and yet, as I have said, I believe that if the large number of 10 or 20-horse horizontal non-condensing engines, employed by manufacturers throughout the kingdom, were examined, and indicator diagrams were taken, it would be found that their pressure upon the pistons did not average much more than 20lb. above atmosphere; and it is a lamentable fact that many makers of steam-engines, men who cannot be properly called engineers, men who are mere manufacturers, not knowing the principles of the art they follow, will boast that their engine is doing very well, it drives the whole of Mr. So-and-so's work and does not require more than 30lb. steam in the boiler, not understanding that if they would raise that steam to 120lb., and then work it non-expansively in a small cylinder, they would thereby be obtaining a great economy, and if they would work it expansively in a large cylinder, that cylinder being properly steam-jacketed, would obtain a still greater economy.

I think there is so little reliable information as to the total horse-power at work in the United Kingdom, as is evidenced by the fact that very recently the number of boilers has been estimated before a Parliamentary Committee as low as 50,000, and as high as double and even close upon quadruple that number, that I feel it would be an unwarrantable waste of the time of the Section if I were to invite them to follow me into calculations, or rather speculations, as to the exact saving that would be made in the consumption of coal, consequent upon improving the whole of our steam-engines up to the present highest standard. It will, however, be quite sufficient, to show the importance of the question, for me to say, and I am sure I should be perfectly safe in saying, that such saving would have to be estimated by millions of tons. Such a saving, as I have said, is one that might be made with our present knowledge; but when we recollect that an engine burning even as low as 2lb. of coal per indicated horse-power per hour is still developing only one-tenth of all the power which, according to calculation, resides in that coal, there is manifestly a vast scope for our mechanical engineers in the exercise of their talents for further economy.

But let not consumers of coal remain indifferent to savings on their present consumption until those improvements are discovered by scientific men; on their power to reduce the consumption to the extent to which present science and, in some instances, present practice show the consumption can be reduced. One is apt, at first sight, to marvel that users of steam-engines should be so blind to their own interest, and should permit waste to go on day after day and year after year—a waste not only prejudicial to the community at large and to succeeding generations, but a waste causing constant expense to those who commit it, and a waste, therefore, that one would think such persons would only be too ready to stop; but the fact is there are several reasons why manufacturers and others permit the waste to go on.

The so-called "Practical Man."

In prosperous times those engaged in manufactures are too busy earning and saving money to attend to a reorganisation of their plant; in bad times they are too dispirited and too little inclined to spend the money, that in better times they have saved, in replacing old and wasteful appliances by new and economical ones; and one feels that there is a very considerable amount of seeming justification for their conduct in both instances, and that it requires a really comprehensive and large intelligence and a belief in the future, possessed by only a few out of the bulk of mankind, to cause the manufacturer to pursue that which would be the true policy as well for his own interest as well as for those of the community. But there is a further and a perpetual bugbear in the way of such improvements, and that bugbear is the so-called "practical man;" and he was in my mind when, in previous parts of this address, I have hinted at the existence of an obstacle to the adoption of improvement.

I do not wish the Section for one moment to suppose that I, brought up as an apprentice in a workshop, and who all my life have practised my profession, intend to say one word against the truly practical man. On the contrary, he is the man of all others that I admire, and by whom I would wish persons to be guided; because the truly practical man is one who knows the reason of that which he practices, who can give an account of the faith that is in him, and who, while he possesses the readiness of mind and the dexterity which arise from the long-continued and daily intercourse with the subject of his profession, possesses also that necessary amount of theoretical and scientific knowledge which justify him in pursuing any process he adopts, which in many cases enable him to devise new processes, or which, at all events, if he be not of an inventive quality of mind, will enable him to appreciate and value the new processes devised by others. This is the truly practical man, about whom I have nothing to say except that which is most laudatory; but the practical man, as commonly understood, means a man who knows the practice of his trade and knows nothing else concerning it—the man whose wisdom consists in standing by seeing, but not investigating, the new discoveries which are taking place around him, in decrying those discoveries, in applying to those who invent improvements, even the very greatest, the epithet of "schemers," and then, when he finds that, beyond all dispute, some new matter is good and has come into general practice, taking to it grumblingly, but still taking to it because if he did not he could not compete with his co-manufacturers, the aim and object of such a man being to insure that he should never make a mistake by embarking his capital or his time in that which has not been proved by men of large hearts and large intelligence. It is such a practical man as this who delays all improvement. For years he delayed the development in England of the utilisation of the waste heat of blast-furnaces; and he has done so so successfully that, as I have already had occasion to remark, that utilisation is by no means universal in this kingdom. It was such men as these who kept back surface-condensation for twenty years. When the Siemens's regenerative gas-furnace was introduced, what said the practical man? "Turn your coals into gas, and burn the gas, and then talk of regeneration! I don't know what you mean by regeneration except in a spiritual sense; I am a practical man, and if I want heat out of coals, I put coals on to a fire to burn them;" and for fifteen years the practical man has been the bar to this most enormous improvement in metallurgical operations.

The practical man is beginning slowly to yield with respect to these furnaces, because he finds, as I have already said, that men of greater intelligence have now in sufficiently large numbers adopted the invention to make a formidable competition with the persons who stolidly refuse to be improved. The same practical man for years stood in the way of the development of Bessemer steel. Now he has been compelled to become a convert.

As I have said, the practical man derides those who bring forward new inventions, and calls them schemers. No doubt whatever, they do scheme; and well it is for the country that there are men that do so. It also may be true that the majority of schemes prove abortive; but it must be recollected that the whole progress of art and manufacture has depended, and will depend, upon successful discoveries which in their inception were, and will be that have been, and will be, unfruitful; but the successful discoveries, because they are successful, are taken out of the category of schemes when years of untiring application on the part of the inventors have, so to speak, thrust them down the throat of the unwilling practical man. Take the instance of Mr. Bessemer, who was beset for years by difficulties of detail in his great scheme of improvement in the manufacture of steel. As long as he was so beset, the practical men chorused "he is a schemer, he is one of the schemers; it is a scheme." It is a species of profanation to suggest, but I must suggest it, for it is true, that Watt, Stephenson, Faraday, and almost every other name among the honoured dead to whose inventive genius we owe the development that has taken place within the last century in all the luxuries, the comforts, even the bare necessities, of our daily existence, would in their day, and while struggling for success, have been spoken of as "schemers," even in respect of those very inventions of which we are now enjoying the fruits.

A Society to Reward Economy.

One word in conclusion. Can we not devise some means by which consumers of coal may be instructed in, shamed into, or tempted to the economical use of that most valuable material? The Royal Agricultural Society of England, by its judicious efforts for many years past, by the institution of trials and the giving of prizes for the best engines, has brought the consumption of coal down from 10lb. per horse-power to a little over one quarter of that quantity. Could we not institute a society which should devote itself to the recording and the rewarding of the performances of steamboats, and of fixed engines for land purposes. I am aware it is supposed there is a difficulty in these cases which does not obtain in the case of portable engines that can be brought for trial upon a dynamometer, and that is that the power exerted by marine engines varies during the voyage, and is not that which is developed at the measured mile, while in a manufactory it varies according to the conditions of the trade, and to the extent to which the British workman condescends to attend to his work. But there are implements which record the horse-power exerted from moment to moment, and register it on indices as readable as those of an ordinary counter of an engine, or as those of a gas-meter.

I believe that one of the very greatest incentives to economical working which the owners of steamboats could offer to their engine-builders and engineers would be the application of such implements as these. Were they employed, the ship-owner would know at the end of the voyage so much horse-power had been exerted as a whole, that so much coal had been burned, and that the result therefore, was a consumption of so many pounds per horse-power per hour. All excuses of head-winds, and all the aid of canvas to the engine-power, would be eliminated from the calculation. The continual indicator would register truly the work the engine had to do, whether that work was made excessive by contending with head-winds, or was rendered light by favourable breezes and the assistance of canvas. In the same way the proprietor of the engine for manufacturing purposes, the cotton-mill, the woollen-mill, the corn-mill, and even the highly irregularly-working rolling-mills and saw-mills, would be able at the end of the quarter to say—"Notwithstanding all the variations of my trade and rate of manufacture, I know that my engines have exerted so much power, I know that I have burned so much coal, and that, therefore, such and such have been the economic results." Assuming that steamboat proprietors and the owners of fixed land-engines would go to the expense of applying such continuous recording implements as these to their engines, and would become members of an association for the purpose of visiting and inspecting, and of reporting upon their machinery, and of giving prizes to the men in charge for careful attention, prizes to the manufacturers for original good design and workmanship of the engines, and prizes to the proprietors for their public spirit in having bought that which was good instead of that which was bad and cheap, and for having employed ,intelligent and careful workmen instead of ignorant and careless ones, I believe, within a few years, as great an improvement might be seen among the marine and manufacturing class of engines as has been effected by the laudable exertions of the Royal Agricultural Society of England among the portable ones. I think the initiation of some such society as this would be a practically useful result from the meeting of section "G."

Orange-Coloured Spectacles.—In a note to the *Journal of Chemistry*, Dr. Stearns, Surgeon at the U.S. Asylum for Disabled Soldiers, at Milwaukee, Wis., referring to the photographic use of orange-coloured glass to exclude the actinic rays of light, expresses his surprise that no optician has had the genius to see that orange is the proper colour for spectacles, instead of green or blue, for persons of weak eyes. Dr. Stearns states the interesting fact that a room in the hospital with which he is connected is lighted through orange-coloured windows, and is used, with very satisfactory results

BRITISH ASSOCIATION GLEANINGS.

Friction of Immersed Substances.—This formed the subject of an elaborate paper by Mr. Froude, F.R.S., who had made experiments with the sanction of the Admiralty, with the view of determining the law of resistance of surface friction, as effected by speed, by quality of surface, and by the length of the rubbing surface operated on. The results generally were that the resistance varied as the power of 1·8 of the velocity with surfaces painted or varnished with any of the ordinary compositions; that with a polished surface of tinfoil it varied as the power of 2·2 of the velocity; that there was a very sensible difference between the resistance per square foot on a plane 50ft. in length, and one 10ft. in length, but the same in circumference; that between a plane of 10ft. and one of 6in., the difference was very much greater; and that the resistance per square foot on a plane 10ft. in length, travelling ten knots, was about ·65 of a pound per square foot of painted or varnished surfaces. That agreed very nearly in what was called Beaufoy's Coefficient.

Aerial Navigation. — Mr. C. A. Bowdler read a paper on this subject which, he thought, would become an important element in military science. Hitherto, captive balloons only had been used, but it was by no means improbable that circumstances would occur where it would be most desirable to pass over the enemy's position, and it would then be important to have the power of severing or deflecting the balloon from the wind course, either to right or left as required. Captive balloons could not be used in safety in high winds on account of violent rocking of the car. He thought that aërial navigation was practical to a certain limit by simple mechanical means. Of the practicability of applying steam power he had no hope, the weight of a steam-engine made as light as possible, consistent with due strength, being much too great for any gas balloon to support. The power he proposed was manual. But propulsion having been secured, the question arose how the power of direction could be acquired, that being of the utmost importance in actual warfare. That was accomplished by rotating the balloon to any required position, and then holding it from further motion, the rotation was completely under the control of the aëronaut. A rudder was the instrument to be used for that purpose, a vertical disc fixed in a line with the axis of the propeller. By turning the plane of the disc the current of air forced from the fan on the rudder caused the whole machine to rotate right or left precisely as the rudder of a ship guided the vessel. Mr. Reynolds said he had found it impossible to get, by manual power, more than two or three miles an hour with a balloon large enough to live. The great difficulty with regard to a flying machine was that its increase of power was in advance of its capacity of carrying.

Rolling of Ships.—Mr. Froude made some remarks on the mode of recording the rolling of a ship in a seaway, and elaborately and ably explained apparatus he employed, which apparatus also indicated the form of the waves. A revolving cylinder, covered with paper, and turned by clockwork, received the marks made by several pens. One of these pens recorded time, jerks being given to it by an exact clock. The apparatus being placed at the centre of gravity of the ship, a pendulum oscillating in a plane transversely with the keel, recorded continuously by a second pen the angles which the ship at each moment made with the mean or effective surface of the wave. Another pen, actuated by a rocking arm, kept level by an observer on deck, who pointed it to the horizon, recorded by a third pen the angle the ship made with the horizon. From the records thus obtained the amount of rolling of the ship was at once shown, and the form of the wave could be easily worked out graphically. Mr. Froude added that he had completed an apparatus in which he employed a heavy stationary wheel so delicately supported as not to receive any rotation from the motion of the ship. This wheel, placed transversely in the ship, would remain still without rotating, and thus supply the place of the horizontal bar above described, held level by the observer on deck.

Variation of Pulse-beats.—Professor Sanderson made a communication on the rhythmical variation of arterial pressure. He pointed out the rhythmical irregularities observable in the pulsation of certain animals, stating that the periods of fast beating correspond to inspiration, and that the periods of slow beating correspond to expiration; and explaining how this is recorded by a graphic method. Discussing the question of the relation of these phenomena, he showed that, when the muscles are subjected to paralysis, so that respiration almost ceases, there is no variation in pulsation, whence he concluded that the phenomena in question are not related as cause and effect, but are results of the same cause. A communication was also made by Mr. A. H. Garrod on Pulse Frequency and the Forces which vary it. Mr. Garrod detailed some experiments with a view of showing that the rapidity of the pulse varies inversely as the resistance to the flow of blood from the arteries; that variations in the amount of blood in circulation do not vary the rapidity of the pulse, and consequently that the pulse rate is not dependent on the blood pressure, as many supposed.

Action of Sunlight on Glass.—Mr. T. Gaffield, of Boston, U.S., read a paper on "The Action of Sunlight on Colourless and Coloured Glass." He showed that most samples of glass, especially those containing manganese, became coloured more or less by the action of light, also that the glass in the stained windows of cathedrals had changed somewhat from the original colours; these colours, however, could be restored by subjecting the glass to the action of sufficient heat. M. Bontemps said that he had found glass containing manganese no good for lighthouse lenses, but that glass containing lead—even as little as five per cent.—did not change colour at all. Mr. Wenham said that traces of carbon would colour glass, but the mixture of a little nitre with the materials would get rid of this colouration in a marvellous manner. He believed Mr. Gaffield's discovery of the restoration of the original colour of glass by heat to be a new one. Dr. De La Rue said that the nature of the action of light upon some of the constituents of the glass appeared to be one of disintegration and decomposition, as the glass appeared to become in all cases more coloured; there was, he supposed, never any bleaching action. M. de Fonvielle had just suggested to him that this action of light upon glass might, in future experiments, be accelerated by means of a lens.

Mirage.—Lecture Experiment.—In the course of a paper read by Professor Everett on this subject he described an experiment devised by Professor Clerk Maxwell, F.R.S. In this experiment the beautiful effects of mirage were obtained by means of three liquids in a cubical vessel with plate-glass sides 6in. square, the lowest liquid being a saturated solution of alum, the highest pure water, and between them a thickness of about a ¼in. of Scotch whisky, containing enough sugar to make its specific gravity intermediate between those of the other two liquids. It is much more refractive than either of them. Triple images were obtained, with great distinctness, of all the objects in an extensive landscape, the middle image being inverted, and either elevated or depressed according to the position of the eye. The range of triple vision extended to objects as far as 10° from the horizontal direction, either above or below, and all three images were sufficiently distinct to show whether white blinds were up, down, or half way down in a row of houses distant 700 yards.

The Colour of Fishes. — M. Georges Pouchet contributed a paper on the mechanism of the changes of colour in fishes and crustacea. The author referred to the fact that fishes often change in colour according to the colour of the objects by which they are surrounded; but he explained that this does not take place when the fish is deprived of the nerves that preside over the peculiar corpuscles to which the colour is due. The change does not take place in blind turbots; and in the seeing turbot, if the nerves are divided which communicate between the eye and the skin, the change does not occur. If the fifth nerve is divided the change takes place all over the body except the part to which that nerve is distributed. These experiments, M. Pouchet said, show that the change of colour is dependent upon impressions received by the nervous system through the organs of vision.

Tame Wasp.—Sir J. Lubbock exhibited a tame wasp which had been in his possession for about three months, which he brought with him from the Pyrenees. The wasp was of a social kind, and he took it in its nest formed of 27 cells in which there were 25 eggs, and had the wasp been allowed to remain there, by this time there would have been quite a little colony of wasps. None of the eggs, however, came to maturity, and the wasp had laid no eggs since it had been in his possession. The wasp was now quite tame, though at first it was rather too ready with its sting. It now eats sugar from his hand and allowed him to stroke it. The wasp had every appearance of health and happiness; and, although it enjoyed an outing occasionally, it readily returned to its bottles, which it seemed to regard as a home. This was the first tame wasp kept by itself he had ever heard of.

Precipitation of Silver by Copper.—Mr. Alfred Tribe communicated an interesting paper on this subject. He stated that in the course of experiments on a rather larger scale, it had been found that silver obtained by precipitation from solution as nitrate, by means of metallic copper, always contained the latter metal, however well the silver might be washed. The constant presence of this metal was considered due to dissolved oxygen in the silver solutions, or to the absorption of that gas from the air by the produced copper nitrate during or subsequent to the precipation. In practice it was found that the presence of the copper was not due to dissolved oxygen in the silver solutions, but to oxygen absorbed from the atmosphere; in one experiment as much at fifteen per cent. of copper was obtained by an exposure of forty-eight hours, and the author expressed it as his opinion that in this way almost any quantity of copper might thus be added to silver. When carbonic anhydride was caused to bubble through the solution during precipitation, the quantity of copper was diminished to a very great extent. It was also found that where an excess of silver remained in the mixture the merest traces of copper were found, but, on the contrary, when the silver was on the point of exhaustion, the proportion of copper increased considerably.

The Fusion of Arsenic.—Professor Mallett, of Virginia, U.S., reported some experiments undertaken by him in view of the generally repeated statement that arsenic cannot be fused, but passes directly from the solid to the vaporous state, and that an attempt to secure increased perfume by using a sealed tube only results in the bursting the tube. He succeeded in procuring fused arsenic by filling narrow strong glass tubes (barometer tubes), which was again inclosed in an outer tube of iron, and heated in a charcoal fire. Arsenic thus treated was found on cooling to have fused into a perfectly compact crystalline mass, of steel grey colour and brilliant lustre, having a specific gravity of 5·709 at 19° C. Specimens of the metal were exhibited to the meeting contained in glass tubes filled with coal gas, and the temperature of fusion lies between the fusing points of antimony and silver.

Meteoric Iron.—Professor Mallett exhibited three specimens of iron from Augusta Co., Virginia. One had been cut from the original mass by a planing machine, and without further preparation had been forged into a tolerably perfect blade for a paper knife. Another had been heated to redness in a vacuous porcelain tube (for the purpose of examining the occluded gases), and had then been with great difficulty forged into a blade of similar kind, in which cracks and flaws were visible. The third had been heated in like manner in vacuo, but to a white heat, and this specimen could not be forged at all. The conceivable causes of this difference were briefly discussed, such as the more or less complete removal of the occluded gases, changed state of combination of the phosphorus and sulphur, and melting out of phosphide of iron, leaving the metal porous.

USEFUL AND SCIENTIFIC NOTES.

Telescopic Walking-Sticks. — Mr. Barnes Richards, of Penzance, has recently patented an improved telescopic walking-stick; *i.e.*, a walking-stick which may be made simply to shut up like a telescope, but may also in addition be furnished with lenses, and employed for all purposes to which the ordinary tourist-glass is applied. In order to arrive at the best design and the most substantial as well as convenient arrangement of the parts he has offered prizes for the construction of telescope walking-sticks in any suitable material, the particulars of the competition for which will be found in our advertisement columns. A serviceable stick, capable of being reduced to pocket size, will be handy in many ways, and its utility will be still further enhanced by furnishing it with lenses.

Fireproof Wood.—Wood may be rendered nearly as capable of resisting fire as brick or stone, without great labour or expense, by soaking the dried timber a short time in a solution of soluble glass, a silicate of soda or potash, and afterwards immersing it in lime water, by which the pores of the wood are filled with a silicate of lime. This substance is fire-proof, and cannot be dissolved in water, and its presence and effect in the fibre of the wood are therefore permanent.

Science in Birmingham.—Through the liberality of Mr. Josiah Mason, who founded the orphanage at Erdington, a science college is to be established in Birmingham. The words of the trust-deed are worthy of publicity:—"Being deeply convinced, from long and varied experience in different branches of manufacture, of the necessity for, and benefit of, thorough systematic scientific instruction, specially adapted to the practical, mechanical, and artistic requirements of the manufactures and industrial pursuits of the Midland district, and particularly of the boroughs of Birmingham and Kidderminster," Mr. Mason "hath determined to devote a portion of his remaining property to the foundation of an institution wherein such systematic scientific instruction may be given." With this object, Mr. Mason assigns certain freehold and leasehold property, estimated at not less than £100,000. Instruction is to be provided by means of classes, in mathematics, physics, chemistry, the natural sciences (especially geology and mineralogy, with their application to mines and metallurgy), botany, zoology, languages, mechanical drawing, and architecture.

Japan.—Much interest has been excited in the United States and England by the movement among the Japanese looking toward the introduction of the English language and its literature into the Japanese empire; and it has even been stated that there is a possibility that our mother-tongue may in time become their national language. The principal difficulty in the way of this desirable consummation lies in the peculiarities of the English language, and the number of irregular verbs characterising it, as also the want of uniformity in its pronunciation. The idea has been suggested of forming an improved English language for the benefit of our Oriental friends by making all the verbs regular, and improving the orthography. The choice of a new language by the Japanese lies, it is said, between the English and the German, and the selection of the latter is warmly urged by the Germans. Indeed, that language appears to be quite a favourite one in Japan, as attested by the existence of an extensive German bookstore there doing a large business, and by the establishment of a number of schools for teaching the tongue.

Economical Cooking Apparatus.—A cooking apparatus, to be used during the Autumn manœuvres, by the 9th Queen's Royal Lancers, was recently tried at Woolwich, under the direction of the Colonel commanding the regiment. The apparatus, which has been invented by Sergeant Mayell, master cook of the regiment, consists of seven kettles or boilers, six saucepans, a frying-pan, gridiron, lantern, and baking tins, all fitting within the largest boiler, which is but 20in. square. A fire was lighted in a trench hastily dug in the open air, and by a judicious economy of fuel, 132 gallons of water were boiled in twenty minutes after the fire was lit; the saucepans being afterwards boiled in 4½ minutes. The present daily consumption of fuel in a cavalry regiment is five cwt., but with this apparatus it is said that six ounces will be sufficient. Two sets can be carried on a horse, fixed in Moody's pack-saddle, and will cook rations for 600 men.

LETTERS TO THE EDITOR.

[We do not hold ourselves responsible for the opinions of our correspondents. The Editor respectfully requests that all communications should be drawn up as briefly as possible.]

All communications should be addressed to the Editor of the English Mechanic, 31, *Tavistock-street, Covent Garden, W.C.*

All Cheques and Post Office Orders to be made payable to J. Passmore Edwards.

"I would have every one write what he knows, and as much as he knows, but no more; and that not in this only, but in all other subjects: For such a person may have some particular knowledge and experience of the nature of such a person or such a fountain, that as to other things, knows no more than what everybody does, and yet to keep a clutter with this little pittance of his, will undertake to write the whole body of physicks: a vice from whence great inconveniences derive their original."—*Montaigne's Essays.*

**** In order to facilitate reference, Correspondents when speaking of any Letter previously inserted, will oblige by mentioning the number of the Letter, as well as the page on which it appears.*

THE MOON.

[4790.]—In answer to W. L. Brown (qy. 12753), it is to be noted that the moon's path being inclined on the average about 5° 8′ to the ecliptic, she passes alternately north and south of the ecliptic by this amount. Now the effect on her range in declination will depend on the position of the points where the moon crosses the ecliptic ascendingly or descendingly. If her rising node coincides with the rising node of the ecliptic on the equator she will be 5° 8′ north of the ecliptic where the ecliptic is 23° 27′ north of the equator, so that she will be in all 28° 35′ north of the equator in this part of her orbit, and (obviously) as far south at the opposite part. If her descending node coincides with the rising node of the ecliptic she will be 5° 8′ south of the ecliptic where the ecliptic is 23° 27′ north of the equator, or she will be only 18° 19′ north of the equator at the part of her orbit where she has her greatest northerly declination; and obviously she will have no greater range south of the equator. In intermediate positions of the rising node an intermediate range of declination will result. (The whole subject wants illustration, however, and detailed explanation.)

The rising node of the moon's orbit performs a complete circuit of the ecliptic in a mean period of 18·5997 years; always regreding on the whole in each lunation, though not always at the same rate, and always advancing for a greater or less portion of each month. The regression is greater when one or other node is 90° from the sun, and least when one or other node is in conjunction with the sun, but it need hardly be said that this condition never prevails throughout a lunation. The inclination also varies, attaining a maximum when the one or other node is in conjunction with the sun. The range of change is about 8′ on either side of the mean value.

There is no cycle in which the moon "returns to the same position precisely with regard to the earth on the same day in the same month, and being also at the same time in apogee or perigee." Nor are these conditions *all* even approximately fulfilled save in cycles of very great length, quite useless for ordinary purposes. In the cycle called the Saros, invented by the Chaldeans, some of the conditions were nearly fulfilled, but this cycle had no reference to the year. It continued 6585⅓ days, or 18 years and nearly 110 days. It thus contained 223 lunations, 242 nodical months less 89 minutes, 239 anomalistic months (or mean intervals between lunar passages of perigee) less 5 hours, and 241 sidereal months less one day.

The lunar perigee on the whole advances in each year (the mean advance being about 40⅔°), but recedes on the whole in some months, advancing on the whole in others, and always both recedes and advances alternately during the course of each month. It performs a complete circuit in a mean period of 3232·575 days. The mean interval between successive conjunctions of the sun and perigee is 411·761 days, the mean interval between successive conjunctions of sun and the moon's rising node 346·6 days. The mean advance of the perigee from the node is accomplished at the rate of about 59° 58′ 4·8″ per annum, so that the interval between successive conjunctions of the perigee and rising node is slightly greater than 6 years.

I may take this opportunity of noticing a slight mistake in Mr. Birt's paper on the moon's libration, in the English Mechanic for July (I think), 1871. The successive returns of the moon to her perigee do not take place in a less time, but (on the average) in a longer time than her successive returns to her rising node.

Richard A. Proctor.

DOUBLE STARS.

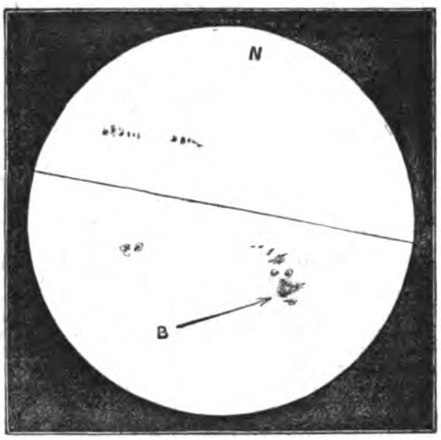
[4791.]—Let me thank Mr. Proctor for his remarks with regard to my "way of classifying" double stars. Nothing was further from my thought than to speak disparagingly either of Mr. Webb's invaluable work, "Celestial Objects," &c., or of Mr. Proctor's no less useful atlas. The only reason I can give for thus speaking is that these two works are the only ones I possess on double stars, and, therefore, I could not say whether such stars are in other works or not. To those of your readers who may have supposed that I was indicating flaws or blemishes in those two works, I will say that whenever I survey the starry heavens with my telescope, Mr. Webb's work is my constant companion; and though I possess another atlas, yet I find Mr. Proctor's so much easier, and superior, that it is the one I exclusively use.

I am very much obliged to Mr. Knott (let. 4748, p. 567) for giving the measures and positions of μ^2 Boötis and δ Cygni. Though the difference of the state of the atmosphere, when the observations were made, may have much to do on so delicate objects, yet, I believe, ξ Cancri more difficult at present with my aperture than μ^2 Boötis. I cannot account for the difference of positions in both instances, but in this way. I have adapted to the eye-tube of my telescope a brass circle with divisions of five degrees each, and it is to these divisions I refer the position of companions in double stars. I am afraid this circle is not in the exact position. Moreover, when I observed the above-named stars, I was obliged to move my telescope out of its usual place, and doubtless its axis was not in the exact direction of the meridian, hence the error.

C. Gaudibert.

SUN SPOTS.

[4792.]—At 6.30 p.m. on the 17th inst., the surface of the sun did not present so particularly interesting an object as it has done for some time past, and I should not have taken note of its appearance had it not been for one particular feature which engaged my attention on careful examination. I may mention that there were but four clusters of spots visible (as the accompanying sketch shows), and each cluster or group required some considerable power to be applied to bring out details. On examining each group separately my attention was drawn to an exceedingly luminous spot in the centre of the dark nucleus shown by the arrow B on the sketch. I examined this group carefully, and in order to avoid any possible mistake which might arise from optical illusion or otherwise, I made use of four eyepieces of different powers, and found the same luminous appearance was presented, more or less distinctly, as the different powers were applied. I am sorry I was prevented from examining



this particular group with a glass of larger aperture consequent upon a tall elm-tree obstructing the view, and I have not had an opportunity since of noting any possible change in its appearance. The spots are drawn somewhat larger than they should be in proportion to diameter of the circle, but they present the same relative aspect they exhibited when viewed at the time mentioned.

James H. Whistle.

THE SOLAR CORONA.

[4793.]—Will Mr. Proctor permit me, as one greatly interested in his able astronomical works, to ask him if he still holds the opinion that "the solar corona is due in great part to the existence of millions of meteoric systems having their perihelia close to the sun." From Mr. Lockyer's spectroscopic observations of the total eclipse of December, 1871, it would appear that it consists of "glowing gas." I can understand that this gas could be produced by the meteorites being vapourised by the intense heat to which they are subjected in their perihelion sweep round the solar orb; but Mr. Lockyer's observations seem to point to the conclusion that the portion of the corona close to the sun's limb derives its substance from the prominences which consist of hydrogen gas; as other elements are known to exist in meteorites I cannot reconcile the two theories. Will Mr. Proctor kindly say which he considers the most probable explanation of this wonderful solar appendage? and oblige

J. E. Gore.

Kussowlee, Punjab, 20th July, 1872.

STARS IN AQUILÆ.

[4794.]—Thanks to "F.R.A.S." (let. 4653, p. 536) for his prompt reply to my request respecting 263 P. Aquilæ. (By a stupid mistake I signed my letter "Epsilon.") I had seen the asterism he points out as that object, but as the "faint comes" he refers to showed very prominently in my object-glass (by Wray), I did not imagine it would not be included with the two closer components and classed as a triple star by Smyth. I see another fainter comes at nearly the same angle (say 20°) as the one mentioned by "F.R.A.S.," and at about three times the distance. Now, with reference to the faint group inquired about in my previous letter, I was led into the error from paying more attention to Mr. Webb's directions given in the first paragraph in taking the object as "closely following ι" (the word "closely" would have been better left out), and I found the faint group the nearest following that star, though it is not so far south in the field as 263 P. I see a faint comes (this immediately follows ι) at about 20° angle, and probably 70″ distance from the triple group, and also another comes rather closer at about 75° angle, all rough estimations. Having no equatorial mounting to the instrument, I use Mr. Proctor's larger star-atlas in connection with Mr. Webb's "Celestial Objects" to assist me, and, with the above exception, I never found any difficulty in identifying objects.

Lamda.

AUGUST METEORS.

[4795.]—I send you a list of the meteors I observed on the evening of August 8, hoping you will publish it, as some of them may be recognised by other observers.

No.	Time.			Mag.	Direction.	Position.
	h.	m.	s.			
1	11	0	32	β	9·5	ι Ursæ Min.
2	11	4	0	γ		
3	11	5	0	γ		
4	11	7	0	γ β		
5	11	9	0	β γ	7·5	δ Boötis.
6	11	19	17	γ		
7	11	20	17	γ	5·5	α Aquilæ.
8	11	24	7	β		
9	11	24	22	γ		
10	11	26	33	γ		
11	11	28	0			
12	11	35	17	β	8·0	α Delphini.
13	11	38	3	β γ	4·5	20 Pegasi.
14	11	46	28	γ	8·0	54 Andromedæ.
15	11	55	33	β	4·5	55 Pegasi.
16	12	6	4	γ	6·2	α Aquilæ.
17	12	11	29	β	6·7	28 Vulpeculæ.
18	12	11	30	γ	7 or 8	About α Pegasi.

The magnitudes are estimated from α to γ. α is the very largest kind, with a long train; and γ the faintest, having no train. Those with two letters are intermediate. The direction of the path of the meteor is estimated by supposing the meteor to start from the centre of a clock-face, of which the 12 o'clock is in the zenith, and the numbers represent the hour towards which it moves. The stars mentioned in the fifth column were in or near the path of each meteor respectively. Numbers 12 and 17 being quite accurate; 5, 7, and 16 nearly so; and the rest more or less so. 17 and 18 were simultaneous, and so 18 was at the best very doubtful as regards direction and position. As I had no assistance, I found it impossible to observe and record more particulars than I have done. Indeed, none of them I saw had trains long enough to need two observations. It will be found that the radiant point of the above meteor is somewhere near 22 Andromedæ. Number 12 appearing to be hardly conformable. The rest converge, however, pretty accurately. After 12 o'clock the sky became overcast, and so it remained on the three following nights. I fear I cannot rely upon the time given; but believe the greatest error to be within 15 seconds of Greenwich mean time.

I have given the above particulars as a guide to others who may wish to record something more than the mere number of meteors they see. Of course those that possess a meteoroscope save the most difficult part of the task—viz., that of recognising some star in or near the path of the meteor. If Mr. Denning cares to have my observations of the meteors on the 12th and 13th of last November I shall be happy to forward them by post.

Wennington, Lancaster. W. Davenport.

A GIANT PLANET.—RING-NEBULA IN LYRA.—ALT-AZIMUTH STAND FOR REFRACTORS.

[4796.]—Referring to my let. 4275, in No. 375, p. 283 (May 31), regarding Mr. Proctor's quotation from two narratives by eminent observers of "dark transits" on Jupiter, mentioned in his paper on "A Giant Planet," and not having seen any reply, I presume Mr. Proctor has overlooked the letter, as he has replied to other correspondents who made objections to his theories.

Might I ask Mr. Proctor (should he have the time at his disposal) to give us some instances from the records of the Royal Astronomical Society (of which he is hon. sec.) of the first and second satellites being seen in "dark transit," with the dates of the observations, and any peculiar features noticed during transits.

In the *Mechanics' Magazine* for July 27, under "Astronomical Notes for August," by Mr. Proctor, he states (p. 53): "The ring-nebula in Lyra may be now studied to advantage with the 4⁷/₁₀in. telescope belonging to the Astronomical Society; the present writer sees it as an oval ring *with the interior as dark as the sky outside the ring* [the italics are mine]; but with larger telescopes (one of Browning's 12¼in. reflectors, for example), the gauzy light inside the ring can be clearly recognised."

In Mr. Proctor's "Half Hours with the Telescope," he says, "It is seen as a ring of light with very moderate telescopic power. In a good 3⅔in. telescope, the nebula exhibits a mottled appearance and a sparkling light; larger instruments exhibit a faint light *within* the ring." Now, with a 4·23in. object-glass by Wray, I see a "glimmering light" within the ring, and cannot suppose the 4⁷/₁₀in. telescope above-mentioned to be so deficient in illuminating power as not to exhibit this fluctuating light. I also see the 11 magnitude (Herschel) closely following the nebula, and stated by Mr. Webb as being seen with his 5¼in. object-glass. Is this star brightening?

I am sure many readers of "ours" will acknowledge with me that we are indebted to Mr. Proctor for much valuable instruction derived from many of his writings. The alt-azimuth tripod stand I use was constructed after the plan illustrated in his "Half Hours with the Telescope," p. 17, with some modification in the details. It is principally made of cast iron, with a brass quadrant, and two screw motions, and cost me a little over £5 (including the cost of patterns). It could be made for a less sum by any amateur mechanic who has a lathe, though the quadrant would likely require to be cut in a machine shop. The stand is very rigid, and I find it very easy to keep a star in the field of view even with the high power of 420. The telescope can be directed to any point of the sky in an instant, with the exception of a circle overhead of about 15° diameter. Should any of "our" readers request it, I will send a drawing of the stand for illustration.

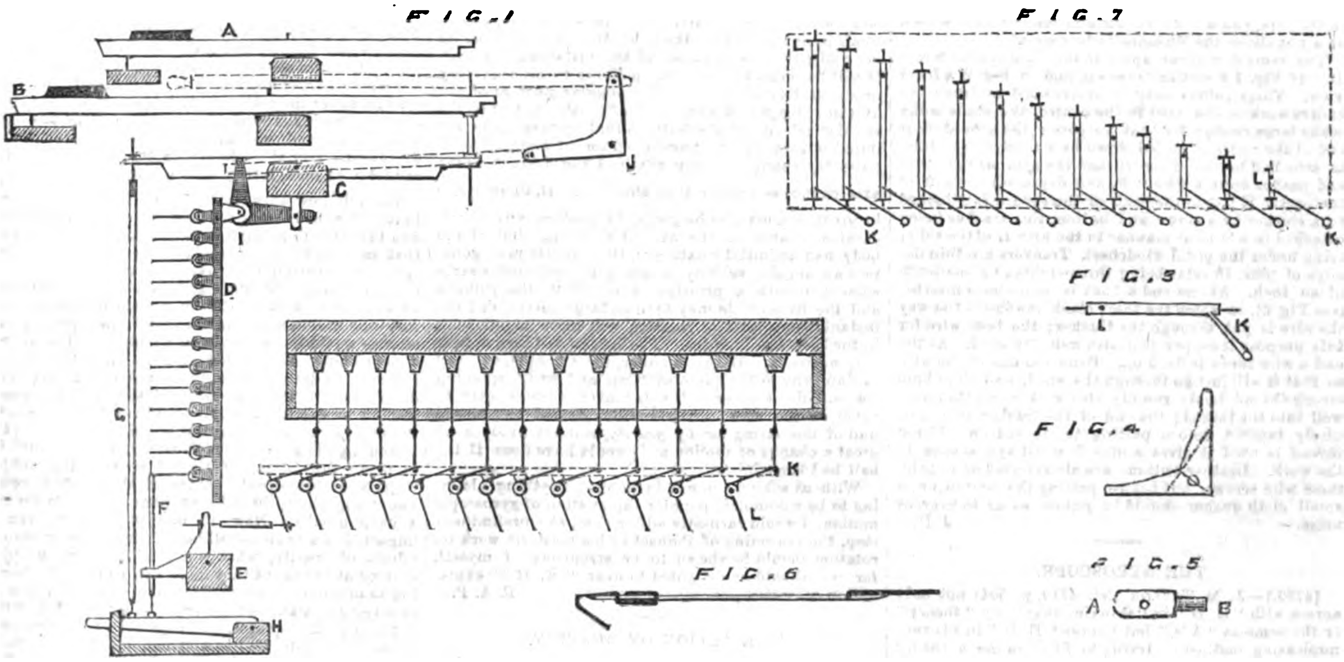
LINEA.

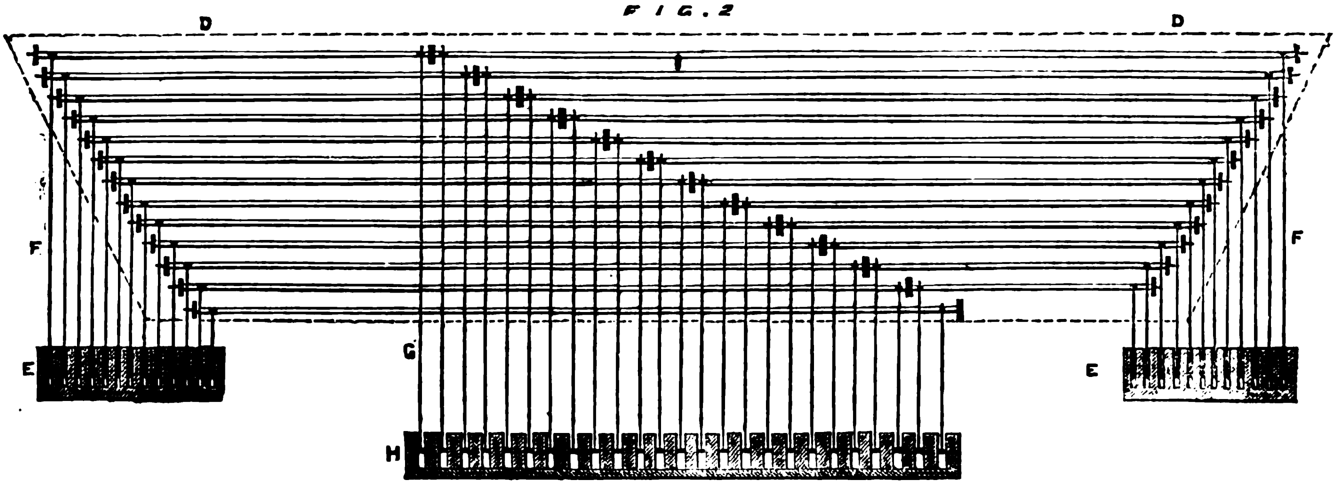
IMPROVEMENTS IN OMNIBUSES.

[4797.]—OCCASIONALLY, whilst passing along our roads in these conveyances, it has occurred to me to what an inconvenience passengers are put in giving the conductors notice to stop when they wish to get out. One is obliged to shout to the conductor, poke him with your umbrella or stick, or trouble one's fellow passengers to stop him. Why cannot there be a bell placed close to the conductor's stand at the end of the omnibuses and tramway cars, attached to a rope or strap running the whole length of the carriages, either inside along the roof, or at the back of the seats, so that each passenger by simply pulling it gives the conductor immediate notice where they wish to be set down. A similar plan might be adopted on the roof for the outside passengers. I think a mode somewhat resembling this is in use in Paris and other parts of the continent. It is a curious fact that matters of this kind are generally managed much better abroad than they are at home. NATHANIEL WATERALL.

THE ORGAN BUILT.—X.

[4798.]—HAVING now got the pedal board made, fix it in its proper position under the keys; the keyboard should project about nine inches over the pedals. Some, however, prefer more and some less; it is quite a matter of fancy. The middle C of the pedal board must be directly under the middle C of the keyboard, although that will throw a two octave pedal board a little to the left of the centre of the instrument. Now fix the lever board H, in Fig. 1, to its place, and find the length of the backfalls in the pedal coupler C, the front end of the backfalls being exactly over the front loop of whipcord in the pedal levers, and the back end of the backfalls under the end of the keys; get a piece of board the length of the pedal board, the width to be the same as the distance between the front and back of the backfalls, and on this board carefully mark the position of the backfalls. Now cut a piece out of the board down the middle the same width as the backfall rail, and





fasten the pieces of board to each side of the rail, so that the surfaces of all three pieces are level, and mark the positions of the backfalls on the rail. From these marks cut the grooves in the rail one inch deep; before, however, cutting the grooves, mark where the wire that the backfall works upon will be, and make a bradawl hole on each side of the wire for a small wire staple to be driven in. Each backfall should have a separate centre wire three quarters of an inch long, and a staple on each side. The hole in the backfall should be bored at right angles to the wood and not sloping in any way. The backfalls are thin bars of mahogany 1⅛in. by ¼in., and shaped as shown in the engraving. They all vary in length, which length will be got by placing them on the marking board. A hole must be bored through at each end large enough for the wires to go through; the holes should be enlarged on the under side to allow play for the wire, but should only be large enough on the upper side to just allow the wires to go through easily. The coupler is thrown in and out of action by raising or depressing the rail. At I in Fig. 1 is a roller of two-inch stuff, having an arm at each end attached to a short stud projecting from the coupler rail; another arm on the roller at right angles to the first arms is connected by a rod to the square J, the other end of the square being attached to the draw stop. The engraving shows the coupler in action, the stop knob being drawn; by pushing the knob in, the front end of the square is raised, and the coupler rail with its backfalls drops down, and consequently out of action. The coupler rail works between guide pins, which are fixed to the frame on which the keyboards lay. The next parts to make are the squares, Fig. 4. They should be made either of mahogany or American birch, a quarter of an inch thick and mitred at the joint; to give the necessary strength a saw cut is made in the back as deep as the dotted lines show, and a piece of veneer well glued in. A hole is bored through as shown for the centre wire, and bushed with cloth; holes are also bored at the ends for the pulls and stickers.

Twenty-five of these squares are required, they are fitted in two rails similar to backfall rails, thirteen go into one rail and twelve into the other; the distance between each square is three-eighths of an inch. Now make the roller studs, Fig. 5. The easiest plan is to get a piece of ⅜in. mahogany, cut off the end of a board, 1⅝in. long, round one end of it slightly as at A; next, with a gauge, run a line down 1in. from A., leaving ⅝in. to form the pin B, and reduce that part to ⅜in. thick. By this means one end of your board will show a section of a roller stud, then cut your board into lengths of three-quarters of an inch, plane off the marks of the saw and round the end for the pin, bore holes an eighth of an inch in diameter, as shown in sketch, and bush them.

Where two rollers work in one stud, as shown in Fig. 2, the studs must be 1¼in. long. The roller boards will be the next part, and it will be better to begin with a horizontal one under the pedal windchest. Rollers may either be made of wood or iron; if of wood they may be made of white pine bars one inch thick and octagon shaped, if of iron make them of quarter-inch gas tubing. The directions for making the rollers will apply equally to iron or wood, but if wood is used wooden arms may also be used; if iron the arms must also be iron, and iron arms may be used with wooden rollers. Get out a board the same length as the windchest, and as wide as the length of the rail in which the squares are fixed. Place a row of roller studs in a line near one edge of the board, Fig. 7. Then mark on the board lines corresponding with the squares, and one inch farther from the roller studs already fixed will be the place for the other studs, which fix in. Next cut the roller rod into lengths to fit each place. If iron rollers, it is now necessary to drill the holes for the arms; they must be $\frac{1}{8}$in. diameter, and carried right through the tubing. After drilling drive a peg of wood two inches long into each end of the roller, and insert the arms in their places. The arms are made of thick iron wire, of a size to fit the holes prepared for them, and for these pedal rollers must be three inches long. They are flattened at one end, and a hole drilled for the pull wires to go through. The arm L is inserted at right angles to the roller, but the arm K is placed as shown in Figs. 8 and 7. Drive a wire pin into the wood at one end of the roller for a centre, and make a bradawl hole at the other end for the pin to go in. Put the roller into its place, and drive the pin in through the stud; the pin should project a quarter inch beyond the stud, so that it may be readily withdrawn if it is necessary to take the roller out. The arm K is attached to the pull of the pallet or screw, or "tapped wire" going through the hole in the arm, and a cloth washer and leather button used as a nut allows the distance to be regulated.

The same directions apply to the large roller board D. In Fig. 1 a section is shown, and in Fig. 2 a front view. These rollers may be either wood or iron; two rollers work in one stud in the centre, the studs being made large enough for that purpose; the arm at that end of the roller is pulled down by a *tracker* G, which is attached to the lever H, and the arm at the other end pushes down a *sticker* F, and depresses one end of the square E; the other end of the square is attached to a tracker by a screw and button, this tracker being attached in a similar manner to the arm L of the roller lying under the pedal windchest. Trackers are thin flat slips of pine, the size being three-eighths by one-tenth of an inch. At one end a hook is sometimes inserted (see Fig. 6), in which the thick black line shows the way the wire is put through the tracker; the best wire for this purpose is copper bell wire well stretched. At the end a wire screw is fixed on. Bend one end of the wire so that it will just go through the wood, and then bind strong thread firmly round; also work some thin glue well into the thread; the end of the tracker should be nicely tapered before putting the thread on. If red thread is used it gives a nice finished appearance to the work. Leather buttons are always used as nuts on these wire screws, but before putting the button on, a small cloth washer should be put on so as to prevent noise. J. D.

THE GYROSCOPE.

[4799.]—J. M. Taylor (let. 4719, p. 564) not only agrees with "E. H." in "thinking that" my "theory" is the same as "A.'s," but follows "E. H." in his very unpleasing method of trying to fix upon me a theory which the merest tyro in dynamics would reject. I have *not* said about "a top flung through the air" what J. M. Taylor asserts—viz., that the top's weight only "eventually changes the direction of flight," and is "insufficient to change the direction in a brief interval." Any one who will be at the pains to refer to my letter (4310, p. 326) will see that the latter words are applied to the rotating top; and that in speaking of a top "flung through the air at a high velocity," I say "its weight would be insufficient to change the direction of the top's motion *appreciably* in a brief interval." There is all the difference in the world between this statement and that which J. M. Taylor ascribes to me. Then *follows* the remark which includes the word "eventually," and every one must perceive that the word "appreciably" extends to that remark also. Surely one may write that when a body is moving at a high velocity, its direction of motion does not change appreciably in a brief interval, but that eventually it does (so) change, without being supposed to support the egregious theory that gravity does not act on a swiftly moving body. It is, of course, easy to cavil at the remark, just as one may cavil at the remark that the sun rises; but it is as absurd to interpret the remark into a statement violating one of the fundamental laws of mechanics as it would be to assert that I believed in the Ptolemaic system, if I chanced to say that the sun rose or set. Richard A. Proctor.

P.S.—As my remarks in reply to "E. H." (let. 4717, p. 563) may seem to imply that I think it possible he may be able to give a popular explanation of gyroscopic motion, I must state that I am convinced that it would be utterly impossible even for a mathematician with ten times the skill of a Newton to effect such an achievement.

It is commonly admitted that Poinsot has done more than any other mathematician to make the mathematical solution interpretable in its entirety. But his treatment of the subject is far beyond the range of any who have not thoroughly mastered the principles of rigid dynamics.

Now, I do not for a moment fear that any of those skilful mathematicians who are to be found among our readers will interpret my remarks in let. 4310, p. 326, otherwise than as they were intended. It is only those who have but lately, as it were, begun to know what the laws of motion mean, who can conceive it possible for these laws to be overlooked even by the tyro. In fact, I wholly acquit "E. H." and J. M. Taylor of intentional rudeness (so far as their original mistake was concerned), since neither of them can be aware how utterly absurd it would be to suppose that such a blunder as they charged to me would be made even by an intelligent schoolboy.

Nevertheless, I shall venture to quote from Routh's "Rigid Dynamics" (a fine work, which I would recommend to "E. H.'s" careful perusal) a passage which presents in mathematical terms the general feature which I indicated in popular words. Readers of Poinsot's papers on Rotation will not need to be told the meaning of the words polhode and herpolhode. In passing, however, I may remark that since in the case of the gyroscope, or of any top, the two principal moments of inertia are equal, the central ellipsoid is one of revolution, the polhode is a circle about the axis of this spheroid, and the herpolhode is a circle about the fixed axis of the couple of impulse. Moreover, the ellipsoid of gyration, being the reciprocal surface of the momental ellipsoid, is also a spheroid.

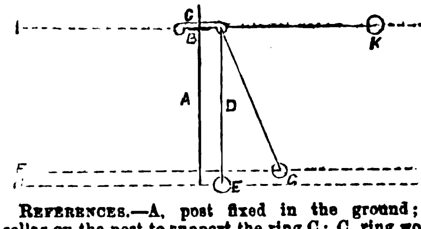
Thus, then, writes Routh, about the stability of rotating bodies:—"It is well known that the steadiness or stability of a moving body is much increased by a rapid rotation about a principal axis. The reason of this is as follows:—The instantaneous axis describes a polhode in the body, and a herpolhode in space. If the body be set rotating about an axis very near the principal axis of greatest or least moment, both the polhode and the herpolhode will generally be very small curves, and the direction of the principal axis of the body will be very nearly fixed in space. If, now, a small impulse act on the body, the effect will be to alter slightly the position of the instantaneous axis. It will be moved from one polhode to another very near the former, and thus the angular position of the axis in space will not be much affected. Let Ω be the angular velocity of the body, ω that generated by the impulse, then by the parallelogram of angular velocities the change in the position of the instantaneous axis cannot be greater than $\sin^{-1}\frac{\omega}{\Omega}$. If, therefore, Ω be great, ω must also be great, to produce any considerable change in the axis of rotation. But if the body had no initial rotation Ω, the impulse may generate an angular velocity ω about an axis not nearly coincident with a principal axis. Both the polhode and the herpolhode may then be large curves, and the instantaneous axis of rotation will move about, both in the body and in space. The motion will then appear very unsteady. In this manner, for example, we may explain why in the game of 'cup and ball,' spinning the ball about a vertical axis makes it more easy to catch on the spike. Any motion caused by a wrong pull of the string *or by gravity*, will not produce so great a change of motion as it would have done if the ball had been initially at rest."

Without asking you not to publish anything claiming to be a complete popular explanation of gyroscopic motion, I would earnestly advise that, as a preliminary step, the reasoning of Poinsot in his masterly work on rotation should be shown to be erroneous. I myself, for one, should be delighted to hear "E. H.'s" explanation *after that preliminary process.* R. A. P.

THE ACTION OF GRAVITY.

[4800.]—I don't feel any inclination to take part in the discussion on spinning tops and gyroscopes now going on in your columns; but as some of the disputants seem to have got into a muddle on the subject, perhaps I may be allowed to set some of them right on one or two points regarding the action of gravity. If I refer to two letters (4594 and 4691) of "A., Liverpool," they will be sufficient for my present purpose. I will refer in the first place to an error into which "A." has fallen, and which your other correspondents have not noticed, and have been rather led astray as to "A.'s" real meaning. He evidently thinks that if a body is set in motion, and the propelling power is not kept up, that the natural inertness possessed by that body will resist its motion, and ultimately bring it to a stand. (See let. 4691.) The fact is that if a body be once set in motion, the tendency of that body is to go on in the same direction and at the same speed for ever.

In let. 4594, "A." observes that "the question is if a cannon-ball be fired horizontally, how is the resistance to change of plane of motion so nullified that it becomes of no effect?" &c. So far as I can see, there is no resistance to any change of the *line* of motion. (See Mr. Proctor's correction, let. 4618.) "A." may think I am contradicting myself because I have just said that the tendency of a moving body is to go in a straight line. This is not a contradiction, however, for a moving body possesses this tendency merely because that is the direction in which it was sent, but as soon as any power is brought to bear on that body to make it change its course, the whole of that power is utilised, and its course changed in proportion to the power applied, consequently there can be no resistance to change. In the same letter he refers to a weight attached to a string and swung round with such force as to attain a horizontal position, and says that the cord has nothing to do with holding the weight up. To make this remark apply to his theory, he must mean neither the cord nor that which supports the cord has anything to do with holding up the weight. I would ask him how is it that but for the string the weight would never rise to a horizontal position? In proof of this, let him study the following diagram:—



References.—A, post fixed in the ground; B, collar on the post to support the ring C; C, ring working loose on the post; D, cord fastened to ring; E, weight attached to cord.

Apply a small force, and the weight E will describe a circle in the plane F at G. By increasing the force the weight may be brought to describe a circle in nearly a horizontal position in the plane I. From the above it will be seen that the length of the string governs the height to which the ball shall rise, for if the string was lengthened sufficiently at the same time that the force was increased, the weight would continue to describe circles in the plane H that it occupies when at rest. But if the string be not lengthened, then part of the power applied is used to raise the weight sufficiently to allow it to describe a circle of the required diameter. I think this will be sufficiently plain to show "A." that the shortness of the string, and not a horizontal force overcoming gravity, is sufficient to account for the weight being raised to nearly a horizontal position. If "A." is not satisfied with this explanation, let him attach a similar ball on each side the ring C, so as to balance each other, and so diminish the friction of the ring on the post. Now apply sufficient force to bring the balls to a horizontal position. Now apply still greater force, and then let him explain why on the force being raised the balls do not rise still higher, and lead the ring off the top of the post. Let him also try another experiment: when he has applied force enough to bring the balls horizontal let him lower the collar B, and then, if his theory be correct, the balls will remain in the same position a short time, and will gradually drop as the motion decreases. But if he be wrong the balls will drop as suddenly as though they were not in motion.

We will now turn to let. 4691, in which "A." says that "if a body be propelled with sufficient velocity and that this propelling power be kept up continually, that said body would maintain a straight course in spite of gravitation." He evidently falls into the error of supposing that the said body would under these circumstances maintain a uniform rate of speed. Any one well schooled in the elementary principles of science would know that such a body would move with a continually accelerated motion. The velocity of a cannon-ball diminishes only on account of the resistance offered to it by the air. If that resistance could be done away with, the ball would reach the ground at the same moment, but as the speed would be kept up it would go farther. One illustration will be sufficient to prove the fallacy of "A.'s" view of this subject. Objects at the equator move at the uniform rate of something like 1,000 miles an hour (rather faster than a cannon-ball). Now, if motion such as can be imparted to a cannon-ball be sufficient to overcome the effects of gravity, what would be its effect on objects moving at the speed they do at the equator? According to this theory, an object which would weigh a ton in a spring balance at the poles would weigh less than nothing at the equator. In regard to the experiment of the light globe tied to a string, "A." would find if he could run with it in a vacuum that the effects would be the same as though he had a ton weight at the end. It is the resistance offered by the air to the passage of a light bulky body which causes it to rise to a horizontal position. Why does "A." use a light globe? would not the same weight of lead do as well if his theory be correct?

Science and Art.

OBJECT-GLASSES.

[4801.]—I have again to thank "F.R.A.S." for his communication, and beg yet once more to trouble him. I have first to observe that it is years since I read the Ross article he alludes to (and which, by the bye, has done much harm to science, for instead of affording information on the vital point of objectives, it dwelt upon a minor matter, the refraction of covers, obviously in order to retain a monopoly of object-glass making, and this he succeeded in doing, although he had very little indeed to do with the invention. Had he explained Mr. Lister Jackson's improvements, hundreds of inventors would have applied their powers in perfecting the instrument long ere this. With the exception of Mr. Wenham's papers in the *Microscopical Journal*, there are no books extant, on the microscopic objective, and amateurs as a rule are wholly in the dark on this all-important head. I consider it both impolitic and barbarous to retain as a trade-secret an invention borrowed from a scientific man. I have spent years in glass grinding, and in the study of optics, but having Montaigne in view, I am diffident as to the quality of my acquirements. Not having filched from Ross, "F.R.A.S." will naturally ask where from, then? Euler, Boscovich, Hugyhens, and lastly Potter, but none of those quite satisfy me, and I would like the proprietor of a first-class Powell and Lealand microscope to apply it both binocularly and otherwise, with various powers, as an eyepiece to a mirror as perfect as may be, and give us the result.

"F.R.A.S." accurately concluded that I considered reflectors better than refractors. I conceive it possible to perfectly figure a speculum (although we are far from that as yet), at the same time I cannot see perfection attainable from refractors. Admirable glasses exist unquestionably—comparatively admirable, that is—but so long as their correction is based on a compromise, they never will bear high eyepieces without distortion. I conceive that instead of two or three lenses an objective ought to consist of many, to give a prospect of perfect correction, and the difficulties are to me insurmountable.

Although foreign to this subject, I beg to point out to my fellow contributors "Hyrab Sea," and "E. L. G." particularly, that they utterly ignore Montaigne's advice, as is apparent to more old women than Betsy Summerhight.

PERSPECTIVE.

[4802.]—I MUST confess I thought you were closing the discussion on this subject rather early; but I now recognise the wisdom of the course you adopted.

The letters of "Bobo" and M. Paris (4702 and 4708, pp. 560 and 561) show that further reasoning would be thrown away; since the former believes that a picture, to be strictly accurate, should show a "vertical line in nature" as a *curve*, "that singular curve" too (as though there were not myriads of such curves, named and unnamed, as the *hyperbola*, *cissoid*, *Witch of Agnesi*, both the *conchoids*, the *quadratrix of Dinostratus*, and a host of others), "that eternally approaches a straight line, but can never cross it," while M. Paris speaks of plumb lines "*converging* in the zenith."

Lest, however, your younger readers should be confused, and imagine that there is a conflict of opinion where in reality no mathematician can entertain the slightest doubt, I would recommend those who may be thus perplexed, to wait, before forming an opinion, until they have mastered the elements of what is commonly called "solid geometry." The first eight definitions and the first nineteen propositions of the eleventh book of Euclid will suffice for a beginning. In reading the propositions the young student should take care to avoid the mistake of regarding the lines in the *illustrations* as those whose equality, parallelism, &c., are referred to in the demonstrations. He must try to conceive the lines and planes in *space* which are meant to be pictured in these illustrations.

The matter which has recently been under discussion may be taken as a "rider" to Proposition XVI., a rather easy rider no doubt, but still not a bad exercise for the young student. It could be worded thus:—

If there be two planes, one containing a given line, and the other parallel to the given line, the planes intersect in a line parallel to the given line. Prove this; and apply the property to show the fallacy of the idea that the perspective view of a tower equally wide at top and bottom should be bounded by lines converging towards the top of the picture.

Such a deduction would, of course, not serve for the tripos at Cambridge, or for like examinations; but for junior classes it would not be wholly unsuitable.

Lastly, in this and other subjects, the learner should work steadily onwards from the beginning towards the end. This is the approved method. By reversing it the learner may be led to all manner of strange misapprehensions. It is in this way that circle-squarers *et hoc genus omne* are generated. For example, we may be sure that the gentleman who believes the three angles of a triangle to be less or greater than two right angles (I forget which) has never gone farther back than Proposition XXXII., Book 1, of Euclid. If he could only work his way thence to the axioms, he would be set right; but there is now small hope of this.

RICHARD A. PROCTOR.

CO-STORES.—TO OTHERS, NOT "HARMONIOUS BLACKSMITH."

[4803.]—WHEN I first undertook to answer the query of "Babbet" (9819, p. 81, volume before last) on "co-operative societies" (not mere "stores"), which I still hold the most important of the 12641 queries yet broached,* and very far from being yet duly treated—when my reply appeared as let. 8044, p. 248, our "Harmonious" friend was as speedily down upon me as at present (let. 8165) with very loud but far from articulate complaints about "superlative madness," my "bad imitation of Thomas Carlyle's stuff," with instead of "an infinite deal of method, precisely what mathematicians term a quantity less than 0"—it is "no use to abuse competition" (which I had been showing how to stimulate and use for good), and so forth; the main or sole intelligible complaint being my not letting "such holy things as co-operation" alone. "Had its injudicious advocates only strength of mind enough to let it alone, at least as far as regards preaching out of season about it (silence is golden, sayeth the sage of Chelsea), we might perhaps have heard less and seen more," &c. Surely, by the way, such complaint directed at me entirely glanced off on the Editor. If it is not presumable that whatever queries he prints are matters in season to be treated, why are they admitted? It was his place, if any one's, to "let it alone," surely not mine after the query had appeared. Well, the "Harmonious" now interposes on the same subject, and in identical style (let. 4670, p. 540) to inform us he is ignorant of this, ignorant of that, and is "also ignoramus in relation to" the other. I often think it necessary, in stating something I know, to distinguish plainly that such and such points connected with it I am quite ignorant upon; and the space thus taken on a late occasion raised "Sigma's" wrath; but I presume there was *something* positive after all, not a whole letter of "ignoramus" like this. Has "Harmonious Blacksmith" ever read the motto from Montaigne that heads every batch of these letters? And if he is *now* so ignorant on these two subjects, "co-operative stores and coins," then in the name of golden silence, "sage of Chelsea," and all other thingummies, to return his words, "can't *he* let it alone," and could he not have let it alone those months ago?

Suppose equal space taken to inform us what particular things, now on the tapis, Mr. Proctor is ignorant of, and so on with other contributors, would the ENGLISH MECHANIC be worth its salt? He does not even favour us with one word of what he says appeared in No. 1 of the *British and Foreign Mechanic*, which he cannot suppose very easily obtainable. I find the British Museum possesses no copy. "The trader," he admits, is "possibly not, as such, a product of Providence;" but he finds it "hard to conceive to what other productive energy we owe his existence." Conception, then, is hard where it ought to be particularly easy, as two letters prefixed give him the cause in question—*im*providence. Why am I (and every Londoner at present) unable to get one pennyworth of food, fuel, or any necessary, without at least another penny going to blast wretched traders' souls, increase all degradation, and pile up pestilent funds for the furthering all iniquity, and hastening every way my nation's and race's ruin? Simply because, in this utter disintegration of what was once a society, a city of two millions does not contain *one hundred* individuals neighbourly or *provident* enough to allow such a paramount duty so much as one hour's thought or discussion! Divine Providence created man. Human *im*providence alone created and creates this ruinous canker. If my querist objects that "improvidence" is not a "productive energy," it is nevertheless the releaser of the evil energies of greed, concealment, and various "Satans" (whether he likes the term or not), that alone are "productive" of cankers like this; as physical corruptions are *productive* of cholera and small-pox, or of maggots and flies; doubtless not of the germs of either. As for an "all-Father," I know not where the term comes from, but in the only writings of recognised authority on such a matter among us, He who taught men to address His Father as "our Father" very plainly tells many others that they are of *their* father, *not* His, because the lusts of *their* father they will do; which seems to exclude at present any "*all* Father;" and I do not see a syllable of the creator of adventure-traders as such (or of adventure-trading), and the Creator of man being aught but enemies to each other. When a type of the latter hears of the appearance, in his field, of types of the former, he says, "An enemy hath done this," but orders both to be let grow together till the harvest. That harvest I infer to be now beginning, because everywhere this manner of products are very visibly being gathered and bound into bundles. And this is just what the harvesters were *first* to do, "gather out all things that do offend, and bind them in bundles to burn them." But afterward (soon, we hope), the wheat to begin also being gathered into the garner. Very "melancholy mental crazes," doubtless, with quantity of method mathematically "less than 0."

For reply to "how the thingummy" those who have things to exchange, and make them, can make a medium of exchange, I will simply copy the back cover of Josiah Warren's pamphlet "Equitable Commerce" (1852, Fowler and Wells, 131, Nassau-street, New York), which professes to be a specimen of notes current in one of the earlier settlements, since greatly multiplied

THREE HOURS' LABOR,

in Carpenter's Work,

OR THREE TWELVE-POUNDS OF CORN.

Joseph Peters.

Full explanation of these and the working of the system is given, in 120 closely printed pages, for 25 cents. His later work "True Civilisation an immediate necessity, and the last Ground of Hope for Mankind" (1863, J. Warren, Boston, and A. C. Cuddon, 73, Falkland-road, Kentish-town, London, N.W.) gives a more elaborate form of note for "One Hour's Labour in Carpentering, or 8 pounds of corn," with 184 pages of explanation, and most interesting historical details of the movement. Carpentering, therefore, seems to have declined in real value in those 11 years, probably from the immigration of skilled Europeans.

As near England as one of the Channel Islands, I believe a market-house was built some years ago without the use of other money than such notes. "Certes," I would conclude with our "Harmonious" friend, "it could not" (therefore *cannot*) "much facilitate exchanges if all purchasers were compelled to exchange one form of wealth—which especial form might not be in local demand—for another they needed;"—that is, precisely what the European coinage system (which, above, he denies to be "necessarily oppression") *does* compel all to do! and moreover to keep all the gold and half the silver (the two most physically valuable metals in nature) sunk, idle, and in a perfectly useless form. Of all the badges imposed by conquerors, this is at once the most flagrantly oppressive (except permanent chattel slavery), and the most blinding, without even *that* exception. Talk of "dark ages," let us hope they are at their darkest, but they are certainly though an end only to be attained by true co-operation, among operatives and wholly against "employers" as now defined, wholly for the superseding and elimination of them as a class, is yet a very minor end of this great holy war and true Armageddon to which Heaven calls us all; an end not to be attempted at the outset, but only after far more important results. At least, though reformers situated as in America may begin with it, we can only hope to end with it. In no truly civilised society will weights of metal "stamped and certified" to save "the trouble of weighing and assaying" be found a bit more requisite than weights of cheese or soap so "certified."

E. L. G.

DESCRIPTION OF A CONCRETE BUILDING CONSTRUCTED OVER THE METROPOLITAN DISTRICT RAILWAY.

[4804.]—I HAVE latterly read with much interest the letters of "Khoda Bux," "M. G. C.," and others on the interesting subject of concrete, which I, alike with "M. G. C." (let. 4692, p. 542), firmly believe will, in time, outdo bricks and mortar, when truth has overcome prejudice, which it certainly will. Our friend "Khoda Bux's" personal experiments show its cheapness and durability, and I may safely state concrete building in every particular, whether monolithic or not, drives the soon-to-become old bricks and mortar plan into the shade. To prove conclusively the largely-discussed question as to the reliable character of concrete exposed to compressive strains, I will bring before "our" readers the tests applied to the experimental concrete bridge, set in cement, erected over that branch of the Metropolitan District Railway which forms one of the junctions between the Inner Circle and the West London Extension. The structure experimented upon spans the open cutting between Gloucester-road Station and Earl's-court-road. It has a flat arch of 75ft. span and 7ft. 6in. rise in the centre, where the concrete is 3ft. 6in. in thickness, increasing towards the haunches, which abut upon concrete skew-backs. The concrete of which the bridge is made is composed of screened gravel and Hilton's Portland cement, mixed in the proportions of about seven to one, carefully laid in mass upon close boarding, set upon the centreing, and inclosed at the sides. The concrete was mixed by hand labour, as many men being employed to mix and wheel into place as there were room for. The bridge was formed in three portions, the centre portion, 12ft. wide, being first made and tested. Each portion was formed in one operation. The amount of concrete employed in the centre portion was about 4,800 cubic feet, which, weighing $1\frac{1}{4}$ cwt. per cubic foot, gave a gross weight of 300 tons for the structure alone. The centre of gravity in the half span being 16ft. 6in. from the abutment, the weight of the same 150 tons, and the rise of the arch 7ft. 6in., the thrust at the crown is equal to 330 tons. The arch being 3ft. 6in. deep in the centre, and 12ft. wide, a sectional area of 42 square feet is available to resist the thrust, which is consequently equal to 7 tons 17 cwt. per square foot. The additional strain imposed upon the concrete in the arch for every ton per foot run of distributed load is equal to $2\frac{1}{4}$ tons per square foot, and the maximum strain for a rolling load of 1 ton per foot run is about $8\frac{1}{4}$ tons per square foot. It occurs when the load covers about five-eighths of the span. In testing the centre portion of the bridge, rails were laid upon sleepers over the arch, which brought a load of $^{2}/_{75}$ths of a ton per foot run upon the structure. Seven trucks weighing, with their loads, 49 tons, were formed into a train, having a wheel base of 57ft., hence the rolling load amounted to $^{49}/_{57}$ths of a ton per foot run. The deflection produced by the passage to and fro of this train four times was noted with a spirit-level upon a standard cemented to the sides of the arch at a distance of one-third the span from the abutments. When one side of the bridge was loaded the extreme rise of the haunch on the opposite side was about $^{1}/_{16}$th of an inch, which was produced by a maximum strain of 10 tons 14 cwt. per square foot.

At a subsequent trial a mass of gravel 10ft. wide, 3ft. thick at the crown, and 6ft. deep at the haunches, was laid over the bridge, and upon this ballast was placed the permanent way. After an interval of a few days the trucks, loaded as before, were passed over the bridge, at first in pairs, and finally altogether. In his test the strain upon the concrete was as follows:—

	tons.	cwt.
The weight of the arch as before......	7	17
170 tons of ballast	4	8
Strain per square foot from dead load	12	5
Strain per square foot from passing load	2	17
Total strain per foot................	15	2

After repeated transit the load was left on the bridge all night, and upon examination showed no signs of failure or distress under the severe strains to which it had been exposed. That a very small stress was developed upon the underside of the arch was evidenced from the fact that none of the comparatively loose pebbles on the inner surface of the arch became detached, the interior of the structure was much denser than the outside, and at 6in. from the outer surface was excessively hard. The exterior of the work was rendered in Portland cement to represent ashlar. Some fine cracks appeared a few months afterwards, attributed to the further shrinkage of the concrete by drying, but these have not extended. Nevertheless, the porous nature of even such good concrete as that used in this bridge is shown by the fact of rain passing through it in the course of a few

* We have once before corrected "E. L. G." as to the number of queries. There have been about three times 12641 queries inserted. We began to number the queries

REPLIES, &c., FROM "SIGMA."

[4805.]—I HAVE to apologise to several querists for not replying, owing to having had my time wholly engaged on business requiring a good deal of absence from home. I will now note the various matters calling for attention in the last three numbers, so far as my present time permits.

"T. H." (let. 4601, p. 488) has not even yet extricated himself from the old confusion of "quantity and intensity." The statement of mine which puzzles him is strictly true, and he should try it; interposed resistance does not affect the weight of copper deposited by a given consumption of zinc, it only prolongs the time and generates heat in the wire; of course, there is the same total heat or energy developed in both cases, but it is differently employed and distributed: of course, also, the excessive consumption of zinc by local action must be allowed for, as it has nothing to do with the deposition. "T. H." should read again my paper in No. 355 dealing with this. The primary of his coil appears to be too long and too small wire, therefore has too much resistance to develop full magnetism in the core; and the cotton covered wire secondary is not good, as it does not lie close enough to get full effect.

INTERNAL RESISTANCE.—My opinion on this matter, to which "Pi" (p. 490) rather objects, relates to general use by our readers, chiefly amateurs, rather than to electricians possessing Thompson's reflecting galvanometer and perfectly arranged resisting coils; they can take care of themselves. My advice is mainly given to those who do not possess these costly appliances, and it is for such I try to devise and select the easiest processes, and most convenient instruments.

I cannot at present go further into the points named by "Beacon Lough," p. 491, because having changed my abode within the last fortnight, and spent most of that away, my books and instruments are unavailable at present, being as yet in a state of chaos.

For the same reason I cannot answer T. Sinclair (12509, p. 497); possibly the carbolate of lime may suit him, but I am not sure.

ACARUS CROSSII.—This was a mistake, the acari were not generated as supposed, but were a well-known creature. The whole of the experiments were described in a previous number at full length. I cannot give the number for the reason just stated.

(12533.)—MAGNETIC MACHINE.—It is only necessary to solder short pieces of wire at the several lengths and bring them out for connecting to studs, so that any of the lengths may be connected to the terminals. My diagram, p. 502, is sufficient aid for so very simple a matter.

(12558.)—ELECTRO-MAGNETISM.—Probably a separate circuit would put an end to the trouble of "Contact Breaker," such as a length of fine platinum wire, or better still, a voltameter through which the extra current at breaking circuit should pass, instead of forming a spark: I suspect a battery of too great force is used. The spare coil tried, to some extent absorbs the extra current; covering the electro-magnets with copper or brass cylinders would do so still more effectively.

(12554.)—GRAPHITE BATTERY.—The glass tube is for adding and removing liquid without disturbing the loose particles or moving the cell; with manganese, saline solutions should be used.

I beg to assure "A., Liverpool" (let. 4691, p. 542), that I have not done anything so absurd as he supposes; nothing I said could be tortured into asserting that a body discharged—horizontally—"with any conceivable velocity would maintain a straight course in spite of gravitation." I said it would do so *but for gravity*, and that a part of the energy was consumed in slightly raising the bullet and so prolonging its time of falling to some small extent. The velocity of the motion has nothing at all to do with either time or rate of fall due to gravity. As to "A.'s" extraordinary illustration, the ball, be it a hollow indiarubber one or a 68-pounder, could by no possible velocity of rotation ever rise to a true horizontal plane, and the cord does most certainly hold it up, by transmitting to it that energy which continually lifts it as fast as gravity tends to make it fall, and before any one troubles to answer "A.'s" pathetic "where, and oh where," it will be as well to have considerably better evidence than a guess of "A." against perfectly proved facts. SIGMA.

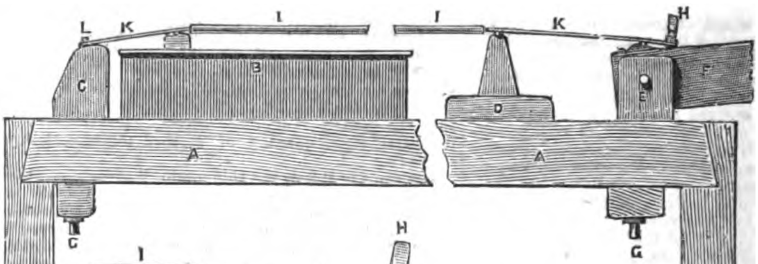
TUNING KEYED INSTRUMENTS.

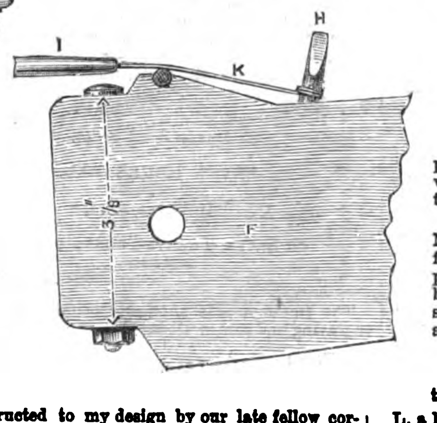
[4806.]—"FIDDLER'S" idea respecting the tuning of keyed instruments could never, I fear, be carried into effect, for the difficulties in the way are very great. At the same time, if anything could be invented to enable such instruments to be played equally in tune in all keys it would increase their value to a marvellous extent, and be the greatest improvement that the musician could desire. But I do not think "Fiddler's" arrangement will accomplish this, for the following reasons. First, he proposes to make the key which plays the tonic of each scale play the leading note also, by a difference in the force of touch, and justifies this, on the ground that the discord of the diminished second is scarcely ever employed, except in a few instances by Beethoven and Mendelssohn. This is quite true; but as these great masters do sometimes introduce it, such an alteration would prevent the works in which it occurs from ever being played. A more serious objection to "Fiddler's" plan is that the difference of tone is produced by so indefinite and uncertain a thing as the varying strength with which the note is struck. Suppose, for instance, that we are playing in the key of C; we must always play B very softly and the tonic loudly, for an increase of power would turn the former note into the latter. What, then, would become of delicate shades of expression? Fancy the result, if in a rapid crescendo passage, the slightest amount of undue pressure would throw all out of tune! Verily, I think, "Fiddler's" remedy worse than the disease, and it would make the piano twice as difficult to learn as it is at present.

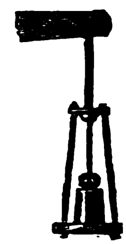
Though the discord of a diminished second is very rarely employed, that of the major seventh, which is practically the same thing, is not at all uncommon, and on "Fiddler's" piano that chord could only be sounded by playing an apparent octave, and striking one of the notes harder than the other. Then, again, the reduction in size of the instrument, which he considers an advantage, is to my mind a mistake, for it would greatly increase the difficulty of performance. Who could play the chromatic scale with smoothness and ease, when he would have to repeat the touch on every note? None but the finest performers could do it satisfactorily, and I doubt if even they could, in this manner, equal the rapidity with which the same thing may be readily done on the ordinary keyboard. In fact, to halve the number of notes, is to double the difficulties in the way of the player rather than to reduce them. Besides this, how are we to manage when we wish to play an accidental flat, say B? The note A will only produce itself, and A sharp, and surely that is not to be used instead of B flat, for if so, what becomes of the improvement? If not, an additional note will be required, and then the keyboard will remain of the same dimensions as at present. I am afraid this notion of "Fiddler's" leaves us as far from the desired goal as ever. VERTUMNUS.

MONOCHORD WITH SOUNDBOARD AND OTHER MUSICAL STRING TESTING MACHINES.

[4807.]—I INCLOSE drawing of very simple apparatus for ascertaining the amount of tensile force—expressed in pounds weight—required for causing a string of given length and thickness to produce a sound of given pitch. Many years ago, about 1850, a far more costly machine







was constructed to my design by our late fellow correspondent "W. T.," but having quite got over my early prejudice in favour of expensive apparatus, also well knowing that most of my friends in the pianoforte trade share "W. T.'s" quite justifiable terror of the probable cost of uncustomary iron work, I have designed this affair to be almost entirely constructed of wood, consequently, any pianoforte-maker (who being unhappily afflicted with the same form of disease which myself and my late friend formerly suffered severely from, to wit curiosity, is desirous to know what he really is doing, and is not quite content with the customary "rule of thumb") may make it for himself at a very trifling cost, certainly not exceeding 20s., if he does what I did—viz., make the back of one of his benches serve for its bed. This he may do by bolting to the bench a piece of (say) beech wood the same thickness as its top, about 4in. or 5in. wide, which also forms a very tolerable makeshift bed for a rough lathe.

In testing piano strings, no very great accuracy is required. In practice, it is sufficient to be able to ascertain the straining force within 1 per cent., which this apparatus is quite capable of doing. If, in consequence of the friction of the lever on the ¼in. round iron pin on which it works, and other causes, the lever acts rather sluggishly, a few gentle taps of the mallet soon, by jarring, cause it to assume its true position under the influence of the weights suspended to it. When great accuracy is needed, probably some such apparatus as that described by the late General Perronet Thompson—which he constructed for facilitating the tuning of his celebrated enharmonic organ—would be about the best that could be employed. In this the string being tested had the straining weight suspended to it directly (the string being perpendicular), and no amount of downbearing on the two bridges which could sensibly affect results was suffered to exist; in fact, a pressure of only 4lb. sufficed to keep the string in contact with its bridge, and even this small pressure was not applied until after the weight which strained it had been in operation for a few seconds of time. Had the pressure been applied in the same plane as that of the bridge's inner surface, it could not have increased the tensile force, because it would then have acted on the string like a mere clip.

I have a rather strong impression, if the covered strings of ordinary cottage pianos were tested, the results would surprise some of their makers. Those commonly employed for FF—if subjected to the same straining force and thickness (I mean the under wire) as middle C—might possibly be heard to sound A, if not B; "I guess," their pitch would rise "pretty considerable." I think I see the look of blank astonishment some of my clever friends in the trade would exhibit, and hear them exclaim, "Well, I could not have believed it if I had not heard it, and yet my covered strings are exactly the same as those of Messrs B., C.," &c., mentioning the names of one or two first-class manufacturers, whose real names I, for obvious reasons, forbear mentioning, and leave the riddle to the reader.

DESCRIPTION OF THE FIGURE.

AA, bed or bench on which the standards E and C are fixed. N.B.—If it be desired to make this apparatus independent of an ordinary bench, the wooden bed of a common lathe, or a similar bed formed of two pieces of common spruce deal 8in. × 4½in., or even 2½in. × 3½in., placed about 1½in. apart, will serve.

B, a soundboard about 16in. to 18in. square, fixed on a rectangular frame, which may rest on the bed A without being clamped thereto.

C, a standard fixed by the bolt G at any required distance from the standard E; of course, the distance these two standards are apart depends on the length of the string which is being tested.

D, a standard which need not be fixed, but may only rest on the bed A.

E, a forked standard fixed to the bed A by the screw bolt G. This standard supports the lever F.

F, a lever, whose two arms are in the proportion of ten to one, by which the straining weight in the scale pan suspended from it is transmitted to the string to be tested.

GG, screw bolts for fixing the beads EC. N.B.—Two of the screws out of my matrimonial four-post bedstead answered admirably for this purpose, and they had the advantage of having been well tried, and not "found wanting." Possibly, in these day of iron bedsteads, such things as bed-screws may be almost unpurchasable.

H, a common wrest-pin inserted in the lever F.

II and KK are the uncovered and covered portions of the string being tested.

L, a hitch-pin in the standard C.

To use this machine proceed as under. Ascertain—by means of a weight suspended at exactly the same distance from the centre which the wire bridge on the lever F is, or by a thin cord carried over a rather large pulley—the weight required to counterbalance the lever F and the empty scale pan, assuming this to be 10lb., that weight must invariably be added to whatever weight is put in the scale-pan, unless it be preferred to counterbalance them permanently.

1. Pass the end of the string through the hole in the wrest-pin H, and coil it twice round it.
2. Put the eye of the string on the hitch-pin L—put a weight equal to about one-quarter the straining force you design to subject the string to in the scale-pan, and fix the standard C sufficiently distant from E, to cause the lever F to incline upwards about 10 or 12 degrees.
3. Place the soundboard B so that the wire bridge is about ¼in. from the end of the covered portion of the string.
4. Place the standard D so that its wire bridge is about ¼in. from the other end of the covered portion of the string.
5. Put the weight into the scale-pan, which subjects the string to the amount of tensile force you desire, and on plucking, striking, or bowing the string, the pitch of the sound it produces will instruct you which note on the instrument it ought to be used for. N.B.—Should the lever descend much below the horizontal position, it may be raised by turning the wrest-pin H.

When this apparatus is employed for ascertaining the force of tension required to cause a string of given length and thickness to produce a sound of given pitch, all that is requisite is to place the bridges on the soundboard, and on the standard D at the required distance apart, and put weights in the scale-pan, which is suspended from the lever F, until the string produces a sound of the required pitch.

Par example, experiment No. 1. Having put a No. 24 steel-wire string on the monochord, place the bridges 24in. apart, and load the lever until the strain is equal to (say) about 290lb., which, I believe, will cause the string to sound middle C of our philharmonic pitch. N.B.—Under the circumstances mentioned below, this would require a weight of 28lb. to be placed in the scale-pan.

No. 2. Increase the distance between the bridges to 26in. = $^1/_{12}$ more, and the straining force will require to be increased about 18 per cent., approximatively.

No. 3. Increase the distance to 28in. = $^1/_6$, and the straining force must be increased about 36 per cent.

No. 4. Increase the distance to 32in. = ⅓, and the straining force must be increased about 78 per cent.

No. 5. Increase the distance to 36in. = ½, and the straining force must be increased about 125 per cent.

If desired to ascertain the amount of tensile force which any string—in any instrument—is subjected to, place the bridges on the soundboard B, and on D the same distance apart those are on which the string rests in the instrument, and put weights in the scale-pan until the string produces a sound of the same pitch as it did—or as a string which is a counterpart of it does—in the instrument.

Should it be desired to judge of the timbres or varying qualities of the sounds obtained from strings of equal lengths, but of different thicknesses (when connected with the same soundboard, and producing unisonous sounds), this apparatus may be slightly modified for that purpose. By inserting three hitch-pins in C, and three wrest-pins in F, the sounds produced by three strings of different thicknesses may be compared, always assuming the apparatus be made strong enough to bear the additional strain of two more strings. Of course, it will be needful to prevent the lever F from rising by putting additional weights in the scale-pan, or otherwise, say by strutting or by tieing it down. I think it would be preferable to substitute for the lever F a spare standard which would do duty for a temporary wrest-plank; but, after all, such experiments are of doubtful value, because in practice the soundboard most suitable for long covered strings is not most suitable for comparatively short uncovered strings, and these results—although far from valueless—not to be depended on equally with trials in the instrument itself for which the strings are designed.

THE HARMONIOUS BLACKSMITH.

PHONOMETERS.—COLONEL PERRONET THOMPSON'S MONOCHORD.

[4808.]—PROBABLY the most accurate instrument ever constructed for "weighing sounds"—to borrow its designer's expression—was the phonometer designed by the late General Thompson. In this the straining force required to bring a string up to a given pitch (and the change of its length needed to produce a given alteration in the pitch of the sound produced by its vibrations) could be ascertained to the greatest nicety. His purpose in having it constructed was to facilitate the tuning of his celebrated enharmonic organ, in which sounds differing in pitch less than one-tenth of a comma were required. The last I heard of the organ was that it had been doing duty in a school attached to a chapel in or near Jewin-street, Aldersgate, but was then—and had for some time been—superseded by an harmonium, the complex key-boards of the enharmonic organ being too difficult for performance by untrained players. My informant could not tell me where the phonometer was. If any fellow reader can, he will greatly oblige me? I think this organ and its phonometer would be valuable additions to the educational department of South Kensington Museum, if only for the purpose of demonstrating that performance in tune is preferable to performance out of tune, which is just what all performances on instruments with fixed tempered scales must be, and which, alas! some performances on the violin—and voice whose intonations are not fixed—have seemed to me distressingly to resemble.

THE HARMONIOUS BLACKSMITH.

RIFLE TARGETS.

[4809.]—WHEN at Hastings a few weeks since I noticed what seemed to me a great improvement upon rifle targets. These were made with two plates of thick steel, fixed on a stalk before an ordinary target, a large plate representing the centre and a smaller one in front the bull's-eye. If either of these plates be struck with a bullet a loud sound like that of a bell is heard, by the tone of which it is known which plate is struck, so that no marker need be exposed to any risk. It is true that the risk is very small if proper attention be paid to signals, but scarcely a season passes without a fatal accident from want of such attention. I do not know whether the cost of such substitutes for markers is considerable, but think it cannot be more than is well worth paying; I should, however, like to know. Perhaps some of our correspondents can give the information.

PHILO.

SINGLE *VERSUS* DOUBLE-CYLINDER ENGINES.

[4810.]—Now that this subject is exciting considerable interest, I send the following extracts from Bourne's "Recent Improvements in the Steam Engine" (p. 51, &c.):—"For all pressures employed in the ordinary class of existing steam-vessel, engines of the common single cylinder type are as efficient as any other, and in practice such engines are found to work quite as economically as engines with any greater number of cylinders, while they are manifestly simpler in construction." "But if the pressure be raised to 60lb. or 70lb. per square inch it will be advisable to double the length of the stroke, and halve the area of the piston." "If such pressures be employed as 150lb. to 200lb. per square inch, it may be proper to introduce double-cylinder engines." "The gain in power producible by a given amount of expansion is equally attained, whether such expansion is accomplished in one cylinder or fifty." Double cylinder engines, however, enable expansion to be carried further without interfering much with the uniformity of the motion.

PHILANTHROPIST.

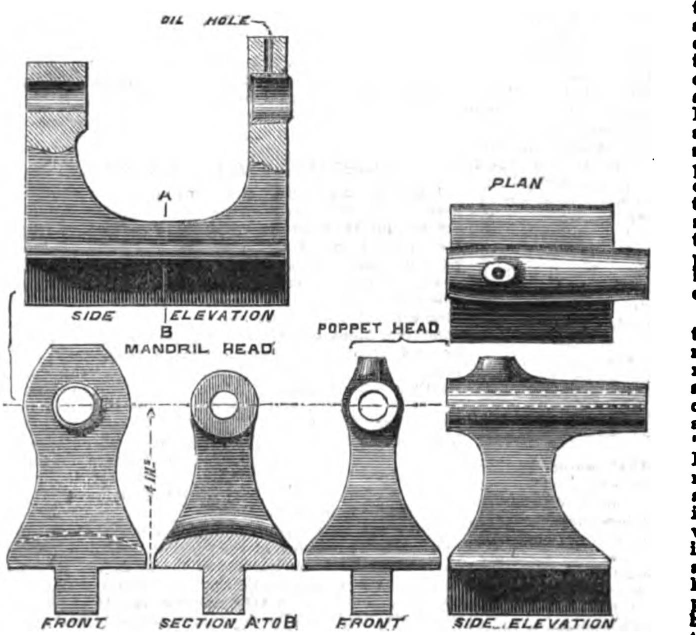
FALL OF BULLET.

[4811.]—WITH respect to Francis Lewis' letter (4682, p. 541), it must be evident that the fall of a bullet can only be regarded as an example of the second law of motion when the earth is considered as a plane; but the earth being a sphere, there are two points that will theoretically affect it. In the first place, when a bullet is projected horizontally, that is at a tangent to the earth's circumference; but as the tangent increases the secant increases, therefore it will take as long reaching the earth as the secant exceeds the radius. And, secondly, as gravity acts inversely as the square of the distance, therefore being further off the attraction will be less, and it will take longer to reach the earth. Therefore, for two reasons, it will theoretically take longer to reach the earth than a bullet dropped from the same height.

ZETA.

LATHE CONSTRUCTION.

[4812.]—I AM sorry to have kept "C. N. M." (qy. 12354) waiting so long, and now send sketches of both heads for a small lathe. The mandril head would be better if it were a little longer, say another inch in a 5in. lathe, and the mandril should be as long as possible, provided you can get it



into its place. The screw of nose of mandril for a tiny lathe such as "C. N. M." wants (only 2¼in. centres) may be ⅜in. or $^7/_{16}$in. diameter, and then the fixed collar may measure about $^9/_{16}$in. or ⅝in. inside in front. I have shown the fillet that goes between the beds nearly 1½in. deep, as it is extremely convenient occasionally to be able to raise the heads from 4in. to 5in. height of centre by the insertion of parallel pieces of wood under them, and if these are not more than 1in. high there is still plenty of the fillet remaining between the beds, to hold the heads true while they are being bolted down. Such a deep fillet to the mandril head has also the effect of stiffening it materially in its weakest place. I should not temper the collar more than to boiling-water heat; both in shrinking it in to the casting and in japanning there is some risk of its being tampered too much. I must refer "C. N. M." to my previous letters on this subject if he wants any more information. The sketches sent are from templates made many years since for a 4in. lathe, and I think for proportion, with the exception mentioned above, will make as pretty a lathe as need be, whether enlarged or diminished as regards actual size. If "C. N. M." resides in or near London, my old address, Pitcairn's Library, King's College-road, N.W., will enable him to appoint a meeting.

J. K. P.

HEATING BY HOT AIR.

[4813.]—IN reply to "E. C. G." (let. 4635, p. 518, No. 384), I beg to refer him to the volumes of the *Gardeners' Chronicle* for 1847-49 (as nearly as I can remember) for an account of a system of hot-air heating called Polmaise. He will find that it is too late by 25 years to claim a first success for hot-air heating of plant houses in 1872. Polmaise forced its way into use by its well proved merit under the able guidance of Mr. Meek, and with the cordial approbation of Dr. Lindley. Having no opportunity of consulting the *Gardeners' Chronicle* for some years after that date I cannot say for what reason or in what manner the system ceased to spread itself or to be spoken of. I speak from much practical experience of its great merits when I say that I know no other argument against it; and the force of this objection is greatly diminished by the fact that in all the cases in which I was personally engaged in its application, where I have been able to ascertain by inquiry, it continues in operation to this day. Its disappearance from the public view may be chiefly accounted for by the fact that the system is represented rather by a principle of hot air circulation than by an apparatus. It can hardly, therefore, form part of the stock-in-trade of high class tradesmen. In other words, men wishing to adopt Polmaise as a system proved to be thoroughly efficacious for hot-houses, churches, &c., would find great difficulty in getting hold of any who should understand it.

The work is that of a common bricklayer, and falls, therefore, into the hands of a class of men who do not trouble themselves generally with the laws of pneumatics. It was very observable too, at the time of the introduction of the system, how very frequently the principle of Polmaise was misunderstood. Those interested in opposing it used to represent it is only a new form of the useless hot-air appliances already in existence, and even of those tradesmen who took up Polmaise and advertised it, some would be changing it into a mere apparatus of iron pipes and hot-air flues, to the neglect of the leading principles and features of the system. I applied the system to a small hot-house of my own construction, and its complete efficiency and remarkable cheapness, both in construction and in use, induced others to try it for the same purpose, and I never heard a word from these friends other than those of commendation. I applied it to a large parish church, and it was applied by plans and instructions furnished by me to several other churches, and in all cases with excellent results; one of these I will specify. A church in Kent was heated at a cost of £45 on the Polmaise system, while another of similar dimensions had a hot-water apparatus supplied at a cost of £200. The fuel bill in the latter case reached the sum of £20, against £5 in the Polmaise for the same period, the two churches being comfortably and efficiently warmed.

With the advantage of the experience already referred to to assist me, I notice points favourable and unfavourable to success in Mr. Housman's apparatus as described in "E. C. G.'s" quotation. He is quite alive to the need of pouring in warm air by cubic feet or yards into the houses to be warmed, instead of niggling with tubular stoves and small pipes. I have known a complicated apparatus of small pipes heated to whiteness—through which nothing short of a steam-engine and fan could have driven heated a into their building (a church) sufficient in volume to warm it—and utterly fail to produce any result. Extensive surfaces for the absorption of the furnace heat is a good feature in the system, but highly heated surfaces imply extravagant consumption of fuel, if they are extensive. They are also injurious to plant life; the great advantage of extended surface residing in the power thus gained for warming large volumes of air moderately. It is much easier also to speak of rapid currents passing over such surfaces than to obtain them, when they have, as in Mr. Housman's system, to pass through lengths of horizontal hot-air flues, every yard of which is an obstruction to the current. The power at command to create a draught through a hot-air apparatus and system of hot-air flues is just that of a chimney of the height of the plant house, a very imperfect chimney indeed.

So far as Mr. Housman's system is described in the quotation of "E. C. G.," it is on the principle of inflation as contrasted with circulation which characterises the Polmaise system. In the former case the whole contents of the house have to be driven out to make room for the heated air. In the Polmaise system the cool air of the house is actively employed in producing or promoting the circulation of the heated air. I have written at sufficient length, but if "E. C. G." or others should desire it, I will illustrate the plan of circulation, and describe the system of Polmaise more perfectly, and point out in what case it is most suitable for plant houses.

J. M. TAYLOR.

Seer Green Vicarage, near Beaconsfield.

OUR COAL SUPPLIES.

[4814.]—WHEN I was a boy at school one of our teachers, a most intelligent man, used to read to us from various treatises, and among the rest from Parkes'

"Chemical Essays," published, if I recollect aright, in four pretty thick 8vo. volumes. In these essays it is stated that on the south coast of England, Sussex possibly, after a heavy gale of wind coal rubble was washed up in such quantities on the beach as to yield very seasonable supplies of fuel to the poor, who, on such occasions, eagerly gathered it. It is very odd that in all the discussions on the subject of possible subterrene supplies of coal in the southern counties this fact, if it be a fact, has never once been adverted to. To me it seems as clear as possible, if the averment in Parkes be correct, that coal crops up in the Channel bed, and consequently, or presumptively extends beneath the contiguous land.

IXION.

DEAR COAL—HOW IT MAY PROVE A BENEFIT.

[4815.]—At p. 564 I described one mode by which meat may be very nicely cooked with very little fuel, and very much better cooked than it commonly is when far more coal is burnt. If, therefore, the dearness of coal has the effect of inducing many to cook their food in a better and cheaper manner, the permanent benefit arising from a temporary loss will be very great. The waste of food from bad cooking is a far greater loss than by the waste of fuel, and as it so happens that meat as well as coal is just now exceptionally dear, it is to be hoped that more attention than usual may be drawn to the great waste of both, that by a little common sense may easily be saved. Some may be deterred by the first cost of Warren's cooking apparatus from using it, though that first cost is quickly repaid by the food and fuel it saves. I will, therefore, describe other simple modes of cooking that answer very well, but require more looking after. First, if the meat to be cooked be suspended or supported upon a trivet in a common pan above water covering its bottom, kept boiling gently, and the steam kept in by a well-fitting lid, the meat may be cooked in the steam constantly maintained by a very small fire or by a gas jet. I do not think meat thus cooked is quite so tastey as when cooked in the hot air of the Warren, and instead of rich gravy we get rather weak soup. Still, it is better than meat boiled in the still too common way by which most of the juices of the meat are extracted by the water, and, to those who do not like broth, lost. This common way is to put the meat into a pan of cold water, which is gradually heated, and then kept boiling until the meat is done, generally too much near the surface and too little within. Few know, or if they know act as if they knew, that the proper way to boil meat is not to boil it at all, but to place it in a pan of boiling water (the temperature of which it immediately reduces) and never to allow the water to reach the boiling temperature again, but only to simmer gently until the meat is cooked throughout. The effect of putting the meat at once into boiling water is, by coagulating the albumen in its surface, to confine the juices inside, while, by the gentle heat afterwards continued, the fibres of the meat are separated, the red blood globules rendered brown, and the meat made tender and digestible with very little loss of nutritive matter. The water is so poor it is hardly worth anything as broth, while meat, which if cooked in the common way would be scarcely eatable for toughness, is made tender and toothsome.

Many cooks seem to think that water boiling violently is hotter than that which boils gently, and acting on this belief waste much fuel in driving off steam uselessly, and making the kitchen uncomfortably hot. It is to be hoped that the dearness of coal will induce many to try if they cannot, as they certainly can, boil just as well without this waste.

Though boiling in some form is the easiest mode of cooking economically, and though I for one prefer it to all other modes, we need not confine ourselves to it. As I have already said, at p. 564, meat cooked in the Warren and browned before the fire, or in a well-ventilated oven, is only distinguishable from roasted meat by its greater tenderness, but those who prefer it may easily have their meat roasted in an oven, the top and sides of which are heated as well as the bottom, and if the air in the oven is not too much confined, meat so cooked is, in fact, roasted, with less risk of being scorched. No gravy or fat must be allowed to fall on the hot bottom of the oven, or the meat may acquire an unpleasant flavour.

I have not tried roasting with gas, but intend to do so by placing the meat to be cooked on a trivet, covered by a beehive-shaped gas stove top made of earthenware, 2in. thick. A small quantity of gas burnt will keep the inside surface of a thick fireclay cover very hot, and I expect that the radiant heat from that surface will roast the meat within the cover nicely. The gravy and fat will fall into a plate below the gas jets, where it cannot possibly get overheated or burnt.

PHILO.

WARMING RAILWAY CARRIAGES.

[4816.]—The plan of warming the feet described in let. 4685, p. 542, by Mr. Menz, is very old, except, possibly, the form in which the fuel is used. It is a very old plan to burn charcoal in a sort of footstool, but now a vessel of hot water is, I think wisely, commonly substituted. What is called chemically-prepared charcoal is, I suspect, common charcoal powdered and formed into a brick, with clay enough to hold it together, which is, I dare say, convenient, but will have no chemical effect. I do not think either burning charcoal in movable vessels of hot water so good a plan for warming railway carriages as blowing waste steam through pipes beneath the floor would be, as was described in "ours" a few months since. The common feet-warmers are too hot at first, and do not keep warm long enough; they would be more comfortable at first, and useful longer, if covered with felt or thick drugget to prevent the heat passing away too much and too quickly. It is remarkable how little discomfort is caused by even very cold air if it be nearly still, and if the feet be kept warm. I believe if the floor of a church were warmed, the air need not be.

PHILO.

LIGHTNING CONDUCTORS, &c.

[4817.]—"J. K. P." (let. 4750, p. 568) is perfectly right in his remarks as to the advantage of a solid rod over the much more costly gas tube recommended by the writer in the *Times* to whom he refers. That writer, no doubt, supposed there was some advantage to be got from the larger surface of the tube, a very natural and common error among those who, knowing little of the subject, confuse in their minds the wholly distinct subjects of capacity for charge and faculty of conduction.

"J. K. P.," however, does not quite apprehend my remark as to the preference of copper. The fact is that a copper conductor need have only one-sixth the sectional area of an iron one, to be equally efficient, and possesses the advantage of not rusting. It is, however, purely a matter of cost and convenience; and I do not in the least doubt that a galvanised iron wire, such as recommended by Mr. Preece, p. 559, would be a cheap and ample protection, if applied to all the prominent parts of buildings, and safely led to earth—*i.e.*, the gas and water mains, not to the mere service pipes.

In reference to "Canada Bear's" suggestion to me, p. 566, to visit Canada to investigate the matter of electric sparks, I doubt if I should much admire a Canadian winter; I had some idea of going over for a month or two this summer had not other engagements prevented. However, as to the special subject, I have had enough for one spell of electric sparks. I do not say this because they happened to serve in these pages the purpose of a false scent, but because a few days ago one selected my next door neighbour's house as the "line of least resistance," thereby sending his chimney-stack down through my roof to my considerable inconvenience, though happily with no further worse effect than a general panic, and its usual accompaniments among the feminines of the establishment.

SIGMA.

LIGHTNING FROM THE EARTH.

[4818.]—"Amateur" (let. 4751, p. 568) reopens a vexed and very interesting question. Without denying the possibility of the flashes he saw proceeding from the earth, I should rather be inclined to think they were discharges from a lower to a higher cloud, discharges between clouds being quite as frequent as between earth and cloud. It appears to me that the discharge of electricity from the earth would be not from one point but from many, and in the form of brush discharge. This quiet mode of discharge is exceedingly common, and is especially so during "thundery weather" on mountains. At sea, it is known to sailors by various names, and was one of the alarming incidents in "The Tempest." "Arago" thinks that these brush discharges are probably rarely absent from elevated points during thunderstorms, and are not seen because not looked for. "Arago" does not deny the existence of upward strokes; he thinks, however, that the evidence is insufficient.

There was near my house during a recent storm an extraordinary instance of the force of lightning. The chimney of a cottage isolated in the fields was struck. The bricks were thrown all round the house with such force that those which hit outhouses twenty yards off were pulverised, and the weather-boarding looked as if covered in places with red powder. Nearer, palings were cut as if by rifle balls; and the masons told me that out of two cartloads of bricks composing the chimney, not one whole one could be found for use again. The pieces flew over the fields to a distance of more than thirty yards, and most of them were no bigger than an egg. The cottagers were numbed for some time, and told me they heard no noise except the falling of pieces of brick upon the roof. They must have been insensible, for I heard the crash of the thunder. What was very odd, the lightning ran down an iron pipe which did not quite reach the ground, and instead of passing straight into the earth from it (the distance being but 8in.), "jumped" on one side to a corner a foot off, and passed down there, making a hole an inch in diameter. The cottagers said they were nearly suffocated by "sulphur," and a baby was stiff for a long time, and unable to move its mouth when its mother offered the breast. If the chimney had not been so utterly smashed, but had been only knocked down, the whole family would probably have been killed, as they were all huddled together in a little room just under it.

M. PARIS.

CHANGES OF LEVEL IN LAND AND SEA.

[4819.]—In one of "E. L. G.'s" remarkable letters (4540, p. 461) he says in effect that it is not worth while to refute Lyell's estimate of the possible antiquity of man based on the idea that land rises so many inches in a century, because Lyell himself speaks of Chili and New Zealand being thrust up 10ft. at a jerk, and the Aleutian Isle 3,000ft. in a year. Unfortunately, I have read but little of Lyell's book, and certainly no recent edition; but I should be glad if "E. L. G." would explain how the instances cited render Lyell's arguments not worth "stooping (!) to refute." In doing so, I hope he will keep clear of the Sacred books, of Nephilim, Deluges, and the like, for they are in no way concerned with what I want to arrive at. It appears to me, then, that land which has been gradually rising out of the seas, or from which the latter has been gradually receding, would present a far different coast-line, both in shape and composition, to that jerked up at the rate of 10ft. at a time. It is beyond dispute, I believe, that portions of our own island have been raised from the sea while others have become submerged—or the sea has receded from or encroached upon the land. Raised beaches and submerged forests are not so remarkably uncommon, and it appears to me that if the contour of the coast, from the water-line to the raised beach, is a gradual or even sharp rise, without abrupt breaks that cannot be accounted for, there is *primâ facie* evidence that the elevation of the land or the recession of the sea has taken place slowly and without jerk; while if the surface of the land only presented beaches at intervals, and did not exhibit uniform water-wear from the water-line upwards, it would conclusively show that the land had been lifted by jerks. At any rate, I cannot conceive but that there must be some difference enabling geologists to arrive at an opinion whether the land had been slowly raised or at intervals and by jerks.

I find in a paper read by Mr. Howorth at the recent meeting of the British Association, some particulars of the rising and falling of the land at different parts of the globe, and I send an extract which may interest your readers; but it does not give the information I want. Mr. Howorth said: "The conviction has been gradually strengthening that the term terra firma is a misnomer, and that the land no less than the sea is constantly moving. The importance of ascertaining and mapping out the areas of rising and subsiding land both for geologists and geographers, and for engineers and practical politicians, can hardly be overrated, yet little has been done in this field, and the best maps show the empirical way in which the question has been treated. The author had collected all the facts he could find bearing on the areas of upheaval. These when arranged are very interesting. The relative height of land and water being our gauge, the coast-line is the only test we have. Judging from this it follows that all Scandinavia except Scamo is rising; this upheaval extends to Siberia and all northern Russia, including Nova Zembla. The coast-line from the White Sea to Behring's Straits is all rising, the same is true of the eastern coast of Asia from Kamtschatka to Formosa, including the Amour country, the Yellow Sea, the islands of Japan, and Loochoo. Siam and the Malay Peninsula are rising, so are all the islands of the eastern archipelago from Borneo to New Guinea. The peninsula of India is probably sinking, so is Ceylon, but we meet with rising ground again at Meckran and trace it along the coasts of Persia and Arabia, including all the Red Sea. Asia Minor is probably rising; so is Syria; so is Europe east of the Adriatic. West of a line joining the Memel in Prussia, Europe is apparently more or less sinking, so is Britain, except the mountainous portions of Scotland. In North and South America all the land is apparently rising except a portion of the United States' coast from Florida to the S. Lawrence and the coast of Brazil. Africa is rising from the Cape to the latitude of Zanzibar. North of this there is an area of depression on either coast, extending on the eastern as far as the Somali country; and, on the western, to the Cameroons. North of this it is again rising, except the northern border, which joins in the movement of depression that is progressing in the Mediterranean, Australia, Tasmania, New Zealand, New Caledonia, and the Chatham islands are all rising. These facts favour the conclusion that all the great masses of land are now rising, and that the probable force of the rising of the land are the two poles of the earth. The areas of subsidence are apparently grouped about the equator." This is at least to me an interesting question, and I should like to know on what portions of the earth the estimates of Lyell are based, and whether the rising is at the same rate at different parts—save, of course, volcanic districts.

SAUL RYMEA.

THE "ENGLISH MECHANIC" GREENHOUSE, AND HINTS ON ITS CONSTRUCTION.

[4820.]—I have read with much interest our esteemed correspondent's plan for a cheap and durable greenhouse ("Saul Rymea," letter 4662, p. 538). It appears to me to be an excellent plan, one that could be erected by all our horticultural and persevering English mechanics; but I do not think, painting and all included, it could be done at the present time, considering the high price of materials, for £5. As to the law of fixtures, which he has correctly explained, I need say nothing, but would strongly advise him and others not to be done with "tenants' fixtures" houses. I think the house should be named, with Mr. Editor's sanction, the "English Mechanic greenhouse," and I hope some more of "our" friends will contribute to its construction. I think the proportions will do admirably, but the floor I should advise to be on the ground level, as sunk floors do not always answer. With regard to the heating, I have found the most economical plan to be the old flue and crystal lamps. Of course hot-water and gas apparatus are the most efficient, but would be too expensive for this purpose. "Saul Rymea's" remark as to the situation—viz., S.E., is correct, as every one knows the morning sun is best for vegetation, but with reference to its being as near to the house as possible, this makes no material difference, as long as the aspect is good. No one can do better than follow "our" friend's instructions as to building—in fact, myself being in want of a small house, I have half a mind to erect one to his directions. Good 21oz. glass is preferable to 16oz. I have never found 16oz. to be better for a hailstorm

—can "our" friend say why? but glaze it on the old putty system, well sprigged and bedded. I am a large owner, and a great opponent to glazing on the iron and other similar new and costly systems. In fact, I denounced it in rather strong terms a few months back in "ours." As I said above, I fear it could not be effectually erected for a £5 note. In the first place, 21oz. or 16oz. sheet could not, at the present fabulous and unprecedentedly high price of glass, be bought for anything like 3d. I should put it at 6d., which would be a fair price; this would double the item to £3 12s. The other items are at a good price; but "Saul Rymea" has not included the painting and glazing, which would cost 50s. to be done, primed, stopped, and painted four coats, and glazed as I have mentioned. I make the cost of the house would be:—

	£	s.	d.
21oz. glass at 6d. per foot	£3	12	0
Other items, as priced by "Saul Rymea," p. 538	3	4	0
Painting and glazing	2	10	0
	£9	6	0

Of course I have allowed, like "Saul Rymea," a good price, and they should think any respectable builder would do it complete for £7 10s. As to the wood and iron, I am of opinion that wood houses, when erected substantially, drive iron into the shade, especially when economy is considered. Nevertheless, an iron house the dimensions he gives would be cheap at £4 4s. 8d.

H. B. E.

CENTRIFUGAL FORCE.

[4821.]—When I read my note on this subject I thought myself too egotistical. I am glad most of your correspondents have taken the right view of the matter. I deemed the term erroneous; and, as such, wished to see an alteration. We mathematicians should be exact. If, therefore, any term is inexact, let us attempt, at any rate, to agree upon some other term, and some other way of explanation. M. Paris rather mistakes me. Many of our text-books devote a chapter to the consideration of centrifugal force; I would have it explained, in the chapter devoted to the "Laws of Motion," not as centrifugal force, but as rectilinear tendency or whatever name we agree upon. Surely, if public opinion is favourable to this change it must be made. I don't say that I agree with the term proposed by M. Paris. C. H. W. B.

DISTANT SIGNALS ON THE MIDLAND.

[4822.]—Many thanks to "C. E. S." (let. 4688, p. 541), for the information respecting the Midland distant signals. Would he say if there is any really practical advantage in this particular form of signal—*i.e.*, an oblong board turning on a perpendicular pivot, over the ordinary kind of an arm on the left of the post? It always seems to me that even with the alteration mentioned it must be more difficult to know if it is the front or back of the board, than it is to remember that unless the arm is on the left of the post it must be the back of the arm, and, therefore, of no consequence. Again, if the ordinary signal answers for the semaphore, why should it not for the distant signal? It seems an unnecessary complication to have two kinds of signals if one would answer the purpose, as the simpler signals are, the better for the drivers.

A. G. Boyd.

Diseased Potatoes.—The Prime Minister has requested the Director of Kew Gardens to give publicity to the method successfully introduced by the late Rev. Professor Henslow into certain villages in Suffolk and elsewhere for utilising diseased potatoes. He says:—"This method depends on the fact that the starch of the potato is not affected by the disease, but retains its nutritive properties, and consists in rasping the peeled tubers upon a bread-grater into a tub of cold water. In a few minutes the starch will be found to have sunk to the bottom, and the diseased matter, woody fibre, &c., will be suspended in the water, and should be poured away with it. Fresh water should then be added, the starch stirred up, and again allowed to settle. Two or three of such washings will remove all impurities, and render the starch fit for use. If thoroughly dried it will keep for any time, and can be used as arrowroot, for puddings and cakes, or, mixed with flour, as bread. A flat piece of tin, prepared as a grater, may be had of a tinsmith for a trifle, and nothing else is required but a knife and a tub of water. But this temporary measure cannot be all that scientific resources may supply. Surely some method (by desiccation or otherwise) is applicable and available to the cottager by which the sound tubers and the sound parts of diseased tubers may be so treated that they may be preserved for winter use; and I cannot doubt but that chemists will suggest such. Lastly, this season, which has favoured potatoe disease, has also favoured an abundant crop of green food; and I would urge upon the clergy, medical men, and intelligent classes of the country parishes, combined action, in the way of precept and example, in introducing the beetroot, the foliage of the turnip, and various other vegetables, as an article of daily consumption. Now, too, is the time for laying in stores of such nutritious articles as dried haricots, calavances, and various other pulses and beans which form the cheap, agreeable, and most nutritious food of the populations of many tropical countries."

REPLIES TO QUERIES.

**** In their answers, Correspondents are respectfully requested to mention, in each instance, the title and number of the query asked.*

[12234.]—**Hairsprings** (U.Q.).—"Jack of All Trades" is a little out of his element in watchmaking. Watchmakers do not use a gauge for hair springs. The wire of which hairsprings are made can certainly be purchased, but having the wire you are a long way from possessing a spring. Hairsprings are not made by hand now so much as formerly. They may be purchased beautifully coiled up and ready for use. In selecting a spring the diameter is determined by the distance of the curb pins from the pivot hole, and the strength by the size and weight of the balance, and number of vibrations wanted per hour, this necessitating an amount of experience by no means inconsiderable.—West Cornwall.

[12272.]—**Electrotyping** (U. Q.).—To fill up the back of copper electrotypes use pewter solder and lead. Dissolve some zinc in muriatic acid, and well cover the back of the electrotype with the solution; place some very small bits of pewter solder on the back which you have covered with the solution, put the electrotype on a lump of charcoal, and apply flame with a blowpipe until the solder has penetrated into the crevices. Afterwards you can use lead, which is cheaper, and will strengthen the electrotype. This is a simpler process than using a fusible metal, the recipe for which I have already given you. You might make a mould of the engraving of the alloy if you can devise a means of doing so without injuring the engraving, and then give it a coating of copper.—W. H. H. C.

[12314.]—**Bleaching Tanned Goods** (U. Q.).—Try a bath of sulphuric acid, one part to from twelve to twenty of water, and afterwards use strong bleaching liquid in the shape of chloride of lime, or subject it to the action of the gas.—Jack of All Trades.

[12324.]—**Spoiled Hams** (U. Q.).—To about every 12lb. of salt put 1lb. of coarse sugar with 2oz. of saltpetre; with this you can use either 2oz. of juniper berries, or ½lb. of coriander seeds in powder, or if smoked flavour, a few drops of creosote; with these well rub your hams and place them upon a wood grating over a pan or cistern of water in a cellar or cool place. Afterwards when had two days of this, give them four more in brine, take out, dry them thoroughly with either bran, pollard, or sawdust, and hang them up to dry.—Jack of All Trades.

[12324.]—**Spoiled Hams** (U.Q.).—Hams or bacon rusted or spoiled, not rotten, cover them in linen cloth, dig a hole three or four feet deep or more, put the hams or bacon in, let them stop there twelve days and nights, then take up, and they will be then as fine to eat as any you can buy.—Outgenious Whitesmith.

[12326.]—**Collodio-Bromide** (U.Q.).—Ordinary bromo-iodised negative collodion may be converted into collodio-bromide by the addition of an alcoholic solution of nitrate of silver; but is not likely to give good results, as a special collodion is required. "Tripod" had better procure a pamphlet, published by Messrs. Mawson and Swan, Newcastle-on-Tyne. — Photo. Bristoliensis.

[12327.]—**Horn** (U.Q.).—I believe this can be done by subjecting them to a bath of potash and water.—Jack of All Trades.

[12342.]—**Pouncing Pattern on Printing Blocks** (U.Q.).—This is, I presume, wanted to transfer the patterns upon blocks for either cutting or pricking out. Brush your block over with either some size or gum water. Having pricked your pattern paper through with a stout pin or needle, fix it to your block with some drawing pins, then take some whiting and tie it up in a piece of muslin, dust it through the holes over the pattern, take your paper off, invert your block over a boiler of water, and steam it; put by to dry; your pattern will be fixed for working. —Jack of All Trades.

[12345.]—**Ontario** (U.Q.).—As to where extremes of heat and cold are least, I should think west of Toronto; as you go west the climate gets milder. The winters are more severe in Lower Canada than in Ontario (Upper Canada). In London, Ontario, where I have been for four years, the heat of an average summer day is about 85° in the shade; the nights are warm, about 18° is the cold of an ordinary winter day. As you go north the winters become colder in a greater ratio than the summers. I do not know about the lake district of Simcoe. Canada is not very like a park. The cleared fields have zig-zag fences of timber, called snake fences. Nearly all the land is forest until it is cleared. The trees vary in different places. A farmer would do well, particularly if he had a family who could help him, as labour is dear. He would have very hard work in the spring, and would have to rough it for a while. The spring season is short. When the snow melts the hot weather comes in with a rush. The people are quiet and sociable enough. There is not much formality; general invitations are usual. Those who have no houses usually live in boarding houses or hotels in the continental fashion, all taking their meals together. Fish and game are abundant. Further information if desired.—Philanthropist.

[12348.]—**Spanish Pronunciation.**—"E.L.G.'s" last interesting note at p. 515 of "ours" (No. 385) will be read with pleasure by all interested in such matters. As I am asked the question by our learned friend, I may answer that I do not believe in any other pronunciation than *blanco* and *bacho*, *hecho*, for the words *blanco* and *bajo*, *hijo*, the guttural sound of the *j* in Spanish being identical with the Scottish sound *ch* in the word *loch*, and not differing at all in quality from the Spanish *g* before *e* or *i*. I do not think the sound of the Hebrew letter *heth* would perfectly represent the Spanish gutturals *g* or *j*; but I am not much of an orientalist. Will "E. L. G." kindly inform me whether the Sanskrit gutturals *kha* and *gha* are sounded in a similar manner? I have Wilson's grammar, but the equivalents given are as in the words *Khan* and *Afghan*. I should also like to know whether the compound letter *kha* is merely a strong aspirate or a weak guttural—if the former, Sanskrit would seem to be deficient in the peculiar guttural sound in question, the same as it is notably so of our soft *s* or *z*, and still more extraordinarily of the short vowel *e*, as in our word *met*. Like the Spanish, however, this "perfect language" is phonetic, and the alphabet with its 47 letters is the key to correct pronunciation, provided its European equivalents are correctly stated.—W. Wray.

[12352.]—**Centrifugal Pump.**—The reason which induced me to criticise "Rat-Tat's" proposed pump was that it was evident he had not tried it himself, and was violating Montaigne's precept by recommending the pulling down of a machine which is known to raise a large quantity of water with a proportionate expenditure of power in order to try a proposed arrangement which has been already tested in several ways and found wanting. The results of some trials which I made in a similar direction are that there is enormous waste of steam in proportion to the quantity of water raised. As some correspondents are recommending a trial of compressing air in a similar manner, it may be useful to state that the result of my experiments in this direction is, that the quantity so compressed, and the pressure obtained, is exceedingly small compared to the amount and pressure of the steam so used.—A., Liverpool.

[12355.]—**Fermenting Bread with Starch.**—If when "Dough's" ferment is alive, he adds some starch from either rice or potatoes, with a small portion of sugar, he will find his dough light enough, and go ramping mad. Potato starch is to be got somewhere, as it is used to a great extent for the adulteration of arrowroot.—Jack of All Trades.

[12378.]—**Bat-Making.**—First question, use a file; second, scrape, then glass paper on a piece of flat cork, &c. For hardening (without special tools) lay the bat on your knees, or on something soft, such as a cloth, rolled in a knob; get your shoemaker to lend you his round-faced hammer, and then hammer the face all over well to shape; if done properly no marks need be seen. For glueing, get the best; the secret lies in making the top of the splice pinch the handle, a good joint cannot be obtained without. Rub a little burnt cork on the V sides of the handle, it will greatly assist in fitting, and put plenty of glue; also warm the joint before glueing. The cane can be got at any basket-shop; you will have to glue some dozen pieces together. I have no doubt these outside tips will be understood, if not, ask again.—A Weymouth Athlete.

[12388.]—**Onions.**—I have some over a foot in circumference, similar to "M. W. G." (p. 493). I planted in September, and transplanted beginning of April.—H. B. E.

[12401.]—**House Painting.**—This is a peculiar question. For 15lb. of "genuine" white lead take 1 pt. of oil, 2oz. dryers, ½ pt. of turps. Don't use turps for outside work. No good painter would do this, or he would have a colour you could see through.—H. B. E.

[12406.]—**Worm-eaten Violin.**—Rub the violin inside with methylated spirit.—H. B. E.

[12408.]—**Quill Pens.** — They are first passed through hot cinders or ashes to purify. This makes a profound stench, but removes all moisture, oil, and fat. They are then washed and dipped in alum water, and afterwards placed on a hot plate to dry, sufficiently cool not to split.—H. B. E.

[12409.]—**Transferring Pencil Drawings on Paper to Boxwood for Engraving.**—I thank "Sarah," "Xylographer," and "John Hopkins" for their kindness in answering my query. I find tracing a finished drawing on paper very tedious, but with outline it suits admirably. When I reverse it on the prepared block, the great difficulty is in filling in the shading as it is on the paper before being transferred —the burnishing process has a blurred, indistinct appearance, which makes it very difficult to engrave properly. Can "Xylographer" tell me of any solution, &c., that by applying to the paper before or after the drawing is made on it, then by placing on the block and damping the back of it, take a facsimile of the drawing as it is on the paper?—E. B.

[12424.]—**Preserving Green Peas and Gooseberries.**—A good plan to enable one to have green peas for Christmas dinner is to put them in an air-tight jar and imbed in the earth about a foot deep. Gooseberries can be done in the same manner for the same time. I have seen this done and the fruit and peas eat as well as at spring time.—H. B. E.

[12441.] — **Ants.** — Lay quicklime or powdered camphor down. They will soon beat a hasty retreat.—H. B. E.

[12448.]—**Wall Papers.**—The most healthy way of decorating walls is undoubtedly "distemper;" it is also, to my taste, the most artistic. Any amount of ornament can be put on by this means. The wall can be divided in panels with gilt lines, and various plans of decoration can be seen in any first-class modern house. The danger from wall-paper can be obviated by covering with paper varnish.—E. M.

[12449.]—**Gnats.**—The query of a "Constant Subscriber" is, to say the least, a very modest one, and I therefore waited till the last minute before answering it, thinking that some one would confer a boon on the civilised world by giving us not only a remedy for gnat-bites, but also a "preventative." Well, arnica has been the best remedy in the cases I have seen; but as to a "preventative" the only one I know of is to kill the *female* gnats (the males don't bite). In the mean time let us rejoice that this "horrid" climate has some advantages over the more favoured countries where the mosquito abounds.—Saul Rymea.

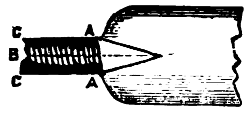
[12451.]—**English Concertina.**—The vibrators which have "gone flat" are probably cracked; if not, scraping or filing the free end will sharpen them. How to get at the inside screws is a doubtful question, for I don't know what "T. W." means. The ends of the instrument can be removed by taking out the screws, when the vibrators will be seen on their frames, slid into grooves in the "soundboard." These slip out easily. I cannot think this is what the querist meant, though.—Saul Rymea.

[12455.]—**Water Supply.**—Apply at the office of the East London Waterworks, Gt. S. Helen's, Bishopsgate-street, for prices, &c. You can obtain their Act by applying to the Queen's printers, or possibly, to Hansard's, Gt. Queen-street, W.C. The water is supposed to be used for domestic purposes only, and if you keep horses, cows, or other animals, or require water for business or garden purposes, you will be charged extra according to the report of the surveyor sent by the company. You can, however, insist on being charged by meter.—Saul Rymea.

[12457.]—**Geometry.**—"E. L. G.'s" answer is imperfect and incorrect. He omits to state that the triangle in which to inscribe the rhombus must be equilateral. In any other triangle his mode of procedure would only produce a rhomboid. He is also incorrect in stating that "P. W. H. J." (p. 546) produces a rhomboid—what is there produced is only a trapezium.—Bobo.

[12504.]—**Sketching from Nature.**—The objection to Wollaston's camera lucida is doubtless, as "A Working B." said, the difficulty of seeing both the image and the pencil at the same time, but not owing to their different distances, which "E. B. H." (p. 570) knows not how to obviate, though it is perfectly easy to do so. All instruments for sketching require that either the object's image be brought to the apparent distance of the paper by a concave lens, or else the paper and pencil magnified and thrown out to the apparent distance of the objects by a convex lens. The concave lens, if used, must be between the landscape and the reflector. The convex one, if used, must be below the reflector, between it and the drawing. In either case, if the solar focal length of lens be a little more than the distance from eye to drawing—or more exactly, if it exceed this distance by the same fraction thereof that this distance is of the object's distance—the eye will focus the two at once. But a lens where "E. B. H." places it, between the eye and instrument, can never be of the slightest use, as it acts on both object and pencil alike, merely making you long-sighted for both or short-sighted for both. The defect of Wollaston's instrument has therefore nothing to do with this matter of focussing, but only with the use of the upper and lower halves of the pupil; one to receive light from the reflector, the other past its edge. This requires a quality of eye that most of us do not possess. I am convinced that no knack or practice can be acquired by the generality of eyes to see in this manner. It is as much a physical endowment as ventriloquism. Amici's modifications of the instrument, therefore (one of which "E. B. H." has figured in p. 570), are really the only ones available for eyes in general, the rays from paper and pencil coming through a parallel glass that at the same time reflects the rays of the object, and both kinds of rays entering the whole pupil at once. But there is no real need for more than this parallel glass, and the lens (concave in front of it, or convex below it), if we are content to trace either a reversed or inverted image. The whole purpose of a second reflection, either in Wollaston's or Amici's forms, either from metallic speculum or within a prism, is merely to get the image at once right-handed and erect—*i.e.*, neither topsy-turvy nor turned right for left. Not finding any necessity for this, I have always used with success a mere fragment of good plate-glass, 1in. by ½in. If there be, in the nature of the scene, a necessity for having the right and left unreversed, you have merely to draw on transparent paper, and turn its back over to finish it. I should observe, however, there is, and always will be, a difficulty in so adjusting the illumination of *white* paper that the pencil thereon and the reflected scene may be well seen at once. The real, and I believe sole, remedy, as I told a querist two years ago, but have never seen stated elsewhere, is to trace with a *white* crayon on a *black* or *dark* surface. Transparent tracing paper may be laid on a black board or slate, and drawn upon with a fine pen or brush and Chinese white (from the bottle undiluted, or rather stiffened with more white). Then turn it over, and retrace the other side with black or colours, finally mounting it on white.—E. L. G.

[12507.]—**Cricket-bat Making.** — Cricket bats should be made from the best seasoned willow which has been kept four or five years. The bat is roughly shaped, much larger than the required size, and kept another year, then the blade or pod is laid in an iron mould, and hammered with a wooden mallet to nearly the required size. The piece is then fixed in a lathe and the handle turned. The bat is then finished by hand and strung in the lathe. The tools used are the paring or draw knife, a spoke shave, and lathe chisels. The bat should on no account be varnished unless on the back,



as otherwise oil cannot soak into the wood. Some bats have cane or willow handles. The cane handles are made of the small cane, ⅜in. diam., to be got at a saddler's, cut square, and glued up, and then turned and strung. These handles are let into the bat as in the accompaning sketch. Two pieces of willow, A A, part of the blade, go a few inches under the string, and sometimes a piece of ash is glued up with the cane as at B, or on the sides, at C C. If this is not clear I shall be glad to give further information.—C. B.

[12515.]—**Mowing Machine.**—"Old Ploughman" is right as to the cause of the sickle bar of "A Countryman's" machine breaking. If the eye of the sickle bar and connecting-rod is worn, rimer them with a square rimer with a taper half round piece of wood at the back, and use hard wood sickle pins; this is how I have treated one of Samuelson's machines.—Hants Farmer.

[12515.]—**Mowing Machine.**—"A Countryman's" machine should have a long roll. This is the cause of breaking, I should imagine.—H. B. E.

[12517.] — **Mathematical Machines and Tables.**—In the *Mechanics' Magazine* for June 16, 1855 (No. 1662, old series), "Tables for Facilitating Addition" are described, by means of which addition, which is certainly the fundamental and also the most tedious operation of arithmetic, may be performed without any machinery and in a manner described by the author as "a mechanical way of making additions as simple as possible, allowing great rapidity of operation, giving results perfectly trustworthy, and requiring no labour of the mind for its application."—C. J. R.

[12518.] — **The Island of Hayti.**—Is "F. S. M. W." sure (p. 571) that the Domingans have been reunited to Spain? They sued for readmission some years ago, but the last I heard was that Queen Isabella's Government refused to have them. They are less purely black than the French-speaking Haytians, but one hears less of them. The Haytians, ever since their independence, faithfully copy the last Paris fashions political, twice a republic, twice an "empire," and now, I suppose, republic for the third time. In the intervals of these changes, they amuse themselves with hitherto fruitless attempts to subjugate their brown co-islanders, of the eastern and flatter half. Such continues the nineteenth century state of the finest land Columbus set foot on; the island second in size, and by universal consent first in richness and natural splendour, of the western world! Glory to thee, O Century!—E. L. G.

[12528.]—**Hay Asthma.**—"Kate" is really entitled to sympathy under this attack. A friend of mine has had it every year for many years, and has tried all kinds of treatment—three years ago he went under homœopathic treatment, and got a little relief from their medicines, the principal of which was "Extract of Hay," but it does not appear to have been lasting, as he has gone back to his old doctor. His latest experience is that he gets the most relief from gentle expectorants, which clear the chest and allow more freedom in breathing.—Johan.

[12528.]—**Hay Asthma.**—I am sorry to see a correspondent, "Lambda," recommend the inhalation of creosote for this complaint. I can assure "Kate" that the use of creosote in any shape or form will inevitably cause violent nervous twitching and even paralysis. But she will find that bathing the chest with vinegar and water every morning, together with the use of Epsom salts and eau-de-cologne, and sea-bathing, will cure the very worst case in a short time if persisted in. I would be glad if "Kate" will communicate the result for the benefit of others similarly afflicted.—Alfred S.

[12529.]—**Improved Machine for Making Aerated Drinks.**—I did not state that the gas for all machines for making aërated drinks was made of sulphuric acid and common whiting. It is in the machine I described, and would appear to be very advantageous from its economy (see reply to "E. L. P. G." last week). The proportions I don't know, but should imagine it would depend on the number of bottles required. No doubt gas for other machines can be made of other compounds. Perhaps "Sodawater" or "L. W. D." can answer this part of the question. I may add full directions are given with the machine for everything. I will forward name of maker on any one advertising address in "ours."—H. B. E.

[12537.]—**Compressing Air.**—On what basis does Dalton's hypothesis or theory rest? The temperatures given appear rather low for the corresponding pressures. I have before me the results of experiments that scarcely seem to bear out Dalton's views. With air-compressing cylinder of 3ft. stroke, area of piston 814·16 square inches, and outer temperature 40° Fahr., 30 strokes per minute for 30 minutes, or 30 × 30 = 900 strokes, each stroke halving the volume and doubling the pressure. That is, the air was allowed to escape at each stroke through a safety-valve, weighted to 15lb. per square inch. At the end of the 30 minutes, when 900 strokes were completed, the temperature of the cylinder was 108° the gain of temperature being 108 − 40 = 68. Second experiment, under similar conditions, except that the escape-valve was weighted to 30lb. per square inch. Result—temperature 158 − 40 = 118° of temperature gained. Third experiment, under similar conditions, excepting that in this the outer temperature was 50°, and safety-valve weighted to 45lb. per square inch. Result—202 − 50 = 152 = the gain of temperature. The safety-valve was now weighted to 58lb. per square inch, and the experiment continued for other 78 minutes, at 26 strokes per minute, further gain of temperature being = 296 − 202 = 94°. An experiment of over two hours' duration, showing the ratio of increase of temperature for every ten minutes, is interesting, commencing at 10.30. Safety-valve weighted to 45lb. per square inch during the whole of the time.

Time.	Registered temperature at cylinder.	Outer. temperature.	Strokes per minute.
10.30	38	38	24
10.40	133	38	24
10.50	166	38	23
11.00	186	38	23
11.10	202	39	24
11.20	214	42	24
11.30	221	40	25
11.40	231	40	26
11.50	237	40	26
12.00	242	41	26
12.10	245	41	26
12.20	250	44	27
12.30	255	44	27
12.32	256	43	27
12.40	256	43	27
12.44	256	42	27

Some portion of this temperature is, no doubt, due to the friction of the piston; but surely not the difference between the above quantities and those given by means of Dalton's formula. I think "E. L. G." forgot to show the work expended in doubling, trebling, &c., the pressures; this is important, as will afterwards be found. Knowing this, and the generation of heat, we shall have secured an important position. I should like "E. L. G.'s" opinion on the resulting temperatures. My object in commencing and sustaining this discussion is merely to elicit the truth, because several querists have lately sought for information about compressed air, but they have asked for too much information at once, more than any one individual can give. By combination, however, and working—*i.e.*, discussing—co-operatively, we can, I think, supply the desired information. I am possessed of the results of very valuable experiments. "E. L. G.," by giving the mathematical parts, and by other correspondents casting in their two mites, we may, I think, secure a general improvement to our knowledge, both theoretical and practical, respecting the use of compressed air as a medium for the transmission of power, and to make this more certain I propose holding that comestary fellow in abeyance, if "E. L. G." will kindly oblige. Our common object is the economical haulage of coal.—Mechanical Equivalent.

[12543.]—**Light Shifting Hoist.**—I beg to thank our editor for his courtesy in inserting my query, and "Sting" and "Vireas" for kindly replying thereto (Aug. 16). Either plan would answer well, but would "Vireas" kindly inform me whether there could not be some better contrivance than pulley blocks, the rope of which would be rather in the way, while a chain, as in Weston's, might knock against and break the bottles? I fancy a modification of the compound wheel and axle with a rotary motion might better suit. It could be inverted, the differential roller being at the bottom, and working in a strap having one or two hooks for lifting. The pulley would then be at the top and inclosed in a strap, the hook of which might be inserted into the eye of the strap D ("Vireas's" diagram). The rope, which would be as it were endless, might, when not in use, be with the roller wound up out of the way. Being no draughtsman, I am unable to give sketch, but "Vireas" will doubtless understand, and will much oblige by aiding me further therein; also, in a mode of dispensing with the trolley as he suggests.—S. Selwyn.

[12551.]—**Picture Framing.**—As the usual way of making cheap frames of German moulding in about ten minutes has not been mentioned, it may be as well to describe it for "Jim's" and others benefit. The tools necessary are a fine-toothed tenon saw, a mitre-block, a mitre-board, a trying plane, a stout vice a light hammer, and a spring bit or two. The saw and plane must be kept very sharp, as the plaster foundation of the moulding speedily takes off the edge, and then the gilding snips off. As most mechanics would know what a mitre-block is, it seems unnecessary to describe it, but the mitre-board may be ... as follows:—Take a piece of board, say 30in. ... 1in., plane up truly, another piece ⅝in. ... thickness of the distance of edge of plan... side of plane, and about 3½in. narrow... board. Nail on securely, now glue on, a... accurately at an angle of 45°, a piece... broad, and as high as the upper edge of t... reaches when the plane is lying upon ... pressing against the straight edge of the ... which is the way it is used, keeping the pl... ing firmly against it with thumb of left h... tried all the ends, catch one in the vi... left hand (this is the most critical pa...

feeling that it is a little higher up than its ultimate position by means of forefinger, bore a small guiding hole with spring-bit, lift up, put a dab of thickish glue on back side (don't cover the whole surface), put in place again, and drive down the spring gently until both mitres correspond (this requires great caution, or the edges will snip off, it must be nicely humoured); other two sides are then done similarly, and lastly, these two are united at opposite corners, which divides any error in the mitreing, if put together continuously the last joints will not coincide.—A., Liverpool.

[12557.]—**Nickel Silver.**—A. H. Allen will find, I think, that contrary to his statement, p. 578, "pure nickel unmixed with other metals" *is* employed, for coinage, and makes the hardest and fittest material yet applied thereto. The Belgian sous are the example nearest to hand; and as they nearly balance two of our groats, the nickel seems to pass for about a fifteenth its weight of silver, making a far more convenient small currency than bronze. Its yellowish tint, closely resembling platinum, will not allow it to be mistaken for silver.—E. L. G.

[12558.]—**Boot and Shoe Making.**—I fancy that "Irish Mechanic's" shoemaker cannot be up to the mark in his trade. He can put in as many fittings as he likes on the toe of the last, without fastening them to it. The last would then come out as easily as possible, and the fittings be taken out with the hand afterwards. As the greatest room is required about the joint of the great toe, these fittings should be pitched in from the toe of the boot when lasting, and not from the top as usual.—J. ROBERTS.

[12568.]—**Smoke and Light.**—If there were any kind of smoke or translucent body that presented the same colour when seen against a dark background and when intercepting light, this would be a truly difficult phenomenon to explain. The general rule is that they reflect one part of the spectrum and transmit the rest, consequently the opposite tint to that which they reflect. The atmosphere at large acts in this way very like tobacco smoke, and renders the sun's transmitted rays more and more orange-coloured, the greater thickness of air they traverse, for the very same reason that it makes distant dark objects more and more blue, and the sky bluest of all. Many liquids and even solids—as opal-glass (made milky by bone-ash or phosphate of lime) and the commoner kinds of real opal—do the same. It is *most natural* for whatever tinges transmitted light yellow or brown to appear before a black background gray or blue.—E. L. G.

[12571.]—**Brake for Bicycle with India-rubber Tires.**—Mr. Shaw will find that the roller has not the same disadvantage as the block brake, presenting as it does a round or curved face instead of an edged or angled surface to the rubber tire. It, therefore, does not bite or wear it away by resting on any particular part, but causes the frictional resistance by merely rolling against the tire. If he thinks, however, that it wears it away he may make the roller revolve horizontally, touching the side of the felloe when brought into action by a lever, handle, or other arrangement. To prevent the wheel wobbling or getting out of position, by using this kind of brake at one side of the wheel, Mr. Shaw can employ a double-action brake. This may consist of two iron rods pivoted in the centre like a pair of scissors, the pivot standing upright behind the saddle in the spring or framework supporting it. Two small wooden rollers, a couple of inches in diameter, are fixed in forked bearings in the ends of the crossed levers. These are the brakes, and to bring them into action the arms, or front parts of the levers, are put farther apart, which may be done by the arms of the rider, or a slight inclination of the body backwards. As either kind of brake may be objectionable, a hoop or spring brake may be employed as in horse-rakes and agricultural machines. It consists of a hoop of thin iron or steel passed round a fixed pulley on the axle, the ends of the hoop being fastened to a hand lever, but a small pedal will do in this instance for a light bicycle. A ground-slide attached to a lever can also be used, and brought in contact by the action of the hands or feet, or simple inclination of the body; or a curved flat rod of steel can be attached underneath the saddle, hanging a small wheel or roller a few inches from the ground in forked bearings. To employ the brake the steel is straightened by the pressure of the feet on an iron pin passed through the rod at a convenient distance from the bottom. A coiled spring, as in the "Phantom-wheeled" bicycle, may be placed underneath the rod supporting the handle, elevating it a few inches. By pressing down the handle a small roller-brake, attached to a rod underneath and fastened in a race or groove to the axle bearings, is brought in contact with the ground. In this last arrangement the position of the hands or feet need not be changed; or the handle may be cranked, having connecting rods with the crank pins of the front wheel, and the power of the hands may be thus brought to bear either in propelling the bicycle, which can be turned as readily as before, or in stop- its motion.—RAT-TAT.

[1]2595.]—**Boat Building.**—Having been out of I could not reply to this sooner, and beg to inform . D." that I do not know of any practical work boat building; also that I am not a ship or boat r by trade, but have built several boats, and will py to give any information in my power. Lee I have only met with upon Dutch galliots, and that from their small size, compared to the of the vessel, they can be of much utility. keels I have seen at New York, but have understood that the quantity of seaweed which lates upon them renders them undesirable in these waters. A sliding keel is contained in a watertight case, carried up, as I presume, from one side of the keel to level of gunwale, and could not be applied to a small boat, as there would not be room to move in her. In order to build a boat about 14ft. keel, erect keel, stem, sternpost and sternboard as described by me in reply 12397. The rebate is to be made as much as convenient with a plough plane, near ends worked up with a chisel after the stem and sternpost are half checked and riveted together. Note: Rivet copper nails wherever possible, as they don't hold well without; use a very light hammer, they are very bad to drive straight or to rivet unless previously hardened by hammering upon an anvil. The keel, stem, and sternpost ought to be two inches thick, as the rebate on each side weakens them so much; it is also advisable to put an elbow or knee piece at each end inside to strengthen the junction of stem and sternpost with keel. Erect the frame as described in 12912, and satisfy yourself that it is the shape you wish the boat to be in the widest part. Note: I began with the tongs as described by "H., Belfast" (reply 12397), but found that the clamp (which I believe is used by bookbinders), is much more convenient to use in adjusting the various boards. It is made thus: Two pieces of ash about 16in. × 2in. × 1¼in., with two wood screws about eight inches long, acting upon opposite sides, leaving the jaws about six inches long at one end, and close to the other end, the screws to be about one inch diameter. The garboard strake I used was American oak soaked for a couple of days in a pond to prevent splitting, as I required a flat floor. This was in one piece from end to end, all other strakes were scarfed, the scarf to be the length of the breadth of strake, and white lead applied when riveting up. Prime each part as you proceed. It will be necessary now to form some idea as to the relative breadth of the strakes at the widest part, and at the stem and stern, as this is influenced by the breadth of the boat, and be particular that each strake lies up close to the guiding frame, by bevilling off the edge of the one it overlaps, or the boat will become much wider than intended. In another letter I will give some more particulars as to steaming, &c.—A., Liverpool.

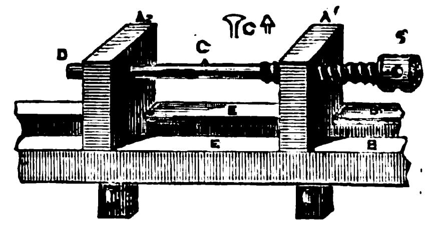
[12596.]—**Canoe.**—As to the safety of canoeing from Hull to Scarborough, it depends on three things—viz., the weather, the craft, and the man in it. Now, the first we presume is settled, as it is not to be imagined any one would be insane enough to attempt such a cruise unless the day was both calm and clear, with a prospect of its continuing so. Then, as to the second—viz., the canoe—I would recommend the *Nautilus* type, the features of which are: good beam, very flat floor, and good sheer and camber. The dimensions of the craft I would prefer for the purpose would be as follows: Length, 16ft.; beam, 28in.; height amidships, 18in.; height at bow, 20in.; at stern, 18in.; camber of keel, 2in., with watertight compartments at bow and stern, and the well with a timber hatch instead of an apron. The great sheer is given to prevent diving into the seas, and is, I think, necessary for any sea going canoe. Now, thirdly, as to the man. I think, from "Paddler's" query, he has not been to sea before in a canoe, and he admits never having tried a sail; then my advice would be not to commence canoe sailing in a sea cruise. Every one that can sail a boat knows it requires practice and skill to do it properly and with safety, and every one that can sail a canoe knows it is more difficult to sail than a boat, and much more dangerous; and again, every canoeist that has sailed a canoe in lumpy water knows the dangerous propensity of the craft to dive when running before the wind with sails, and the difficulty of managing it properly. Canoes of the *Rob Roy* type are not fitted for sea work; and though I cruised for miles along the south coast of Ireland in one of the *Rob Roy's* dimensions, only built of spruce, fir, and canvas-decked, it was simply foolhardiness. From this, "Paddler" can see I would be inclined to dissuade him from the attempt; but if he *will* go, I shall be happy to give him any more information in my power.—CANOEIST.

[12599.]—**Dimensions of Mail Boats.**—I abridge the following from "Recent Improvements in the Steam-engine," by Bourne, page 139:—"The example of modern engines by these makers that I shall select is the oscillating paddle engines of the Holyhead steamers *Ulster* and *Munster*, for although I might have selected a more recent example, I could not have selected a more perfect one, &c. These vessels are each 328ft. long, with 35ft. breadth of beam, 21ft. depth of hold, and they each measure about 2,000 tons, builder's measurement. Each vessel is propelled by two oscillating engines of 96in. diameter of cylinder, and 7ft. stroke; the pressure of steam in the boiler is 26lb. per square inch. The nominal power of each pair of engines by the Admiralty rule is 750 horses. They make 23 strokes per minute, and they work up to 4,100 actual or indicated horses' power. The draught of water when ready for sea and complete with stores and 75 ton of coals was, forward 13ft., and aft 13ft. 4in. The paddle wheels are feathering 33ft. 9in. in diameter to the inner edge of the outer ring. These vessels, and two similar vessels, the *Leinster* and *Connaught*, the engines of which were constructed by Messrs. Ravenhill, Salkeld, and Co., have realised a speed of upwards of 20 miles an hour, and an average speed in all weathers during the first six winter months of 18 miles an hour." Further information, principally about boilers, &c., if required.—PHILANTHROPIST.

[12602.]—**Extinction of Fires.**—I have made no experiments on the subject; but reasoning from analogy, I should be inclined to give the preference to carbonic acid. As to employment of some salt which would generate an uninflammable and fire-extinguishing gas, I believe a strong solution of bicarbonate of ammonia would be of great service, if it could be produced at a sufficiently low price.—S. BOTTONE.

[12603.]—**Acoustics.**—In "Tyndall on Sound," I read:—"We have now to examine how sonorous motion is produced and propagated. When a flame is applied to this small collodion balloon, which contains a mixture of oxygen and hydrogen, the gases explode, and every ear in the room is conscious of a shock, to which the name of sound is given. How was this shock transmitted from the balloon to your organs of hearing? Have the exploding gases shot the air-particles against the auditory nerves as a gun shoots a ball against a target? No doubt, in the neighbourhood of the balloon, there is to some extent a propulsion of particles; but air shooting through air comes speedily to rest, and no particle of air from the vicinity of the balloon reached the ear of any one present. The process was this:—When the flame touched the mixed gases they combined chemically, and their union was accompanied by the development of intense heat. The air at this hot focus expanded suddenly, forcing the surrounding air violently away on all sides. This motion of the air close to the balloon was rapidly imparted to that a little further off, the air first set in motion coming at the same time to rest. The air, at a little distance, passed its motion on to the air at a greater distance, and came also in its turn to rest. Thus each shell of air, if I may use the term, surrounding the balloon, took up the motion of the shell next preceding, and transmitted it to the next succeeding shell, the motion being thus propagated as a pulse or wave through the air."—W. M. COLLES.

[12608.] — **Bookbinder's Press.**—There surely must be some mistake, or "Dublin Subscriber's" men must be phantoms; he must mean a 8½in. screw. If he has a lathe, let him fit up two heads of wood according to sketch, and he will make what was formerly hard work easy. AA are two head-stocks; S is a hard wood screw the same as you are going to cut; it screws into



A 1, and is plain in A 2; C is a cutter which is made the shape of thread. Now, if the cutter is made to work out and in, and the block bored and bolted upon the lathe bed at EE, with the hole in a line with S and D, when you put the screw into A 1, and screw it through, it is evident that it must cut a thread in the piece at EE; you may afterwards finish with the tap.—JACK OF ALL TRADES.

[12609.] — **Packing Grapes.**—The mode universally adopted in Italy is to divide an egg-box into little compartments about 6in. square (with thin wooden partitions). In each compartment place one or two bunches of grapes according to their size. Now fill in each compartment with fine old sawdust or linseed. The grapes must not be over ripe.—S. BOTTONE.

[12612.]—**Action of Oil on Waves.**—If you place a piece of silk cloth upon a polished table, and press the table obliquely with your finger, the cloth yields, and glides over the table, which is thus in a great measure relieved of the effect of the push. So also when water is covered with a layer of oil which does not cling to it, the oil acted upon by the wind glides over the surface of the water, and thus lessens the action of the wind upon the surface. It is true, oil cannot level down the larger waves when they have been once formed, but the sides of large waves are always ridged and furrowed by smaller ones, which render the large ones rough, and thus enables the wind to act upon them with greater power. The oil hinders the formation of these smaller ones, and by thus lessening the friction, diminishes the effect of the wind. Graham Young can experiment for himself by going on a windy day and pouring a little oil on the windward side of a pond.—VIRCAS.

[12613.]—**Drying by Steam.**—I think if T. King uses steam of a high temperature he will never finish mending joints if made with indiarubber washers. By far the best material for such joints is Charlton's vulcan cement, which is obtained in a powder and mixed with boiled oil and a little spun yarn cut fine; it must be mixed just before using; if this joint is well made, not too thick and well screwed up, there is nothing to beat it for standing heat. I would recommend T. King, if possible, to have his flanges planed, and to make his joints as thin as possible, and not to have his cement too stiff. In making the joints with planed flanges a piece of twine similar to that used by railmakers should be laid round the flange inside the bolt holes and bedded in the cement. Red and white lead is the next best thing, but vulcan cement will stand any heat, and if T. King has many joints I should advise him to get a small cask of this cement from the manufacturers.—VIRCAS.

[12614.]—**Corpulence.**—Get "Banting on Corpulence," a good work on the subject. The book, with others of its class, is published by booksellers in Paternoster-row, London, price 1s. In many people the physical organisation prevents them from growing stout. Those who are loose in frame and the bones are not, as the saying is, packed closely, are inclined to be corpulent. Others, again, from trying to grow stout, generate fat on the liver, which is the most susceptible to obesity in delicate constitutions. As the querist is an "Anti-Banting," he must have heard or read of the book recommended, but the work may be useful to others. Let "Anti-Banting" try another. There are several pamphlets on the subject.—Rat-Tat.

[12614.]—**Corpulence.**—No procedure will enable you to acquire bulk that does not aim at promoting the general health of the system—at improving the tone of the digestive apparatus and establishing a healthy state of the blood; disordered digestion will result in defective nutrition, by causing a deficiency in quantity or quality of the chyle, and an unhealthy state of the blood may be the immediate cause of defective nutrition by interfering with a certain nice adaptation existing in healthy nutrition between the blood and the tissues. It is no precise regimen that I would lay you down:—Common sense and experience will teach you what is best adapted for you. The ordinary every-day diet is adequate, but avoid excesses in tea or coffee. I beg to submit a few directions, all of which aim at promoting the general health, and which, I believe, will serve your end:—Take regular and general but not fatiguing exercise; it is well known that inactivity of a limb invariably leads to its attenuation. Walking is the best exercise; it calls into play more muscles than any other. Fresh air is positively necessary, that your blood may be in a healthy condition. Let your walking be in the country as much as possible, and I would suggest early morning. It is not so much the kind of food, as that you masticate it well. Never hurry over a meal—no "bolting." Eat when you are hungry, and not because it is meal hour; you are certain to derange digestion if you impose work upon your digestive organs when they make no call by hunger. Take very light suppers, if any. If you obey these directions, you will seldom have a disturbed night's rest; sound sleep being all important in the process of "bulking." Drink a tumbler of cold water each morning on rising, in sips; it will prove an efficient tonic for your stomach. Avoid constipated bowels; regulate by enema rather than by drugs. Sponge your body each morning with cold water, and rub with a coarse towel. Avoid excessive smoking; it enfeebles digestion, and the spitting accompanying it proves a great draught upon the system. Thus you may invigorate your system and facilitate nutrition.—Ventricosus.

[12621.]—**Black Dye for Leather.**—If "R. M." does not wish to dye leather on a large scale, the following is best plan: 1d. worth of potash to one pint of warm water, let it dissolve, then brush the leather over with the solution; when nearly dry, sponge over with writing-ink, when it will be a good and permanent black. If on a large scale I can send recipe for black dye.—Saddler, Kendal.

[12628.]—**Lampblack.**—I cannot say the quantity of tar, pitch, &c., required for one ton of lampblack, but any one can see that it is a profitable business, though not a very enviable one. The accompanying sketch will easily be understood. The tar, &c., is burnt

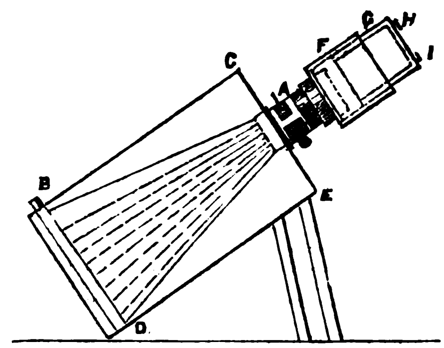
in the iron furnace, and the dense smoke passes into the chamber, which is lined with either sacking or sheepskins. The interior is swept from time to time and sold without any further preparation. The hollow cone of sheet iron inside has a small hole in the top to allow the smoke to escape slowly after it has deposited the greater part of its carbon; by raising and lowering the cone it scrapes the sides of the canvas or leather, and detaches the lampblack.—Saddler, Kendal.

[12634.]—**Photography.** — "Art Photo." had better try the "Collodio-Chloride Process," which gives splendid results on either opal glass or porcelain. For full particulars of the process refer to a manual, to be procured of the publishers of the *Photographic News*.—Photo. Bristoliensis.

[12634.]—**Photography.**—One very good plan to produce photographs on opal glass, or porcelain, is to take a transparency in the camera. This admits of altering the size of the picture, and I have found it to give very fine results. Of course, a plate of opal glass or porcelain must be used for taking the picture on instead of the ordinary glass. If the picture wanted is to be the same size as the negative it can be done without the camera. The prepared plate is placed behind the negative in a printing frame, as a piece of paper would be if wanted to print the picture on it. The plates, however, must be kept from touching, or the surface will be spoiled. A small slip of folded paper placed at each end will do this if the pressure of the springs is light. I don't bother with a frame, but hold the plates together at the ends with my fingers. Care must be taken that all the light falling on the negative comes at a right angle to it, or the picture will not be sharp, as the two surfaces are not in contact. I find that standing about 6ft. back from a window, and keeping the plate perpendicular, is a good plan. If artificial light is used, the plate should be held about 1ft. from it for a small negative, and farther for a large one. There is also the collodio-chloride process for getting a picture on opal glass, which gives very fine results. I think that a carbon print transferred to a porcelain or opal plate, would have a very fine effect, and would probably take colour well. I have never tried either of the two last methods, nor do I know anything about colouring them; at least, not practically, and therefore cannot write from experience.—Occasional Photo.

[12634.]—**Photography.**—Take a smooth sheet of opal glass, coat it in the ordinary "albumen process" mode. When dry, place a negative in contact, and expose for a few seconds to diffused daylight. Develop the image by gallo-nitrate, fix, and if desired tone in gold; varnish. Any of the dry collodion processes may be used instead of the albumen. I can give no information with regard to colouring.—S. Bottone.

[12636.]—**Enlarging Photographs.**—The inclosed sketch will show "Industrious Will" my method of enlarging photographs from small negatives. A is an ordinary ¼-plate portrait lens, which is affixed in a long bodied camera B C D E, taking a 10in. × 8in. plate in the dark slide at B D. On the hood of the lens A is fitted a square deal box F, in which slides a slightly smaller box G, blackened inside with lampblack; H and I are two small catches holding the negative to be enlarged with the film side towards the lens. On pointing the camera to a clear sky, an enlarged image of the negative will be thrown upon the focussing screen at B D, the size and sharpness of the image being regulated by sliding the inner box backwards or forwards as required. A collodion plate 6in. × 5in. is now prepared in the ordinary way and inserted in the dark slide; the negative at H I is now covered with a dark



cloth, whilst the dark slide is placed in the camera, and the shutter raised. Expose by removing the dark cloth for the time required, which may vary from thirty seconds to fifteen minutes, according to the intensity of the light, density of the negative, and state of the chemicals, but be careful not to under expose, rather go wrong on the side of over exposure. Develop with ordinary protosulphate of iron, as for negatives, but do not intensify. The resulting picture, is, of course, a transparency; to procure an enlarged negative the 6in. × 5in. transparency is placed in the box G, in the same way as the original small negative, and the operation repeated, this time enlarging to the full size of 10in. by 8in.; the resulting picture being a negative, which, if the operations have been properly conducted, should be equal in sharpness to the original small picture. Great cleanliness is, of course, indispensable, as every spot and speck is, of course, enlarged tenfold. —Photo Bristoliensis.

[12638.]—**Fleas in Dogs.**—Refer to Vol. XIII., No. 328, p. 387.—N. O.

[12639.]—**Worms in Pony.**—An old man near me often came and begged "box" from my garden for this purpose, telling me that he chopped it up and mixed with the food. The man is now dead, or I would have made particular inquiries, and been fully satisfied.—Benenoke.

[12642.]—**Ice Creams.**—Various ingredients are used as well as refrigerators, the most general consist of milk thickened with some ingredients, and flavoured with some of the essences. The freezing apparatus consists of two pewter cylinders and a bucket when ice can be got; ice and salt are used in the outer bucket, and a freezing mixture of sal-ammoniac and soda between the cylinders. The smaller one is furnished with a piston that fits slack, and is worked up and down by this. The thin film of ice is thrust down to the bottom, and continues accumulating until all is frozen. If wanted solid it must remain a few minutes after it feels firm under the piston, otherwise it is like finely divided snow. Whether there is any improvement upon this I know not.—Jack of All Trades.

[12643.]—**Dictionary of Scientific Terms.**—There is a book published by Lockwood and Co., in Weales' Series, called "A Dictionary of Technical Terms used in Civil and Naval Architecture, Building and Construction, Early and Ecclesiastical Art, Civil and Mechanical Engineering, the Fine Arts, Mining, Surveying, &c." to which are added explanatory observations on various subjects connected with applied art and science, price 4s.—Vircas.

[12643.]—**Dictionary of Scientific Terms.**—Buchanan's "Technological Dictionary" is a useful book, and will probably suit "Plough-Driver." Having reached the shady side of fifty, I find its small type a disadvantage.—R. S.

[12643.]—**Dictionary of Scientific Terms.**—Simmonds' "Dictionary of Trade Products and Technical Terms," Routledge and Co., is the most recent, cheap, and portable work of reference.—P. L. Simmonds.

[12645.]—**Utilising Old Paper.**—The process of moving ink from printed paper and working it into pulp has been in operation some ten or twelve years, and R. Lambert (the inventor's) process was adopted, I think, by Bradbury & Evans, at the Kennet Paper Mills. I do not know if it is still worked at the Sheffield Mill, Theale, near Reading.—P. L. Simmonds.

[12646.]—**Alcohol.**—If methylated spirit be distilled, the shellac or other resinous matter which it contains remains in the retort. If it be necessary to obtain a spirit richer in alcohol, redistil this with lime. I consider that good methylated spirit redistilled will give a product pure enough for "J. A's" purpose.—Analyst.

[12646.]—**Alcohol.**—Put it into a still and draw over two-thirds.—Jack of All Trades.

[12648.]—**Moisture on Tin Surface.**—The phenomenon which "Tintub" has observed is most easily explained. Water is one of the products of the combustion of coal-gas, arising from the hydrogen which it contains. This vapour of water is, of course, condensed when a cool surface is exposed to the heated gases produced by that combustion, and remains there until the heat is sufficient to re-volatilise it.—Analyst.

[12648.]—**Moisture on Tin Surface.**—In the process of combustion, the hydrogen and oxygen of the atmosphere combine and form water, which, in the shape of vapour, is condensed by coming in contact with your cold tank.—Jack of All Trades.

[12648.]—**Moisture on Tin Surface.**—The cause of the water forming on the bottom of "Tintub's" tin cistern is due to the condensation of water vapour formed by the combustion of the hydrogen of the gas flame in contact with the oxygen of the atmosphere, which condenses on the cold surface, water always being formed when hydrogen or coal-gas is burned in air. I found that in 1869 the quantity of water produced by the burning of coal-gas, in Ramsgate, amounted to 16 tons 19cwt.—A. J. Jarman.

[12648.]—**Moisture on Tin Surface.**—The gas, in burning, generates water, its escaping gases are therefore a mixture of nitrogen, carbonic acid, and steam, and the latter is condensed on the cold surface. There is no contradiction to "acknowledged theory," but perfect accordance therewith.—Sigma.

[12649.]—**Kites.**—In kite making the shape of the kite, although the usual one always flies best, is not material, so long as it is light, evenly balanced, and lies at the right angle to the wind. In obtaining and preserving this angle lies the whole art of the kite-flier, and to this end he depends principally on the tail, the best form of which is a string of three or four small conical bags (more or less, according to their size, and also according to strength of wind, which experience will show). The bottom of one tied to the mouth of the other some 6ft. or 8ft. apart. The mouths of the bags are kept open by a piece of split cane made into a hoop, and sewn into the calico or other material of which the bags may be made. For general use and weather I make the tail in about these proportions:—For a 6ft. kite of the common form I should have the first bag of the tail—*i.e.*, the one nearest the kite (and that should be some 8ft. away) about 7in. in diameter at the mouth and 10in. deep to the point, and three others at intervals of 8ft. of string, of diameters gradually reduced, so that the last should be only about 2in. in diameter. With this tail no running is required to raise the kite, it will go up, as it were, of itself in a straight breeze, that is to say, away from the influence of trees or houses, by merely pulling the string with a slight jerk, about thirty or forty yards out and away from the kite, which has been laid with its face on the ground and with the tail clear.—Q. Yorke.

[12653.]—**Poultry Keeping.**—Bring electricity to bear upon this, which may be done very simply and very effectually.—Jack of All Trades.

[12655.]—**Core Box.**—The interior of your box must be made the same shape as you require your steam ways, allowing extra length to fit the prints upon your pattern, that the core can be properly supported.—Jack of All Trades.

[12656.]—**Photographic.**—Transparencies for the magic lantern may be toned to a rich black colour by flowing over the surface of the film a solution of chloride of gold of the strength of 1gr. of gold to 1oz. of water, or by immersion in a 5gr. bath of bichloride of mercury, followed by a solution of ammonia 3 minims to the ounce of water. The former method will be found the better of the two, giving greater delicacy than the latter, which is apt to cause harshness. Transparencies should, if developed with a suitable developer, require neither toning or intensifying. If "Kent" will make a solution of protosulphate of iron 15gr., citric acid 8gr., water 1oz., and use the mixture to develop his transparencies, he will obtain a rich black colour, without any after toning.—Photo Bristoliensis.

[12656.]—**Photographic.** —Print from a thin negative. Do not expose too long under the negative;

develop with pyrogallic acid only, not with sulphate of iron. By these means you will generally get your outlines black enough. Should this not be sufficient, tone with gold.—S. BOTTONE.

[12657.] — Cutting Cylindrical Glass as Bottles and Chimneys.—Take a fine file and nick it all round; afterwards take a long tobacco-pipe, make it red hot, and follow it round carefully, and the glass will drop off.—JACK OF ALL TRADES.

[12657.]—Cutting Cylindrical Glass as Bottles and Chimneys.—W. Pike may cut the above easily without a diamond; let him take a worsted thread and wind two or three; ply a little (say ½in.) beyond the part he wants it cut at, let the thread be thoroughly soaked in water, then let the edge of the flame of a clear gas-burner strike it as close as he can to the thread, turning it all the while, and it will soon fall in two. Should the thread get dry or very hot, wet afresh. I have cut a quart bottle by such a process very neatly.—W. D. T.

[12657.] — Cutting Cylindrical Glass as Bottles and Chimneys.—W. Pike may cut his bottle in the following way: Get a piece of round rod-iron pointed at one end, just long enough to handle conveniently; heat the pointed end to redness (not whiteness), lay it on his bottle where he wants to cut it, and in a second or two he will hear a sound which indicates that his cut, or rather crack, has commenced. Now draw the iron on slowly, and he will find the crack follow after in whatever direction he wishes; repeat the heating process when necessary. He will find it best to make a small "nick" with a file wetted with saliva before applying the heated iron.—OPTICAL BRICKLAYER.

[12659.]—Water Pressure.—If your supply-pipe from the meter is to be of a certain diameter only, of course put that size pipe in, say it is a 4in. Common sense will tell you more than the full of it cannot come through it, but you can increase the rapidity of the flow greatly by enlarging the bore after leaving the meter, and, therefore, get a greater discharge in a given time. After a few yards of the 4in. pipe, continue through a 6in., and your best result will be obtained.—M. A. B.

[12659.]—Water Pressure.—Make your entrance or feed trumpet-mouthed, never mind the rest, as long as your pipe is the full size of meter.—JACK OF ALL TRADES.

[12659.]—Water Pressure.—I should think you would find it best to commence with the smallest pipes, as water would evidently pass through a large pipe with more facility than a small one; you would, therefore, have the resistance lessened every mile, so that if it was able to pass through the first mile satisfactorily, I should think it would be certain to do so in the others.—R. D. D. M.

[12660.]—Aerated Bread Making Machine.—You could not use the machine otherwise than for generating the liquor for wetting. You would want a trough and mixer.—JACK OF ALL TRADES.

[12664.]—To Stereotype Brass Blocks.—Are they some blocks you want to get some copies of, or do you want to cast them in brass, the same as stereotypes are done ?—JACK OF ALL TRADES.

[12665.]—Sea Sickness.—A cure is said to have been discovered by Dr. Landerer, a medical man at Athens. His remedy is to give from ten to twelve drops of chloroform in water. The chloroform in most cases removes nausea, and persons who have taken the remedy soon become able to stand up, and get accustomed to the movement of the vessel. Should the sickness return a fresh dose is to be taken. It was tried on twenty passengers on a very rough voyage from Zoa to Athens, and all, with the exception of two, were cured by one dose. The minority, two ladies, were able to resist the feeling of illness on taking a second dose.—SAMARANG.

[12665.]—Sea Sickness.—Twenty drops of chloric ether in a little water taken when commencing the voyage has been found efficacious.—S.

[12665.]—Sea Sickness.—Keep on deck. Should you feel any nausea, lay flat down, as near the centre of the deck as possible, and fix your eyes and attention on a book, that shuts out from your sight the view of the moving spars, &c. Before going on board, neither starve nor gorge yourself. Avoid fat food, and do not drink brandy.—S. BOTTONE.

[12666.]—Works on Artillery. — Emerson's "Story of the Guns" is worth reading, although not a very technical book.—PHILANTHROPIST.

[12668.]—Auburn Hair.—I do not think it impossible to turn dark hair into an auburn shade, but I have produced fine auburn shades in hair of a middle tint, by means of strong nitric acid. Care must be taken not to dip the hair for too great a length of time. I believe that this is the active ingredient in the "golden" dyes.—ANALYST.

[12669.]—Lottery Laws.—Read the following Acts of Parliament:—17 Geo. II., chap. 5; 42 Geo. III., chap. 119; 5 Geo. IV., chap. 83.—WILLIAM H. HEY.

[12670.]—Engine-Turned Seals.—Take equal parts of nitric acid and water, and turning the face upwards pour some upon it. When it has been on for a few seconds well rinse it in clean water. This process takes the burrs off; to prevent it getting black have it gilded.—JACK OF ALL TRADES.

[12671.]—Dressing Jack Line.—Take a small portion of turps, in which dissolve a small portion of camphor, mix this with six or seven times its bulk of raw linseed oil, and straining your line, dress it. A line dressed any way is not so strong afterwards.—JACK OF ALL TRADES.

[12671.]—Dressing Jack Line.—Make a coil of your line, tie in three or four places with thread. Dissolve half a pound of best glue in water, half a pint in a pipkin. When dissolved, boil your coil of line in it for half an hour, remove it, and dry it on grass, uncoiling it. When dry (4 to 6 hours), recoil it and boil for an hour in a solution of half a pound of terra japonica (catechu) in a pint of water. Hang it up to cool for half an hour, well wash it in clean cold water, dry, and stretch.—M. A. B.

[12672.]—Grove's Cell.—The best way to construct a Grove's cell is to have two platinum plates in a porcelain flat cell, and a single zinc plate in a porous cell, also flat, clamped in the same manner as a Smee. Sulphuric acid 1 part to 8 of water, to be used in the porous cell; and concentrated nitric acid 6 parts to 1 of concentrated sulphuric acid for the outer cell, the platinum plates being immersed in this. Although the arrangement is very costly in the first place, it is the cheapest in working, as the whole of the zinc is consumed without waste. The zinc should be well amalgamated.—A. J. JARMAN, Ramsgate.

[12674.]—Plant Boxes.—The colours are probably glazed tiles. May be got at any pottery and set in wood.—C. B.

[12674.]—Plant Boxes.—I have some pretty ones in my windows, which were made by nailing pieces of oil-cloth of suitable designs on to the wood work for centres, and putting a wooden moulding round the margins, the latter painted any colour to suit the patterns they inclosed.—T. H.

[12675.]—Hay.—This plan, I think, would prove a failure, inasmuch as I do not believe that it is possible to get one drop of juice from a ton of hay, however great the pressure applied.—JACK OF ALL TRADES.

[12675.]—Hay.—The best process is a very simple one for hay, grain, &c., and would often pay well. It only requires a chamber with perforated floor and a fan to draw warm air through the mass.—SIGMA.

[12676.] — Book-Keeping.—The value of the machinery should be put to the credit side of the capital account. It should also appear in the stock account, this account shews what you possess.—PHILANTHROPIST.

[12678.]—The Bluecoat School. — "Tawse" should get a list of governors who have presentations for the current year. This can be obtained at the counting-house of the hospital, I think for 6d. He should then write to any one or two of the governors whose names he may know, stating his circumstances. If he has any friend who can interest himself with a governor his chance would be easier. Boys are received from 7 to 11 years of age. The examination for entrance at 7—8, the Gospels, read any elementary book, write legibly, say the multiplication table. 9—10, ditto as above, spell fairly from dictation, work the four simple rules of arithmetic. 10—11, ditto as above, and fair knowledge of the compound rules of arithmetic, and the Latin Accidence.—AN OLD BLUE.

[12679.]—Papier Mache.—Is no more than old paper reduced to a pulp, or paper pulp mixed with paste and pressed into a mould, it is then dried and stoved, treated to lacquer or a solution of asphalte and stoved again, then dressed off smooth, lacquered again or japanned as the case may be, according to what the articles are.—JACK OF ALL TRADES.

[12680.]—Darkening Graduations on Scales. —Try Brunswick black. Rub quickly over the divisions, wipe off excess with clean soft rag.—S. BOTTONE.

[12681.] — Is the Interior of the Globe Vacuum ?—This was rather fully discussed in No. 167, Vol. VII., "Seven Fundamental Errors in Geology," which "Balcairn" will find worth answering before he proceeds further.—E. L. G.

[12682.]—Evaporation of Water.—The rate of evaporation increases rapidly with the temperature, it varies as the surface; other circumstances, such as temperature, being the same. Increased pressure diminishes evaporation, and *vice versâ*.—PHILANTHROPIST.

[12682.]—Evaporation of Water.—In proportion to surface, not bulk. Increased pressure would lessen the evaporation.—CERVUS.

[12685.]—Garden Models.—Instead of the man turning the grindstone the grindstone turns him. A small windmill might be attached to the shaft of the grindstone, and be concealed from view in some manner. The figures may be made of light wood painted. A weight might be used instead of the windmill, but the mechanism would not be so simple. A spiral of paper placed on an axis some distance over a lamp rotates, and might be connected with a figure. I saw this in Canada.—PHILANTHROPIST.

[12686.] — Gravel for Aquarium. — I have always found simple washing in cold water amply sufficient to remove all impurities deleterious to fish from gravel. I do not think the salt would be in sufficient quantity to injure the fish unless a very large quantity of gravel in proportion to the size of the aquarium was used. I make it a rule to have as little gravel, rock-work, &c.—and, therefore, as much water—as possible in my aquariums.—LOACH.

[12686.]—Gravel for Aquarium.— Boil the gravel well two or three times.—V., Cambridge.

[12687.]—Marking Ink.—If the ink marks turn brown your remedy is to damp the part, and smooth it over with a hot iron, they will then be black.—BALCAIRN.

[12688.]—Training for Bicycle Races.—Let "R. M. D." run a mile daily on a good road, noticing each time how long it takes, in this way he will soon be able to perform the distance in a very short space of time, and will, therefore, stand a fair chance in any bicycle race that takes place.—E. B. SHAW.

[12689.]—Horses' Hoofs.—Oil the hoofs occasionally with neatsfoot oil (to be obtained at the saddlers). Some people stop the hoofs at night with salt mud from the sea shore, or simply wash them in brine. Having tried both plans I think the oil is much to be preferred.—SHYLOCK.

[12689.]—Horses' Hoofs.—Try painting them over the outside with treacle, and packing the bottoms with cow-dung and treacle when put up at night.—JACK OF ALL TRADES.

[12689.]—Horses' Hoofs.—The easiest and best remedy "W. H. K." can apply to his carriage-horse is to get his saddler to make large horse-boots, and fill them each evening with fresh cow-dung (some use large sponges inside boots, wet with water or tar-water), but cow-dung is best; in a short time the hoofs will get in proper order; there are other sorts of coverings for hoofs which have sand-cracks.—SADDLER, Kendal.

[12689.]—Horses' Hoofs.—If "W. H. K." will take of Stockholm tar two parts, and white tallow one part, put it in an old saucepan or ladle, boil it gently together, let it go cold, then apply it to the hoofs two or three times per day with a brush, I think he will find the hoofs in a short time all that he requires. Have the horse shod with a stiff shoe.—ONE WHO HAS BEEN TROUBLED WITH THE SAME THING.

[12690.] — Fire Marks on Silver Goods. — "J. J. N." may easily remove the marks he complains of by well rubbing and brushing the article with strong liquid ammonia, if this will not remove them dip the article into a boiling hot solution of cyanide of potassium, 1oz. cyanide to 1qrt. water, to be made hot in a porcelain basin (never use a metal saucepan) rub the article also with the solution with a brush (never dip the hands into it); this done, well wash the article, dry, burnish, and polish in the usual way.—A. J. JARMAN.

[12690.]—Fire Marks on Silver Goods.—Use nitric acid in water instead of sulphuric to make the pickle. Have your stained silver hot, throw it in, and it will be perfectly clean and free from stain, no matter how much discoloured it may have been.—BALCAIRN.

[12690.]—Fire Marks on Silver Goods.—Try nitric acid, and wash with cyanide of potassium. I am afraid you have given them too much fire—if so, there is no cure.—JACK OF ALL TRADES.

[12692.]—Deliquescents.—There are many salts which on being rubbed up in a mortar together, deliquesce. This is owing to a double decomposition taking place. Generally speaking, two salts, containing water of crystallisation, and acids which have a stronger affinity for each other's bases than for their own, run to a liquid when powdered together. The most deliquescent bodies are calcium chloride and chromic acid.—S. BOTTONE.

[12693.]—Yeast or Barm.—A half gallon of malt and ½lb. of hops will make three gallons of what is called patent yeast. Boil them together for an hour and when luke-warm set them with a cup or half pint of fresh ale yeast. Next day bottle for use; the proportion used is about one quart to a bushel.—JACK OF ALL TRADES.

[12697.]—The Harp.—I would not advise "Un Bouts" to make his sound-box of metal, for it would not be likely to produce the soft mellow tone of wood, nor would it be as easy to work up, and as far as sound giving capabilities go, wood is less affected than iron by variation of temperature. If he lives in London he would do well to visit the Exhibition and there take the measurement required, for he does not say what kind of harp he wishes to make. For the practical details of the manufacture, he could not do better than follow out the suggestions of "The Harmonious Blacksmith," or, if he wants to make the Irish one-keyed affair, of "Ixion."—VERTUMNUS.

UNANSWERED QUERIES.

The numbers and titles of queries which remain unanswered for five weeks are inserted in this list. We trust our readers will look over the list, and send what information they can for the benefit of their fellow contributors.

Since our last "West Cornwall" has answered 12284; "W. H. H. C.," 12272; "Jack of All Trades," 12314, 12324, 12327, 12342; "Outgenious Whitesmith," 12324; "Photo. Bristoliensis," 12326; "Philanthropist," 12345; "J.K.P.," 12354 (see letter 4812).

12433 Pie-Heater, p. 471
12434 Castings, 471
12435 The Dragon-fly, 471
12437 Brickmaking Machine, 471
12440 New Oil Light, 471
12451 English Concertina, 471
12454 Southern States of America, 471
12460 Four-valved Cornet, 471
12468 Exhibited Inventions, p. 472
12471 Wheels, 472
12472 Electrical, 472

QUERIES.

[12756.]—**Etching on Stone.**—Would "A Working B." be good enough to give as lucid a description of the art of etching on lithographic stone as he has given of chromo-lithography, and explain why lines cannot be drawn so fine on the stone as to match those etched?—W. R., Royal Engineers.

[12757.]—**Hand-railing.**—Can any of your practical readers tell me the method for taking waste wood off top and bottom of wreath of handrail when cut out to fit well; and also best means of moulding same, whether by routers made to suit moulding (it being winding surface), or separate planes to work each member separately?—English Mechanic.

[12758.]—**Socket Handles.**—I should be obliged to some one giving me information as to the best means of making socket handles, such as are fixed on all cast-iron saucepans. I have a very large quantity to make, and I am now turning them on a mandril in a crease, which is a very tedious process. I hope some one can tell me of a more expeditious method, or if I could get some simple machine to assist in the work?—Chester.

[12759.] — **Leaking Indiarubber Bottle.**— Can any one tell me how to repair an indiarubber hot-water bottle that leaks?—W. Davenport.

[12760.]—**Bringing Slate to Surface of Quarry.**—I have a slate quarry which is 400ft. square and 60ft. deep, from which up to the present all the stone has been brought up by horses and carts. I have an 8-horse engine at the surface for the purpose of working the pumps which keep the water down. Now, as the engine is only required to work half time I wish to utilise it for bringing the stone to the surface, by tramway or otherwise. I want to know what is the best and cheapest way of doing this? Would a steam winch fed by the present boiler bring up (say) a ton at a time up an incline of 1 in 6? Any hints brother subscribers may give would greatly oblige—A Poor Irishman.

[12761.]—**Electrotype Moulds.**—Have any of your readers ever used stearine wax for this purpose. I have found that when mixed with a small proportion of rotten-stone (to prevent brittleness) it takes a sharp impression and is easily detached from the mould.—Zeta.

[12762.]—**Curve of Mirror.**—What is the shape of the curve of a mirror for reflecting telescopes? Is it a parabola? Is there any machine for grinding them, or are they done by hand?—Zeta.

[12763.]—**Preparation of Carbon.**—How is carbon prepared from loaf sugar? I have tried in various ways, but with no satisfactory result.—Zeta.

[12764.]—**Fringe Making.**—Can any of the readers of the English Mechanic tell me if a machine is made, and where to get it, for making fringe or ruchings, for ladies' dresses of silks, cottons, or wool cloths? Also a machine to take out of these the warp or woof as the case may require.—Hugh.

[12765.]—**Sun-dial.**—I want to construct a sun-dial as correct as possible, but do not know how to go about it scientifically, will some one help me? It is for lat. 40° N., is it necessary to know the minutes and seconds? I want the outer circle to be 12in. diameter. What height should the gnomon be and what angle? Should it point true N. and S., or would the magnetic variation of the place interfere? If any kind friend in a leisure hour would describe a 12in. circle, and mark off the hour, half and quarter hours on circumference, and cut out size and shape of gnomon and let me have it with directions for fixing, I would advertise my address and thank him many a day when it would be set up in a far-off land. I would engrave it on slate. I think a practical paper on the construction of a reliable sun-dial would be of great interest to many an—Emigrant.

[12766.]—**Fiddles and Fiddling.**—Many useful wrinkles have lately appeared about fiddles and fiddling. I have been watching to see if anything should meet my case. I am in a difficulty that many brother readers will, I think, gladly help me out of. I am troubled with the bow slipping on the strings (as it seems to me); my notes, many of them, are squeaky and offensive, although I try my best to avoid it. Is the fiddle in fault, the strings (I have been told it is bad strings, I always ask for the best, however), the resin (too much or too little), the bow, or him that boweth? My instrument, I "fancy," is a pretty good one—labelled Antonius Strad., &c., Cremona, 1719. Powerful toned.—H. H.

[12767.]—**Puddling Fishponds, &c.**—I have a fishpond to puddle—about 20 yards by 30 yards, by 3ft. 6in.—with blue clay. Would any brother subscriber inform me how to proceed as regards mixing the clay and putting it in, and what thickness will be sufficient, as it has been puddled before with 5in. of yellow clay, but has always leaked, as it is a sandy bottom. Also what thickness of lime will be sufficient to keep the worms out.—A Constant Reader.

[12768.] — **Specific Gravity.—Sykes's Hydrometer.**—I have a Sykes's hydrometer, but am at a loss to take specific gravities with it. I should take it as a great favour if some one would give a comparative table of degrees, as marked on Sykes's, Baumé, and Twaddle's hydrometers.—Spirit.

[12769.]—**Oval Turning.**—I shall be obliged if W. Winkle will kindly give his promised information as to adapting the lathe for oval turning, the bed of lathe being birch 2in. in thickness.—Photo. Bristoliensis.

[12770.]—**Boring for Water Jet.**—I have somewhere read that the Chinese have practised boring—I don't mean each other—but for water, for many centuries, probably long before the adoption of that practice in Artois, whence we derive the name (artesian) of wells so formed. Can any fellow reader oblige me with information concerning the antiquity of this process—when first used in Western Europe and Northern Africa; also in what books I can "read up" its history? I trust my fellow readers are not treated like artesian wells—*i.e.*, bored—by my many inquiries, and that I shall not be considered to be "boring" for information.—The Harmonious Blacksmith.

[12771.]—**Colorado, U.S.**—I am about to emigrate to Colorado, United States. Can any of "ours" give me any reliable information on any of the following points: 1. Best way of getting there—Quebec, New York, or Baltimore? 2. Expense for intermediate and 2nd class. I do not mean the steamer or rail fares, I can find them out, but incidental cost, such as average cost per day in moderate hotels, cost of diet on railways (I believe there are dining carriages in the trains), transit of luggage by cart or cab, &c. 3. I am going to Denver City first, and have a little capital to buy land and either grow fruit, raise stock, or farm; what part of Colorado would be best for each? 4. I am told the climate is the best in the world; is half this true? 5. Are there any books on Colorado or on American farming and life, &c., procurable in this country? 6. Should I take tools and implements or anything particular out of a regular traveller's kit? 7. What are the prospects of success for hard work, some intelligence, and thorough determination? Is it mere competence and comfort or wealth?—Emigrant.

[12772.]—**Bee Keeping.**—Many thanks to Mr. C. N. Abbott for his good advice so frequently given; will he be so good as to inform me how he proposes to deal with bar-frame hives that have movable partitions; if he would advise taking some of the frames that have sealed honey in the comb from each end, and leaving the ends vacant, to be filled another year; and the best way to transfer bees out of one movable frame-hive into another; also the best plan of ventilating or letting off the breath of the bees from bar-frame hives during the winter months?—John Walton.

[12773.]—**Boot and Shoemaking.**—I shall feel obliged to our indefatigable friend "Jack of All Trades" if he will inform me what tools are required for repairing? Also, how are the pieces of leather put on heels' or toes' ends so as to make them appear straight or one piece? Also, is there a tool to take out the old nails?—Harry Macpherson.

[12774.]—**Harmonium Keys.**—Not being in a position to buy ivory for the keys of a harmonium, would any reader kindly oblige by stating the best kind of wood as a substitute, and whether it is advisable to varnish them?—E. W. P.

[12775.]—**Artificial Marbles and Stones.**—Can any reader give directions for making these, and for producing them in various colours? I put this question some time ago, and there was but one answer, and the directions given were too general to be of any use.—Thos. Hackett.

[12776.]—**Gas.**—Like "Philo," I am a gas consumer, also a gas producer (shareholder). I feel with him we ought to have some means of knowing the quality of the gas we burn. Could he or any of your scientific readers tell me the most reliable instrument for testing the quality of gas? It is a notorious fact that with more care and less light we are called upon to pay more; or, in other words, our gas bills increase every corresponding quarter without receiving any extra advantage. I have received valuable suggestions from the columns of the Mechanic respecting gas, but I feel we are too much in the hands of gas companies, and they, as a rule, produce bad gas and good dividends; in short, we require justice.—H. J. W.

[12777.]—**Object-Glass.**—"F.R.A.S." is so kind in answering queries that I am tempted to submit to him the following. I am about constructing a telescope, and in the purchase of the object-glass I cannot exceed a certain sum, and for this amount I can purchase a 2in. glass or a 2¼in. glass of best quality from an optician of great repute, whilst with the amount I intend expending I can buy a 3in. or 3¼in. glass of ordinary quality, such as those supplied in the £5 telescopes. I want my telescope both for astronomic and terrestrial observations, and will thank our kind savant to direct me in the purchase of the object-glass. Which will be the most satisfactory, the 2in. or the 3in.?—Zealous.

[12778.]—**Printing Metal Leaf on Silk and Cotton.**—Will any of our American subscribers oblige by telling me what is used in America for printing metal leaf on silk and cotton for felt hats? A man who has just come from America can print metal leaf on almost anything, whereas I have to make three or four impressions sometimes to get a good one, and he has always good work first impression. I know that he uses a transparent varnish, and that it does not affect the silk or cotton, but leaves it just the same as if it had none on. It drys in one minute, so that they are ready for printing at once. It is made of three things, and they are rather expensive; but what they are, and how the varnish is made, I cannot find out. The French printers and some of the London printers use the same. For some years I have used powdered rosin and shellac. I got a good recipe from this paper, but it is nothing compared with this American recipe. A drawing of the American press would also oblige.—J. B. Sharpley.

[12779.]—**Lightning and Thunder.**—1. What is the cause of the different phenomena of lightning, yclept, forked and sheet? Is it that the flash appears forked when seen directly, and sheet otherwise? and does not the fact of so much sheet lightning being seen at night, unaccompanied by thunder (and, therefore, we may presume, at an extraordinary distance away), prove this? 2. Is the sound produced by an electric explosion, single and distinct, afterwards echoed and re-echoed, causing the continuous sound known as thunder? 3. When an animal, tree, or other object is struck by lightning, what is the material that strikes? Is it simply the concussion caused by the explosion, or is the "electric fluid" a material which may be analysed as well as felt? No doubt an answer to these queries would interest many at this peculiarly lively season.—G. L.

[12780.]—**Turning Spokes of Carriage Wheels.**—Could any reader inform me how or what machinery is needed to turn a spoke for carriage wheel in a common lathe?—Amateur.

[12781.]—**Applied Mechanics.**—If P be the breaking weight of a column fixed at both ends, f and a two constants $= 36{,}000$ and $\frac{1}{3{,}000}$ respectively; s = area of cross section in inches, l = length of column, and h = dia. of column; then

$$P = \frac{f\,s}{1 + a\,.\,\frac{l^2}{h^2}}$$

Now I wish to know to what units P, l, and h are referred—that is, does P represent pounds or tons, l and h feet or inches?—T. Tebeck.

[12782.]—**Full Moon.**—I wonder whether some of your kind readers can give the dates of the full moon for three or four years to come. If so I fancy it would be a great help to many secretaries of societies.—J. G.

[12783.]—**Sash Planes.**—Can any of your correspondents tell me why sash planes are sold in pairs? They are numbered 1 and 2, and cannot be had separately, but so far as I can judge they are exactly alike.—Science and Art.

[12784.]—**Libraries.**—Will some kind reader please to give a few suggestions on the management and conducting of public libraries? How are the books backed and numbered? Is there no better and more lasting way of numbering than by gummed tickets, which are often torn off and lost? Could some kind of a stamp be used for that purpose—if so, where is one to be had?—A Librarian.

[12785.]—**Trompe or Water Blowing Machine.**—Could any correspondent tell me if there is such a machine going in England, as I am not aware of any in Scotland; and if the blast is so moist as to render it unfit for cupola purposes? Any information regarding its advantages or disadvantages will much oblige—W. D. T.

[12786.]—**Photography.**—I shall esteem it a great favour if some of our able photo. correspondents will kindly reply to the following queries. 1. What can be done to silvered paper to make it keep a week or fortnight before using it? 2. Can anything besides kaolin be used for restoring the colour of discoloured nitrate bath? I always find the solution wants filtering several times after using kaolin. 3. How can mounted carte de visites be pressed flat? Mine always curl after rolling. 4. I wish to produce some very opaque transparencies for magic lantern from negatives. How am I to go to work? 5. I shall also be glad of information respecting copying from the carte de visite print, same size and enlargement, without artificial light, if possible. Perhaps our friend "Photo. Bristoliensis" will oblige by replying to some of the above queries.—Camera.

[12787.]—**Dear Coal.**—Will "Philo" kindly tell us the price of the half open stove alluded to in his letter (4723), and also the probable cost of the double fire apparatus?—C. W. A.

[12788.]—**Design for Marble Inlaid Table.**—Will any correspondent give a good design for an inlaid marble table, about 20in. on top, and pieces (say) from 1½in. to 3in.? I understand the practical part very well, but I wish for a good design.—M. & S. Mason.

[12789.]—**Staining Fanlight.**—I wish to stain or colour a fanlight over door to show some view or picture, such as the Last Supper, &c. I have seen the lamps over publicans' doors stained a very bright crimson or green, with picture in uncoloured or plain glass; for instance, the Bridge Inn, with view of a bridge and scenery. If some one would kindly give the information it will probably oblige many as well as—Kendal Saddler.

[12790.]—**Watch Repairing.**—Being in town the other day for the purpose of procuring some watch materials, I found that the same had increased in price. Now, I consider that I would be justified in making a small advance upon my present scale of charges. Being a country jobber, I should feel obliged if any of our brother pivots would inform me what is the usual charge for putting in a mainspring, a balance staff, and a verge; also, if they would kindly say which is the best method of hooking in a mainspring with a steel hook, or with a brass one, same as in a Geneva watch. I also wish to know (perhaps "Practical Seconds" will tell us in his paper) how to take the height of a cylinder from the broken one. P.S.—Thanks to J. McKay for his wrinkle in bumping a Geneva escape-wheel. I only wish I had known it sooner. I see that another jobber adopts the same method.—J. H.

[12791.]—**Table Fountain.**—Will some one explain the action of the self-acting table fountains shown in No. 22 room of the International Exhibition?—Glatton.

[12792.]—**Tempering Needle.**—Ought I to temper the steel for a magnetic needle to a blue or to a straw colour? I wish to weight one end with solder. Will the heat necessary to do this destroy the temper?—Glatton.

[12793.]—**Oil of Peppermint.**—Will any of your readers kindly inform me how to extract from the plant peppermint the oil or essence of that name?—J. W.

[12794.]—**Ammoniacal Liquor.**—I would thank any chemical friend to explain how to compute the number of gallons in a ton of ammoniacal liquor of 5°, 6°, or 7° Twaddle.—J. W.

[12795.]—**Test for Whiting in Paint.**—Will any of our chemical friends kindly inform me the test for whiting in house paint.—R. R.

[12796.]—**The Spanish Language.**—Having decided to acquire a knowledge of the Spanish language, I would thank "E. L. G." or some other correspondent of "ours" to give his opinion with regard to the best grammar for self-tuition. I should use an Ollendorff if there is one published. I find that by such means I can learn a language in much less time than with a grammar and dictionary only.—J. Roberts.

[12797.]—**Rats and their Habits.**—Dr. Livingstone, in his recently arrived despaches, speaking of the elephant tusks left by the Manyema in the forests where the animals were slain, says of them: "Many were half rotten or gnawed by a certain rodent to sharpen his teeth as London rats do on leaden pipes." A common opinion among sailors is that rats gnaw leaden pipes and wooden planks to get at the water they hear rushing past. Can any one acquainted with the habits of those animals say which gives the right reason for the rat's operations, Jack or the Doctor?—Common Sense.

[12798.]—**Air Vessel on Suction Pipe.**—I have a 10in. bucket pump with a 6in. suction pipe, 30ft. long, and on this pipe is fixed a large air vessel 4ft. from pump. Would any kind reader inform what advantage is gained by having one on it.—Doubtful.

[12799.]—**Speculum.**—Will Mr. A. W. Blacklock (in No. 4222), kindly say what thickness his glass was that he got his speculum out of, and also how he managed to get the edge to shape?—Anti-Flatite.

[12800.]—**Pantelegraph.**—I should feel obliged if "Rat-Tat" or some other correspondent would describe the above.—Philanthropist.

CHESS.

ALL communications intended for this department to be addressed to J. W. ABBOTT, 7, Claremont-place, Loughborough-road, Brixton, S.W.

The correspondence match between the City and Vienna Chess clubs, to which we alluded a few weeks back, has been commenced. Two games will be played concurrently, Vienna having the move in one and London in the other. In game No. 1 the Austrians opened the ball with the orthodox P to K4, and London answered by moving P to K4 also. In game No. 2 London commenced with P to QB4, to which Vienna replied with P to K4. The great caution displayed by London in adopting an irregular opening may possibly be a tribute of respect to the known or suspected powers of their adversaries, but whatever influence it may have upon the ultimate destination of the stakes (£100) it is certain to deprive the game of all interest to those amateurs who have been looking forward to this match for some new development of the theory of chess. One of the Vienna papers prints a list of gentlemen appointed by the club to conduct the games on their behalf—viz., Dr. Meitner, Jos. Berger (the well-known problem composer), A. Czank, O. Gelbfuhs, and Dr. Fleissig, favourably known as a blindfold player. London will be represented, we believe, by J. Lowenthal, Horwitz, Potter, Steinitz, and Blackburne.

The score in the match between Steinitz and Zukertort stands:—Steinitz, 4; Zukertort, 1; drawn, 8.

ENIGMA II.—BY J. W. ABBOTT.

White.

K on K Kt 8; Kts on K Kt 7 and K Kt 8; B on Q 8; Ps on K Kt 5 and K R 4.

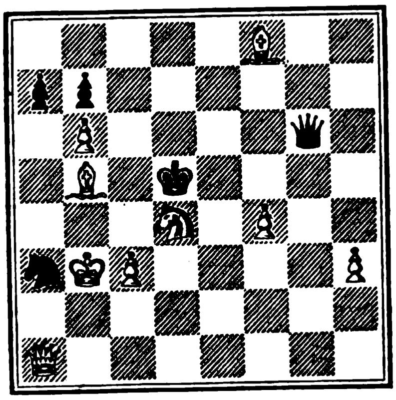
Black.

K on K Kt 3; Rs on K B 4 and K 6; B on Q sq; Ps on K 2 and K 8.

White to play, and mate in *two* moves.

PROBLEM XIII.—BY J. G. SLATER.

Black.



White.

White to play and mate in four moves.

SOLUTION TO PROBLEM XI.

White.	*Black.*
1. Q to Q 7 (ch).	1. K takes Q.
2. P to Kt 8, becoming a Kt (ch).	2. K to Q B 2.
3. Kt. to K 6 mate.	

O. A. BROWNSON (Dubuque, Iowa).—We shall take an early opportunity of noticing the contents of the August number of the *Chess Journal* which you have obligingly forwarded to us.

W. N. P.—Thanks; shall always be glad to hear from you, even if the communication is a little delayed.

S. H. THOMAS (Plymouth).—The problem shall be examined, and reported on next week. In Problem XI. the B P on Q 6 shuts out the ch. of B Q at Q 6, and allows more play at White's command, which adds to the construction of the problem.

ARGO (Yarmouth).—The problems last sent are not equal to your previous effort. No. 1 is very easy, and in No. 2 the capture on the first move is inartistic.

SOLUTIONS to Problem X. (continued).—S. H. Thomas (Plymouth); R. H. Macleod; C. J. L. (Portsmouth); A. R. Moleson (Swansea); J. Hall (Chester).

THE following have sent correct solutions to Problem XI. —W. N. P. (London); J. Hall (Chester); C. J. L. (Portsmouth); S. H. Thomas (Plymouth); A. W. Cooper; S. M. Banker; H. Cherry; W. Nash (S. Neot's); R. L. Conderford; A. R. Moleson (Swansea); W. Airey (Worsley); A. L. (Lincoln). All others are wrong.

Soldering Flux.—It may be important to many to know, on the authority of M. Gaudin, that a mixture of equal parts of cryolite and chloride of barium forms a flux superior to borax for soldering iron, or brazing copper, brass, or bronze. Cryolite is found in great abundance in Greenland; it is a double fluoride of aluminium and sodium, and has been largely employed in the production of the metal aluminium.

ANSWERS TO CORRESPONDENTS.

*** *All communications should be addressed to the* EDITOR *of the* ENGLISH MECHANIC, 31, *Tavistock-street, Covent Garden, W.C.*

HINTS TO CORRESPONDENTS.

1. Write on one side of the paper only, and put drawings for illustration on separate pieces of paper. 2. Put titles to queries, and when answering queries put the numbers as well as the titles of the queries to which the replies refer. 3. No charge is made for inserting letters, queries, or replies. 4. Commercial letters, or queries, or replies, are not inserted. 5. No question asking for educational or scientific information is answered through the post. 6. Letters sent to correspondents, under cover to the Editor, are not forwarded; and the names of correspondents are not given to inquirers.

The following are the initials, &c., of letters to hand up to Tuesday morning, August 27, and unacknowledged elsewhere:—

Geo. Hy. Cox.—W. M. Simpson.—Robert Hirons.—Rev. E. R. Mountford.—Wm. Fryer.—W. Davenport.—John Jones.—G. R. Nichols and Co.—W. D. Skelton.—T. Bond and Co.—Frances Radcliffe.—H. Young.—J. M. Wilson.—W. R. K.—R. D.—W. E. and B.—Pat.—J. O'Brien.—G. Wilson.—Geo. Dawson.—E. L. J.—Filmouse.—Pro Bata.—J. B. W.—J. B. B.—N. and Co.—J. Dresser.—J. Billock.—B. Richards.—G. C. Price.—H. Hird.—J. T. Sprague.—G. R. Nixon.—Solomons & Co.—Charles J. Harcourt.—J. C. Lambert.—J. Frances.—Cunliffe & Croom.—J. A. McKean.—D. Harcourt & Co.—Thomas Atkinson.—M. E. Horley.—John G. Phillips.—F. R. Leyden.—Charles Mace.—Wm. Oldfield.—R. L. G.—J. A. T.—Changki.—Screw Cutter.—Atmospheric Burner.—J. S.—Alfred T. Jenkins.—J. K.—W. M. Parker.—Norwich.—S. Broughton.—Toivo.—W. S. C.—Malt.—W. S. B.—Beta.—Limbo.—D. Duplex.—Manus.—Dutchman.—Mutual Tom.—Sam Weller.—A. D.—Another Paddler.—W. V. Clarke.—Convertion.—C. N. Abbott.—South Line.—Wm. MacNaught.—Rasselas.—Horatio.—Alfred H. Allen.—C. H. W. B.—R. H.—E. M.—W. Brown.—Mechanical Equivalent.—J. Pugh.—N. S. Heinsken.—J. Tregaskis.—Arotes.—T. A.—R. T. Grays.—Alastor.—Ajax.—H. O'B.—Successful.—Prudentia.—A Carlow Mem.—Tintub.—Good Intent.—M. F. P.—J. B. Clay.—A. S.—Zeta.—E. R. Wigan.—Linea.—Enquirer.—E. S.—E. E. G.—One who has Passed.—W. Baker.—J. W. Fennell.—Smalker.—G. H. Goodman.—A. K. C.—Definition.—H. G. W.—A. Z. Y.—C. E.—J. B. Harris.—Samuel Smither.—John Hopkins.—J. Gunn.—Salmo.—E. T. E.—M. F.—M. A.—From one Afflicted.—A Carpenter.—Young Glasgow.—E. T. E.—J. G. H.—E. H.—J. B. H.—Outgenious Whitesmith.—R. A. Proctor.—Sigma.—Beacon Lough.—G. F. H.—F. R. A. S.—J. C. J.—Harmonious Blacksmith.—Edward Gardner.—Samuel Hill.—Saul Rymes.—J. M. Hayward.—One in a Fix.—Albert Lyon.—C. B.

SPINE.—Consult a medical man.

S. K. So. T.—There is no doubt there is much in what you say, but the case you mention must be an exception to the general rule.

STOCK AND DIES.—If you want any definite information that may be useful to yourself and others ask for it, but we cannot afford space to ask for opinions on speculative points.

R. D. S.—Consult back numbers about brewing.

A GRATEFUL READER is a very indifferent one, or he would not ask us to insert a query which is an advertisement.

NIL DESPERANDUM.—You say you "have had several communications from the spirits, and in some cases with startling accuracy with regard to the past, but those of the future are not nearly so much so, for in some cases they have been radically wrong," and you "want some correspondent to explain how this is accounted for." Why not ask the spirits who are so "startlingly correct with regard to the past"? Certainly they, with their vast experience and wealth of wisdom, ought to know more about your affairs than strangers!

PALE.—You say you want to remove a mole spot, and you have been trying to remove it and made the matter worse, for where you had a mole now you have a sore. Leave it alone, or you may make the matter still worse.

C. E. L.—Your only way would be to rent a private wire of the Post-office. Write the secretary.

AN IRON MANIPULATOR, John, W. H. Murch, J. Lucas, A Canny Scot, C. M. M. B. (second question), Etna, A Glasgow Artisan, Herbert, are referred to indices to back volumes.

Communications which can only appear as advertisements to hand from E. J. W., E. Ward Jackson, C. M. M. B. (first question), South Devon.

J. L. M.—Your illiterate vulgarity is only to be pitied, but your spiteful attacks on a correspondent who has always been willing to afford readers all information in his power render you unworthy of further notice.

LOVATT.—See excursion advertisements in the daily papers. Boulogne preferable.

ONE IN THE DARK.—Your query on bronze for brass work has been answered before, and your query on drills for mending china is an advertisement.

T. D. W., L. W. D., J. R. Watson, Optical, Jas. McL., Partner, J. Murdock, see "Hints to Correspondents," No. 4.

W. T. K., J. Laurie, Tam o' Shanter, E. W. S., J. L. L.—Your queries have been answered in back numbers.

H. O. BRIEN.—Your "copy" if written in the same hand and bearing the same signature can be sent to the editor in a halfpenny wrapper.

A. Z. Y., Tom O'B., No. 790, Young Carpenter.—Your queries are inadmissable.

JAMES POLGLAZE.—Most of the information in your letter is good enough, but unfortunately you use twice as many words as are necessary. Make your next letter little and good, and we will insert it.

T. RUSSELL.—You send a long letter on "Lightning Conductors," but the letter is an advertisement after all, and therefore not inserted. Besides, the same letter has been sent to other publications.

J. H. B.—You send a letter written partly in pencil and partly in ink, and the letter altogether is so badly put together that we have not time to endeavour to make out what you mean to convey. As a postscript you say "I hope you will excuse bad writing," &c. We do do not excuse you, as we believe you can do better, and as a punishment drop your letter into the waste basket. What is worth doing is worth doing well, and no one has a right, to save his own time, to trespass on the time of another.

J. W. WALKER.—Pray try and inform yourself on so delicate a matter before you attempt to instruct others.

B. B.—We know of no such a book, and again refer you to back numbers. We find as a rule that correspondents who give us most trouble are those who are neither subscribers nor readers, but who write us when they want any information without troubling themselves to ascertain what has been said on the subject.

J. HAMPDEN.—You appear to forget that you have been bound over to keep the peace before more than one tribunal, as you write a letter which, if published, would subject you to another criminal prosecution. It is said that a burnt child dreads the fire, but you write as if you liked to rush into it. We have several times stood your best friend by preventing you criminating yourself, and, as a matter of course, you have rewarded us by ribald abuse.

EXCELSIOR.—Too legal for us.

WAKENAAR.—Your description of slide-rest next week.

ENQUIRER.—We devoted as much space as we can spare to shorthand about two years since. The discussion on it was somewhat exhaustive.

TO SEVERAL CORRESPONDENTS.—The space we have devoted to reports of the British Association is one reason why a large number of letters, replies, and queries, are pressed out till next week.

F.R.A.S.—Your second article on "The Equatoreal" has been in type two weeks. It shall appear in our next.

THE INVENTOR.

APPLICATIONS FOR LETTERS PATENT DURING THE WEEK ENDING AUGUST 13, 1872.

2334 J. Ellison, Bury, Lancashire, for improvements in self-acting tilts for casks, barrels, or other receptacles.

2335 G. Bray, Leeds, for improvements in gas-burners.

2336 F. M. H. Motard, Paris, for an improved mode of recovering and regenerating steam in motive-power engines.

2337 T. Richardson, J. W. Richardson, and A. Spencer, West Hartlepool, for improvements in the manufacture of iron and steel, and of revolving puddling furnaces or convertors, and apparatus to be employed therein.

2338 D. K Clark, Buckingham-street, Strand, for improvements in the lubricating arrangements of axle-boxes for railway rolling stock. A communication.

2339 J. Holmes, jun., Dublin, for a new or improved method or methods of building dwelling-houses and other buildings.

2340 T. Spittle, Newport, Monmouthshire, for improvements in cask stands.

2341 C. Morfit, Southampton-buildings, for improvements in the manufacture of pure phosphates of lime.

2342 W. R. Lake, Southampton-buildings, for an improved ink-erasing compound. A communication.

2343 L. Newton, Birkenhead, and J. T. Swallow, Manchester, for improvements in cups, glasses, tankards, soup-basins, and other vessels used for drinking purposes.

2344 C. Morfit, Southampton-buildings, for improvements in the chemical treatment of mineral and other crude phosphates of lime.

2345 W. H. Berry and F. Berry, Leeds, for improvements in machinery for bending iron, copper, brass, or other metals into complete or part circles.

2346 J. R. Readett, Dover, for improvements in machinery or apparatus for expressing or obtaining oil from seeds or vegetable substances.

2347 J. W. Lewis, Coventry, for an improved machine or machines for making and covering all classes of cords, gimps, and other twisted materials and fabrics.

2348 T. Hudson, W. Walker, and J. Robson, North Shields, for an improved metallic sheathing for preventing the fouling and corrosion of iron ships or vessels.

2349 W. Ansell, Birmingham, for improvements in breech-loading small arms.

2350 T. Silver, Moorgate-street, City, for an improved air-rarefying lamp-burner.

2351 G. M. Moore, Liverpool, for improvements in the process of evaporating or concentrating alkaline liquors in the manufacture of caustic soda, caustic potash, soda ash, and other similar substances; also for heating or boiling and refrigerating solutions in breweries, distilleries, chemical and other manufactories, and in the apparatus employed therefor.

2352 R. Turner, Lancashire, and J. Hibbert and J. Cheetham, Hyde, Cheshire, for improvements in machinery for blocking hats.

2353 W. Grimshaw, Ashton-under-Lyne, for improvements in machinery for "planking" or "felting" hats and other coverings for the head.

2354 A. M. Clark, Chancery-lane, for improvements in magazine and other breech-loading fire-arms and cartridges. A communication.

2355 A. Clark, Rathbone-place, Oxford-street, for improvements in the manufacture of corrugated metal revolving shuttles and in machinery for the same.

2356 J. Sabberton, Great Portland-street, Oxford-street, for improvements in the means of and apparatus for ventilating railway carriages.

2357 C. Morfit, Southampton-buildings, for an artificial substitute for "redonda guano," "alta vela" guano, and other natural phosphates of alumina to be used in the defecation of sewage, in the manufacture of sugar from cane and beet-root juices, and in the preparation of certain chemical products, such as pure alumina and the alkaline and earthy phosphates and aluminates.

2358 T. Warren, Glasgow, for improvements in and connected with furnaces employed in the manufacture of glass.

2359 J. Oldroyd, Leeds, for improvements in the construction and working of hydraulic engines.

2360 A. Maw, Salop, for improvements in apparatus to be employed in preparing the clay used in the manufacture of encaustic tiles and other articles requiring similarly prepared clay.

2361 A. Jaynor, Regent's-park, for improvements in the manufacture of artificial stone or compositions suitable for pavements, architectural and other purposes.

2362 S. Myers, Vale-terrace, Maida-vale, for improvements in gas-lighting apparatus. A communication.

2363 R. W. Morris, Ulverstone, Lancashire, for improvements in revolving shutters.

2364 R. Hornsby, J. E. Phillips, and J. Innocent, Grantham, Lincolnshire, for improvements in reaping and mowing machines.

2365 S. H. Hadley, Hampstead, for improvements in cleaning wheat and other grain, and in apparatus employed therein. A communication.

2366 J. Lane and W. Onions, Liverpool, for improvements in apparatus used in brewing.

2367 R. Mill, Jersey, for improvements in or connected with steam-boilers.

2368 J. Drummond, Edinburgh, for improvements in reaping and mowing machines.

2369 W. R. Lake, Southampton-buildings, for improved nutritious compounds. A communication.

2370 G. H. Nussey and W. B. Leachman, Leeds, for improvements in machinery or apparatus for pressing woollen and other woven or felted fabrics.

2371 B. D. Harrison, Leeds, for improvements in kilns or ovens for burning bricks, tiles, and other plastic forms.

2372 F. G. M. Stoney, Glasgow, for improvements in stop valves or sluices.

2373 B. Bagster, Bushy, Herts, for improvements in locks or fastenings for railway and other carriage doors, and for other uses.

2374 R. Willis, Jermyn-street, Piccadilly, for an improved apparatus for clipping horses and other animals.

2375 E. Shaw, Manchester, for improvement in perambulators.

2376 F. W. Scott, Lancashire, for improvements in belts or bands used for colliery winding, suspension bridges, and other purposes.

2377 A. G. Speight, Spencer-street, Goswell-road, for a new or improved manufacture of fronts for personal wear.

2378 T. H. Rushton and W. Dobson, Bolton, for improvements in machinery for ginning cotton.

2379 W. M. Adams, B.A., Salisbury-street, Strand, for an instrument for the solution of triangles.

2380 T. Broughton, Dalston, for improvements in the construction of iron girders, joists, or beams used in constructing buildings.

2381 J. Pickering, Manchester, for improvements in the construction of spring mattresses and other articles for sitting or reclining upon.

2382 T. H. Rushton and R. Tonge, Bolton, for improvements in machinery for spinning and doubling.

2383 J. J. Bodmer, Sheffield, for a new or improved instrument or appliance for sharpening knives and other cutting tools.

2384 D. Macfarlane and R. Macfarlane, Paisley, Renfrewshire, for improvements in dyeing and in the apparatus employed therein.

2385 T. J. Denne and A. Hentschel, Cambridge-road, Mile end, for improvements in waterproofing.

2386 R. Sutcliffe, Idle, Leeds, for improvements in apparatus for utilising exhaust steam for heating feed water for boilers and other purposes.

2387 R. F. Fairlie, Victoria-street, Westminster, for improvements applicable to locomotive-engines.

2388 H. Gledhill, Halifax, Yorkshire, for improvements in machinery or apparatus applicable for either scouring or washing worsted or other textile fabrics in the piece.

2389 H. A. Bonneville, Piccadilly, for a new or improved process of manufacturing cast steel. A communication.

2390 J. Macneill, Brompton, for an improved means or apparatus for communicating signals from passengers to guards and drivers of railway trains.

2391 W. Youngman, Lowestoft, Suffolk, for improvements in apparatus for raising and lowering casks or other vessels without disturbing the contents.

2392 R. M. Letchford, Three Colts-lane, Bethnal-green, for improvements in the manufacture of matches.

2393 S. Barton, Cannon-street, City, for improvements in apparatus for protecting the face and head and permitting respiration in places where the atmosphere is charged with noxious gases or vapours, smoke, or other impurities.

2394 G. Dixon, Cockspur-street, Middlesex, for improvements in the manufacture of fringes and upholsterers' trimmings, applicable also in the manufacture of textile fabrics.

2395 J. G. Williams, Blaenavon, Monmouthshire, for improvements in apparatus for heating, cooling, and fermenting liquids, and for infusing, attemperating, and mashing, especially applicable in brewing and distilling.

2396 R. Hadfield, Sheffield, for an improved process for combining crucible steel with pig iron or other similar metal.

2397 G. Haseltine, Southampton buildings, for improvements in apparatus for adjusting the screw propellers and rudders of canal boats and other vessels. A communication.

2398 E. Probert, Hatfield, Herts, for improvements in asphalte roads and pavements in combination with wood.

2399 J. Richardson, Brighouse, Yorkshire, for improvements in the process of dyeing textile fabrics.

2400 G. Heyes and T. Entwistle, Accrington, Lancashire, for improvements in warping or beaming machines. A communication.

2401 T. Joseph, Glamorganshire, for a new or improved method of cooling mines, and of cooling and ventilating houses, ships, churches, factories, and other structures or places, applicable also for abating heat, smoke, and steam in tunnels and other confined places.

2402 J. Newton, New Wortley, and W. Price, Hunslet, Leeds, for improvements in the means of and apparatus for consuming smoke and economising fuel.

2403 A. M. Clark, Chancery-lane, for a new or improved medicinal compound. A communication.

PATENTS SEALED.

1096 J. Betteley, for improvements in the construction of ships or vessels and in appliances connected therewith.

1391 F. G. Fleury and A. Tylor, for improvements in apparatus for measuring and recording the flow of liquids or fluids.

1479 H. A. Bonneville, for improvements in the construction of two-wheeled vehicles for the conveyance of passengers or goods on common roads.

1570 R. Thomas, for an improvement in tinting or colouring spectacle and other lenses.

818 G. Allibon and A. Manbre, for improvements in steam boilers or steam generators.

429 W. Ireland and J. Ireland, for improvements in the manufacture of cast or Bessemer steel ingots.

440 R. Burn, jun., for an improved apparatus for signalling on railways.

451 A. W. Pocock, for improvements in the construction of fasteners for window sashes.

454 F. H. Warlich, for improvements in the manufacture of artificial fuel, and in apparatus to be used for this purpose.

455 J. D. Nichol and J. Eckersley, for improvements in apparatus for drying and pressing or calendering printed paper.

456 W. Richardson, for improvements in machinery for burring and cleaning or opening wool, cotton, and other fibrous materials.

467 J. Colborne, for an improved apparatus for facilitating the teaching of military drill.

469 T. J. Smith, for improvements in apparatus for retarding and stopping railway trains.

471 O. Walch, for an improved apparatus to be used in the manufacture of matches.

477 T. J. Smith, for an improved means of and apparatus for communicating between railway carriages and for ventilating the same.

510 A. Browne, for an improved method of and apparatus for treating and preparing the stalks of a certain vegetable fibrous substance, known and distinguished in France as "la Filasse d'Alfa (Sparte)," to adapt it for manufacturing purposes.

587 W. E. Gedge, for improvements in rolling mills or machines for manufacturing bar iron.

606 S. T. Vanel, for a new composition and process for waterproofing all sorts of tissues, linen, paper, and other materials.

677 S. H. Stephens, for improved machinery for reducing tin stuff and other partially pulverised ores, to extract the metal therefrom, and also for grinding paint, cement, and other hard substances, together with feed apparatus therefor, which is also applicable to other pulverisers.

876 J. Lewis, for improvements in joining or connecting the parts of the head, foot, and side rails of metallic bedsteads and cots, and metallic railing for various purposes, which improvements are also applicable to the connecting of metallic ornaments to articles of metallic furniture.

922 B. Richards, for improvements in walking-sticks.

1478 H. A. Bonneville, for improvements in the production of motive power, and in the apparatus connected therewith.

1611 I. Brown, for improvements in watering streets and roads, and in the apparatus or means for effecting the same.

1754 J. Ducomet, for improvements in steam gauges.

1917 S. J. Wallis, for new or improved mechanism for discharging both locks or barrels of a double-barrelled gun by one trigger.

472 T. Johnson, for improvements in valve for sewers or drains for preventing or arresting the passage of noxious or offensive gases.

476 T. Rowan, for improvements in preparing carbonates or oxides of lead and zinc for use as pigments and otherwise.

489 A. V. Newton, for improvements in sewing machines.

490 R. Graham and M. D. Wood, for improvements in apparatus used in the production of artificial teeth, known as "dental articulators."

491 H. Gardner, for improvements in treating certain fibres, and more especially the fibre derived from the Baobab tree or Adansonia digitata, to render them fit for spinning and other useful purposes, and in machinery therefor.

Terms of Subscription,

PAYABLE IN ADVANCE.

5s. 6d. for Six Months and 11s. for Twelve Months, Post Free to any part of the United Kingdom.

Volumes VI., VII., VIII., IX., XII., XIII., and XIV. bound in cloth, 7s. each.

Indexes for each half-yearly volume, up to Vol. X. (except Vols. II., V., and X.) inclusive, 2d.; Post Free, 2½d. Cases for Binding, 1s. 6d. each.

⁂ Subscribers are requested to order Cases and Vols through their booksellers, and not to send direct. The new regulations of the Post-office prevent their transmission through the Post.

To American and Belgian Subscribers.

☞ American and Belgian Subscribers, *especially when renewing their subscriptions*, are *particularly requested* to advise the Publisher of the transmission of the Post-office Order, and the exact amount for which it is made payable.

Subscribers in the United States and Belgium can be supplied with the ENGLISH MECHANIC post free from this Office, for the sum of 18s. (3 dols. 25 c. gold, or 15fr. 60c.) per annum, payable in advance.

The remittance should be made by International Post-office Order. Back numbers cannot be sent by the ordinary newspaper post, but must be remitted for at the rate of 5d. each to cover extra postage.

Notice to Subscribers.

Subscribers receiving their copies direct from the office, are requested to observe that the last number of the term for which their Subscription is paid, will be forwarded to them in a *coloured wrapper*, as an intimation that a fresh remittance is necessary, if it be desired to continue the Subscription.

Front Page Advertisements 9d. per line.

The address is included as part of the advertisement and charged for.

Advertisements must reach the office by mid-day on Tuesday to ensure insertion in the following Friday's number.

OUR EXCHANGE COLUMN.

Exchange ***Advertisements are charged at the rate of Sixpence for the first Sixteen Words, and Sixpence for every succeeding Eight Words.***

Excellent Galvanic Medical Apparatus, 2 splendid Needle Telegraph Instruments for exchange.—Alfred Crofts, Clarendon-road, Dover.

Bicycle for exchange (cost £10).—Address, H. Young, Rockview, Rathgar, Dublin.

Double Engine, nearly ready, cylinders 2¼in. by 6in.; for a Sewing Machine or Foot Lathe, or Theodolite; offers.—Richard Roberts, Coedpenmaen, Pontypridd.

Two Model Horizontal Slide-valve Engines, quite new; for articles of equivalent value.—For particulars send stamp to Geo. Jas. Smith, Hope-street, Norton, Malton.

Photographic Dark Tent, Rouch's Pattern Stand all complete, not soiled, for plates 15 by 12 (cost £7 7s.; offers.—J. Belam, 8, John's-street, Chichester.

A Tricycle in exchange for a Standing Desk.—S. Cook, 17, Cotham-street, S. Helen's, Lancashire

Screwing Tackle, Gas-meter, and Bread-maker, for Revolvers, Sewing-Machine.—R. P., 10, S. Leonard's street, Manchester.

4in. Lathe, iron frame (value £6); offers, anything useful.—8, St. George's-terrace, Fort-road, S.E.

4in. Compound Slide-rest, and 4in. Ornamental ditto, useful offers.—As above.

Grover & Baker Sewing Machine; for Lever Watch.—As above.

ARTICLES.

THE EQUATOREAL—ITS USE AND ADJUSTMENTS.

BY A FELLOW OF THE ROYAL ASTRONOMICAL SOCIETY.

(*Concluded from page 552.*)

WE said above that we should give directions for finding a meridian line, and since we require to obtain one in the outset before we can even place the iron framework, shown at S in Fig. 4, correctly upon the top of the pillar, or pier, which is to carry it (and to which it is ultimately to be immovably fastened); we will deal at once with the most simple mode of making the determination. It is that of—what is called—equal altitudes. The principle upon which this method depends may be gathered from a study of Fig. 2, where it will be seen that a telescope moving round a vertical axis cuts the diurnal path of a star in two points, and two only, so that an instant's reflection will show the student that as, in the description of such path, the altitude of any star is continually varying, and that if we conceive it to be (for example) 42° 8' above the horizon, when it is 3 hours and 14 minutes east of the meridian it will continue to get higher and higher until it actually transits it; after which it will begin to descend again, and precisely 3 hours and 14 minutes after it culminates will be once more at an altitude of 42° 8'. By the aid of an instrument known as an Altazimuth, the observation of equal altitudes can be made, and the horizontal angular interval between the two positions of the telescope bisected, with all conceivable accuracy; but as these papers are not written for those who can be assumed to be familiar with instruments of this character, we will proceed to describe the very much better known way of getting a north and south line by the use of the shadow of a vertical stick placed on a truly horizontal surface, in sunshine. There is one drawback to this method, however, and that is that it is only rigidly applicable about the end of June or December, when the sun's declination changes very slowly. During March and September the rapid motion of the sun in declination introduces a source of error into the determination of the meridian, which renders it decidedly undesirable that those seasons should be selected for finding it; but even at those epochs a very close approximation to it may be made. The mode of proceeding is illustrated in Fig. 5, in which A B D E represents the top of the pillar (supposed to be square) upon which our equatoreal is to be fixed. The first thing is to level this very carefully with a spirit level. This accomplished, we take the centre C of the slab, and round it describe a series of circles, of which three are shown in our sketch. Then (by the aid of a plumb-line, or otherwise) we erect a rod C R on C accurately vertical. As we commenced by levelling the surface A B D E truly, the rod referred to will evidently be at right angles—or square—to it. This rod should be as thin as is consistent with its rigidity; a perfectly straight knitting-needle answering capitally.

Now, *in limine*, it is apparent that the lower the sun is down the longer will be the shadow of this rod; that it will continue to shorten as the sun ascends; be at its shortest when he is on the meridian; and then, at once, begin to lengthen again, and so on. Let us, then, observe when the shadow of the *top* of our rod falls on one of the circles, four hours or so before noon; this will be at, say, *a* in our figure. Then let *c* be the place just touched by the shadow half an hour later, and *e* that where it falls later still. Now, let us notice where the shadow falls at corresponding instants after noon. We will mark its points of contact *f*, *d*, and *b*. All that remains for us to do is to join each of these pairs of points and bisect the intercepted arcs (*a*, *b*, *c*, *d*, *e*, and *f* in our figure). Should this be properly performed, the line of bisection will be a diameter common to all the circles, and will be the meridian of the place of observation. We have represented it above by the line N S, which may, when once determined, be conveniently marked on the top of the pier permanently. This done, the equatoreal framework is to be so placed on the pier that two plumb-lines dropped, one from the centre of the top of the polar axis, and the other from the corresponding point at the bottom of it shall touch N S. Having effected this, the iron framework S, Fig. 4, may be bolted or cemented down on to A B D E, the more refined adjustments being provided for in the construction of the instrument itself. So far, then, as we have gone, we have got our equatoreal, presumably constructed especially for the latitude of our place of observation, and very approximately in the meridian. How must we now proceed to get it accurately into adjustment.

Before passing to instrumental adjustments proper, we must find the line of collimation, or optical axis of the telescope. To do this let us insert the transit eyepiece (the field of which we have shown in Fig. 6) into the eye end of the telescope.

FIG. 5

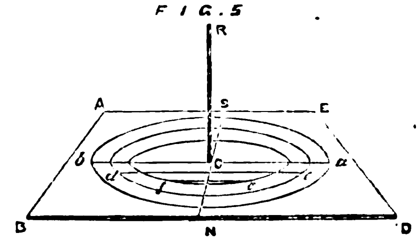

FIG. 6

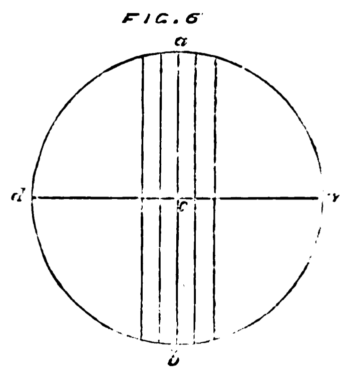

FIG. 7

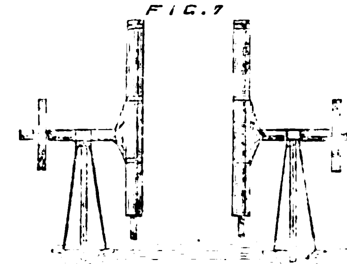


Turn it round until stars run accurately parallel with the declination wire *d w*, clamp the declination circle D C', and by the slow motion *b b'* thread some star upon it. Now, without moving the telescope, turn the whole eyepiece through an angle of 180°, so that the bottom of the field becomes the top, *a* being at *b* and *w* at *d*, and observe if the star is still threaded on the wire. If it be not, move the frame and wires (by the aid of the proper screws) until the declination wires *w d* is *half way* towards the new position of the star. Once more bring it on the wire, again reverse, and so on until the star continues threaded on *d w* after it is turned through 180°. It must then evidently bisect the field of view horizontally. It is pretty evident that by making *a b* horizontal in the same way, and repeating the same adjustment with that (being careful to make it only by the screws at *a* and *b*), we shall with equal ease and certainty get that to bisect the field too; and hence the point of intersection of these two wires *c c* must, *ex-necessitate*, be in the optical axis or line of collimation of the telescope.

This effected, we proceed to the adjustment of the different parts of the equatoreal, *inter se*. As we shall have frequent occasion to speak of the reversal of the telescope, we subjoin a sketch in which the instrument is delineated in two aspects, the first with the telescope to the west of the polar axis, while in the second it is seen to the east of it. We have marked these A and B for convenience of future reference. We may here mention, once for all, that the instrument is employed in position A for the observation of objects to the east of the meridian, and in the position B for observing those to the west of it.

The first thing, then, is to place the declination axis D (Fig. 4), at right angles to the polar axis P. In many cases this is done by the maker; is effected by the most delicate filing of one of the Y's, and once completed is practically permanent. It may be tested by placing the equatoreal in position A, Fig. 7, and carefully levelling the declination axis by the aid of a striding level, which stands upon its cylindrical extremities. The hour circle is then read. Then, the whole instrument is turned over into position B, the declination axis again carefully levelled, and the hour circle once more read. This last reading ought to differ precisely 12 hours from the first one, and will do so if the two axes be accurately square to each other. Should the readings differ from 12 hours, the hour circle must be placed half way between its present wrong position and its proper one, and the declination axis made horizontal, either by the screws at *l* Y in Fig. 4, or, in their absence, by *the maker* of the instrument delicately scraping one of the Y's.

Adjustment 2 consists in setting the optical axis, or line of sight of the telescope, at right angles to the declination axis. To effect this we must insert the transit eyepiece (Fig. 6) and, as before, make a star run along the declination wire *d w*. Now, with the telescope in position A, (Fig. 7), clamp it a little in advance of a star; read the hour circle by means of the vernier *h v*, and note by a sidereal clock the exact instant of the star's passage over *a b*, the middle wire.* Turn the instrument half round on the polar axis, into the position B, again clamp it a little in advance of the same star, again read the hour circle, and, once more, note the instant of the star's transit over the middle wire. Then, if this adjustment be correct, the interval of time between the two transits and the difference of the two readings on the hour circle will be identical. If there be any difference, the wires (Fig. 6) must be moved through half of it, by the screws at *d* and *w*. This must all be repeated until the interval indicated by the two hour circle readings and that elapsing between the two transits of the star are precisely alike. Let us illustrate this by an example. We will suppose that the equatoreal is clamped in position A at 0h. 22m. We will further imagine that, under these circumstances, the field of view is as represented in Fig. 6—*i.e.*, with the end *a* of the wire at the top, or true south, of the field, and the end *b* at the bottom of it. We will suppose, then, that we note, by the aid of a sidereal clock, the transit of *a* Serpentis, and find that it crosses *a b* at 15h. 59m. 59s., as indicated by it. This observation made, we reverse the instrument, and place it in the position B, thus evidently turning the field of the eyepiece over, and having the end *b* of the middle wire at the south, or top of the field of view. We will now clamp the hour circle at 12h. 26m., and wait until *a* Serpentis again crosses the middle wire. Let us assume that it does so at 16h. 4m. 11s. This is obviously *too late*, as it ought to have been on the wire at 16h. 3m. 59s., whereas its transit has been observed 12 seconds after that time. The half of this, then, or 6 seconds, we must correct for. If we suppose that the interval occupied by the passage of our given star from wire to wire is 18 seconds, we must move the frame carrying the wires through one-third of this interval to make this adjustment. It will be seen that, inasmuch as the star (as we face the south), enters on the right hand of the field, and travels across to the left, and inasmuch as we are supposing the transit of our typical one to have taken place *too late*, the wire frame must be too far *to the left* in the second position B of the instrument. We must, then, lower it to the horizon, bisect some object by the wire *b a*, and move the screw at *d* (bear in mind that Fig. 6 is now *inverted*) until the given object is one third of the distance between the centre wire and the next one to it.

Our 3rd adjustment will be to cause the verniers *dv*, *d'v'* of the declination circle D C' (Fig. 4) to read 0° when the optical axis of the telescope is directed to the equinoctial, or, in other words, is parallel to the equator. In making this adjustment, we would counsel the

* For all needful information as to the nature of sidereal time, &c., and the method of taking the transit of a star, the reader is referred to the tenth vol. of the ENGLISH MECHANIC, pp. 595, 620, and 647; and to Vol. XI., p. 1.

beginner to confine himself to *one* vernier, and to attach a piece of paper, or other mark, to it for the purpose of recognition, and to prevent mistakes. When all is complete, the second vernier may be caused to read identically with it, by one operation. Suppose, then, that we select the vernier *d v* in our Fig. 4 (or that which is next to us when the telescope is to the west of the polar axis, as at A, Fig. 7), and let us make any star, the nearer to the meridian the better, run along the declination wire *d w*, Fig. 6, and read the declination circle by the aid of our selected vernier. Now, turn the telescope half round the polar axis into position B; again bring the same star upon the wire; and, again, read the declination circle by the same vernier (this will now be on the farther side from us). If now this latter reading be identical with the former, the vernier is accurately in adjustment; if it be not, half the difference of the readings is an index error which may either be applied as a correction should it be small, or eliminated by shifting the vernier bodily if it is large. Here, as in the previous adjustment, an example may help us. With the equatoreal in the position A, and the star α Ophiuchi threaded on the declination wire, the declination circle reads 12° 41′; but on reversing the telescope, and again running the star along the wire we find the reading to be only 12° 38′. The difference between these two readings being 3′, the index error is evident 1′ 30″, by which quantity the circle reads too low when the telescope is to the east of the polar axis, and too high when it is to the west of it. This observation (and that in connection with the 2nd adjustment) should be repeated several times, and a mean of the results taken. If we suppose that this mean gives exactly 1′ 30″ as the index error, and that the vernier reads too high by that amount in position A, the simplest way for the tyro to proceed is to clamp the declination circle securely (with the telescope to the west of the polar axis), so that the vernier reads 1′ 30″ north of zero, and then releasing the screws which hold the vernier bring it down and make it read 0° 0′ 0″, after which it may be permanently fixed. Two cautions are needful to the beginner. The first is, in readjusting the vernier to take care not only that the *middle division* or zero of it coincides with the mark 0° on the limb of the circle, but that the *ends* also coincide precisely with divisions on the same limb. The next is, *not to screw any one screw tight up at once*, but to turn them up very gently one after another, half a turn or so at a time. Neglect of this latter precaution may throw the adjustment all out again. When it is completed, we have only to loosen the opposite vernier *d′ v′* and cause it to read identically with the one which we have finished, and this part of our work will be complete.

In the 4th place, we must level the declination axis, with all possible accuracy, by the aid of the striding level, as in adjustment 1. Then, releasing the screws which confine the vernier of the hour circle *h v*, we must, by the aid of the tail piece *i j* in our figure, make this vernier read either 0 hours or 12 hours (according as the telescope is in the position A or B), and, this effected, screw it up and make it a fixture there.

Having thus (practically for our present purpose), eliminated what may be called instrumental errors, it only remains for us to place the equatoreal in such a position that its principal axis shall correspond accurately with that of the heavens; and, it must be obvious to any one who has studied our 1st and 3rd figures, that the first thing to do is to make the elevation of the polar axis exactly equal to the latitude of the place.

We have, from the beginning, assumed that the mounting of the instrument is so constructed that this adjustment is very nearly made; and, therefore, a slight motion of the bottom of the polar axis (effected by a contrivance hidden in Fig. 4 by the hour circle), is all that we shall need to render it perfect. For this purpose we must select a star from the *Nautical Almanac*, which is as near as possible to the meridian at the instant of observation; and the higher up this star is, the less will refraction complicate the matter, and the more accurate the result will be. The following are very good stars for the purpose on these latitudes:—α Persei, Capella, Castor, ι Ursæ Majoris, θ Ursæ Majoris, α Canum Venaticorum, η Ursæ Majoris, ζ Herculis, β Draconis, γ Draconis, Vega, α Cygni, 61^1 Cygni, or ζ Cygni. The meridian altitude of our chosen star we may calculate by adding its north declination to the colatitude; and we must now find from a table of refractions (such as appears in every book of astronomical tables, what is the refraction for that altitude, and must thereupon set the declination circle to the declination of the star, with this refraction added (if it be *south* of the zenith). Then, waiting until it enters the field of view, we must raise or depress the end of the polar axis, until the star runs along the declination wire. This adjustment will then be complete.

We may here, in parenthesis, say, that a table of refraction for all altitudes greater than 10° above the horizon may be calculated by any one, with abundant accuracy, from the formula, refraction = 58·49″ × tan. of zenith distance.

We have now only to get the polar axis into the meridian. For this purpose the ordinarily-prescribed way is to set the telescope upon a standard star about 6 hours from the meridian, either east or west, and read the verniers of the declination circle. This reading corrected for refraction ought to be same as the star's declination given in the *Nautical Almanac*. Supposing, for illustration, that the star is east of the meridian, and its declination, as shown by the declination circle, exceeds that given in the *Nautical Almanac*, the lower end of the polar axis is to be west of its true place (and *vice versa*) and must be moved accordingly. There is, however, a simpler mode of performing this adjustment, which will probably suit the beginner better, should he be the possessor of a sidereal clock. It is this: Once more carefully level the declination axis and clamp the hour circle; calculate the instant of transit of a known star near the equator, bring that star on to the centre wire of the transit eyepiece (*a b*, Fig. 6), a few seconds before its transit, follow it by the screws at the bottom of the polar axis, count the beats of the clock by ear, and stop at the precise second computed. Should the observer have no other means of obtaining time he may do so by levelling the declination axis of the equatoreal and taking the transit of a star close to the zenith. For all details as to time-taking, however, we must refer to paper spoken of in our footnote on p. 629.

This concluding adjustment made, the declination circle must be now levelled for the last time, and the vernier *h v* made to read accurately either 0 or 12 hours.

The very great, and unexpected, length to which our directions for the adjustment of the equatoreal have extended, compels us to be much more brief than we had anticipated in our directions for its use. We will deal, in the first place, with finding an object from a catalogue, and will give an illustration without the enunciation of any merely formal rules. Suppose, then, that at 18h. 4m. 32s. sidereal time, on August 30, in latitude 51° 30′ N., we wish to direct our telescope to 61^1 Cygni, how are we to proceed? The right ascension of 61 Cygni we find from the *Nautical Almanac* to be 21h. 1m. 12s.; so that it is, at our presumed instant, 2h. 56m. 40s. to the east of the meridian. Placing the instrument now in position A, we set the hour circle to read 2h. 56m. 40s. Its declination we see by the almanac is 38° 7′ 10″, and the refraction corresponding to this, at the then altitude of the star, may be roughly taken at 50″, adding this, then, to the declination we get 38° 8′, to which we set the declination circle to read, and the star ought to be very near indeed to the middle of the field. We should, perhaps, add that, to preserve the sequence of our remarks, we have reversed the order of the settings of the two circles. In practice we should set for declination first and for right ascension afterwards.

We will now imagine, though, that we have pitched upon an unknown object, say a comet, the place of which we wish to fix with all possible accuracy. In what way are we to determine its place? We should proceed thus: Clamping the telescope firmly in right ascension, a little in advance of our unknown body, we must note the instant of its transit; and then, leaving the hour circle clamped, raise or depress the telescope, until a known star following the object, whose place we are seeking to obtain, enters the field; when it does so we must carefully observe its transit too. As the hour circle has been fixed, the difference of these two times will give the difference of right ascension of the two bodies. To obtain that of their declination all that is necessary is to thread our comet, say, upon the declination wire, and read the declination circle; then, if we turn the telescope upon our standard star, bring *it* on to the same wire, and once again read the declination circle, and we shall have the difference of their declination. After the first observations it does not matter whether the star of comparison precedes or follows the strange object. It is, however, a sine quâ non that it be close to it, and the closer the better. An example may tend to render this explanation clearer. The transit of a comet over the middle wire of the eyepiece is observed to take place at 19h. 37m. 54s. sidereal time, and that of the star β Aquarii (to which it is near) at 19h. 41m. 41·5s.: therefore their difference in right ascension is 3m. 47·5s. The reading of the declination circle when β Aquarii is on the wire *d w* being 6° 6′ 20″ south, and its reading when our imaginary comet is bisected by it 6° 5′ 50″ south, the comet must be just 30″ north of the star. Turning now to the *Nautical Almanac* we find the right ascension of β Aquarii is 21h. 24m. 51·5s., and taking from this 3m. 47·5s. we get 21h. 21m. 4s. as the R. A. of the comet at the time of its observation. The declination of β Aquarii is stated in the same work to be 6° 7′ 48·4″ south, and if from this we take 30″ we obtain 6° 7′ 18·4″ as the comet's declination.

It was our intention, in commencing this series of articles, to have given a description of the position micrometer, and its use in measuring double stars, the diameters of the planets, &c., as also of the ring micrometer, and its employment in mapping the heavens. We have, however, already exceeded the space which we proposed to ourselves to occupy; and a detailed account of these two forms of instrument must certainly itself expand into another essay. We are compelled, then, reluctantly to pause here. If we have not fulfilled all that we proposed to ourselves to do, we trust that, at all events, we have succeeded in giving the student such plain and intelligible directions, as shall enable him not only to place a telescope mounted in the way we have described in accurate adjustment, but also to understand thoroughly the *reasons* for every successive step that he is called upon to take. Should our studiously simple instructions have enabled him to do this, and to employ this admirable instrument more effectively, and with a better appreciation of its powers and capabilities than he previously possessed, our essay on the equatoreal will not have been written in vain.

THE MUSEUMS OF LONDON.—III.

South Kensington Museum (2).

HAVING in the previous article described the educational department of the Museum, we propose now to speak of the collections of objects of art, which are so numerous and so varied as to preclude any methodical and detailed arrangement throughout. Perhaps in no other single building has such a miscellaneous collection ever been brought together, and in consequence of the frequent changes of the loan objects, and the addition of purchases and gifts, the details of the arrangement are constantly in a state of transition. After premising so much we will take the corridor to the right on entering, which leads to the large courts, and which is hung in part with a large series of photographs published by the Arundel Society, comprising historical characters, art objects in the Museum, and figures and groups of figures from the Raphael cartoons. Copies of these can be had at a cheap rate at an adjoining office, as also negatives for home printing. We are glad to see this branch of education obtaining more favourable recognition than has hitherto been accorded it—*e.g.*, the publication of the photographs from the British Museum; for by what better means can the sphere of usefulness of museums, themselves necessarily local, be extended than by enabling every one to possess accurate representations of their most valued treasures? In a small side room are placed the engravings, miniatures, and books (many of them with interesting autographs), of the Dyce bequest. As an example of the way in which the Museum has grown, we might mention that this gentleman—Rev. Alex. Dyce—in 1869 bequeathed to it 80 pictures, 63 miniatures, 802 drawings; 1,511 prints, 74 rings, 27 art objects, and 13,596 books.

The two large courts—North and South—form the larger part of the new buildings; they are both spacious and lofty, open to the roof above. The South Court is decorated from the designs of the late Godfrey Sykes, and contains in the upper parts of its side walls a series of thirty-six alcoves, each containing a portrait in mosaic (by different makers and of different materials) of some celebrated character in the history of art—William of Wykeham, Raphael, Dürer, M. Angelo, Wren, Reynolds, &c. The "Prince Consort Gallery" (connecting with the picture galleries) runs down the whole length of the court, dividing it into an east and west portion; the latter, which the visitor first enters, is devoted mainly to loan objects, the special loan exhibitions, however, being usually held in the North Court. The visitor will at once remark the exceedingly great variety of objects which are here gathered together, and as a consequence of this the confused manner of their arrangement. The collections admit of no entire classification, and all we can do is to point out the general features of the various divisions, and notice specifically a few of the most prominent articles.

A large altar-piece on panel of the fifteenth century, from Spain, in this court is worthy of careful attention, as it is illustrated with scenes of of the different modes of martyrdom then practised in that country. At the back of the altar-piece is placed an electro-reproduction of one of Ghiberti's famous gates, made for the Baptistery of S. Giovanni at Florence, about the beginning of the fifteenth century. In this neighbourhood are numerous examples of the modern cabinet work of various nations, English, French, Dutch, Japan, &c., and further examples will be found in other parts of the building. In the cases are mineralogical specimens, some ancient jewellery and watches of quaint construction, and small isolated series of pottery, &c. The radiating frames which stand about in many parts of the Museum are very convenient and economical as regards space. They consist of a series of square frames disposed at a medium height by means of lateral hinges round a centre pillar, and for some classes of objects are far superior to the horizontal cases—*e.g.*, medals can be held so as to show both sides. In the cloister between the Dyce gallery and the courts are shown the Abyssinian trophies, very interesting and instructive as regards that country, and an extensive collection of ecclesiastical vestments, amongst which is the "Syon Cope."

The eastern portion of the South Court has, till the present special exhibition of musical instruments, been chiefly devoted to that class of objects. In the large cases is a very showy collection of electrotype reproductions of numerous pieces of plate, comprising the regalia in the Tower, specimens from Windsor Castle, and from private individuals. There is also a reproduction by similar means of the famous violin said to have been given by Queen Elizabeth to the Earl of Warwick, the original of which—lent by the present earl—is now in the Museum. In the centre of the court is an entire pulpit of carved and inlaid wood, and surmounted by a minaret, brought from a mosque at Cairo. Among the furniture at the end of the court is a cabinet of various woods inlaid and carved, secured for the Museum for the sum of £2,750 as being the most elaborate piece of furniture in the 1867 Paris Exhibition. In the gallery above is a picture (best seen from this court) of a meeting of the Commissioners of the Exhibition of 1851, presided over by Prince Albert.

The narrow cloisters on the eastern side of this court are devoted to Oriental objects; they were decorated by Mr. Owen Jones. At the end was a very interesting example of a Parisian boudoir of the latter part of the eighteenth century, decorated by artists of the period, and bought for £2,100. It is a small room about 12 or 13ft. square, the walls and ceiling elaborately ornamented, but all in good taste. This boudoir is said to have been originally fitted up by the wife of the Marquis de Serilly, with the assistance of Marie Antoinette, and among the furniture of the room is a harp supposed to have belonged to that queen. Here are several radiating cases of splendid photographic views taken in India, including landscapes, architecture, &c., in looking carefully over which an hour may profitably be spent. We can only stay to direct attention to a small series of miniatures on ivory by an Indian artist, and to a painting on silk of a crouching tiger, excellently done by a native of Japan—Gauko, a celebrated animal painter, date about 1700.

The North Court is frequently used for the special loan exhibitions. It is a fine room 107ft. by 106ft. and 33ft. high, with an elevated glass roof for lighting. Only the larger objects in this court are permanent; among them are casts of two large pulpits from Pisa. Specimens of screens and gates of wrought iron will also be found here, and some have recently been removed. Among them were portions of the iron railings round Hampton Court Palace (English, date about 1700), taken from that place on account of the signs of their rapidly perishing from exposure. Two colossal statues here are casts of the works of Michael Angelo, one being a figure of Moses, the other of David as a youth. In connection with this artist will be found in a case in this court a number of Italian figures modelled in wax and terra-cotta, and evidently intended as art studies; of these twelve are attributed to M. Angelo. An electric clock, from the Exhibition of 1862, made at Clerkenwell, serves for use as well as show. In the northern cloisters, besides a large number of architectural casts, is contained a very complete collection of Della Robbia ware, which may be almost described as earthenware sculpture, and the character of durability attributed to this ware is attested by a large shield, exposed externally in a villa near Florence from 1442 A.D. to its removal a few years ago. The adjoining small fernery is for the purposes of instruction in the schools of art. Following on to the left we come to the circulating portion of the Museum, consisting of representative art objects which are lent to various local museums, exhibitions, and schools of art, and this is not one of the least important branches of the Museum's organisation. The cloisters contain numerous specimens of ironwork (among which is a *couvre feu*) and of the coffers and chests of the last two or three centuries. In one of the end alcoves is a sumptuous French bedstead of the period of Louis XV., with gilt frame and blue silk drapery, and with a fine circular mirror intended to be fixed in its upper portion. By a careful arrangement of the mirror among the drapery in the bottom of the case reflection from the under surface of the glass case top presents the appearance of the upper portion of the bed.

The western portion of the Museum contains examples of ancient state carriages and sedan chairs, locks, carving (among which are some remarkable carved bellows from Italy of the sixteenth century), and also typical specimens of French bronzes, timepieces, vases, &c., intended to illustrate their cheapness as compared with similar objects of home manufacture. These and similar objects, as well as all purchases, are marked with the price on the label. The food collection—now removed to Bethnal Green Museum—was formerly placed here; the rooms are at present occupied by drawings and designs from art schools.

The neighbouring staircase, the decorations of which are not yet complete—leads to the ceramic gallery, which, in construction and arrangement, we consider to be the finest in the whole Museum; it is quite a model gallery. Owing to good ventilation, it is always cool and pleasant (more especially so by contrast in the evenings), and the lighting is good, and not too glaring. The ceiling and side walls are completely but tastefully covered with decorations and gilding, and the names of the various schools of pottery-manufacture, with date, are painted in chronological order round the cornice. The pillars and the side walls of the staircase are of enamelled earthenware tiles, which have the advantage of cleanliness. We have not space to particularise the collection, but we might state that it is typical rather than comprehensive. Two specimens of household stoves from Germany; French cabinets, stands, &c.; Spanish, majolica, Palissy, Sèvres and Wedgwood wares; and some very fine examples of modern pottery, find a place in the collection.

We next come to the pictures, of which we will only speak collectively. The foundation of this "National Gallery of British Art" was laid by J. Sheepshanks, Esq., who gave a large number of very valuable pictures for that purpose. Before these galleries were opened in the evening, a scientific commission (including Tyndall and Faraday) reported on the effects of coal gas that no injury might be apprehended, but advised that the sulphurous acid gas produced by combustion be properly carried off. Among the artists represented are Reynolds, Landseer (many of his finest animal paintings), Wilkie, Turner, Maclise, (his fine picture of the play scene from "Hamlet"), Gainsborough, Mulready, &c. The "Worship of Bacchus," by Cruikshank, attracts more visitors than any other single picture. A room is specially devoted to the celebrated seven original cartoons by Raphael and some other works of that artist. A gallery of water-colour paintings has recently been opened. Those who delight to examine the ground-work and details of art will find much pleasure in examining a large series of sketches and experiments in colouring by Turner—his "Liber Studiorum," and in another room several hundred pen-and-ink sketches and designs by Mulready. Jewellery and other art-objects are contained in some of the rooms. The manner of lighting the gas-jets in this part of the Museum is worth seeing.

We have not yet spoken of the Art Library, a large and rapidly-increasing collection of books and engravings connected with art—very valuable in connection with the schools. When removed from Marlborough House in 1856 it contained only 5,000 volumes; now it comprises 25,000 volumes and pamphlets, 8,000 original drawings and designs, 600 illuminations, 21,000 engravings, and 35,000 photographs. W. H. W. T.

REVIEWS.

Patterns for Turning, comprising Elliptical and other Figures Cut on the Lathe without the Use of any Ornamental Chuck. By H. W. ELPHINSTONE. 216 pages and 70 illustrations. London: John Murray.

THE title of Mr. Elphinstone's work is a somewhat negative explanation of its contents, but in the preface we learn that all the patterns given in the book can be cut on a lathe furnished with a division plate, a slide-rest suitable for ornamental turning, an excentric cutting-frame, and an overhead motion. The figures or patterns forming the illustrations consist of excentric circles disposed upon circular, elliptical, epicycloidal, and other curves, and the object of the book is to explain how these and other patterns can be produced by the simple apparatus mentioned, and without the aid of chucks and complicated mechanism.

With the geometric chuck highly ornamental curves are generated by continuous rotation, and very similar figures are produced, step by step, with the excentric chuck and excentric instrument, by the method known as "double counting." It occurred to Mr. Elphinstone, however, that as by the horizontal motion of the slide-rest, combined with the circular motion of the lathe, the axis of the excentric cutting instrument might be brought into line with any and every point upon a surface attached to the lathe spindle, the excentric cutting instrument could be made to cut circles upon any line or curve whatever, and by these means patterns produced similar in nature to those obtained by ordinary "double counting." By Mr. Elphinstone's invention the figures are still obtained by double, or, as he terms it, "dual counting;" but whereas in "double counting" the two motions are those of the lathe division plate and the excentric chuck wheel, in "dual counting" the two movements are those of the division plate and the horizontal slide of the rest. By this latter method it is possible to very closely imitate many of the most complicated and intricate patterns produced by a geometric chuck of any number of slides, but the preliminary calculations necessary to enable the amateur to locate the separate circles are such as will limit its adoption for comparatively simple patterns only.

Chapter I. is devoted to general explanations of the terms and adjustments. Chapter II. gives rules for determining the size, number, and portion of circles in contact. Chapter III. is on miscellaneous simple patterns; and it is not until we reach Chapter IV. that the reader finds any explanation of the principles of "dual counting." Mr. Elphinstone then proceeds to give instructions for the production of looped figures, circular figures, straight lines, ellipses and waved ellipses, stars, polygons, and other figures, whilst the remaining part of the book is devoted to "settings" of the apparatus for the reproduction of the various patterns and tables to facilitate the calculations. Most of the patterns are good, but many are extremely neat and well cut. We may pick out as amongst the best, Nos. 20, 34, 42, 43, and 62; but we do not see why they could not be placed consecutively, instead of No. 62 being at the beginning, 68 at the end, and 69 and 70 in the middle of the book. We think, also, the reader should be made acquainted with the principle of the system in the first page instead of at the sixty-seventh. But in other respects the book is very complete, and Mr. Elphinstone deserves the thanks of amateur turners for his very thorough explanation of a system which enables them to produce such pleasing patterns with so few apparatus.

The book is extremely well got up, the letter-press having an ample margin, and each figure a leaf to itself. Some of the patterns, more especially 21, 41, and 63, look rather small to occupy alone such a large page, and much of the print is also needlessly large. Without in the slightest degree injuring the work either in utility or appearance, the cost might, we think, be easily reduced. And cost is considered, even by amateur turners.

CHEMICAL NOMENCLATURE.

DR. A. CRUM BROWN read a paper on this much discussed subject at the meeting of the British Association. He said that setting aside in the mean time "trivial" or "proper names" (names which are simply arbitrary words or marks, each indicating, in virtue of a convention applicable to each individual case, a particular substance), there are two systems, or kinds of systems, of chemical nomenclature. These may be distinguished as 1st, the composition system, and 2nd, the functional or relational system, or class of systems. In the first the name of a compound indicates the elements or radicals contained in it, and sometimes their proportions. Thus Chlornatrium, Chloriod, Dreifach chloriod, Silicium Wasserstoff, &c. In English we have few names so distinctly compositional in form (we have, indeed, zinc methyl and all other allied names), but many of our names, although apparently functional in form, are really compositional. Thus, chloride of A means with us nothing more than, or different from, a compound containing the elements chlorine and A; and chloride of sodium, chloride of iodine, terchloride of iodine, siliciuretted hydrogen, not only represent the same substances as the German names just quoted, but tell us neither more nor less about the substances than these German names do. On the other hand, functional names present the chemical relations between substances.

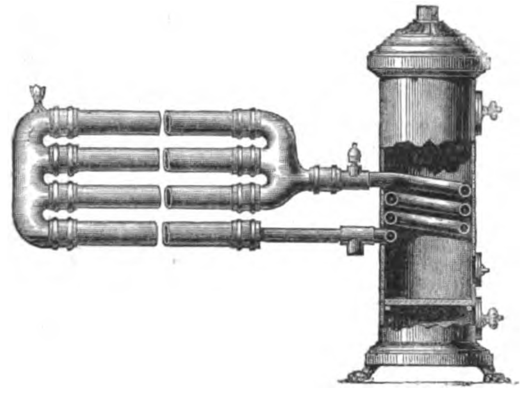
We may take as examples such names as the anhydride, the amide, the aldehyde, the nitrite of acetic acid. These derivatives of acetic acid contain no acetic acid, but they stand in certain definite relation to that substance, and the anhydrides, amides, aldehydes, and nitrides of other acids stand in the same relation to them. What is still, notwithstanding the efforts of modern chemists, the common popular nomenclature of salts, although originally intended as a compositional nomenclature, might, with perfect consistency, be retained as a functional nomenclature. The objection to the term "muriate of soda" was that the substance so named contains no soda. But the amide of benzoic acid contains no benzoic acid. Soda contains oxygen; muriate of soda contains none (unless chlorine be an oxide), but the nitrite of benzoic acid contains no oxygen, although the acid itself does. The name muriate of soda originally meant the *compound* of anhydrous muriatic acid, $2HCl-H_2O$, and anhydrous soda $Na_2O-(2HCl-H_2O)+Na_2O$. We may now, if we please, use the name to mean the result of the action $2HCl+Na_2O-H_2O$. If we do so, the name becomes a fractional one, and the phrase "muriate of," or, what is neither better nor worse, "hydrochlorate of," expresses the complex operation. Addition of hydrochloric acid and simultaneous separation of water. Similarly, in the case of such names as sulphate of potash, nitrate of oxide of silver, &c., the phrases "sulphate of," "nitrate of," express the complete operations, addition of sulphuric, or nitric acid, and simultaneous separation of water.

While the old view that salts are compounds of anhydrous acids and anhydrous bases is now abandoned by most theoretical chemists, a relic of this view still remains in the most advanced systems of nomenclature, producing an inconsistency really inconvenient to the teacher and student. The objection taken to the name hydrochlorate of soda was not only that the substance contains no soda, but also that it contains no hydrochloric acid, this objection is perfectly valid against the name as a compositional one, but does it not equally hold against the words sulphate, nitrate, acetate, &c.?

If we are to have hydric sulphate and hydric acetate for sulphuric and acetic acids, why not hydric muriate for muriatic acid? That this question is not altogether an absurd one will be obvious if we consider that all chlorides are not muriates. Those substances which are by general consent called salts stand in a definite genetic relation to the corresponding acids (or the hydric salts of the series), and it is inconvenient to have the same general name—chloride—applied to substances which do stand in this relation to hydrochloric acid, and also to those which do not. We may divide the chlorides into two groups, very different in character in their extreme members, and gradually shading into one another. We may take chloride of sodium as a representative of the one, and the chloride of phosphorus as a representative of the other. Chloride of sodium is a muriate; the chloride of phosphorus might be better described. We may call the acids and acid anhydrides negative, the hydratic bases, anhydrous bases positive—arranged in a series, we find the series a continuous one from the most positive or basic oxides or hydrates to the most negative; it is however convenient to have a zero point, and it is no disadvantage if this zero point be an arbitrary one. When we come to express numerically the amount of positiveness or negativeness of these oxides and hydrates, it will be necessary to have a zero point, and a very convenient one is that which corresponds pretty nearly to the generally understood limit between bases and acids, and depends upon the direction in which the action takes place.

HOT-WATER HEATING APPARATUS.

THOSE of our readers who are in want of a heating apparatus for their greenhouses, which, while economical in fuel, requires but the minimum of attention, will probably find the desideratum in the arrangement shown in the annexed illustrations, representing the patented centrifugal heating apparatus of Mr. S. Deards, of Harlow, Essex, for which he received a medal at the recent Royal Horticultural Show at Birmingham, as the best "Amateur's Heating Apparatus." The illustrations are sufficiently explanatory of the arrangement, which appears to be constructed on sound principles, and from its simplicity is not liable to derangement. The "boiler," it will be seen, consists of a coil of pipe surrounding the fire; and the advantages claimed by the inventor are economy in fuel, true circulation, and self-cleansing action. It is stated that with one of these "boilers" 60ft. of 4in. pipe can be heated at a cost of less than 6d. for 24 hours, and, what is of equal importance, so little attention is required that the fire may be made up at ten at night and at seven in the morning will be found still alight, with the water but slightly, if at all, lowered in temperature. By means of dampers and the door of the ash-pit the combustion can be easily regulated, so that the boiler may be used either for getting up a high temperature with rapid circulation or for obtaining the more moderate heat required in a greenhouse. The larger sizes can, of course, be so set in brickwork that the fire acts upon both sides of the coil, when the greatest economy of heating power is obtained. One of these large-sized boilers, at the recent trial at Birmingham, went 15 hours without attention, and although in the open air and exposed to several showers of rain, the temperature only fell



off 20° during the whole night. It will be observed that danger of fracture from unequal contraction or expansion is reduced to a minimum in this apparatus, while the perfect circulation prevents injurious incrustations in the pipes.

LUNAR METEOROLOGY.

THE Committee appointed by the British Association for the Advancement of Science to discuss observations of lunar objects suspected of change presented its report at the late meeting at Brighton. The report, which is very short, and merely introductory to Mr. Birt's elaborate report on the streaks and markings on Plato, fully indorses the view of the effect of solar influence in darkening the floor of Plato (see ENGLISH MECHANIC, No. 367, April 5, 1872, p. 53) in the following words:—"One interesting and important change has been fairly shown; the floor of Plato becomes darker with the increase of the sun's altitude. Mr. Birt has suggested an explanation of the phenomenon. Whatever be the true cause of this change it is very difficult to account for it by the ordinary laws of reflection. When we consider the varying aspect of the streaks at the same time of the luni-solar day we cannot but think that with careful observations made with powerful instruments, such as the Newall refractor and many others, we may be able to confirm or otherwise a physical explanation of these curious changes involving the existence of certain gases and vapours on the surface of the moon."

With so successful a termination of the labours of the Committee it is a matter of some little surprise that the report should have been closed without recommending a continuance of observations that appear to be opening up effective means of investigating the moon's surface and throwing light on phenomena observed, more or less, from the epoch of the invention of the telescope. The Committee regard the study of lunar physics as in its infancy, and trust that in *future* years the Association will not overlook so important a branch of astronomical inquiry, yet, to use a homely simile, they do not strike the iron while it is hot, but allow the interest of the public to cool until on some future occasion the Association may for the *fifth* time turn its attention to lunar physics. We have some reason to believe that the observations will not be allowed to drop through. The development and dissemination of truth is the highest prestige the working philosopher can have.

THE SPHEROIDAL STATE OF WATER AND BOILER EXPLOSIONS.

AT the meeting of the British Association, Mr. W. F. Barrett, F.C.S., read a paper on the spheroidal state of water, and its possible relationship to certain boiler explosions. The following is an extract, "On one occasion, some six years ago, I wanted to cool a red-hot copper ball. For this purpose I plunged it into some water in which I had just washed my hands. The hot ball went in without any hissing or visible evolution of steam, and on removing it from the water it appeared as hot as before, in fact it remained brightly incandescent, somewhat below the surface of the water. I was astonished to see this, as I did not know that the spheroidal state of water could be so readily produced and maintained by a body at this temperature. So I tried other red-hot bodies in the same water, and with the same result. I then threw away the soapy water and used plain water; the result was now quite different, the hissing was loud, and the evolution of steam copious. Hence the soapiness of the water was concerned in the phenomenon. Adding a little soap to the water immediately reproduced the result first noticed. Other bodies that dissolved in water were also tried, and the results are briefly these:—Albumen, glycerine, and organic liquids generally facilitate the acquisition of the spheroidal state, probably by increasing the cohesion of the water, whilst of course bodies, such as ammonia, which readily yield vapour have the same effect, but not so marked. Oil shaken up or even placed on the surface of the water has the same effect as the soap. The best method of exhibiting the experiment is to pour a little of Plateau's soap solution into a large beaker of water, and then, by means of a hooked wire, lower into the liquid a white-hot metal ball, some 2lb. weight, and of copper is best. The ball smoothly enters the water, and glows white-hot at a depth of a foot or more below the surface. Notwithstanding the considerable hydrostatic pressure it is seen to be surrounded by a shell of vapour, perhaps half an inch thick. This vapour shell is bounded by an envelope that resembles burnished silver, and has a most striking appearance. In fact, the hot ball blows a soap bubble of steam, from the limiting surface of which the light is totally reflected. As the ball cools (mainly by radiation) the shell of vapour is seen to grow thinner, and finally collapse altogether, when immediately there follows a loud report, volumes of steam are produced, and often the glass is broken. I have heard that traces of oil often get into the boilers of steam-engines, and there can be no doubt that dissolved organic matter often finds its way in. If in any way we increase the density of the water we render it possible for a corroded boiler to give way under the pressure of the steam suddenly generated in the way I have indicated."

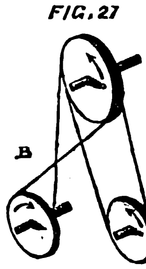
An inventor of Genoa, M. Lamonica, has, remarks *Galignani*, invented a machine for reproducing speech with the rapidity of thought, and destined to suppress stenography.

MECHANISM.*

(Continued from p. 609.)

IF straps have to be shifted on pulleys it should be done when in motion. They are then easily moved, but not so when they are at rest, for there is all the force of their cohesion on the pulley, which causes them to drive it, but if they are moving the strap needs only to be guided, and the pressure of the hand at one side throws the strap to another part of the pulley immediately. That is the only mode of moving the straps with ease. For thus, in fact, the machinery moves the strap, and the workman guides or directs the machinery by his hand on the strap, as a coachman directs the horses by his hand on the reins. Fig. 27 is a diagram with cords showing how they may be arranged so as to cross each other as at B, or act direct as at A. The advantage of crossing is this, that a strap embraces more of the surfaces of the pulleys. Nor is it with cords only that this crossing may be accomplished. The half turn given to crossed straps in passing from pulley to pulley so accommodates itself to the construction that at B the straps pass without even touching each other.

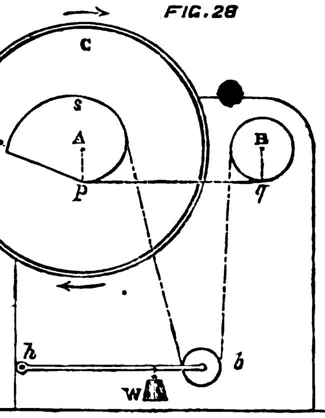
FIG. 27



Cam Pulleys.

These are not generally used, but they have properties which might under many circumstances be utilised. Fig. 28 represents an arrangement by which the peculiar action of cams may be studied in their transference of motion to cords. C is a pulley driven in the direction of the arrows; *s r p* is a cam, around which is passed the cord. From *p* the cord passes to *q*, then round the pulley B and under the stretching pulley *b* to *s*, *r*, and *p*. W is a weight which by means of the arm *h b*—hinged at *h*—maintains the tension of the cord.

FIG. 28



Assume that the cord is round the circumference of the circular pulley C, then the point *q*, in the line B *q*, will be moved uniformly round the centre B, and the directional relations and velocity ratios will be constant. Transfer the cord to the position shown in Fig. 28; then the motion imparted to B *q* will be a variable one. The travel of *q* evidently depends upon the length of cord passing off the cam, *s r p*. Now, the cam may be fixed on any part of the face of the pulley C.

If it be so fixed that the centre of the pulley A is within the cam, then the directional relations of the motions of A and B will be constant, but the velocity ratios will be variable.

Let the centre A, and the cusp *r*, coincide, then in *q* there will be a period of rest. Hence whilst the directional relations are constant the velocity ratios are such that one has vanished and motion has become rest. This, therefore, is a transition stage.

Let now the centre A be without the cam, the point *q* will advance, pause, and then retrograde. Thus, with a cam pulley and a cord, we may, without any alteration in the mechanism, pass from directional relation and velocity ratio constant to directional relation and velocity ratio both varying.

One example of an application of a cam to produce a variable circular velocity in the slide-rest of a screw-cutting lathe may be given. Some years ago the connecting and other long rods in engines were "barrelled," that is, they were in longitudinal section curved, being of a larger diameter in the middle than at the ends. Upon the proportions of the varying diameters much of the beauty of the curve depended. Uniformity was secured thus:—The handle of the slide-rest was removed, and a cam (as *s r p*, Fig. 28), or some other form, was fixed in the stead of the handle. A cord was passed round this cam, and one end tied to the end of the lathe-bed. As the slide-rest was advanced uniformly by the action of the change-wheels, the cord caused the cam to be moved at a varying rate. Having given the required data, it was then easy to form a cam which should give any predetermined curvature to the "barrelling."

Here is an apparatus containing two pulleys of different diameters. It is an old-fashioned Chinese windlass, one of the oldest of wrapping contrivances. The object is to get a motion dependent on the diameters of the two pulleys. You will find that a very large amount of cord passes, and a very small motion of the weight takes place. This arrangement has been chiefly regarded as an illustrative experiment until Weston's pulley blocks were adopted; then, by a peculiar contrivance, that which was nearly useless, owing to the large amount of cord needed and the small motion resulting, became useful, and is now frequently met with in the workshop. Here is a pair of large pulleys by which the action can be seen. The peculiarity is that there are grooves cast in the rims of each of these two pulleys, and the links of a chain drop into them, so that "slip," is destroyed. If the chain does not slip it is held in, and must force the pulley round. One man can lift heavy weights with great ease, leaving them suspended in any position without a counterprise. The weights are lowered by drawing the chain in the reverse direction.

There are various other arrangements of strap gearing, both for the reversing of motion and for producing variable motion, which have been kindly lent. Here is a machine for reversing motion, and producing different velocities. There are two spur or toothed wheels of different diameters, so as to give two speeds. One wheel is brought into use, causing the tool to do its work, and the other wheel causes the tool to run back at a much quicker speed, the reverse motion being obtained by changing the strap from the outside pulley at one side over a loose pulley in the centre on to a pulley at the other side, so that there is a period of rest between the two, preventing any jerk in the machinery. Here is another of the same principle, but without variable velocity. Here is one with two straps, one being crossed. Observe, there are four pulleys—the two centre ones being loose on the shaft. The direction of the machine is determined by moving either the crossed or the other strap on to its correspondent outer pulley.

This subject of strap gearing is far from exhausted. We must, however, turn to a piece of mechanism which is as extraordinary as any ever invented. It is a machine for making cards. The cards which it makes consist of very fine pieces of wire bent and pushed through pieces of leather. They are used for the combing of cotton. Cotton fibre, before it is manufactured into thread, must all be laid in the same direction, and these cards do with the fibre what we with combs do with our hair. Messrs. J. Thompson and Co., of Kendal, have kindly sent one of their machines, and a piece of the leather card it was making before being taken down.

This piece of leather, through which the bent wire is to be put, passes between two grooved rollers, and is led over a pulley, being stretched by a weight of twelve pounds. On the right hand of the machine is a light lantern-wheel, which carries a coil of wire. There are no toothed wheels; it is exclusively a cam machine. Upon one short shaft are thirteen cams, each of which takes its part in a proper sequence in one rotation of the shaft. On the black board is a statement of the sequence of actions, and a few notes as to the character of the cams:—

Action of Cams in Cardmaking Machine.

Cams.	Duties.
1	grips the wire to be advanced.
2	advances the gripped wire.
3	holds firmly the advanced wire.
4	cuts the advanced wire to the required length.
7	actuates prickers of the leather.
8	withdraws prickers.
5	advances fingers to hold and bend the wire.
6	withdraws bending fingers.
9, 10 }	cause the bent wire to enter the pricked holes.
13	raises front nippers and bends the wire.
11	releases the wire-holding pieces.
12	advances a skeleton stepped cam-wheel.

Notes on Cams in Card-making Machine.

1, 2, is a double cam; 1 grips the wire by a cylindrical contrivance; 2 advances it by a swash-plate.

4 not only operates on the cutting-blade, but causes the machinery to stop if the wire should be broken.

5, 6, 7, 8. These rotating cams act in combination with inclined planes which are rectilineal cams—and with springs.

The very fine wire, about the size of a "full stop," passes through a small hole, above which is a pin that can be pressed down so as to hold the wire, and lifted up to release it. When the wire is gripped it is advanced as far as is needful, being adjusted for any required length by a set screw.

As soon as it is advanced, this piece lifts up, leaving the wire so advanced. Another piece now comes down and grips the wire. The piece which originally advanced it goes back and repeats the same operation. The piece that held it down after being advanced retains its hold until a couple of pieces like fingers, operated upon in the centre of the machine, come forward, and a third piece corresponding to them comes from above, so that the wire lies across the two underneath, and the third holds it above. It lies there freely. Whilst so lying another operation is performed. The wire is now lying in what may be called a loose grip, and a motion then takes place which pushing two fingers a little in advance, the wire is gripped firmly. Whilst thus held, as in a vice, two other fingers come forward and bend it. They bend it forward and then close in, causing the points of that wire nearly to touch each other. That, however, is not what is wanted, but the wire has a certain amount of elasticity, and the pressure of these fingers beyond what is required is just sufficient to overcome this excessive elasticity. These bending fingers then withdraw, the elasticity of the wire causes it to open so as to remain with its bent ends exactly opposite the two small holes which have been made in the leather at a previous stage by two prickers. The wire being passed through these two holes as a thread through the eye of a needle, two hooks rise up on the outside, close in, clip the wire, and bend it down, and you will find, on examining this card, that all the wires are bent exactly alike. When so bent, all the operating pieces withdraw, and the wire is left in the leather. Then it is that an action takes place which advances the leather ready for another operation. The processes are these. First, the wire is gripped in the way described by a piece falling upon it; the gripped wire is then advanced. Having been advanced, a piece drops and holds the advanced wire as in a second vice. Whilst so held a knife comes forward and cuts off the required length. These two fingers, previously described, hold the cut-off piece, which has been laid, as it were, upon them; they hold it balanced, projecting an equal length on each side. Whilst so held, a piece descends in front, and, in combination with the two fingers, grips the wire firmly; then two other fingers come forward. Whilst that is going on with the cut-off wire, two little prickers make holes in the leather, through which the wire is to be pushed. A cam withdraws these prickers, then the bending fingers begin to act; when they have bent the wire to the proper position, those bent fingers withdraw themselves and the holders insert the wire through the leather, the hooks in front coming up and bending the inserted wire. Now a wheel, such as few if any in this room have ever seen, called a skeleton wheel, moves. It is a kind of compound side cam stepped wheel, an outline of which has been traced on the board. It is gripped by two clams, and every time the wire is advanced this wheel causes the leather to be pushed sideways. The cams which work the machine are some of them single cams, some swash plates, and some compound cams. There is also one cam which has a very peculiar province. It has no part in the mechanism of the work, but it does this. There is a cam which cuts off the wire at the proper length with a little knife. Upon the wire rides a piece of light metal. This light metal rests as it were upon the wire, so that if the wire should break the light metal would fall down a quarter of an inch, and that falling of a quarter of an inch causes a small piece to rise up which stops the whole machine by throwing the strap wheel out of gear. If the piece of wire were to break, unless the machine were stopped work would go on, the leather being perforated and no wire inserted. It is essential, therefore, that the whole of the machinery should stop when the wire breaks. A similar contrivance causes the stoppage of large silk and cotton looms in case the shuttle thread be broken.

* By the Rev. ARTHUR RIGG, M.A., being the Cantor Lectures delivered before the Society of Arts.

PRESERVED MEAT, CONDENSED MILK, AND EXTRACTS OF MEAT.

DR. EDWARD SMITH commenced his paper read before the British Association, on the principal preserved foods, by stating that the enormous consumption which these foods had obtained rendered it very desirable that the public should understand their value. There was much ignorance and misconception on the subject. First, as to preserved milk. This was sold as a thick fluid in tins, and was manufactured in England, Switzerland, and America. One pint of the product represents four pints of milk, which would cost in this country from 4d. to 8d., according to the locality. The tins held 16oz., and represented a little more than two-thirds of a pint of extract, which would be worth, therefore, about 6½d., whereas the price of the tins was 10d. to 1s. Therefore, instead of being economical, it was very dear to the consumer, though it was a most profitable invention to the manufacturer. The sugar generally used amounted to 20 per cent. of the weight of the tin. Competition would doubtless show its results in two directions, an increased proportion of water or sugar, and a less proportion of cream or butter.

The "preserved meat" brought under consideration was that now so widely known as the "Australian." Dr. Smith described the process of preservation, and stated that 6lb. of raw meat, with a proportion of fat, were placed in a tin, which was put into a bath of chloride of calcium, and exposed to a temperature higher than that of boiling water, namely, from 230° to 250° Fahr. The tin was soldered and closed except at one point, where there was a hole through which the steam escaped. The object to be obtained was primarily the expulsion of the air from the tin, consequently a high temperature was required; and secondly, the cooking of the meat, which, however, might be effected at a much lower temperature. The tin, to prevent too great loss of weight, was "primed" from time to time, so as to keep up the weight of the contents. The circumstances to be remarked in the process were—first, that the meat was neither roasted nor boiled, but stewed in its own vapour; second, that it was overcooked, so that a larger proportion of the soluble materials was extracted than occurred in the ordinary process of boiling, and the solid part was more or less broken up into bundles of fibres; third, the extracted juices were more valuable than from ordinary boiling of meat; and by so much the solid mass was less valuable than ordinary boiled meat; fourth, the peculiar flavour was given partially by the mode of cooking, but chiefly by the addition of the flavour of roasted meat, which was agreeable. The solid matter, although soft, was not easily masticated, since it eluded the grasp of the teeth, and without free mastication it was less perfectly digested. The conclusions to be deduced were classed under different heads. The nutritive value of the whole of the contents of the tin could not be greater than that of the raw meat put into the tin, and hence, although the meat was cooked, the comparison of the value must be with raw meat and not with cooked meat. If, therefore, a dietary was four ounces of cooked meat, the Australian meat would have to be supplied in the same quantity as the raw meat in weight before being cooked—namely 5½ ounces to 6 ounces. He also held that the Australian beast was not equal to the English beast. The pecuniary aspect of the question showed that there was manifestly an advantage to the Australian producer, since he could by this process make larger returns than by boiling down the carcasses of animals for the production of tallow and fat, and, so far, the wealth of the Colonies was increased. Moreover, the process added to the amount of food for man, and therefore must be of universal advantage. As to the English consumer, taking beef supplied to institutions as at 7d. and 7½d. a lb., he thought there was little gain in the use of the Australian tin-meat in those cases, but there was a gain to the individual consumer who had to pay more to the butcher for his meat in this country. He advised that the recommendations laid down by the original importers of the meats should be adhered to in respect of not cooking the meat further than by preparing it in a stew or soup, without more than warming it, and to use it only as a change of food.

Respecting Liebig's extract of meat, he pointed out that it was claimed for this that 1lb. jar represented 32lb. of fresh meat. Its composition was water, and, in large quantity, the salt of meat and the phosphates. It contained only the soluble parts of meat, and only such as could be preserved from putrefaction. The fibrine or solid substance of the meat was excluded, for that was insoluble in water. The fat was excluded most carefully, as it would become rancid. Gelatine and albumen were excluded because they would decompose. When, therefore, fibrine, gelatine, and albumen were excluded, it was certainly not "meat," which was left as the word was understood, for nearly every part of the meat which could be transformed in the body and act as food was excluded; therefore, Liebig's extract of meat was not meat, and to give the meat-power the 32lb. of meat from which it is said to be taken must be added to it, for as it was, it was the play of "Hamlet," with Hamlet left out. The product was of less value to the consumer than to the producer, and the preparation was of a delusive rather than a real advantage; but, although he said this, he held that it had a value as a stimulant in the same way as theine or caffeine; but its economic value was very small as representing 32lb. of meat in a 1lb. jar. There had been much misconception respecting the product, for Liebig never affirmed that it was meat, or the equivalent of meat.

In the discussion which followed the reading of the paper, it was urged that there was one item which ought to be taken into account, viz., that the meat was ready cooked, and so the cost of fuel for cooking was saved. The introduction of the meat into public institutions had, it was stated, reduced the expenditure considerably; and there were the usual stock arguments to prove what is incontestable, namely, that Australian preserved meat must be cheaper, because it is cooked and without bone—the latter being a large item in ordinary "butcher's meat." The assertion that the contents of the tins were underweight was contradicted, with a counter-statement that they are, as a rule, overweight. The condensed milk was considered a great boon where the fresh article could not be obtained; and Liebig's extract was said to be exceedingly valuable as a stimulant. Dr. Smith, in reply, said that the general average of bone throughout the animal was 10 per cent., but it must not be imagined that the bones were of no value. The butchers would allow twopence a pound for them. It must also be recollected that, in boiling a leg of mutton, there was in reality no loss, because whatever nutriment left the meat went into the broth, and the broth should be eaten in some way or other so that the whole produce of the joint was consumed. As to the saving in firing, that had been rather exaggerated, because a fire must be kept up for personal comfort in winter, and in the summer it would be required for boiling a kettle in order to make tea, or for cooking vegetables. He quite admitted that it was very convenient to have cooked food at hand at any time, but that was not a point which he had dealt with in his paper.

THE AIMS AND INSTRUMENTS OF SCIENTIFIC THOUGHT.

THE following is the lecture delivered by Professor W. K. Clifford, before the members of the British Association: Mr. President, Ladies, and Gentlemen—It is my duty to speak to you for a short time about the aims and instruments of scientific thought. It may have occurred (and very naturally too) to such as have had the curiosity to read the title of this lecture, that it must necessarily be a very dry and difficult subject, interesting to very few, intelligible to still fewer, and above all, utterly incapable of adequate treatment within the limits of a discourse like this. It is quite true that a complete setting forth of my subject would require a comprehensive treatise on logic, with incidental discussion of the main question of metaphysics; that it would deal with ideas demanding close study for their apprehension, and investigations requiring a peculiar taste to relish them. It is not my intention to present you with such a treatise this evening. The British Association, like the world in general, contains three classes of persons. In the first place, it contains scientific thinkers, that is to say, persons whose thoughts have very frequently the characters which I shall presently describe. Secondly, it contains persons who are engaged in work upon what are called scientific subjects, but who, in general, do not, and are not expected to think about the subjects in a scientific manner. Lastly, it contains persons who suppose that their work and their thoughts are unscientific, but who would like to know something about the business of the other two classes aforesaid. Now, to any one who, belonging to one of these classes, considers either of the other two, it will be apparent that there is a certain gulf between him and them; that he does not quite understand them, nor they him; and that an opportunity for sympathy and comradeship is lost through this want of understanding. It is this gulf that I desire to bridge over, to the best of my power. That the scientific thinker may consider his business in relation to the great life of mankind; that the noble army of practical workers may recognise their fellowship with the outer world, and the spirit which must guide both; that this so called outer world may see in the work of science only the putting in evidence of all that is excellent in its own work—may feel that the kingdom of science is within it. These are the objects of the present discourse, and you will see that they compel me to choose such portions of my vast subject as shall be intelligible to all, while they ought at least to command an interest universal, personal, and profound.

Scientific and Technical Thought.

In the first place, then, I want to explain what is meant by scientific thought. You may have heard some of it expressed in the various sections this morning. You have probably also heard expressed in some places a great deal of unscientific thought, notwithstanding that it was about mechanical energy, or about hydrocarbons, or about eocene deposits, or about malacopterygii; for scientific thought does not mean thought about scientific subjects with long names. There are no scientific subjects. The subject of science is the human universe—that is to say, everything that is, or has been, or may be related to man. Let us, then, taking several topics in succession, endeavour to make out in what cases thought about them is scientific, and in what cases not. Ancient astronomers observed that the relative motions of the sun and moon recurred all over again in the same order about every nineteen years. They were thus enabled to predict the time at which eclipses would take place. A calculator at one of our observatories can do a great deal more than this. Like them, he makes use of past experience to predict the future; but he knows of a great number of other cycles besides that one of nineteen years, and takes account of all of them; and can tell about the solar eclipse of six years hence exactly where it will be visible, and how much of the sun's surface will be covered at each place, and, to a second, at what time of day it will begin and finish there. This prediction involves technical skill of the highest order; but it does not involve scientific thought, as any astronomer will tell you. By such calculations the places of the planet Uranus at different times of the year had been predicted and set down. The predictions were not fulfilled. Then arose Adams, and from these errors in the prediction he calculated the place of an entirely new planet, that had never yet been suspected; and you all know how the new planet was actually found in that place. Now this prediction does involve scientific thought, as any one who has studied it will tell you. Here there are two cases of thought about the same subject, both predicting events by the application of previous experience; yet we say that one is technical and the other scientific. Now, let us take an example from the building of bridges and roofs. When an opening is spanned over by a material construction, which must bear a certain weight without bending enough to injure itself, there are two forms in which this construction can be made, the arch and the chain. Every part of an arch is compressed or pushed by the other parts; every part of a chain is in a state of tension, or is pulled by the other parts. In many cases these forms are united. A girder consists of two main pieces or booms, of which the upper one acts as an arch and is compressed, while the lower one acts as a chain and is pulled; and this is true even when both the pieces are quite straight. They are enabled to act in this way by being tied together, or braced, as it is called, by cross-pieces, which you must often have seen. Now, suppose that any good practical engineer makes a bridge or roof upon some approved pattern which has been made before, he designs the size and shape of it to suit the opening which has to be spanned, selects his material according to the locality, assigns the strength which must be given to the several parts of the structure according to the load which it will have to bear. There is a great deal of thought in the making of this design, whose success is predicted by the application of previous experience; it requires technical skill of a very high order, but it is not scientific thought. On the other hand, Mr. Fleeming Jenkin designs a roof, consisting of two arches braced together, instead of an arch and a chain braced together, and although this form is quite different from any known structure, yet before it is built he assigns with accuracy the amount of material that must be put into every part of the structure in order to make it bear the required load, and this prediction may be trusted with perfect security. What is the natural comment upon this? Why, that Mr. Fleeming Jenkin is a scientific engineer. Now it seems to me that the difference between scientific and merely technical thought, not only in these but in all other instances which I have considered, is just this. Both of them make use of experience to direct human action; but while technical thought or skill enables a man to deal with the same circumstances that he has met with before, scientific thought enables him to deal with different circumstances that he has never met with before. But how, you will say, can experience of one thing enable us to deal with another quite different thing? To answer this question we shall have to consider more closely the nature of scientific thought. Let us take another example. You know that if you make a dot on a piece of paper, and then hold a piece of Iceland spar over it, you will see not one dot, but two. A mineralogist, by measuring the angle of a crystal, can tell you whether or not it possesses this property without looking through it. He requires no scientific thought to do that. But Sir William Rowan Hamilton, the late Astronomer Royal of Ireland, knowing these facts, and also an explanation of them which Fresnel had given, thought about the subject, and he predicted that by looking through certain crystals, in a particular direction, we should see not two dots but a continuous circle. Mr. Lloyd made the experiment and saw the circle, a result which had never been even suspected. This has always been considered one of the most signal instances of scientific thought in the domain of physics. It is not distinctly an application of experience gained under certain circumstances to entirely different circumstances. Now, suppose that the night before coming down to Brighton you had dreamed of a railway accident caused by the engine getting frightened at a flock of sheep, and jumping suddenly back over all the carriages, the result of which was that your head was unfortunately cut off so that you had to put it in your hat-box, and take it back home to be mended. There are, I fear, many persons even at this day who would tell you that after such a dream it was unwise to travel by railway to Brighton. This is a proposal that you shall take experience gained while you are asleep—when, as the President says, you have no common sense—experience about a phantom railway, and apply it to guide you when you are awake, and have common sense, in your dealings with a real railway. And yet this proposal is not dictated by scientific thought. Now, let us take the great example of Biology. I pass over the process of classification, which itself requires a great deal of scientific thought; in particular when a naturalist, who has studied and monographed a fauna or a flora, rather than a family, is able at once to pick out the distinguishing character required for the subdivision of an order quite new to him. Suppose that we possess all this minute and comprehensive knowledge of plants and animals and intermediate organisms, their affinities and differences, their structure and functions; a vast body of experience, collected by incalculable labour and devotion. Then comes Mr. Herbert Spencer; he takes that experience of life which is not human, which is apparently stationary, going on in exactly the same way from year to year, and he applies that to tell us how to deal with the changing characters of human nature and human society. How is it that experience of this sort, vast as it is, can guide us in a matter so different from itself? How does scientific thought, applied to the development of a kangaroo fœtus or the movement of the sapinexogen, make prediction possible for the first time in that most important of all sciences, the relations of man with man? In the dark or unscientific ages men had another way of applying experience to altered circumstances. They believed, for example, that the plant called Jew's-ear, which does bear a certain resemblance to the human ear, was a useful cure for diseases of that organ. This doctrine of signatures, as it was called, exercised an enormous influence on the medicine of the time. I need hardly tell you that it is hopelessly unscientific; yet it agrees with those other examples that we have been considering in this particular—that it applies experience about the shape of a plant, which is one circumstance connected with it, to dealings with its medicinal properties, which are other and different circumstances. Again, suppose that you had been frightened by a thunderstorm on land, or your heart had failed you in a storm at sea; if any one then told you that in consequence of this you should always cultivate an unpleasant sensation in the pit of your stomach, till you took a delight in it, that you should regulate your sane and sober life by the sensations of a moment of unreasoning terror; this advice would not be an example of scientific thought. Yet it would be an application of past experience to new and different circumstances. But you will already have observed what is the additional clause that we must add to our definition in order to describe scientific thought and that only. The step between experience about animals and dealings with changing humanity is the law of evolution. The step from calculated places of Uranus to the existence of Neptune is the law of gravitation. The step from observed behaviour of crystals to conical refraction is made up of laws of light and geometry. The step from old bridges to new ones is the laws of elasticity and the strength of materials. The step, then, from past experience to new circumstances must be made in accordance with an observed uniformity in the order of events. This uniformity has held good in the past in certain places; if it should also hold good in the future and in other places, then, being combined with our experience of the past, it enables us to predict the future, and to know what is going on elsewhere; so that we are able to regulate our conduct in accordance with this knowledge. I want to make a little clearer the fact that what you call the evidence for a thing depends upon the assumption that this uniformity is valid at places and times at which it has not been observed. The aim of scientific thought, then, is to apply past experience to new circumstances; the instrument is an observed uniformity in the course of events. By the use of this instrument it gives us information transcending our experience, it enables us to infer things that we have not seen from things that we have seen; and the evidence for the truth of that information depends, as we have seen, on our supposing that the uniformity holds good beyond our experience. I now want to consider this uniformity a little more closely; to show how the character of scientific thought and the force of its inferences depend upon the character of the uniformity of Nature. I cannot, of course, tell you all that is known of this character without writing an encyclopædia; but I shall confine myself to two points of it about which it seems to me that just now there is something to be said. I want to find out what we mean when we say that the uniformity of nature is exact; and what we mean when we say that it is reasonable.

Exactness of Natural Laws.

When a student is first introduced to those sciences which have come under the dominion of mathematics, a new and wonderful aspect of nature bursts upon his view. He has been accustomed to regard things as essentially more or less vague. All the facts that he has hitherto known have been expressed qualitatively, with a little allowance for error on either side. Things which are let go fall to the ground. A very observant man may know also that they fall faster as they go along. But our student is shown that, after falling for one second in a vacuum, a body is going at the rate of 32ft. per second, that after falling for two seconds, it is going twice as fast, after going two and a half seconds, two and a half times as fast. If he makes the experiment, and finds a single inch per second too much or too little in the rate, one of two things must have happened; either the law of falling bodies has been wrongly stated, or the experiment is not accurate—there is some mistake. He finds reason to think that the latter is always the case; the more carefully he goes to work, the more the error turns out to belong to the experiment. Again, he may know that water consists of two gases, oxygen and hydrogen combined together; but he now learns that two pints of steam at a temperature of 150° Centigrade will always make two pints of hydrogen and one pint of oxygen at the same temperature; all of them being pressed as much as the atmosphere is pressed. If he makes the experiment, and gets rather more or less than a pint of oxygen, is the law disproved? No, the steam was impure, or there was some mistake. Myriads of analyses attest the law of combining volumes; the more carefully they are made, the more nearly they coincide with it. The aspects of the faces of a crystal are connected together by a geometrical law, by which, four of them being given, the rest can be found. The place of a planet at a given time is calculated by the law of gravitation; if it is half a second wrong, the fault is in the instrument, the observer, the clock, or the law; now, the more observations are made the more of this fault is brought home to the instrument, the observer, and the clock. It is no wonder, then, that our student, contemplating these and many like instances, should be led to say, "I have been shortsighted; but I have now put on the spectacles of science, which nature had prepared for my eyes; I now see that things have definite outlines, that the world is ruled by exact and rigid mathematical laws: 'Kai su, theos, geometreis.'" It is our business to consider whether he is right in so concluding. Is the uniformity of nature absolutely exact, or only more exact than our experiments? At this point we have to make a very important distinction. There are two ways in which a law may be inaccurate. The first way is exemplified by that law of Galileo which I mentioned just now; that a body falling in vacuo acquires equal increase of velocity in equal times. No matter how many feet per second it is going, after an interval of a second it will be going thirty-two more feet per second. We now know that this rate of increase is not exactly the same at different heights, that it depends upon the distance of the body from the centre of the earth; so that the law is only approximate; instead of the increase of velocity being exactly equal in equal times, it itself increases very slowly as the body falls. We know also that this variation of the law from the truth is too small to be perceived by direct observation on the change of velocity. But suppose we have invented means for observing this, and have verified that the increase of velocity is inversely as the squared distance from the earth's centre. Still the law is not accurate; for the earth does not attract accurately towards her centre, and the direction of attraction is continually varying with the motion of the sea; the body will not even fall in a straight line. The sun and the planets, too, especially the moon, will produce deviations; yet the sum of all these errors will escape our new process of observation, by being a great deal smaller than the necessary errors of that observation. But when these again have been allowed for, there is still the influence of the stars. In this case, however, we only give up one exact law for another. It may still be held that if the effect of every particle of matter in the universe on the falling body were calculated according to the law of gravitation, the body would move exactly as this calculation required. And if it were objected that the body must be slightly magnetic or diamagnetic, while there are magnets not an infinite way off; that a very minute repulsion, even at sensible distances, accompanies the attraction; it might be replied that these phenomena are themselves subject to exact laws, and that when all the laws have been taken into account, the actual motion will exactly correspond with the calculated motion.

I suppose there is hardly a physical student (unless he has specially considered the matter) who would not at once assent to the statement I have just made; that if we knew all about it, Nature would be found universally subject to exact numerical laws. But let us just consider for another moment what this means.

Practical and Theoretical Exactness.

The word exact has a practical and a theoretical meaning. When a grocer weighs you out a certain quantity of sugar very carefully, and says it is exactly a pound, he means that the difference between the mass of the sugar and that of the pound weight he employs is too small to be detected by his scales. If a chemist had made a special investigation, wishing to be as accurate as he could, and told you this was exactly a pound of sugar, he would mean that the mass of the sugar differed from that of a certain standard piece of platinum by a quantity too small to be detected by *his* means of weighing, which are a thousand-fold more accurate than the grocer's. But what would a mathematician mean, if he made the same statement? He would mean this:—Suppose the mass of the standard pound to be represented by a length, say a foot, measured on a certain line; so that half a pound would be represented by 6in. and so on. And let the difference between the mass of the sugar and that of the standard pound be drawn upon the same line to the same scale. Then if that difference were magnified an infinite number of times it would still be invisible. This is the theoretical meaning of exactness; the practical meaning is only very close approximation; how close, depends upon the circumstances. The knowledge, then, of an exact law in the theoretical sense would be equivalent to an infinite observation. I do not say that such knowledge is impossible to man, but I do say that it would be absolutely different in kind from any knowledge that we possess at present.

I shall be told, no doubt, that I do possess a great deal of knowledge of this kind, in the form of geometry and mechanics, and that it is just the example of these sciences that has led men to look for exactness in other quarters. If this had been said to me in the last century, I should not have known what to reply. But it happens that about the beginning of the present century the foundations of geometry were criticised independently by two mathematicians, Lobatscheffsky and the immortal Gauss, whose results have been extended and generalised more recently by Riemann and Helmholtz. And the conclusion to which these investigations lead is that although the assumptions which were very properly made by the ancient geometers are practically exact—that is to say, more exact than experiment can be—for such finite things as we have to deal with, and such portions of space as we can reach, yet the truth of them for very much larger things, or very much smaller things, or parts of space which are at present beyond our reach, is a matter to be decided by experiment, when its powers are considerably increased. I want to make as clear as possible the real state of this question at present, because it is often supposed to be a question of words or metaphysic, whereas it is a very distinct and simple question of fact. I am supposed to know, then, that the three angles of a rectilinear triangle are exactly equal to two right angles. Now, suppose that three points are taken in space, distant from one another as far as the sun is from Sirius, and that the shortest distances between these points are drawn so as to form a triangle. And suppose the angles of these points to be very accurately measured and added together; this can at present be done so accurately that the error shall certainly be less than one minute, less therefore than the five-thousandth part of a right angle. Then I do not know that this sum would differ at all from two right angles; but also I do not know that the difference would be less than ten degrees, or the ninth part of a right angle. And I have reasons for not knowing.

This example is exceedingly important as showing the connection between exactness and universality. It is found that the deviation, if it exists, must be nearly proportional to the area of the triangle. So that the error in the case of a triangle whose sides are a mile long would be obtained by dividing that in the case I have just been considering by four hundred quadrillions; the result must be a quantity inconceivably small, which no experiment could detect. But between this inconceivably small error and no error at all, there is fixed an enormous gulf, the gulf between practical and theoretical exactness, and, what is even more important, the gulf between what is practically universal and what is theoretically universal. I say that a law is practically universal which is more exact than experiment for all cases that might be got at by such experiment as we have. We assume this kind of universality, and we find that it pays us to assume it. But a law would be theoretically universal if it were true of all cases whatever, and this is what we do not know of any law at all.

I said there were two ways in which a law might be inexact. There is a law of gases which asserts that when you compress a perfect gas the pressure of the gas increases exactly in the proportion in which the volume diminishes. Exactly; that is to say, the law is more accurate than the experiment, and experiments are corrected by means of the law. But it so happens that this law has been explained; we know precisely what it is that happens when a gas is compressed. We know that a gas consists of a vast number of separate molecules, rushing about in all directions with all manner of velocities, but so that the mean velocity of the molecules of air in this room, for example, is about 20 miles a minute. The pressure of the gas on any surface with which it is in contact is nothing more than the impact of these small particles upon it. On any surface large enough to be seen, there are millions of these impacts in a second. If the space in which the gas is confined be diminished, the average rate at which the impacts take place will be increased in the same proportion; and because of the enormous number of them, the actual rate is always exceedingly close to the average. But the law is one of statistics; its accuracy depends on the enormous numbers involved; and so, from the nature of the case, its exactness cannot be theoretical or absolute.

Nearly all the laws of gases have received these statistical explanations; electric and magnetic attraction and repulsion have been treated in a similar manner; and a hypothesis of this sort has been suggested even for the law of gravity. On the other hand, the manner in which the molecules of a gas interfere with each other proves that they repel one another inversely as the fifth power of the distance; so that we have found at the basis of a statistical explanation a law which has the form of theoretical exactness. Which of these forms is to win? It seems to me, again, that we do not know, and that the recognition of our ignorance is the surest way to get rid of it. The world has made the remark that I have attributed to a fresh student of the applied sciences. As the discoveries of Galileo, Kepler, Newton, Dalton, Cavendish, Gauss, displayed ever new phenomena following mathematical law, the theoretical exactness of the physical universe was taken for granted. Now, when people are hopelessly ignorant of a thing, they quarrel about the source of their knowledge. Accordingly many maintained that we know these exact laws by intuition. These said always one true thing: that we did not know them from experience. Others said that they were really given in the facts, and adopted ingenious ways of hiding the gulf between the two. Others, again, deduced from transcendental considerations sometimes the laws themselves, and sometimes what through imperfect information they supposed to be the laws. But more serious consequences arose when these conceptions derived from physics were carried over into the field of biology. Sharp lines of division were made between kingdoms and classes and orders; an animal was described as a miracle to the vegetable world; specific differences which are practically permanent within the range of history, were regarded as permanent through all time; a sharp line was drawn between organic and inorganic matter. Further investigation, however, has shown that accuracy had been prematurely attributed to the science, and has filled up all the gulfs and gaps that hasty observers had invented. The animal and vegetable kingdoms have a debateable ground between them, occupied by beings that have the character of both and yet belong distinctly to neither. Classes and orders shade into one another all along their common boundary. Specific differences turn out to be the work of time. The line dividing organic matter from inorganic, if drawn to-day, must be moved to-morrow to another place; and the chemist will tell you that the distinction has now no place in his science except in a technical sense for the convenience of studying carbon compounds by themselves. In geology the same tendency gave birth to the doctrine of distinct periods, marked out by the character of the strata deposited in them all over the sea; a doctrine than which, perhaps, no ancient cosmogony has been further from the truth, or done more harm to the progress of science. Refuted many years ago by Mr. Herbert Spencer, it has now fairly yielded to an attack from all sides at once, and may be left in peace. When, then, we say that the uniformity which we observe in the course of events is exact and universal, we mean no more than this, that we are able to state general rules which are far more exact than direct experiment, and which apply to all cases that we are at present likely to come across. It is important to notice, however, the effect of such exactness as we observe upon the nature of inference. When a telegram arrived stating that Dr. Livingstone had been found by Mr. Stanley, what was the process by which you inferred the finding of Dr. Livingstone from the appearance of the telegram? You assumed over and over again the existence of uniformity in nature. That the newspapers had behaved as they generally do in regard to telegraphic messages; that the clerks had followed the known laws of the action of clerks; that electricity had behaved in the cable exactly as it behaves in the laboratory; that the actions of Mr. Stanley were related to his motives by the same uniformities that affect the actions of other men; that Dr. Livingstone's handwriting conformed to the curious rule by which an ordinary man's handwriting may be recognised as having persistent characteristics even at different periods of his life. But you had a right to be much more sure about some of these inferences than about others. The law of electricity was known with practical exactness, and the conclusions derived from it were the surest things of all. The law about the handwriting, belonging to a portion of physiology which is unconnected with consciousness, was known with less, but still with considerable accuracy. But the laws of human action in which consciousness is concerned are still so far from being completely analysed and reduced to an exact form that the inferences which you made by their help were felt to have only a provisional force. It is possible that by-and-by when psychology has made enormous advances and become an exact science, we may be able to give to testimony the sort of weight which we give to the inferences of physical science. It will then be possible to conceive a case which will show how completely the whole process of inference depends on our assumption of uniformity. Suppose that testimony, having reached the ideal force I have imagined, were to assert that a certain river runs up hill. You could infer nothing at all. The arm of inference would be paralysed, and the sword of truth broken in its grasp; and reason could only sit down and wait until recovery restored her limbs and further experience gave her new weapons. I want in the next place to consider what we mean when we say that the uniformity which we have observed in the course of events is reasonable as well as exact.

"Reasonableness" of Nature.

No doubt the first form of this idea was suggested by the marvellous adaptation of certain natural structures to special functions. The first impression of those who studied comparative anatomy was that every part of the animal frame was fitted with extraordinary completeness for the work that it had to do. I say extraordinary, because at the time the most familiar examples of this adaptation were manufactures produced by human ingenuity; and the completeness and minuteness of natural adaptations were seen to be far in advance of these. The mechanism of limbs and joints was seen to be adapted far better than any existing ironwork to those motions and combinations of motion which were most useful to the particular organism. The beautiful and complicated apparatus of sensation caught up indications from the surrounding medium, sorted them, analysed them, and transmitted the results to the brain in a manner with which at the time I am speaking of no artificial contrivance could compete. Hence the belief grew amongst physiologists that every structure which they found must have its function, and subserve some useful purpose; a belief which was not without its foundation in fact, and which certainly (as Dr. Whewell remarks) has done admirable service in promoting the growth of physiology. Like all beliefs found successful in one subject, it was carried over into another; of which a notable example is given in the speculations of Count Rumford about the physical properties of water, to which the President has already called your attention. Pure water attains its greatest density at a temperature of about $39\frac{1}{2}°$ Fahr.; it expands and becomes lighter whether it is cooled or heated so as to alter that temperature. Hence it was concluded that water in this state must be at the bottom of the sea, and that by such means the sea was kept from freezing all through; as, it was supposed, must happen if the greatest density had been that of ice. Here, then, was a substance whose properties were eminently adapted to secure an end essential to the maintenance of life upon the earth. In short, men came to the conclusion that the order of Nature was reasonable in the sense that everything was adapted to some good end. Further consideration, however, has led men out of that conclusion in two different ways. First, it was seen that the facts of the case had been wrongly stated. Cases were found of wonderfully complicated structures that served no purpose at all; like the teeth of that whalebone whale of which you heard in Section D the other day, or of the dugong, which has a horny palate covering them all up and used instead of them; like the eyes of the unborn mole, that are never used, though perfect as those of a mouse until the skull-opening closes up cutting them off from the brain, when they dry up and become incapable of use, like the outsides of your own ears, which are absolutely of no use to you. And when human contrivances were more advanced it became clear that the natural adaptations were subject to criticism. The eye, regarded as an optical instrument of human manufacture, was thus described by Helmholtz, the physiologist who learned physics for the sake of his physiology, and mathematics for the sake of his physics, and is now in the first rank of all three. He said, "If an optician sent me that as an instrument, I should send it back to him with grave reproaches for the carelessness of his work, and demand the return of my money."

The extensions of the doctrine into physics were found to be still more at fault. That remarkable property of pure water, which was to have kept the sea from foraging, does not belong to salt water, of which the sea itself is composed. It was found, in fact, that the idea of a reasonable adaptation of means to ends, useful as it had been in its proper sphere, could yet not be called universal, or applied to the order of nature as a whole.

True Meaning of "Explanation."

Secondly, this idea has given way because it has been superseded by a higher and more general idea of what is reasonable, which has the advantage of being applicable to a large portion of physical phenomena besides. Both the adaptation and the non-adaptation which occur in organic structures have been explained. The scientific thought of Dr. Darwin, of Mr. Herbert Spencer, and of Mr. Wallace, has described that hitherto unknown process of adaptation as consisting of perfectly well-known and familiar processes. There are two kinds of these: the direct process, in which the physical changes required to produce a structure are worked out by the very actions for which that structure becomes adapted—as the backbone or notochord has been modified from generation to generation by the bendings which it has undergone; and the indirect processes, included under the head of Natural Selection—the reproduction of children slightly different from their parents, and the survival of those which are best fitted to hold their own in the struggle for existence. If the naturalists here were able to talk to you for weeks, they might give you some idea of the rate at which we are getting explanations of the evolution of all parts of animals and plants, the growth of the skeletons, the nervous system and its mind, of leaf and flower. But what, then, do we mean by explanation? We were considering just now an explanation of a law of gases; the law according to which pressure increases in the same proportion in which volume diminishes. The explanation consisted in supposing that a gas is made up of a vast number of minute particles always flying about and striking against one another, and then showing that the rate of impact of such a crowd of particles on the sides of the vessel containing them would vary exactly as the pressure is found to vary. Suppose the vessel to have parallel sides, and that there is only one particle rushing backwards and forwards between them, then it is clear that, if we bring the sides together to half the distance, the particle will hit each of them twice as often, or the pressure will be doubled. Now, it turns out that this would be just as true for millions of particles as for one, and when they are flying in all directions instead of only in one direction and its opposite, provided only that they interfere with each other's motion. Observe now; it is a perfectly well known and familiar thing that a body should strike against an opposing surface and bound off again; and it is a mere every-day occurrence that, what has only half so far to go should be back in half the time; but that pressure should be strictly proportional to density is a comparatively strange, unfamiliar phenomenon. The explanation describes the unknown and unfamiliar as being made up of the known and the familiar, and this, it seems to me, is the true meaning of explanation. Here is another instance. If small pieces of camphor are dropped into water, they will begin to spin round and swim about in a most marvellous way. Mr. Tomlinson gave, I believe, the explanation of this. We must observe, to begin with, that every liquid has a skin which holds it; you can see that to be true in the case of a drop, which looks as if it were held in a bag. But the tension of this skin is greater in some liquids than in others; and it is greater in camphor and water than in pure water. When the camphor is dropped into water it begins to dissolve and gets surrounded with camphor and water instead of water. If the fragment of camphor were exactly symmetrical, nothing more would happen; the tension would be greater in its immediate neighbourhood, but no motion would follow. The camphor, however, is irregular in shape; it dissolves more on one side than the other; and consequently gets pulled about, because the tension of the skin is greater where the camphor is most dissolved. Now, it is probable that this is not nearly so satisfactory an explanation to you as it was to me when I was first told of it, and for this reason. By that time I was already perfectly familiar with the notion of a skin upon the surface of liquids, and I had been taught by means of it to work out problems in capillarity. The explanation was, therefore, a description of the unknown phenomenon which I did not know how to deal with as made up of known phenomena which I did know how to deal with. But to many of you, possibly the liquid skin may seem quite as strange and unaccountable as the motion of camphor on water. And that brings me to consider the source of the pleasure we derive from an explanation. By known and familiar, I mean that which we know how to deal with, either by action in the ordinary sense, or by active thought. When, therefore, that which we do not know how to deal with is described as made up of things that we do know how to deal with, we have that sense of increased power which is the basis of all higher pleasures. Of course, we may afterwards by association come to take pleasure in explanation for its own sake. Are we, then, to say that the observed order of events is reasonable, in the sense that all of it admits of explanation? That a process may be capable of explanation, it must break up into simpler constituents which are already familiar to us. Now, first, the process may itself be simple, and not break up; secondly, it may break up into elements which are as unfamiliar and impracticable as the original process.

It is an explanation of the moon's motion to say that she is a falling body, only she is going so fast and is so far off that she falls quite round to the other side of the earth, instead of hitting it; and so goes on for ever. But it is no explanation to say that a body falls because of gravitation. It seems that the motion of the body may be resolved into a motion of every one of its particles towards every one of the particles of the earth, with an acceleration inversely as the square of the distance between them. But this attraction of two particles must always, I think, be less familiar than the original falling body, however early the children of the future begin to read their Newton. Can the attraction itself be explained? Le Sage said that there is an everlasting hail of innumerable small ether particles from all sides, and that the two material particles shield each other from this and so get pushed together. This is an explanation: it may or may not be a true one. The attraction may be an ultimate simple fact, or it may be made up of simple facts utterly unlike anything that we know at present; and in either of these cases there is no explanation. We have no right to conclude, then, that the order of events is always capable of being explained.

Cause and Effect.

There is yet another way in which it is said that Nature is reasonable; namely, inasmuch as every effect has a cause. What do we mean by this? In asking this question we have entered upon an appalling task. The word represented by cause has sixty-four meanings in Plato and forty-eight in Aristotle. These were men who liked to know as near as might be what they meant; but how many meanings it has had in the writings of the myriads of people who have not tried to know what they meant by it will! I hope, never be counted. It would not only be the height of presumption in me to attempt to fix the meaning of a word which has been used by so grave authority in so many and various senses; but it would seem a thankless task to do that once more which has been done so often at sundry times and in divers manners before. And yet without this we cannot determine what we mean by saying that the order of Nature is reasonable. I shall evade the difficulty by telling you Mr. Grote's opinion. You come to a scarecrow and ask, what is the cause of this? You find that a man made it to frighten the birds. You go away and say to yourself "Everything resembles this scarecrow. Everything has a purpose." And from that day the word cause means for you what Aristotle meant by final cause. Or you go into a hairdresser's shop, and wonder what turns the wheel to which the rotary brush is attached. On investigating other parts of the premises you find a man working away at a handle. Then you go away and say "Everything is like that wheel. If I investigated enough, I should always find a man at the handle." And the man at the handle, or whatever corresponds to him, is from henceforth known to you as cause, and so generally. When you have made out any sequence of events to your entire satisfaction, so that you know all about it, the laws involved being so familiar that you seem to see how the beginning must have been followed by the end; then you apply that as a simile to other events whatever, and your idea of cause is determined by it. Only when a case arises, as it always must, to which the simile will not apply, you do not confess to yourself that it was only a simile and need not apply to everything, but you say "The cause of that event is a mystery which must remain for ever unknown to me." On equally just grounds, the nervous system of my umbrella is a mystery which must remain for ever unknown to me. My umbrella has no nervous system; and the event to which your simile did not apply has no cause in your sense of the word. When we say, then, that every effect has a cause, we mean that every event is connected with something in a way that might make somebody call that the cause of it. But I, at least, have never yet seen any single meaning of the word that could be fairly applied to the whole order of Nature. From this remark I cannot even accept an attempt recently made by Mr. Bain to give the word a universal meaning, though I desire to speak of that attempt with the greatest respect. Mr. Bain wishes to make the word cause hang on in some way to what we call the law of energy; but though I speak with great diffidence, I do think a careful consideration will show that the introduction of this word cause can only bring confusion into a matter which is distinct and clear enough to those who have taken the trouble to understand what energy means. It would be impossible to explain that this evening; but I may mention that energy is a technical term out of mathematical physics, which requires of most men a good deal of careful study to understand it accurately.

Doctrine of Contradictions.

Let us pass on to consider, with all the reverence which it demands, another opinion, held by great numbers of the philosophers who have lived in the brightening ages of Europe: the opinion that at the basis of the natural order there is something which we can know to be unreasonable, to evade the processes of human thought. The opinion is set forth first by Kant, so far I know, in the form of his famous doctrine of the antinomies or contradictions, the nature of which I will endeavour to explain to you. Kant said, then, that space must either be infinite or have boundary. Now, you cannot conceive infinite space; and you cannot conceive that there should be any end to it. Here, then, are two things, one of which must be true, while each of them is inconceivable; so that our thoughts about space are hedged in, as it were, by a contradiction. Again, he said that matter must either be infinitely divisable, or must consist of small particles incapable of further division. Now you cannot conceive a piece of matter divided into an infinite number of parts; while on the other hand you cannot conceive a piece of matter, however small, which absolutely cannot be divided into two pieces; for however great the forces are which join the parts of it together, you can imagine stronger forces able to tear it in pieces. Here again, then, are two statements, one of which must be true, while each of them is separately inconceivable; so that our thoughts about matter also are hedged in by a contradiction. There are several other cases of the same thing, but I have selected these two as instructive examples. And the conclusion to which Kant was led by the contemplation of them was that on every side when we approach the limits of existence a contradiction must stare us in the face. The doctrine has been developed and extended by the great followers of Kant; and this unreasonable, or unknowable, which is also called the absolute and the unconditioned, has been set forth in various ways as that which we know to be the true basis of all things. As I said before, I approach this doctrine with all the reverence which should be felt for that which has guided the thoughts of so many of the wisest of mankind. Nevertheless, I shall endeavour to show that in these cases of supposed contradiction there is always something which we do not know now, but of which we cannot be sure that we shall be ignorant next year. The doctrine is an attempt to found a positive statement upon this ignorance, which can hardly be regarded as justifiable. Spinoza said "a free man thinks of nothing so little as of death;" it seems to me we may parallel this maxim in the case of thought, and say "a wise man only remembers his ignorance in order to destroy it." A boundary is that which divides two adjacent portions of space. The question, then, "Has space (in general) a boundary?" involves a contradiction in terms, and is, therefore, unmeaning. But the question "does space contain a finite number of cubic miles or an infinite number?" is a perfectly intelligible and reasonable question, which remains to be answered by experiment. The surface of the sea would contain a finite number of square miles, if there were no land to bound it. Whether or no the space in which we live is of this nature remains to be seen. If its extent is finite, we may quite possibly be able to assign that extent next year; if, on the other hand, it has no end, it is true that the knowledge of that fact would be quite different from any knowledge we at present possess, but we have no right to say that such knowledge is impossible. Either the question will be settled once for all, or the extent of space will be shown to be greater than a quantity which will increase from year to year with the improvement of our sources of knowledge. Either alternative is perfectly conceivable, and there is no contradiction. Observe especially that the supposed contradiction arises from the assumption of theoretical exactness in the laws of geometry. Now, the other case that I mentioned has a very similar origin. The idea of a piece of matter, the parts of which are held together by force, and are capable of being torn asunder by greater forces, is entirely derived from the large pieces of matter which we have to deal with. We do not know whether this idea applies in any sense to the molecules of gases even; still less can we apply it to the atoms of which they are composed. The word force is used of two phenomena; the pressure, which when two bodies are in contact connects the motion of each with the position of the other, and attraction or repulsion; that is to say, a change of velocity in one body depending on the position of some other body which is not in contact with it. We do not know that there is anything corresponding to these phenomena in the case of a molecule. A meaning can, however, be given to the question of the divisibility of matter in this way. We may ask if there is any piece of matter so small that its properties as matter depends upon its remaining in one piece. This question is reasonable, but we cannot answer it at present, though we are not all sure that we shall be equally ignorant next year. If there is no such piece of matter, no such limit to the division which shall leave it matter, the knowledge of that fact would be different from any of our present knowledge, but we have no right to say that it is impossible. If, on the other hand, there is a limit, it is quite possible that we may have measured it by the time the Association meets at Bradford. Again, when we are told that the infinite extent of space, for example, is something that we cannot conceive at present, we may reply that this is only natural, since our experience has never yet supplied us with the means of conceiving such things. But then we cannot be sure that the facts will not make us learn to conceive them, in which case they will cease to be inconceivable. In fact, the putting of limits to human conception must always involve the assumption that our previous experience is universally valid in a theoretical sense, an assumption which we have already seen reason to reject. Now you will see that our consideration of this opinion has led us to the true sense of the assertion that the order of nature is reasonable. If you will allow me to define a reasonable question as one which is asked in terms of ideas justified by previous experience, without itself contradicting that experience, then we may say as the result of our investigation, that to every reasonable question there is an intelligible answer, which either we, or posterity, may know.

Conclusions.

We have, then, come, somehow, to the following conclusions:—By scientific thought we mean the application of past experience to new circumstances, by means of an observed order of events. By saying that this order of events is exact, we mean that it is exact enough to correct experiments by, but we do not mean that it is theoretically or absolutely exact, because we do not know. The process of inference we found to be in itself an assumption of uniformity, and that as the known exactness of the uniformity became greater, the stringency of the inference increased. By saying that the order of events is reasonable, we do not mean that everything has a purpose, or that everything can be explained, or that everything has a cause, for neither of these is true. But we mean that to every reasonable question there is an intelligible answer, which either we or posterity may know by the exercise of scientific thought. For I specially wish you not to go away with the idea that the exercise of scientific thought is properly confined to the subjects from which my illustrations have been chiefly drawn to-night. When the Roman jurists applied their experience of Roman citizens to dealings between citizens and aliens, showing by the difference of their actions that they regarded the circumstances as essentially different, they laid the foundation of that great structure which has guided the social progress of Europe. That procedure was an instance of strictly scientific thought. When a poet finds that he has to move a strange new world which his predecessors have not moved, where, nevertheless, he catches fire from their flashes, arms from their armoury, sustentation from their footprints, the procedure by which he applies old experience to new circumstances is nothing greater or less than scientific thought. When the moralist, studying the conditions of society, and the ideas of right and wrong which have come down to us from a time when war was the normal condition of man, and success in war the only chance of survival, evolves from them the conditions and ideas which must accompany a time of peace, when the comradeship of equals is the condition of national success; the process by which he does this is scientific thought and nothing else. Remember, then, that it is the guide of action; that the truth which it arrives at is not that which we can ideally contemplate without error, but that which we may act upon without fear, and you cannot fail to see that scientific thought is not an accompaniment or condition of human progress, but human progress itself. And for this reason the question what its characters are, of which I have so inadequately endeavoured to give you some glimpse, is the question of all questions for the human race.

BRITISH ASSOCIATION GLEANINGS.

Astronomical Refraction.—Mr. G. Forbes read a paper on "Astronomical Refraction." He pointed out sources of error in the observation of stars, due to the moisture of the atmosphere, variations of barometric pressure in two separate places of observation, as well as other sources of inaccuracy. He stated that, although Greenwich and Chiselhurst were only five miles apart, he had found that there was a range of barometric difference between them of nineteen-thousandths of an inch during a period of one month selected at haphazard. These things might cause differences of atmospheric refraction, which would explain discrepancies in observations of the polar distances of the stars.

Rainfall and Trees.—M. Lemoine read a paper on this subject, in which he said:—The action of forests on the climate of a country must be considered as extremely doubtful. In the basin of the Seine it has been established in respect to forests, as compared with soil covered with grass, or even with other permanent cultivation, that they have no influence on the watercourses. The only absolutely certain action of forests is their influence on the protection of the soil. They prevent the earth being carried away; it follows that, in mountainous countries, they retard the flow of torrent waters. In fact, in the Hautes Alpes, the presence of forests prevents the formation of torrents; the replanting of woods extinguishes torrents already existing; but in most cases turfing alone is sufficient to produce the same effect. These conclusions must be carefully limited to the countries in which they have been obtained. Mr. Brown said there were indications that a great portion of South Africa had been under water, but at what period had not been ascertained. The trees varied in magnitude in different quarters, and yet were of the same magnitude in each locality. The desiccation of the country has been going on since the draining off of the waters, owing to evaporation. The destruction of herbage and grass by fire, the use of the axe by native and colonist, and the formation of sheepwalks, facilitated the process of evaporation. Mr. Blore sunk two cylindrical jars, of the same size, in the ground to the depth of 4in., leaving them projecting 1in. above the surface. One was placed where it was practically protected; the other was sunk in a newly cleared plot. Into each jar was put 20oz. of water on January 31. On February 5th the water remaining in each was carefully measured, and it was found that the evaporation from the jar in the open ground had been more than double that from the other jar, which was partially protected, though not covered by bush.

Vesuvian Dust.—Mr. G. Gladstone, F.C.S., said that, during the eruption of Vesuvius which took place last spring, Naples and the surrounding country was visited by a shower of fine black dust. In some places the fall was very heavy, and even in Ischia, at twenty-five miles distance from the mountain, where the dust examined was collected, the quantity was sufficient to cause great annoyance to the inhabitants. It consisted of aggregations of crystallised quartz, dotted over with the magnetic oxide of iron. The ferrosoferric oxide was also crystalline, and possessed a high metallic lustre. The grains were very uniform in size, and would pass through a wire gauze, the apertures of which measured the 16,000th part of a square inch. By boiling the sand in hydrochloric acid the whole of the iron is removed, and nothing but crystals of pure white quartz remained. Its composition is the same as that of the iron-sand which is formed in the soil in some parts of the country round Vesuvius, and which is the product of former eruptions. The latter, however, contains a larger relative proportion of iron, and the grains show a waterworn appearance under the microscope. Neither of the Vesuvian specimens contain titanium, which is found in the magnetic iron-sand of New Zealand, which has most likely been ejected from the great volcano of Mount Egmont.

Vital Movement.—Dr. Radcliffe read a paper entitled, "Whether the Causes of Vital Movement are yet Clearly Appreciated." The author commenced with a résumé of the opinions of ancient and modern writers on the subject of vital movement. He ridiculed the current doctrine which, he said, assumes that vital movements are distinct from those manifested in inert matter, and which can at best be only regarded as a hasty deduction from superficial observations. The highest aspirations of philosophy, he contended, are in direct contradiction to this assumption; and the doctrine of the correlation of physical and vital forces implies a grand centralisation, by which what have been regarded as separate forces are made to appear as various aspects of some central force. Dr. Radcliffe then referred to some investigations which he had recently made with Sir William Thomson's electrometer, and which had tended to confirm the views of Galvani. He mentioned, by way of illustration, a singular experiment that he had made with a strip of indiarubber, coated on the two surfaces with metal, which was elongated by the attraction of two opposite charges; the discharge causing the rubber to contract to its original length.

The "Fossil" Man.—Mr. Moggridge, F.G.S., read an account of the discovery, by Dr. Rivière, of the "fossil" man at Mentone (see p. 478); after which Mr. Pengelly gave a description of the remains. He said the apparently finished tools lying around the skeleton were not artificial tools at all, but appeared to be what were known as whetstones. They were not instruments in the proper sense of the word. Any person looking at the skeleton would see the attitude was such as was assumed in quiet, tranquil sleep. This might be accounted for by the supposition that the man died tranquilly where Rivière found him, possibly from charcoal fumes, for there was plenty of charcoal discovered about him, and that he was here buried by his friends, who simply covered him over. The remains of a *Kjokkenmodding* were found at the mouth of the cavern. Mr. Boyd Dawkins thought there were no facts to lead to the belief that this skeleton was of any enormous antiquity, or that it dated back to the age when extinct animals were living in that part of Europe.

Evolution, and the Human Arm.—Professor Struthers exhibited a number of bones and dissections, showing the presence in the human arm of a supracondyloid process, to which special interest attaches from its mention in Mr. Darwin's recent work. This little projecting spur, just above the elbow, occurs, Professor Struther says, much more extensively than has been generally supposed. He finds it in about one case in fifty, and it may be observed in a very rudimentary state in almost every subject. It was impossible, he said, to explain this variation on the old ideas of final cause and type, and it was a strong piece of evidence in support of the doctrine of evolution. In some animals the process had a specific function to fulfil, but in man it served no purpose whatever.

The Origin of Alphabets.—Mr. John Evans, F.R.S., &c., read a paper on this subject, in which he spoke of the immense importance attached to writing, and the reverence with which it is regarded by tribes who do not possess the power, and stated that such tribes still had an idea of preserving a record of events by a sort of pictorial writing. So early as the time of the caves of the reindeer period in the south of France, bones and horns were found bearing pictorial representations which seemed to give a history of some character. Similar representations were found on the bone instruments of the Esquimaux. The north American Indians had considerable powers of representation by picture signs, and copies of some tombstones erected over the graves of their chiefs were exhibited bearing such a record. The earliest form of Chinese writing was pictorial, and Mr. Evans showed numerous examples of the manner in which the ancient pictorial forms had been shortened into the characters in use at a later period. There could be no doubt, he said, that the Phœnicians were the first inventors of the alphabet in use among the Greeks and Romans of classical times. The period at which it was introduced was uncertain, but in all probability was not more than 1,000 years B.C. The exact form of the Phœnician letters was shown by the Moabite stone which commemorated the acts of Mesia, King of Moab in the days of Omri, King of Israel, about 2,700 years ago. Diagrams were exhibited showing how the Roman alphabet was derived from this Phœnician alphabet. The word "alphabet" was composed of two Phœnician words, "aleph" and "beth," in an Hellenised form combined together. Lastly, from whence was this alphabet in use among the Phœnicians derived? Was it pictorial or arbitrary? Here, although following in the steps of Gesenius, he could not feel that he was treading on such safe ground as in the former part of the subject. Every letter in the Phœnician alphabet had its name, and they were in nearly all cases able to recognise the meaning of the name of the letter. Aleph was stated by Plutarch to have been placed first, because the ox was the first necessary of life. Aleph meant the head of an ox, and the Phœnician A might be taken to be a representation of the head of an ox. Beth, the second letter, meant a house, and the B might represent the roof. The third letter, "Gimneah," meant a camel," and the Phœnician C represented the head and neck of a camel. Mr. Evans went through the remaining letters of the alphabet, and exhibited diagrams suggesting their original pictorial forms.

Raised Beach in Ireland.—Professor E. Hull read a paper on this subject. All along the eastern coast of Ireland, from Dublin Bay northwards, there is to be found at intervals distinct evidence that the coast has been raised in recent times. This evidence is divisible into two kinds; first, the occurrence of a narrow fringe of varying elevation, forming a terrace extending for some distance inland from the coast, and composed of stratified sands and gravel, containing marine shells belonging to species now inhabiting the Irish Sea; and secondly, the existence of old sea-worn cliffs, forming the inland margin of these terraces, which are now beyond the reach of the highest tides. In the North of Ireland these cliffs are penetrated by caves, which have yielded bones of animals, some of which are extinct in that part of the country, while the gravels of the old beach contain amongst the sea shells worked flints in considerable quantity in County Antrim, which prove the elevation of the coast to have taken place since the human period. The height attained by the beach above the present sea-level is about 8ft. in the south, but it rises gradually northwards, and there attains a height of 20ft. The author considered this to be of the same age as the 25ft. beach of the west coast of Scotland, which falls somewhat in level towards the Solway; southwards this decrease in level continues, till the evidences of a raised beach almost disappear towards the estuary of the Mersey. The identity, therefore, of the phenomena on both shores is evident, and is a matter of some interest in the physical geology of these islands.

Decomposition of Water.—A paper on the "Mutual Helpfulness of Chemical Affinity, Heat, and Electricity, in Producing the Decomposition of Water," by Dr. Gladstone and A. Tribe was read. Some metals are able of themselves to displace the hydrogen of pure water, while other metals are unable. Zinc, if perfectly pure, is incapable of doing so, but if it be brought into contact with another metal still further removed from the power of effecting the decomposition of water, the electric force started by contact of the metals enhances the chemical affinity sufficiently to make it effective—or, otherwise expressed, the electrical tension, *plus* the chemical tension, upsets the state of equilibrium between the oxygen and the hydrogen. The amount of action may be measured by a Thomson's galvanometer. The effect of varying the distance of two plates of zinc and copper was tried, and it was found that the chemical action increases slowly till the plates are within an inch or so of each other, but on continuing to bring them together the action increases at a rapidly accelerating ratio. Heat assists the action considerably. Magnesium is capable by itself of decomposing water, but its action is greatly increased by touching it with a piece of copper, and some of the hydrogen gas makes its appearance on the copper. If, instead of magnesium, a metal less capable than zinc of decomposing water be used, there is still found a deflection of the galvanometer, if it be united with a metal still more negative. The order for pure water seems to be—platinum, silver, copper, iron, tin, lead, zinc, magnesium.

The Geological Distribution of Goitre.—Mr. Lebour has collected a great amount of information upon the distribution of this disease in England, and his facts are of the more importance as no information can be obtained upon the subject from Government statistical returns. He traced in detail the range of goitre over the various formations, and showed that the accepted beliefs on this subject were frequently erroneous. Thus, as regards magnesian limestone, which is commonly believed to be a very goitriferous rock, he showed that goitre was by no means so common there as in some other formations. Again, whilst on some regions occupied by carboniferous limestone the disease abounds, in others, where the general character of the rock is apparently the same, it is entirely absent. In searching for a general cause regulating the distribution of goitre, the author rejected as insufficient that generally given—the hardness of water. He showed it to be more probable that metallic impurities in the water were the cause. The carboniferous limestone was characterised by goitre almost in exact proportion to the metalliferous nature of the rock. Districts where ferruginous water occurs very commonly have goitre, particularly where the iron is derived from the decomposition of iron pyrites.

Glass Plummer-Blocks and Axle-Bearings.—From what is stated it would appear that MM. De Camus and Haret have successfully substituted glass for bronze in the above-named parts of machinery. The use of glass for the purpose alluded to seems to be attended with many advantages, and amongst them that of requiring less labour in making the articles, and greatly decreased consumption of lubricating materials.

LETTERS TO THE EDITOR.

[We do not hold ourselves responsible for the opinions of our correspondents. The Editor respectfully requests that all communications should be drawn up as briefly as possible.]

All communications should be addressed to the Editor of the English Mechanic, 81, *Tavistock-street, Covent Garden, W.C.*

All Cheques and Post Office Orders to be made payable to J. Passmore Edwards.

"I would have every one write what he knows, and as much as he knows, but no more; and that not in this only, but in all other subjects: For such a person may have some particular knowledge and experience of the nature of such a person or such a fountain, that as to other things, knows no more than what everybody does, and yet to keep a clutter with this little pittance of his, will undertake to write the whole body of physicks: a vice from whence great inconveniences derive their original."—*Montaigne's Essays.*

*** *In order to facilitate reference, Correspondents when speaking of any Letter previously inserted, will oblige by mentioning the number of the Letter, as well as the page on which it appears.*

MOONRISE—TELESCOPE STOPS—THE EARTH'S INTERIOR—ELONGATIONS OF THE INFERIOR, AND OPPOSITIONS OF THE SUPERIOR PLANETS—MIRA CETI, AND ALGOL—HEIGHT OF MOUNTAIN—CLOCK RATE—ROUNDABOUT THEORY—LUNAR MOTIONS—57 M. LYRÆ—SPECULA—PURCHASE OF AN OBJECT-GLASS—AND A FEW FULL MOONS IN ADVANCE.

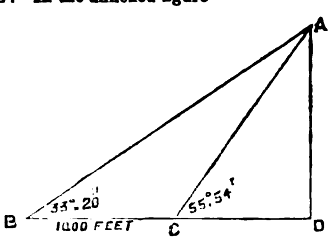
[4823.]—Writing from the locality whence this is penned, I can *not*, off-hand, tell "Delta" (query 12583, p. 574) the title of any book which contains the calculation of the rising and setting of the moon, but have very little doubt that he would find it in such a book as Chauvenet's "Spherical Astronomy," or in any of the larger works on Navigation, such as Raper's, Norie's, Merrifield & Evers's, &c. As for the rising and setting of the superior planets, they may be obtained with abundant accuracy by the aid of a table of semi-diurnal arcs (with an allowance for refraction), such as I have previously advised him (p. 556) to make for himself.

"Tyro" puts a question (12677, p. 574) which it is simply impossible to answer, inasmuch as he gives not the slightest hint either as to the focal length of his telescope or with regard to the internal diameter of his stops. In the absence of these absolutely essential details, I may tell him that he may arrive at the proper places for the stops by the following simple formula: As the diameter of the object-glass : its focal length : : the internal diameter of the stop : *its distance* from the focal point—*e.g.*, suppose that "Tyro" has a telescope of 3in. clear aperture and 45in. focal length, and has a stop belonging to it of 2in. internal diameter, where ought such stop to be placed? We say 3 : 45 : : 2 : x, and this, as a common rule-of-three sum, comes out 30. The stop, then, must be placed 30in. from the focal point, or 15in. from the object-glass. Or, again, imagine the stop to have an opening of ⅓in., we shall have 3 : 45 : : ⅓ : x—*i.e.*, 5, so that such a stop must be fixed 5in. from the focus of the instrument, or 40in. behind the object-glass.

If "Balcairn" (query 12691, p. 575) were to pick up a ball of an inch in diameter, whose external surface was formed of cork, and, putting it into a balance, discover that it weighed two ounces, he would at once be convinced that its interior must consist of some material considerably heavier than that of which its surface was composed. Assuredly he would see, instantly, that our hypothetical sphere was not merely a simple cork shell, with an internal vacuum. Let us apply this reasoning to the case of the earth. The rocky material of which its exterior is composed has a mean density of less than three times that of water. The mean density of the whole earth, however, is *at least* 5·5 times that of water, and is very probably even greater, so that, so far from the interior of the earth being a *vacuum*, it must actually contain matter (in some form) of considerably greater density than that composing those parts which are accessible to us.

I may answer Mr. Somerville (query 12701, p. 575) by telling him that Mercury is at his brightest when his elongation from the sun is about 22°, and that when he is an *evening* star such brightness is at its maximum a few days *before* his greatest elongation. On the other hand, when he rises before the sun, or is a morning star, he is at his brightest a few days *after* his greatest elongation. Thus, for example, he will attain his greatest elongation east (21° 25′) at 1h. 29m. a.m. on November 28, so that he will be at his greatest brilliancy during the week between November 20 and that date. Mercury was, or ought to have been, very visible with proper optical aid on the 3rd August, but a "terrestrial telescope" is scarcely competent to pick the planet up in the daytime. Mercury does not "always recede the same distance" from the sun, its orbit being much more eccentric than that of any of the other large planets; in fact, its distance from the sun at aphelion differs from that at perihelion by something approaching to one-fifth of the major axis of that orbit. I have said that Mercury will attain his greatest eastern elongation on November 28 of the present year. I may further inform my querist that he will arrive at his greatest western elongation (23° 8') about 2 o'clock in the morning on January 6, 1873, so that (according to the intimation conveyed in the beginning of the answer to this particular query) he will be at his brightest about a week after that time. Venus attains her greatest brilliancy some 36 days before, and again 36 days after her inferior conjunction, her elongation being then (as Guillemin, according to your correspondent, correctly says) about 40°. Thus, at 8h. 40m. on the night of February 22nd, 1873, she will be at her greatest elongation E (46° 30'), and will be actually at her greatest brilliancy on the 30th of the succeeding month, March. At this date she will be perfectly visible to the naked eye in bright sunshine if her position, be accurately known. Then, passing her inferior conjunction at 5h. 51m. in the afternoon of May 5, she will again be at her brightest on the 10th of June, attaining her greatest elongation west (45° 38') 17 minutes after midnight on July 14th. Referring to the next part of Mr. S.'s question I may say that Mars will next be in opposition at 2h. 40m. in the afternoon of April 27th, 1873; Jupiter at 52 minutes past 1 a.m. on February 15th, 1873; Saturn at 4h. 57m. a.m. on July 22nd, 1873; Uranus at 5h. 56m. in the evening of January 23rd, 1873; and Neptune at 11h. 14m. on the night of October 17th, 1872. With regard to Mira Ceti, it must have been at its maximum of brightness on or about the 27th of last May. We have only to add 334 days to this to obtain the time at which its next maximum may be expected. I may conclude my reply to Mr. Somerville by saying that his suggestion that I should give the time at which Algol will be at its greatest brilliancy every month has been made before, and I will only here repeat what I have said in these columns on a former occasion with reference to this very subject. It is briefly this, that I could only arrive at "the time at which Algol will be most brilliant" by a method equally open to your correspondent himself—*i.e.*, by actually watching it. If he will do this, and add 2 days 20 hours 48m. 55s. to the instant of the particular phase which he is observing, he will get the time of its recurrence. With regard, however, to the particular star under discussion, he must remember that it remains at its maximum (appearing as a second magnitude) for, as nearly as may be, 61 hours. It then begins to diminish, and in about 4 hours is reduced to a star of the fourth magnitude. It remains at its minimum for about 20 minutes, and in another four hours returns to its maximum again. This is not a very easy sequence of phenomena to tabulate in Greenwich mean time, as even Mr. Somerville must admit.

"Quercus" (query 12711, p. 600) may obtain the height of his inaccessible mountain by the aid of a sextant and a common table of natural sines, &c., without even employing logarithms. He can proceed as follows: In the annexed figure



Let AD represent the mountain whose altitude we wish to ascertain. Then we will imagine the observer standing at C, a spot at an unknown distance from it, and on measuring the angle ACD, finding it to be, say, 55° 54'. Now, let him travel backwards in a perfectly straight line, exactly 1,000ft., to B, and then, measuring the angle ABD we will suppose him to find it to be 33° 20': what is the height of AD? BD is evidently = AD cot. 33° 20', and CD is = AD cot. 55° 54' ∴ BC (= 1,000ft.) = AD (cot. 33° 20' − cot. 55° 54') ∴ AD = $\frac{1{,}000\text{ft.}}{\text{cot. } 33^\circ 20' - \text{cot. } 55^\circ 54'}$. In other words, we have only to take the natural co-tangent of 55° 54' from the natural co-tangent of 33° 20', and to divide 1,000ft. by the result, to get the length of AD, or height of our supposed mountain.

Let us do this. Referring to our tables of natural sines, &c., we find—

Cot. 33° 20' = 1·5204261
Cot. 55° 54' = 0·6770509

0·8433752) 1000·0000000 &c. (1185·7

And performing the division we get as a final result, 1185·7 feet as the height of the mountain.

Unable, myself, to answer the question (12735) of "Rho," on p. 600, I shall be equally glad with him to be furnished with a formula for computing the influence of varying atmospheric pressure on the rate of a clock; inasmuch as I find the effect of change of temperature to be comparatively subordinate as a disturbing influence, to that of any considerable barometric fluctuation.

"Balcairn" in his query—if it be a query—(12737, p. 600) is really a trifle too much for me. *Imprimis*, he confuses revolution and rotation. In the next place, he seems to fancy that the earth's axial rotation causes the seasons, which it does not. And thirdly, there is a pervading absence of pronouns, which obscures even his obscurity. The sentence "It follows that the globe travels 8,760,000 miles a year" contains some great mystery. Why, the globe travels something like 574,810,000 of miles in her annual orbit alone (neglecting the motion which she possesses in common with the sun and the whole of the solar system in space). As for "Balcairn's" concluding sentence, it seems to me to be only paralleled by that famous one commencing, "What, no soap! So he died, and she, very imprudently, married the barber," &c. Œdipus left four children, Polynices, Eteocles, Ismene, and Antigone; but I cannot trace my own descent from any of them; nor am I acquainted with any one who is able to do so.

Mr. W. L. Brown (query 12753, p. 601) puts a question, or string of questions, with reference to one of the most abstruse and recondite subjects which can occupy the attention of astronomers—the motions of the moon. These may be—in your correspondent's own words—"very easy to understand to those who know all about it;" but it may be as well to say in the outset that the astronomers who "know *all* about it" might be counted upon his fingers without the smallest difficulty. It will easily be imagined, then, that it is almost a hopeless task to attempt to do more than popularise the leading features of the lunar movements; and all I can hope to do is to indicate some of the reasons for the phenomena with regard to which Mr. Brown feels a difficulty. To begin, then, with the changes in the moon's declination. It must be remembered that the plane of her orbit is inclined to that of the ecliptic about 5° 9', by which quantity she will be sometimes to the north and sometimes to the south of it. Here, then, is a fertile cause of varying declination. And it must further be borne in mind that the moon's path varies from month to month both in form and position, changing even its eccentricity within small definite limits. The major axis of the ellipse which she describes moves forward on the ecliptic some 41° every year; in fact, goes right round it in something short of nine years; so that in less than 4½ years the perigee arrives at the former position of the apogee. Even this motion is irregular, being direct, or in the order of the signs, when the moon is in conjunction or opposition, and retrograde when she is in quadrature. The former movement must, however, obviously exceed the latter. Again, the line where the moon's orbit cuts the ecliptic, or, as it is called, the line of nodes retrogrades at the rate of about 19° per annum; so that the nodes make a mean tropical revolution in about 18 years and 224 days. This, as in the preceding case, is an irregular movement. Without, then, going any farther it will be seen that the moon's path *does not return into itself*, but is a curve of the most intricate kind, and one in a condition of perpetual change. To answer the concluding part of query 12753 rigorously would involve a tremendous amount of calculation. *Pro hac vice*, then, it must suffice to say that at the end of 223 lunations (or a few days over 18 years) the moon will return very nearly, *but not quite*, to the position which she occupied at the beginning of the cycle—*i.e.*, will be in the same position in the sky, in the same position in her own orbit, and in the same position with regard to the ecliptic. This period is the so-called "Saros" by the aid of which the Chaldæans calculated eclipses. It is, however, quite apparent that as this number of lunations by no means corresponds *exactly* with 18 years, the lunar phenomena will not occur on the same *days* at its expiration. To obtain a cycle which shall fulfil this latter condition, we must go to that of Meton, which is one of 235 synodical revolutions of the moon. These differ only from 19 years of 365¼ days by something more than an hour, so that at the expiration of this period New Moon, Full Moon, &c., will recur on the same days of the year. Yet another cycle, known, from its inventor, as the Calippic, is obtained by multiplying the Metonic one by four, inasmuch as 76 solar years (minus 1 day) contain 940 lunar months almost exactly. It is, perhaps, worth while to mention, too, with reference to the "Saros" of which we have spoken above, that we may obtain a cycle of increased accuracy by multiplying it by 3, since 669 lunations correspond very closely indeed with 54 common years, excluding leap years. By this time I think it will have dawned upon Mr. Brown that the computation of the exact interval which must elapse before the moon will return to precisely the same position in her orbit, as respects her nodes and syzygies, and have exactly the same right ascension and declination at the same instant of the same day of the week and month, is one which is *not* "very easy," even to those who do "know all about it," and that it involves an amount of mere numerical work which very few people would care to undertake, save with some very specific object indeed.

The quotation made by "Linea" (let. 4796, p. 614) from Mr. Proctor's article in the *Mechanics' Magazine* only shows how largely idiosyncrasy, or "personal equation," enters into every observation of a celestial object by different eyes. *I* invariably see the interior of the ring in 57 M. Lyræ, with a 4¼ Dallmeyer object-glass, perceptibly lighter than the surrounding sky; whereas we find him, with an instrument whose light-grasping power exceeds mine in the proportion of 22 : 17 describing this same nebula as "an oval ring with the interior as dark as the sky outside the ring." I remember Mr. Proctor, some considerable time ago, in these columns, trying to deprecate an attempt on my part to lay down a hard and fast line with reference to the visibility or non-visibility of stars of a certain magnitude in a telescope of given aperture, and I certainly think that the instance now under discussion affords a fair illustration of the general soundness of the views which he then advanced. Albeit, I must adhere to my opinion that the 5th star in θ¹ Orionis is *not* visible in one of the much be-puffed "light 5-pounders."

I may answer "Zeta" (query 12762, p. 626) by telling him that the mirror of a reflecting telescope is a segment of a paraboloid of revolution; and that though in years gone by they were figured (by a tentative process) by hand, they are now invariably ground and polished by machinery, several forms of which he will find described and illustrated in back volumes of the ENGLISH MECHANIC.

I would by all means advise "Zealous" (query 12777, p. 626) to purchase "a 2½in. object-glass of the best quality" for the purpose he requires. A man like Wray would construct him one of the smaller aperture, which would be as, practically, effective as the larger glass, and I fancy be quite within his means.

It is somewhat difficult to conceive in what way "the secretaries of societies" are to be benefited by the knowledge of the dates at which the moon will be full for some years to come, as implied by "J. G.," in query 12782, p. 626; but, assuming that some occult advantage is derivable, or to be derived, from such knowledge, I append a list of dates of her opposition up to December, 1875. She will, then, be full in 1872 at 3h. 35m. p.m. on October 16; at 5h. 8m. a.m. on November 15; and at 9h. 44m. p.m. on December 14. During 1873 she will be full at 4h. 23m. p.m. on January 13; at 11h. 33m. a.m. on February 12; at 5h. 44m. a.m. on March 14; at 9h. 51m. p.m on April 12; at 11h. 18m. a.m. on May 12; at 10h. 1m. p.m. on June 10; at 6h. 33m. a.m. on July 10; at 1h. 52m. p.m. on August 8; at 9h. 9m. p.m. on September 6; at 5h. 31m. a.m. on October 6; at 3h. 48m. p.m. on November 4; and at 4h. 20m. a.m. on December 4. In 1874 full moon will occur at 7h. 3m. p.m. on January 2; at 11h. 36m. a.m. on February 1; at 5h. 21m. a.m. on March 3rd; at 11h. 19m. p.m. on April 1; at 4h. 9m. p.m. on May 1; again at 6h. 46m. a.m. on May 31; at 6h. 48m. p.m on June 29; at 4h. 43m. a.m. on July 29; at 1h. 28m. p.m. on August 27; at 10h. 6m. p.m. on September 25; at 7h. 21m. a.m. on October 25; at 5h. 34m. p.m. on November 23; and at 4h. 56m. a.m. on December 23. During 1875 there will be full moon at 5h. 41m. p.m. on January 21; at 8h. 1m. a.m. on February 20; at 11h. 52m. p.m. on March 21; at 4h. 30m. p.m. on April 20; at 8h. 50m. a.m. on May 20; at 11h. 56m. p.m. on June 18; at 1h. 27m. p.m. on July 18; at 1h. 34m. a.m. on August 17; at 0h. 42m. p.m. on September 15; at 11h. 14m. p.m. on October 14; at 9h. 30m. a.m. on November 13; and, finally, at 7h. 45m. p.m. on December 12.

A FELLOW OF THE ROYAL ASTRONOMICAL SOCIETY.

THE SOLAR CORONA.

[4824.]—MY opinion that the phenomena of the solar corona are in great part due to the existence of meteoric and cometic systems near the sun, was maintained *after* the discovery that the light of the corona is in part due to glowing gas. This discovery was not made by Mr. Lockyer, or in December 1871, as supposed by Mr. Gore (let. 4798, p. 614), but by Professors Young and Harkness during the American eclipse of August, 1869. It was somewhat pertinaciously opposed by Mr. Lockyer, even after Professor Young had renewed his observations in an unmistakable way, in December, 1870; but this circumstance scarcely brings the credit of the discovery home to Mr. Lockyer. Soon after the last-named eclipse, Professor Young devised a very ingenious method for yet further testing the matter, and that method was applied by Mr. Lockyer in December, 1871, unsuccessfully so far as the corona was concerned. The method consisted in viewing the eclipsed sun through a train of prisms, without any slit; and no doubt is capable of showing monochromatic images of the corona. Indeed, a method depending on the same general principles was applied successfully by Professor Respighi, who saw three monochromatic images of the corona about 8' high. Mr. Lockyer saw images only about 2' high, and therefore not ranging above the height of medium-sized prominences, an observation which could prove nothing. But the great spectroscopic success in December, 1871 (a success only surpassed in value by that which the photographers achieved), was obtained by Janssen, who recognised *several bright lines* in the spectrum of the corona, and moreover *several dark lines* in the continuous spectrum (belonging also to the corona). These results are of extreme interest and importance.

There can be no question, I think, that Mr. Lockyer would have obtained interesting results if he had given his whole attention to spectroscopic work. His skill as an observer would have stood him in good stead, as well as his familiarity with the practical details of spectroscopy. (This is not a case where a knowledge of the theory of the subject was in any sense important.) But unfortunately Mr. Lockyer attempted to do too many things. Stationed at the very worst part of the track of central totality (so far as duration was concerned), we find that (1) he looked for the reversal of the Fraunhofer lines at the beginning of totality (failing, says Dr. De la Rue, in his address to Section A of the British Association, through the temporary derangement of his instrument); (2) he tried to record the naked-eye aspect of the corona (with the result that it was "rigid," and "like a decoration"); (3 and 4) he made polariscopic observations in two different ways (getting directly contradictory results); (5) he examined the corona through the telescope (with the result that it was "like Orion"); (6 and 7) he looked for the spectrum in the usual way, and he applied Young's method (results negative); (8) he adjusted the twin telescope for Maclear to see the spectrum (no result); and (9) he looked, I suppose, for the reversal of the Fraunhofer lines at the end of totality. It is no disparagement to his unmistakable skill as an observer to say that no good could possibly result from observations so crowded upon each other. (The eclipse at Bekul only lasted two minutes.) There was something singularly generous in the attempt to do everything in this way; but success was an impossibility. Moreover, all the best instruments being with Mr. Locker at Bekul, the other members of the Expedition were rather ill-provided.

I need hardly say that I do not regard the discoveries made by Young and Harkness in 1869 and 1870, or those made by Respighi and Janssen (severally) in 1871, as in any sense opposed to the meteoric theory of the corona. This theory was never meant to account for every feature of the corona, but only (1) for a portion of its light and (2) for some of the most remarkable of its peculiarities. Janssen's recognition of the dark lines in the coronal continuous-spectrum confirms (what, however, needed no confirmation) the theory that a portion of the coronal light is due to reflection from meteors travelling (at the moment) close to the sun. The existence of these meteors in millions of millions is as nearly a scientific certainty as the existence of a zone of asteroids.

But other features of the corona seem only explicable by recognising the extension of gaseous matter to a great distance from the sun. And again, there are several features which appear due to the action of an energetic repulsive force exerted by the sun on certain forms of matter in his immediate neighbourhood. We have also evidence of eruptional action intense enough to affect the condition of the corona to its very outermost extension.

On all these points—as well with respect to what we know as to the matters which yet remain undetermined—my views now are those which are expressed in the chapters on the prominences and corona in the second edition of my book on the Sun (pp. 242—424).

RICHARD A. PROCTOR.

THE AUGUST METEORS.

[4825.]—IN the neighbourhood of Salisbury, on the night of the 28th, the August shower was partially renewed, and though the meteors were not of such brilliancy as on the 8th, still their numbers made them worthy of notice. They were observed from 8 to 10 p.m., the clouding up of the sky at the latter hour preventing further observation. I was unable, on account of the darkness, to register the exact time of each appearance, and the following list contains all the data I am able to furnish:—

No.	Time.	Direction.	Magnitude as compared with stars.	Apparent starting point.
	h. m.			
1	8 5	W.	4 white.	B'tw'n 23,22 Ur. Mj.
2	8 20		2 "	
3		N.W.	3 "	δ, ε Cassiopœiæ.
4		W.N.W.	3 "	
5	8 45	towards α Ursæ M.	1 green.	α Pegasi.
6	9 10		3	δ Cassiopœiæ.
7*			4 gr.	
8	9 30	towards β Cameli.	3 red.	β Andromedæ.
9	9 50	towards θ Ur. Maj.	3 wh.	ε Ursæ Majoris.
10			2 wh.	
11	10 0	N.W.	2 wh. gr.	δ Cassiopœiæ.

The one marked with an asterisk appeared and disappeared suddenly, leaving a small train. There were several seen to start from the neighbourhood of Pegasus, Lacerta, and Andromedæ, which could not be noted as regards position. In most cases the course was short, and in that of 5, 8 it was extremely curved. No. 5 was of a brilliant green, with a short train of sparks.

P. W. WYATT.

COMPARING ELECTRO-MOTIVE FORCES.

[4826.]—I REGRET that I must still insist on the incorrectness of the equations stated by "O." The law enunciated by him in letter 4697 (p. 543) is true, not generally for all closed circuits, but only for those in which all the electro-motive forces act homogeneously, which is not the case in "O.'s" experiment. For, assuming the law to be universally true, we shall have, as "O." states—

$$i_1 (x + R) + i_3 g = E_1,$$
$$i_2 (y + r) + i_3 g = E_2.$$

From which we get—

$$i_1 (x + R) - i_2 (y + r) = E_1 - E_2. \quad (1)$$

But the circuit $x R r y$ is a closed circuit;

$$\therefore i_1 (x + R) + i_2 (y + r) = E_1 + E_2. \quad (2)$$

Hence from equations (1) and (2)—

$$i_1 (x + R) = E_1,$$
$$\therefore i_3 g = o$$

—*i.e.*, either $g = o$, which reduces the case to two independent circuits having no portion in common, or $i_3 = o$; so that these two are the only cases in which the law, as applied to this experiment, holds good, or "O.'s" equations are true, as stated in my former letter. (Because "O." can obtain, as he has done, a correct expression for i_3 from his equations is no more proof of their accuracy than that the combination of the equations $x = a$, $x = b$, giving $x^2 = a\,b$, shows that a and b are the roots of that equation.) The true mathematical demonstration is that indicated by "O." in his last letter. In answer to "S. T. P." (let. 4739, p. 566), I beg to say that "Sigma," in his letters on electricity, described Fitzgerald's method of measuring internal resistance, a year or more ago, and I gave Mance's method a few months back. If he looks back he can easily find them.

PI.

WALL TRANSIT INSTRUMENT.

[4827.]—IN the hope that it may be of service to some of the readers of the ENGLISH MECHANIC, I herewith forward a photograph and description of a simple transit instrument, which was contrived by me in 1838. A more complete instrument I described in that year in the London *Mechanics' Magazine*, Vol. XXX. The transit is fixed to the face of a wall or side of a window as near as may be in the meridian by three screws passing through the lower plate. This plate has a stem terminating in a ball screwed into its centre. The upper plate has a corresponding hollow turned in it to receive the ball. It has also on its under surface a projecting flange or rim which has a screw cut upon it. Upon this a stout brass ring is screwed, the inside of which fits the lower part of the ball, forming, in fact, the well-known ball and socket. The stem proceeding from the upper part of Plate 2 has its interior turned out slightly conical to receive an axis to which the telescope clip is fixed. At the top of this axis are a screw and washer by which it can be tightened. The lower part of the clip passes through a loose ring, which can be clamped to the clip by the small thumb-screw shown in the photograph. The axis and ring will then revolve together. This ring has a piece of wire pro-

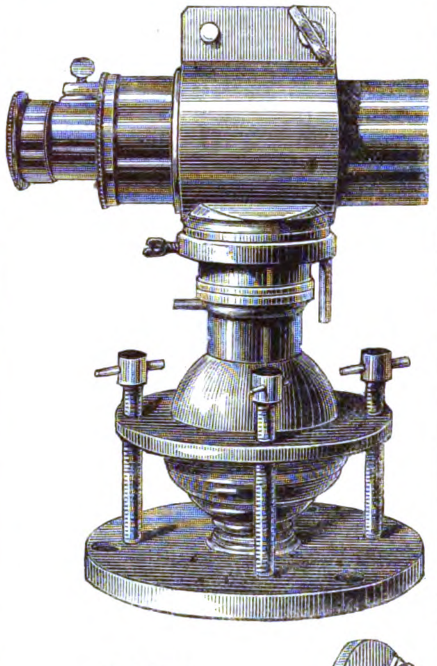


FIG. 1

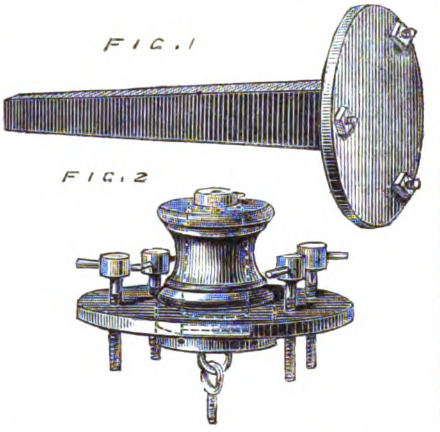

FIG. 2

jecting from it at a right angle. From the top of the stem of the upper plate another piece of wire projects. The end to be answered by the above arrangement is the ready finding a star when the instrument is used for ascertaining the rate of a clock by the acceleration of the fixed stars. Thus, a star having been chosen, the two projecting pieces of wire are brought into contact when the star is on the cross-hair of the telescope and the ring is then clamped. On a succeeding night the telescope will, therefore, be stopped by the pins at the same elevation without further trouble. The four long screws which pass through the upper plate serve—two of them—to level the axis and the other two to adjust the telescope to the meridian. When the instrument is fixed to the wall the two levelling screws are placed vertically (as near as may be) by the coincidence of a dot in their centres with a fine plumb-line suspended at a short distance. The eye-tube of the telescope is turned about for the adjustment of the cross-hairs, and is then clamped by the screw shown in the photograph. The accuracy of the levelling, &c., can be tested by viewing a star by direct and reflected vision, or more roughly by a plumb-line suspended at some distance. The telescope with the cross-hairs is adjusted to the meridian by the methods adopted for the adjustment of the real transit instrument. Fig. 1 represents a circular plate of iron having a wedge-shaped projection at the back, and three screws with nuts in the front. This projection can be driven into the joints of a wall, and the telescope, &c., attached by the three screws to the plate. In Fig. 2 a simple substitute for the ball and socket is shown. The piece of brass to which the rings are fixed screws into the bottom of the stem of the levelling plate and presses against the lower end or the conical telescope axis, shown by dotted lines, which can then be tightened without interfering with the telescope itself. The clip is attached to the axis by a flat headed screw and stud. In conclusion, I would remark that the above, as is evident, is merely the ordinary level modified so as to answer the purpose of a rough transit, which any clockmaker can construct.

N. S. HEINEKEN.

LUNAR METEOROLOGY.

[4828.]—THE success attendant upon the discussion of the observations of the floor of the lunar crater Plato, in the determination of a *darkening* of the floor as the sun increases in altitude (see ENGLISH MECHANIC, No. 367, p. 53), has induced a series of observations during the August lunation, which, if continued, may lead to some very important results. The objects observed form a group of dark spots S.S.E. of the Mare Serenitatis, the principal being Julius Cæsar (No. 7 in table), and the spot named Boscovich by Lohrmann (Nos. 4 and 5). This spot is divided by a mountain range into two portions, east and west. The western portion appears to be differently affected by the sun's rays as compared with the eastern, exhibiting a *steady* tint, with altitudes varying from 80° to 12°, while the eastern appears to become *lighter* under the higher sun. The spot originally named Boscovich by Schröter is the *largest* between Manilius and Menelaus. The observations are given in parts of unity—a light tint = 0·33, medium = 0·50, and dark = 0·66, as in the Plato observations. All the objects were very carefully compared *inter se* on each occasion, the intermediate tints being expressed by intermediate quantities, as in the table. For finding the objects, "Schröter's Fragments" (Table LXII.) and "Lohrmann's Sections" are the best authorities. By giving publicity to these observations you will oblige.

No.	Objects.	August, 1872.					
		16	17	18	19	20	21
1	Mare Serenitatis, near Bessel		0·50	0·50	0·50	0·40	[illegible]
2	Mare Serenitatis, border near Pliny		0.60	0·60	0·60	0·60	[illegible]
3	Boscovich (Schröter)		0·55	0·55	0·60	0·60	[illegible]
4	Boscovich (Lohrmann) W. part	0·66	0·66	0·66	0·66	0·66	[illegible]
5	Boscovich (Lohrmann) E. part	0·33	0·33	0·33	0·16	0·33	[illegible]
6	Spot between Boscovich (S) and Julius Cæsar ...			0·60	0·63	0·63	[illegible]

8	Plato			0·63	0·70	0·70	[illegible]

W. R. BIRT.

A GIANT PLANET, &c.

[4829.]—THE ENGLISH MECHANIC for May 31 reached me when I was on a journey, and "Linea's" letter escaped my notice. I have not the number by me. I fear I cannot find leisure for the search "Linea" proposes. During my time in the Royal Astronomical Society, the records of the appearances presented by Jupiter's satellites in transit have been few and far between. I shall endeavour, however, to secure an answer to "Linea's" query from another source.

There is a misprint in the passage quoted from *Mechanics' Magazine*, so that I appear to make the absurd remark, "The ring-nebula in Lyra may now be studied to advantage with the 4⁷/₁₀in. telescope belonging to the Astronomical Society," &c.; the semicolon should have followed the word "advantage." I have not seen the nebula with the instrument in question on a good night yet, but only when there was a residuum of twilight. Doubtless the instrument will show the faint interior light when the conditions are more favourable. So soon as I am settled in town again, I am going to employ some eyepieces by Browning, which, from their work on double stars, promise to do much better than the eyepieces belonging to the instrument.

I am glad to hear "Linea" has found my plan for an alt-azimuth convenient. I remember I used to find it work very handily for keeping a star in the field. Instead of a toothed-quadrant working with a pinion, a cord taken with a twist round a small cylinder can be used as readily and much more cheaply. I thank "Linea" for the pleasant terms in which he speaks of my attempts to be of use.

RICHARD A. PROCTOR.

SUN SPOTS.

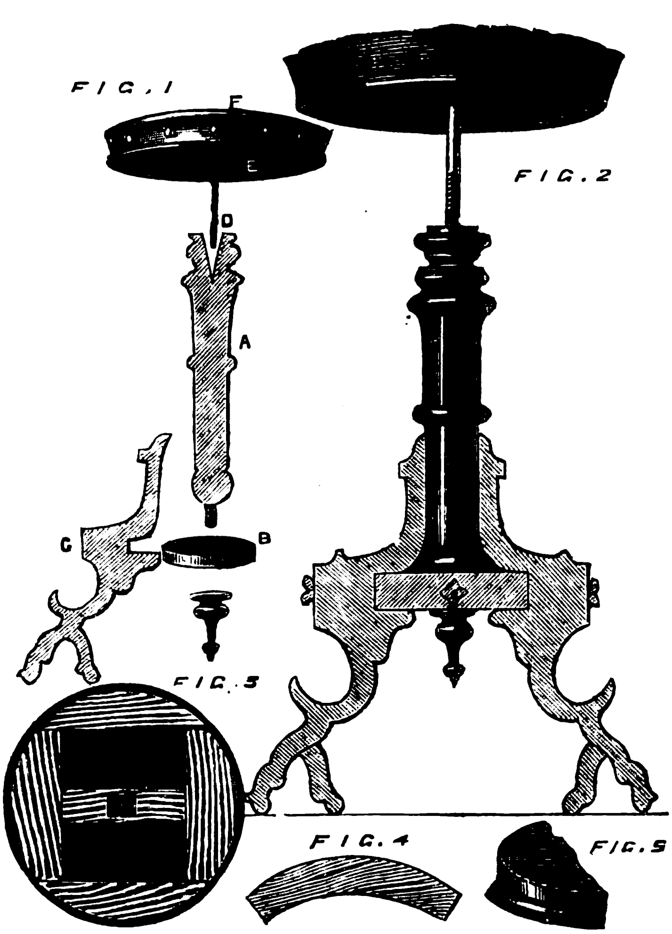
[4830.]—MR. PROCTOR'S letter on sun spots (4712), in which he describes certain dark spots as "broken umbræ," leads me to venture to bring forward my theory (4453) again. When a sudden jet of flaming hydrogen gas springs up, it must produce cyclones that denude part of the sun's surface. If the surface of the sun is in a molten state, it may cool in those places sufficiently to harden, like the lava in Hawaii (see let. 4898), and to remain hardened for a time; and the larger the surface so acted on, the longer it would continue as a "crust" (*i.e.*, as a rule), since the centre would be the farthest removed from the influence of the sun's fiery "envelope." Then it might break up and sink, or float away in pieces for some distance before sinking. The penumbræ might be caused by cracks being formed in the outer—the last-formed, and therefore thinner—parts of the crust, and letting the light from the molten matter below shine through (see again let. 4898). Such "spots" would prevent inflammable vapour from arising from where they were, and thus would preserve themselves for a time. A. (not of Liverpool).

[4881.]—Mr. Proctor (let. 4712, p. 562) speaks of seeing the granules. Does he mean on the body of the sun, or on or near the spots? Also, if these were well seen, were not the nuclei in the umbræ perceptible? Having myself generally noticed them in moderate-sized spots with a much smaller telescope, their absence in those Mr. Proctor drew is rather noticeable.

T. H. B.

ORNAMENTAL TURNING.—XIV.

[4882.]—In my last letter I described a boring collar. As this article is very useful, and can scarcely be dispensed with by the general turner, I propose to show in several ways its use. This week I describe a music-stool and its complete manufacture. Procure a piece of wood, say walnut wood, 12in. in length, 3½in. square; fix in the lathe and turn it the pattern A; at the bottom end turn a pin, and tap it with the screw-box (described a few numbers back); next turn a collar 6in. in diameter, 1in. thick; screw the collar on the bottom of the pillar; next cut out four claws in shape of Fig. C, carve them and fix them by means of screws to the collar B previous to fixing, and after the pillars are turned fix it in the boring collar, and bore a taper hole; the size of the hole can be judged if the iron screw for the top is purchased beforehand; a socket will be found with the screw when purchased, this socket must fit into the pillar at D, after which fix on the brass cap on the rabbet of the pillar which went into the boring-collar. The cap prevents the pillar from splitting. Next the seat or top of the pillar has to be made, the sketch 3 is the under part of the top when made. It consists of five pieces of beech mortised and glued together, with piece of walnut the shape of Fig. 4 glued upon it, then fixed in the lathe and turned; first the rough or top side, then the under part, which consists of a thumb moulding; but as the top is rather difficult for an amateur to make, a solid top will answer, merely a circle 14in. in diameter, 1½in. thick, turned with a rabbet, as shown in Fig. 5, for the purpose of stuffing.



To Stuff and Polish.—After well papering, brush the music-stool over with brown hard varnish, let the stool stand by a day, or even more, then paper, and rub down with flour glass-paper, using a little linseed oil. The whole of the varnish must not be papered off, only the rough part. Next polish with French polish, using a rubber of wadding covered with old linen rag, moisten the rubber with polish, cover with rag, one drop of linseed oil or olive oil, and gently rub all the parts accessible. Give it two or three coats, but it must dry between each application; when quite dry, finish off with methylated spirits on the same rubber, only clean rag, use a little oil at first, finish off with a light and quick stroke. If any difficulty is found from the spirit not bringing up a gloss, a makeshift can be used, namely, spirit glaze, it will look as well, but not last half as long. To stuff the top (the trade use a seaweed called alva; it is very pliable and springy), nail a piece of stout cloth on the top, put a layer of hay, flock, or alva to the required thickness, cover with a piece of sacking, pressing at the same time as much stuffing as can be got in; but the shape must be retained, nail the edges with stout short tacks. Trim the edges, and cover with American cloth the desired colour, trim off the same, cover the edges where tacked with braid a deeper colour than the cloth; if the top is a solid one nine holes should be bored underneath for the following purpose (in the regular top, holes will not be required):—Procure a stuffing-needle with a point at each end, also some buttons and some stout twine. Take the needle when threaded with double twine, pass it through the shank of the button, pass the needle through the exact centre of the American cloth at the top to a hole underneath, pass it back again to the same place. Having caught up a piece of the cloth in the descent, draw the twine tight, and fasten off underneath with another button; the buttons underneath must be a trifle larger than the hole, but the holes need not be larger than ⅜in. If these directions are carried out a handsome music-stool can be made at a small cost.

15, Diss-street, London. Samuel Smither.

THE CHEAP OBSERVATORY CLOCK.

[4883.]—The home-made mean and sidereal time clock (figured and described at p. 630, Vol. XIV. of the English Mechanic) has now been in action for more than six months, and the steadiness of its rate and arc has been very remarkable, notwithstanding the wide range of temperature to which it has been subjected.

I wish now to describe an addition lately made to this clock, which greatly adds to its convenience for observatory use; although the obvious simplicity of the contrivance, when seen, or explained, makes me doubt whether it can be so original as I supposed when it occurred to me.

All practical astronomers know the value of some audible signal, marking the expiration of each minute of time, and an observatory clock or chronometer is sometimes made to strike a bell for the purpose; but this is objectionable, as it involves the friction and inertia of raising the bell hammer by means of a cam or similar contrivance, and a "journeyman clock" is very generally used as a substitute.

I have attained the same object, at the cost of a few shillings, by means of a very simple apparatus, which was added to the A1 clock without even stopping it, and whose action involves no appreciable amount of friction. The following description will be intelligible without a diagram if the reader will refer to the drawing of the A1 clock above referred to: Resting upon the crossbar which supports the front pivot of the pallet arbor there is a small slip of ebonite, in which two insulated wires connected with a small galvanic battery are separately conveyed to a point just above the seconds dial. One of these wires terminates in a short horizontal wire of platinum, on which a little slip of platinum foil (bent at a right angle like the letter F) hangs at the bend or angle. The other wire terminates in a small strip of thin and elastic platinum foil, which is placed just above, but without actually touching, the extreme end of the letter F. The seconds' hand of the clock, when taking its leap forwards at the sixtieth second of every minute, just grazes the bottom of the letter F, causing the upper arm to rise and press against the elastic slip of platinum foil, and thus completes the circuit, sending the current through the coil of a miniature electro-magnet, whose armature is attached to the hammer of a small electric bell, which is thus made to strike one with the utmost precision.

By touching a wire beneath the clock, the slip of ebonite carrying the wire can be raised so as to disconnect the apparatus and suspend its action until again lowered by pulling down the wire. But the friction involved in making contact is so exceedingly small that I have allowed mine to remain constantly in action, and the bell has never ceased to announce the completion of each minute of time during the two months that it has been connected with the clock. The force required is indeed so very small that when the cover is removed from the clock my breathing near the pendant slip of platinum foil is alone sufficient to make contact with the battery, and to ring the bell.

As regards the cost, I at first used for a battery a single plate of zinc and carbon in a small preserve jar filled with an acidulated solution of bichromate of potash, and this was amply sufficient for the purpose; but it required frequent renewal, and I have since obtained a small manganese battery, requiring only about a pound weight of salt to evolve a sufficient current for a period of six months or more without further trouble or attention. The electric bell I first used was one of the smallest of those sold for house use, but I have since made one myself of much greater power and sensibility, costing for the materials less than a tenth of the price charged for the one previously purchased. The apparatus above described might be added to any clock, but the peculiar form of the A1 clock frame made it easy to accomplish it without even stopping the pendulum. John F. Stanistreet.

Abercromby-square, Liverpool, Aug. 29.

THE PARALLELOGRAM OF FORCES.

[4884.]—As the subject of the parallelogram of forces seems to have been dropped, I may be permitted to try to convince "Marine Engineer" that it is in perfect "harmony" with the law of quadruple force in the theory of projectiles. Call the length of the side of the parallelogram s, let its length in feet represent the force in pounds, write this F, put M for the weight of the body considered as its resistance or inertia, t for the time, v the velocity, and g the rate of acceleration produced by gravity—viz., 32ft. per second, then—

$$\frac{2\,M\,s}{F\,g} = t^2 \quad (1) \quad \text{and} \quad \frac{2\,F\,g\,s}{M} = v^2 \quad (2).$$

Now, by mere inspection of the first equation we perceive that as the angle diminishes (let. 4649), and the resultant A D approaches to 2 s—the force also approaching to 2 F—both numerator and denominator increase in the same ratio, and therefore t^2 is unaltered, because double the force produces double velocity in the same time. But if we double both F and s in the second equation, the numerator becomes quadrupled, and v^2 becomes quadrupled—that is, v becomes doubled in consequence of a double force having acted through a double space upon the same mass. But in projectiles the space s is the length of the gun, minus the charge, and does not alter materially, therefore to produce 4 v^2 or 2 v, the force F must be quadrupled. For example, let the side of the parallelogram be 6ft., representing 6lb., then the diagonal ultimately becomes 12ft., representing 12lb. That is, $s = 6$, and $s^1 = 12$, also $F = 6$, and $F_1 = 12$. Let $M = 24$lb., then, if "Marine Engineer" will insert these values in equation (2), he will find $v = \sqrt{96} = 9{\cdot}75$ft., and $v^1 = \sqrt{384} = 19{\cdot}5$ft. per second, and by using equation (1), t in both cases is $= \sqrt{1{\cdot}5} = 1{\cdot}092''$. By inserting $s = 6$, and $F_1 = 24$, he will obtain $v^1 = 19\tfrac{1}{2}$ as before, but t^1 will be $= \sqrt{\cdot 375} = \cdot 546''$, or half the former. This is the same as if the body was a projectile.

Crawford House, Rochdale. Wm. McNaught.

ENGLISH MECHANIC TURNERS' SOCIETY.

[4885.]—Has "Faber" any practical suggestions to offer on the formation of the above society? if so, I for one shall be glad to co-operate with him. Several weeks ago I proposed what I deemed best, but met with no response. One thing I will state, if six gentlemen will start the affair, I will give the said six gentlemen gratuitous insight into my own business—viz., general band and circular sawing; at present I have no lathes at work, or I would include that, but have a portion of room I could spare in my mill for that purpose; after which, if the society was advertised in the English Mechanic weekly, I would fix up a general workshop on certain terms, and include instruction in the following branches:—Ornamental turning, fret-cutting, sawing, cabinet-making, and carving. Being well known in the trade, I would advocate the society to my best ability. I hope to hear from some of our old subscribers soon.

15, Diss-street, London, E. Samuel Smither.

ADJUSTING MAINSPRINGS.

[4886.]—I am afraid many will be misled on one point in "Seconds' Practical Watchmaker's," article upon adjusting mainspring, p. 529, first column: "If the rod passes over equally except the last turn, hesitate whether any further alteration should be made," and so on, and he states it can be safely left so, as no watch is supposed to be let down. Now, many watches are allowed to go down, customers forgetting to wind them up at night. Mainsprings frequently lose their power, and the spring not being set up to take the last turn over the same as at first many evils occur. The watch loses time, the chain gets out of position on barrel, and I have had watches brought in with the chain quite loose on the barrel for the want of the adjusting rod passing over the last turn the same as at first. Conversion.

SPINNING TOPS AND GYROSCOPES.

[4837.]—I THINK it should be obvious to any one whose attention has been attracted to this subject for the first time by reading some of the most recent letters upon it in the ENGLISH MECHANIC, that these letters are but the continuation of a discussion, and I think that such a one should read and study the whole of the discussion before ventnring to take part in it himself. If "J. K. P." (let. 4718, p. 563) had done this I believe he would not have commenced his letter in the manner he has done. Even if he had carefully considered the very letter of mine to which he refers, I fancy he would have hesitated before referring to the fact of a spinning-top commonly rising from an inclined to a vertical position under ordinary circumstances as contradicting my statement, for that statement did not refer to ordinary circumstances, but to the case supposed by "Gy," in which friction and resistance of the air were assumed to be absent. The problem of explaining why a top not only does not fall but rises (under certain ordinary circumstances) is a very interesting one, but cannot be grappled with until the explanation of the top's not falling is thoroughly understood. It may seem paradoxical, but it is nevertheless the fact, that the rising is due to the frictional action of the top's peg on the horizontal supporting surface. And this action is a compound one, as is shown by an interesting experiment to which I have already referred (January 7, 1870). Take a common gyroscope with its one ring, and fix a short peg to the ring almost in the continuation of the axis of the wheel; the gyroscope can then be supported on this peg in the position of a common spinning-top. If the peg were exactly in the continuation of the axis the ring would very soon acquire the velocity of the wheel and make the conditions the same as those of a common top, but when the peg is the least thing to one side it prevents the ring from acquiring the spinning motion from the friction of the journals or pivots. The spinning-motion is thus, as it were, separated from the gyratory motion, the ring and peg having only the lattter. Well, when this apparatus is set (with the wheel spinning, of course) on a hard surface like glass with the axis in an inclined position, the inclination of the axis from the vertical increases; but if the peg is set on a surface like that of rubber or leather, the inclination decreases. As the ring does not spin it can be taken hold of whilst the wheel is spinning, and during one ordinary spin of the wheel, the apparatus may be repeatedly transferred from the hard to the soft support and back again, and so be made to rise and fall several times alternately, thus showing that the change is not caused by the gradually-diminishing velocity of the spinning motion. I have already said that those attempting to explain the action of a gyroscope or top have to deal with several phenomena besides the ordinary one; this rising or falling, according to the nature of the support, will, I imagine, be found rather a puzzler to some of them.

Now, for another phase of the subject, in reply to "Gy" (letter 4720, p. 564). Imagine friction and resistance of the air absent—imagine the point of the top's peg supported on a fixed point, with perfect freedom for the top to spin, and with perfect freedom for it to assume any inclination, even an inverted position, but not able to leave the fixed point of support. First, suppose the top is not spinning, but is placed in an inclined position and let go; it wil swing for ever like a pendulum continually rising to the height from which it falls alternately on diametrically opposite sides of the point of support. Next, suppose the top to have a very slight spinning motion when it is let go, it will swing, but not exactly as before—it will always rise again to the same height, but the position into which it rises will not be diametrically opposite to that from which it falls. If the change of position is measured by a horizontal angle of 180° in the first case, it will be measured by a smaller angle in the second case. Then, as the spinning velocity imparted to the top is assumed to be greater the horizontal angle will be less; and as this angle is less so will the angle of descent be less. If the top has any spinning motion at all it does not pass through the lowest point, but swings past it on one side, as it were. Supposing the first swing of the top measures 40° horizontally the next swing does not take place backwards through the same angle to the starting point but onwards, so that at the end of the second swing it will be 80° from the starting point. Whether the top will swing to the right or the left of the starting point depends simply on the direction of the top's spinning motion. If the spinning velocity of the top is very great the horizontal and vertical angles of each successive swing will become very small, so that the centre of gravity of the top will move round almost horizontally. But for the centre of the top to move round quite horizontally a certain horizontal force or impulse must be added to the other conditions, as was first pointed out by Poinsot, and the slower the top's spinning velocity is the greater must this horizontal element be to produce the common gyratory phenomenon. In a top, or gyroscope, under common conditions this horizontal element of force becomes supplied through friction, resistance of the air, and otherwise in a very curious manner. As the spinning motion of a top decreases its gyratory motion increases, and for a time the horizontal element increases also, but eventually this element is not sufficiently increased, and the swinging motions begin to appear in what is known as the wobbling of the top just prior to its coming to rest.

If, then, "Gy" wishes a top to gyrate with a very small spinning motion in the manner in which it does when spinning rapidly he must contrive means to supply the necessary horizontal impulse and to maintain the spinning motion.

It must not be supposed that in the foregoing I have proposed to explain any gyroscope phenomena: I have merely stated what would be the phenomena exhibited under certain conditions, with a view of leading others to consider some of the less known parts of the subject, and thereby, perhaps, arrive at a better comprehension of the interesting phenomena of rotary motions.

Glasgow. E. H.

PROPERTIES OF THE GYROSCOPE.

[4838.]—THIS false-explanation mania seems hydraheaded! The gyroscope does not act "according to Hoyle," at any rate, not according to the William Hoyle at p. 582, August 23. His explanation is not unlike Mr. Proctor's at p. 446, 21st January, 1870, and it is equally faulty. He does not correctly apply the proposition he refers to as Frisi's, paragraph 15. According to that proposition, and under the conditions stated, the body will "revolve on another" axis; therefore, not on the axis constituting the centre line of the wheel's spindle. Again, the new axis will be "in the same plane," which, in the case considered, is the horizontal plane. Therefore the end of the spindle must be outside of the new axis, and it (the end of the spindle) must, in taking part in the rotation of the body about the new axis, begin to move either upwards or downwards. The complete application of the proposition would show that the spindle should begin to move downwards. The proper application of the proposition is a step towards the explanation of the ordinary gyroscope phenomenon, but it is obviously not the whole explanation, for we know the spindle does move horizontally and not downwards. I submit that Mr. Hoyle's sixth paragraph is not an explanation, but a mere guess at what is supposed to take place, and that unless the assumption in that paragraph is granted his whole attempted reasoning fails. Clause 1 under paragraph 16, is incorrect and inconsistent with 2. The orbital motion or gyration would not be accelerated if the spinning motion were maintained uniformly. The acceleration observed arises from the gradual diminution of the spinning motion.

Really, Mr. Editor, I think it would save valuable space, when correspondents send you new attempts at explaining the gyroscope, if before printing their papers you would first ascertain whether they have read and studied the many letters you have already published on the subject, and particularly whether they are prepared to explain not only the common phenomenon but also the other phenomena referred to in those letters.

In reply to J. M. Taylor (let. 4719, p. 564) the whole weight of a tree (or let us say of a non-spinning top), when in the act of falling, is not exerted at the base or point of support, and it is a part of the explanation of gyroscope properties to show how the whole weight is exerted at the point of support when the top is spinning. But when a top spins in an inclined position the peg point is affected by something besides the downward pressure of the weight; for supposing the peg point were upon a perfectly frictionless horizontal surface it would not remain stationary, but would describe a circle in such a way as to keep the centre of gravity of the top vertically over the centre of that circle. If a common gyroscope, instead of being set on the usual pointed supporting pillar, be set on a pointed support capable of horizontal motion this tendency of the gyroscope to keep the centre of gravity of the floating mass in one spot will be exhibited, and may be made to produce a variety of very curious movements. I have tried it with the horizontal motion of the supporting point limited to a circle by fixing that point on the outer end of a long balanced lever set on a stationary pointed pillar. In this case the inertia of the lever and the limitation of the motion combine to affect the results, whilst these may be varied by starting the gyroscope from different positions. One half gyration of the gyroscope tends to move the lever in one direction and the next half gyration in the opposite; and in one experiment one half gyration may be got to simply neutralise the momentum derived from the preceding one without actually producing reverse movement, so that the lever moves round always in the same direction, but intermittently.

Glasgow. E. H.

DEATH OF THE CRANK.

[4839.]—"G. J. H." (let. 4708, p. 561) calls attention to a supposed American invention, "Mr. Morton's Substitute for the Crank." The very same plan, and several others, for changing an alternate rectilineal into a continuous circular motion I proposed to several engineers in 1862, but could not prevail upon them to take it in hand. Mr. Morton, however, is wrong, if he asserts that the dead points are the cause of the loss of nearly one-half the power in the crank, for, theoretically speaking, as is well known by all engineers, there is no loss of power; it is true that the connecting rod only exerts the greatest force at half centre, which then gradually diminishes to zero as the dead point is reached, but what is lost in power is gained in distance, for it is evident that the circle is greater than twice its diameter, and in this manner the direction of the force is changed without loss.

In my endeavours to get the invention introduced, I could only urge, as generally made, that cranks and their connections were subjected to great strains, which must cause a loss of power, and this view seems to be correct, seeing that there is an occasional smash.

CHANGEL.

BEE MANAGEMENT.—FEEDING.

[4840.]—IN a former letter I advised all those who had weak stocks to commence feeding their bees forthwith, and, lest it might have seemed whimsical, I repeat the advice, notwithstanding all that may have been written about October feeding, and deliberately say that now, when the honey-crop is failing, and the queens are relaxing in their ovipositing, is the time to supplement the one, and stimulate the other, if the said weak stocks are worth any attention at all. Langstroth's "Old Fogey" will say, "Who ever heard of such a thing? Feeding bees in the middle of August; in such beautiful weather, too! Absurd," and so on.

Well, sir, "Old Fogey" has had "his day," and a pretty long one it has been; he has stuck to his text for several thousand years, and has crammed all his disciples with his antiquated ideas, until it is almost wicked and against nature to suggest any alteration or improvement, and, as a consequence, the question of bee-feeding and bee-feeders is as little understood as ever. Before feeding at all, the cause of weakness should be correctly ascertained, for there are some causes which feeding will not remove; for instance, the disease called foul brood, which is always progressive, and apparently incurable. A hive overcharged with pollen cannot be strengthened in bees by feeding, but may be increased in weight, but after giving several empty combs for those filled with pollen, the breeding of young bees may be promoted by gentle feeding, and this should be done now, for as no young bees will be hatched out for at least three weeks, and the stock will be dwindling all that time, the importance of immediate action cannot be over estimated.

Queenlessness after swarming is a very common cause of weakness, but this, of course, cannot be cured by any amount of feeding alone. It is necessary to provide the stock with a queen, or give them the means of raising one for themselves, but as the latter leaves a chance that the young queen may fail in her search for a drone, and as at least sixteen or seventeen days would elapse before oviposition commenced, and three weeks more before the numbers of bees would increase, the former process is much to be preferred, but when the cost of a queen is an insuperable difficulty, it will be necessary to extract one from a full hive (by driving, as described last week), and give it to the weak one, leaving the strong stock to raise a new one for themselves, and then by feeding to stimulate the queen to increased exertion in her new home, and this it is almost unnecessary to say should be done now, if hitherto delayed. Another great cause of weakness is the hiving of late swarms without giving them help at first, and in their case what can possibly be gained by delay? Simply nothing, but on the contrary much valuable time and opportunity lost, for by feeding gently and continuously now, the queen will be stimulated into enlarged oviposition, the bees would probably enlarge the combs, and fill the hive, and even if more drone comb should be built than might be required for the ensuing year, it will be easier to excise that for use in supers, than it would have been to keep the stock through the winter by any other means.

A fifth cause is the presence of an antiquated queen, against which bee-keepers cannot be too strongly cautioned, for as physically she becomes unable to deposit sufficient eggs to keep up the numerical strength of a hive, so does the hive gradually become overcharged with pollen, and although after her natural autumn repose she may in spring be enabled to lead off a swarm it will be necessarily a small one, and later on many of her progeny will be attenuated and physically unable to labour, and hundreds of them will be killed by their stronger brethren, and cast out as useless. These attenuated bees are little fellows with small pointed tails, which are, if Italians, invariably jet black, but on the abdomen near the thorax there is usually one bright broad yellow band. In this case a new queen should be substituted, and the same principle of feeding adopted as in the former case, and the best time to do that is now. A sixth cause of weakness may be the presence of too much drone comb in the hive, and the consequent preponderance of non-workers, which are large consumers; this may arise from the stupid practice of cutting out honey-comb from stock hives, and leaving the bees to fill the space again, in which, as I have before remarked, they almost invariably build drone comb.

The remedy in this case is to feed so as to stimulate the breeding propensity to the utmost now the drones have departed, and in early spring to remove all the drone comb so as to prevent the early breeding of drones, and later on, as the strength of the stock increases, and the more breeding space is required, the bees will build a large proportion of new worker comb. The indiscriminate cutting out of honey-comb from the stock hive is about the stupidest folly a bee-keeper can be guilty of, and is almost sure to result in the ruin of the stock. In large hives with movable combs it is sometimes good policy to cut out the drone comb from the stock hive, and fill up the spaces thus made with worker comb if it can be obtained. In practice I very seldom exchange combs from one hive to another, having such a wholesome dread of transmitting disease, beside which it is seldom that the combs of different hives will exactly fit each other, notwithstanding their "interchangeability," as it is called.

Let me again advise that all feeding be done forthwith, so that the bees may evaporate the moisture from the hives before the cold weather prevents their sealing it over.

Dysentery is a disease which is seldom discovered until it is too late to repair the mischief. Foulness at the entrance of the hive is no positive index, as it is generally left by the bees as they return to the hive after their cleansing flight, which is perfectly natural and healthy. But when the bees are physically unable to take that flight, and perforce, exude the filth inside the hive, and so poison the whole atmosphere, and further vitiate the already vitiated honey, and bees die and rot in between the combs, then it is that the effect of late feeding and ill ventilation become apparent, and dysentery is rampant.

It is a physiological fact that bees in a healthy condition always evacuate their fæces on the wing, and never in the hive unless diseased; indeed, bees that are the subjects of dysentery in cold weather, often actually burst, through the fermentation of their food within them, and smear their combs and their fellows with the filth, causing increased disease and death, and until the cold spell is broken, the bee-keeper gets no sign, and when the discovery is made it is often too late.

Hanwell, August 20. C. N. ABBOTT.

BEES AND BEEHIVES.

[4841.]—THE perusal of Mr. Abbott's prescription to "W. T. L." (see reply 12392, No. 383) of a course of "Langstroth," suggested the idea that by the same means I, too, might be purged of some misconceptions, and might find it a useful tonic, not only for next spring, but for this autumn and winter. Accordingly, the "Hive and Honey Bee," published by Lippincott, Philadelphia, was procured and has been read with some care. Notwithstanding its cost—and it is as dear in proportion as a Woodbury hive — I thank Mr. Abbott for the advice, and would urge many of your other correspondents to do as I have done, in the hope that, as Langstroth says, we may become bee-masters as well as bee-keepers. Space permitting, I should like to transcribe some of Mr. Lippincott's paragraphs, such as some of his "Requisites of a Complete Hive," and "The Beekeeper's Axioms," but I will only ask room to print Oettl's golden rule—"Keep none but strong colonies." Doing so, in twenty years "there has not occurred a season in which the bees did not procure adequate supplies for themselves and a surplus besides;" neglecting this rule, "the more money you invest in bees the heavier will be your losses."

Best thanks also to Mr. Abbott for his letter (4764 in No. 387), on transferring our "industrious subjects" from straw skips to hives with movable frames. He must, however, forgive me for adding that this letter only increases our regret that his specification of the hive he now uses is still deferred. If he cannot give it us at once, I hope he will answer the following queries:—(1) Should we do wrong—I mean, run the risk of having to begin again, because our frames are of wrong dimensions, or for some other reason—in following the mode of construction explained in letter 3162, No. 350, provided we make the interior dimensions 20½in. × 17in. × 11in., and introduce the other improvements described in subsequent letters? (2) Should bottom boards be fixed? Mr. Langstroth seems to prefer them, but for cleaning, for artificial warming, &c., the movable boards give greater facility. (3) If the hives are to be in a windy locality, would Mr. Abbott add a porch? For economy, it need not extend laterally much beyond the entrance, say 10in. wide inside; we might then use the triangular entrance-regulators, as well as a large alighting cloth. (4) Would it be profitable to procure a Ligurian queen at this time of year, or would it be safer to wait for the spring?

E. T. GRAYS.

TUNING KEYED INSTRUMENTS.

[4842.]—I FEEL personally obliged to "Vertumnus" for the attention he has given to my idea. Fiddles and fiddlers are not thought much of at any time, and now that the best of fiddles, or rather violins, are on show at the South Kensington Museum, not more than a dozen persons assisted during the three hours I had the pleasure of viewing them—I mean the viols d'amour, &c. I noticed that one of these instruments had the wires (for tone reflection, hardly repetition, eh!) without tuning-pegs, for they were merely stretched through holes in the bridge, and attached at either end of the breast by pins. This I call trusting to chance, for how could one tell if the wires would sound in unison with the gut strings unless tuned to correspond? Another I found with the full complement of pegs for strings and wires; so far so good, but I fully expected to see an improvement on this, by allowing the stopping to take place on string and wire together, thus insuring the peculiar whirr of sound in all the tones. I have no doubt many will regret not seeing this collection when it is too late.

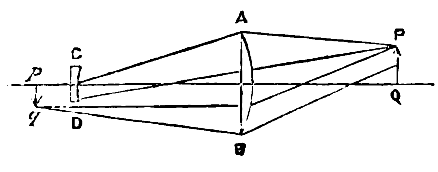
With respect to my idea, I don't back it up as being first-class, but I think there is more in it than "Vertumnus" sees as yet. First, I have a great objection to the finger-board being altered in the slightest degree. No, let there be a key for every finger, in the same way as you have a finger for every note while playing on the violin. Excuse my putting this so curiously, but in violin playing the fingers form themselves the action of the keys, and it is this I want to introduce in part in piano, organ, or harmonium playing. By using two keys to the same string, or pipe, we bring the tone and its expression more under our command. Mark the difference between a flute solo and the same tootled by an organ, yet give the organist a direct command over the pipes and there would be greater effect, besides better tuning. "Vertumnus" says, "A more serious objection is that the difference of tone is produced by so indefinite and uncertain a thing as the varying strength with which the note is struck." Now, this I consider to be the cream of the whole affair. All solo instruments are constructed so as to be under the control of the player. The most perfect in this respect is the violin. The certainty is in the will of the performer, if he can play at all. Of course we must have an instrument constructed to produce certain sounds, and where there is a keyboard various appliances are used (under the control of the player). All I want to see is more variety allowed, and not for a lever to come down on a string always in the same style and place; and as our object is to insure perfect harmony by better tuning, I cannot conceive anything better than that each string, pipe, &c., should be under the performer's will. I beg to state that the hammer, or the wind, would have nothing to do with changing the tone, any more than the bow of a fiddle does now. The same wind and the same hammer would do, but another action must be given to the other key to produce another tone when it is pressed down, using the same hammer as the first key. So half the hammers and half the strings are dismissed, also half the pipes and half the size of the organ, &c.

With respect to the third objection, I am to blame for making an obvious mistake, for if the lever presses on the string as the finger does, a higher tone is the consequence. I supposed the key note to be C, and reckoned down to B, whereas I should have gone up to C sharp; and this makes all the difference, as I have no doubt "Vertumnus" will see, for here we are out of the way of the major seventh, and continuing the process with every key, yet having the complete keyboard, we can play with facility all the chords and discords that happen, nine hundred and ninety-nine times out of a thousand, in any species of composition. I have played on a keyboard constructed on this plan, and it answered better than the present one, for it gave more power to the performer over the tone. I acknowledge that the major seventh will crop up in the more difficult keys, but so very seldom that I think that part of the question may be waived, or perhaps remedied by a movable keyboard that has been adjusted to Debain's harmoniums—an idea that I do not like "at all, at all." Perhaps some other artist will help with an idea.

FIDDLER.

ON THE DISREGARD OF THEORY FREQUENTLY SHOWN IN THE CONSTRUCTION OF THE OPERA OR FIELD-GLASS.

[4843.]—THIS kind of telescope has the rays of light passing through the object-glass in such a manner that except in the centre of the field of view only a portion of them falls on the eye-glass, that portion becoming smaller towards the edge of the field. Thus, let P Q be the object, *p q* its virtual image—that is, the image which *would* be found only for the eye-glass



C D. It will be seen from the diagram that only the rays falling on the upper part of the object-glass from P reach the eye-glass; hence, if the object-glass were not larger than the pupil of the eye in a greater ratio than the magnifying power of the glass bears to unity, we should have deficient illumination, and I think a small field of view, owing to the excentrical refraction through the object-glass. Low powers only are suitable for these glasses. PHILANTHROPIST.

RADIUS OF SURFACE OF OBJECT-GLASS.

[4844.]—IN reply to Mr. Cash (let. 4696, p. 543), as he will spare no trouble in correcting his object-glass, I send him the following assistance, which I promised some time ago, and which his last letter enables me to give. The results of Mr. Cash's last experiments have verified my belief, because the refractive index corresponds very nearly to my own (for Chance's dense flint, specific gravity 3·645; and crown, specific gravity, 2·553), and I have found by experience that when their sheets of flint and crown glass have one specific gravity up to the fourth place, the refractive index is the same. As Mr. Cash has tried or tested the flint and crown for veins, which his object-glass is composed of, he may grind them to the following radii—viz., with flint lens, specific gravity, 3·6452; with refractive index, 1·6375. Flint lens, first surface, convex, 156·0 – 26·0, radii = 63·40, RR = 1·95, 26·8 × 40·0, R = 32·0. Crown lens, white, specific gravity, 2·5529; refractive index, 1·529. Focus for parallel rays, 72in. As regards Mr. Cash's doubts about the strength of the flint and crown lenses composing his object-glass, he can rest contented about that. There is no particular fault in a flint or crown lens having plenty of strength; the greatest fault is when the lenses are thin, which in many cases causes them to spring in the working, and when that is the case they are of no use. It is in microscope achromatic object-glasses that the strength has to be taken into account so minutely. Before commencing to grind his flint and crown lenses to the curves above, Mr. Cash must curve a piece of common plate glass, of the same size as the flint and crown lens, to the same curve as the other or opposite side to which he is about to grind, and must lay on it a piece of thin cloth dipped in melted pitch. On this the lens must be fastened, and every surface he grinds he must fix a glass holder on the opposite side, to prevent the lens from springing in the working of it. A cork or bung, about 2½in. or 3½in. in diameter, dressed into shape so as to be pleasant to the hand, is fastened with pitch on to the glass holder, and used as a holder in the working. Great care must be taken in making the grinding tools to the exact radii, and also in working them true before the lens is worked on them. The tools must be worked in pairs, to true each other; and in working the lenses care must be taken that the lens is turned round in the hand regularly about every ten strokes taken with the lens. In grinding and polishing six sizes of emery are generally used in fining the lens after it has been ground up on the true tool. A cement for polishing object-glasses is made by mixing lampblack with soft pitch until it becomes hard, when it is softened to the proper state, according to the work for which it is required, by the addition of beeswax. If Mr. Cash is anywhere near to Sheffield, and will advertise his address, I will send him a piece of cement which will be suitable for a room of 70° temperature Fahr., which will save him a deal of trouble. I would have given the recipe for it, but it would be hardly fair, because it has cost my late father and myself a nice fortune; when I have done with it I may divulge the secret. The cement, the ingredients of which are given above, is a good one, and has polished good object-glasses up to 10in. diameter, though I have not seen it for several years. As regards eyepieces, I send the proportions for three or four powers of the Huyghenian form:—

A eyepiece: First lens, ·70in. focus, diameter five-tenths of an inch, plano convex; second lens, 1·50in. focus, diameter nine-tenths of an inch, plano convex, diameter of stop six-tenths of an inch, distance from lens to lens (inside measure) 1·10in., exact power 70 times.

B eyepiece: First lens, 0·50in. focus, diameter three-tenths of an inch, plano convex; second or field lens, 1·25in. focus, diameter six-tenths of an inch, plano convex, diameter of stop four-tenths of an inch, distance from lens to lens 0·85in.; power about 110 times.

C eyepiece: First lens, 0·30in. focus, diameter two-tenths of an inch, diameter of stop two-tenths of an inch; second or field lens, 0·70in. focus, diameter five-tenths of an inch, distance from lens to lens (exact inside measure) five-tenths of an inch; power 160 times.

D eyepiece: First lens, 0·20in. focus, diameter 0·15in., diameter of stop, 0·15in.; second or field lens, 0·50in. focus; diameter 0·4in., distance from lens to lens 35-100ths of an inch, power 250 times.

If Mr. Cash will follow these instructions exactly, he will have a different and a better instrument than he would have had if Mr. Vivian or I had sent him the curves to alter his object-glass to. On its present principle it would never have made a good one at the best. I have no doubt but Mr. Vivian—if he has had much practice in the construction of large astronomical telescopes—knows that object-glasses ground with the inside surfaces to fit, or as he recommended (the crown slightly deeper in radius on the inside surface), never make a first-class telescope; I do not consider one worth its mountings. The greatest fault with Mr. Cash's object-glass at the present time is the botheration of the inside surfaces fitting; or in the working very probably the crown has worked slightly deeper, and when it is screwed up in the cell causes the crown lens to tip, and produces the effects Mr. Cash speaks of. Before I close this letter I wish to remind him to be very very careful in the re-centreing of his object-glass after he has worked it to the curves I have sent, which will, I have no doubt, make him a good telescope.

Sheffield. WILLIAM OLDFIELD.

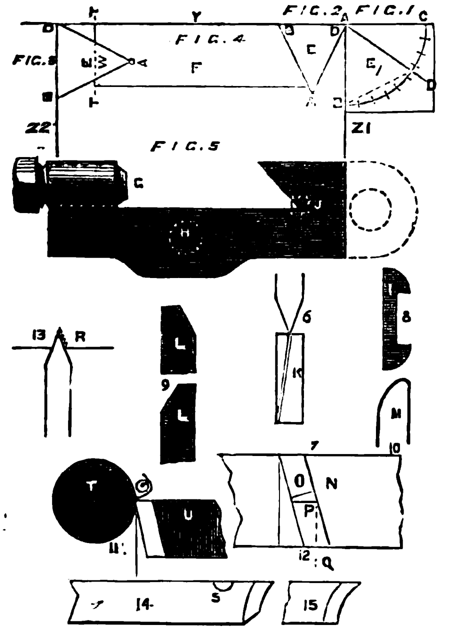
ECONOMY IN USING COAL.—STOVES.

[4845.]—"PHILO," in his interesting letter (4723), refers to the escape up the chimney of a large proportion of heat derived from the fuel; it is a fact, and one which was observed and commented upon, both in England and abroad, more than thirty years ago, one writer fixing the waste at seven-eighths, another at fifteen-sixteenths of the whole, but a better plan, though diligently sought after, has not yet been found (except in theory). Practical experience shows it to be one of the least of the evils attendant upon the production of artificial heat, while its use as a means of ventilation to an apartment in which persons live is a set-off against its extravagance. Perhaps the point which deserves more attention in stoves is the exact angular form which is calculated to radiate the heat to the greatest extent—the one familiarly known as the "Register" is the nearest approach to the perfect form. To avoid this waste of heat with open stoves, Dr. Arnott invented a close one, more than thirty years ago, which it was thought would supersede all others; it has not done so, nor, on the other hand, has it been superseded by any other of the like principle. One of Dr. Arnott's stoves was fitted up in the Customs House, where a number of clerks were employed, and in as far as it thoroughly heated the large apartment, at a very trifling cost, it was a success, and effected a great saving of fuel, but in a short time it had to be removed, being very injurious to health, for like all close stoves, which necessarily warm the air by conduction, instead of radiation, it destroyed the humidity of the atmosphere, so I think we shall have to waive the objection to open chimneys for the present. Again, British prejudice is in favour of the present plan. Our people are very sentimental regarding a cheerful looking fire, which can scarcely be enjoyed without an open chimney. Of course, these remarks do not apply to cooking stoves of any kind.

TINTUR.

SCREW CUTTING.

[4846.]—PERHAPS a few tips from "Jack" would not be amiss, and enlighten some of our junior hands. First, we will start with the tools requisite for the job. These, though not absolutely necessary, will facilitate the operation. These few sketches will illustrate what is wanting. First get a piece of saw plate about an inch (see Fig. 1), with a small prick punch put a centre in one angle A, take a pair of dividers and strike a quadrant B C, true the edge up A B to the centre, and the other edge, A C, truly square or at right angles. Divide the quadrant C B into nine equal parts, take 5½ parts, as shown at D, and draw a line through the centres, D A. File up truly to the lines, and thus you are furnished with the angle 55, the angle of Whitworth's threads in general use, in the shape of a cone, and of which B D is the base. Keep this as a standard gauge. Now take a piece of the same stuff—saw-plate or sheet steel, I mean—and, filing it true upon the edges, and parallel, about ⅝in. or ¾in. wide, and from 1½in. to 2in. long (see Fig. 4 F), take your



square, and place the stock against the planed edge of your lathe-bed, the blade resting upon the bed. Apply one edge to the stock and the angle piece, with the base B D at 2, keeping them both together. Mark the angle off upon Fig. 4, A B, which is 27, and half file this off true, then reverse the order of things, and, applying the square blade upon the other side, apply your angle to the square blade, Z 2, the base B D being to the blade, and mark off the angle W 3 in F 4, and, drilling a fine hole, file it carefully out. This, squared off at T, constitutes the screw cutting gauge.

Figure 5 is an adjusting stop to regulate the feed of cut and dispense with the chalking operation. It is made to fix upon the slides, either a tool stock slide or transverse slide, and can be made of a piece of ⅜in. or ⅝in. square iron. G is the fixing or clamp screw. In H a screw is put—a screw for the regulating of the cut, with a milled head, and acts against the end of slide. If made in the first instance with the dotted addition, it will suit most lathes. I (Fig. 8) is a gibb which, if fitted in J, gives it a longer bearing. Fig. 6 shows front and top of a screw tool, which, with some there is so much bother about to have twisted the same angle as thread, which is not needed, the rake of thread will give you clearance upon one side, therefore you can leave it wall-sided, as shown in the dotted line 7 P N, supposed to be the piece upon which a screw is to be cut, L L 9 is the shape of tools for a bracket thread, 10 a tool for a thread for a metal screw for wood, 11 position of V tool at work, 12 for square thread, the diagram of which I shall have to refer to again, 13 how the work is to be performed by steps, and G 14 the practical and best rake of comb or chaser, thereby keeping the proper angle and depth of thread, not like 15. Straight tip No. 1. JACK OF ALL TRADES.

[4847.]—"APPRENTICE TURNER" (let. 4760, p. 589) is quite right in saying that shopmates are afraid of another knowing the "tips." I will give him one of my "tips," as he terms them. Suppose he wants to cut ten threads per inch with a leading screw of two per inch: Multiply the wheel upon the lathe spindle by half the number of threads required to be cut, again multiply by small wheel on the intermediate spindle, divide by the large wheel on the same spindle, and the result will be the wheel required on the leading screw. For example, $\frac{20 \times 5 \times 20}{40} = \frac{2000}{40} = 50$, the wheel required for the lathe-screw; this is compound or double gear. Now, suppose I am going to cut (say) eleven threads per inch, which is gas thread, and also odd pitch, I just find the wheels by the above-mentioned rules, then mark the face or chuck-plate with chalk, also a mark on the lathe spindle opposite, a small piece of wood or chock against the loose headstock; this is to allow the saddle to come against it when the tool is beyond the work required to be cut. This piece of wood is instead of the mark on the lathe-bed, which I think would take too much time to bring the saddle exactly up to the mark. If he got it past the mark, or not quite up to it (say a sixteenth part of an inch either way), he would still be able to get the nut into gear, and also have a cross thread for his trouble, whereas if he uses the wood it would be an impossibility for him to get the saddle too far back. SCREW CUTTER.

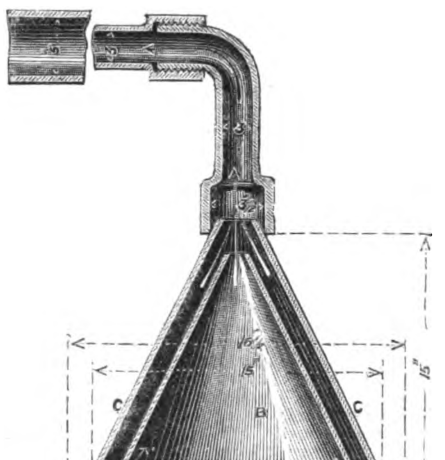
AURORÆ BOREALES AND GALES.

[4848.]—IN the *Weston Mercury*, a short time ago, I read a letter signed O. S. Round, having reference to the supposed connection between auroræ boreales and the occurrence of gales. The writer made the remark that subsequently to the display of aurora on the evening of August 3rd last, "within 48 hours we should have a gale," and so it turned out, as August 5th testified, for it blew a tremendous gale throughout that day. On reading this I determined to test, if possible, the accuracy of the statement. An occasion soon occurred, for on the evening of August 8th I witnessed from this town (Weston-super-Mare), a somewhat bright exhibition of the aurora borealis. I observed the streamers for some time, and noticed with what rapidity they changed both in their positions and in their intensity. On August 10th (*i.e.*, within 48 hours after the occurrence of the aurora), a tremendous gale blew, and it was scarcely possible to make any headway against the extreme force of the wind. This fact supports Mr. Round's statement, and it would be interesting to refer to former meteorological registers and endeavour to find if there is any corroborative evidence forthcoming. No doubt many of your scientific readers have sufficient data in their possession to enable them to accomplish this without much difficulty, and I think it would afford matter of interest if they would send you the result.

August 31. WILLIAM F. DENNING.

GREENHOUSE HEATING.

[4849.]—WITH your permission I will give an outline of an apparatus used in connection with atmospheric burner described on p. 592. The sketch will fully explain it. Over the burner A is placed a cone of sheet iron B, or, more correctly, the head of burner is inserted some distance into cone, which concentrates the intensely-heated current, and directs it into 3in. bend and short 3in. pipe in connection therewith. As the cone would quickly become white hot, a second cone C C is placed over and surrounding the first, leaving an air space of ⅜in. all round. As a consequence of this arrangement (which is common in sunlights, a rapid current of air rushes up between the cones, keeps B from overheating and destruction, and, what is more to the purpose, sends almost all the heat into the greenhouse. The outside cone is flatted in against the inner one at three points at the bottom, and riveted to it. Pipes 5in. inside diameter are laid through the house as required, and suitably connected with the first



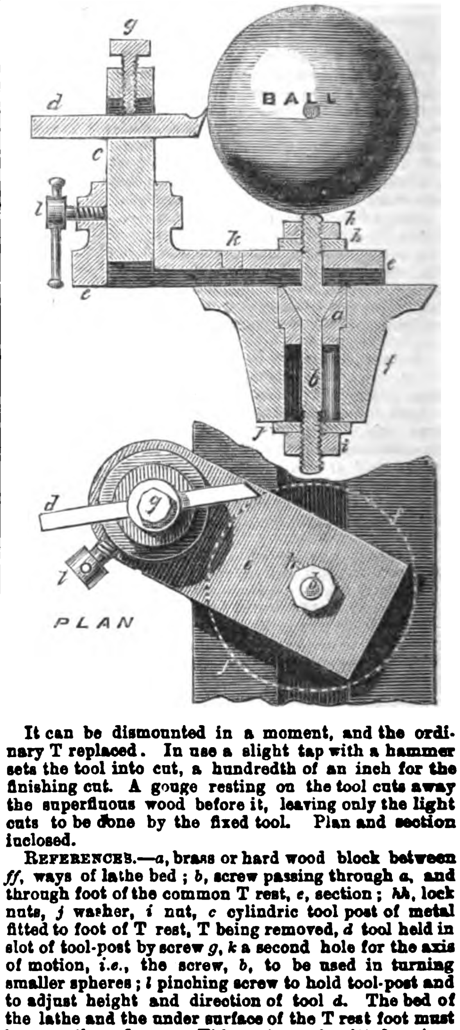
3in. pipe. A chimney at the furthest end completes the apparatus. The joints are made with fireclay, made into stiff paste and rammed in tight. About 30 feet of 5in. downspout piping will absorb the heat generated by gas from two No. 3 burners. The pipes require a rise of about half an inch per lineal foot. In the greenhouse I speak of, 3in. pipes were first used, but the first few feet absorbed most of the heat and burned the air; 5in. pipes obviate this, as the draught is more perfect. If the first portion should overheat it should be surrounded with sand. If of interest I can give a sketch of a very effective fire-grate and arrangements for coke burning which I built for a friend.

ATMOSPHERIC BURNER.

[Please send.—ED].

THE WASHINGTON SPHERICAL REST.

[4850.]—YESTERDAY and to-day, before breakfast, I fitted the T rest of my 4in. centre lathe with a brass slotted tool post, and bored it with two holes for an axis secured in a shifting block between the ways of the lathe bed, so as to fit it for spherical turning. The spherical rests described in the books, so far as I have seen them, are complex and costly. This arrangement is cheap, and a few hours' work makes all the additions to the lathe needed. It will turn, having two holes for the axis, balls from 6in. to ½in. diameter. Possibly it may be interesting to some of your mechanical amateurs, who, with a good spherical rest, could quickly turn their own croquet and billiard balls. This plan dispenses with everything not necessary, but contains everything really needed. The tool-post can be revolved right and left, so as to present the tool at a most convenient angle. It shifts, also, to regulate height of tool.



It can be dismounted in a moment, and the ordinary T replaced. In use a slight tap with a hammer sets the tool into cut, a hundredth of an inch for the finishing cut. A gouge resting on the tool cuts away the superfluous wood before it, leaving only the light cuts to be done by the fixed tool. Plan and section inclosed.

REFERENCES.—*a*, brass or hard wood block between *ff*, ways of lathe bed; *b*, screw passing through *a*, and through foot of the common T rest, *e*, section; *hh*, lock nuts, *j* washer, *i* nut, *c* cylindric tool post of metal fitted to foot of T rest, T being removed, *d* tool held in slot of tool-post by screw *g*, *k* a second hole for the axis of motion, *i.e.*, the screw, *b*, to be used in turning smaller spheres; *l* pinching screw to hold tool-post and to adjust height and direction of tool *d*. The bed of the lathe and the under surface of the T rest foot must be smooth and even. This rest can be fitted up in a few hours, is cheap, effective, and as perfect in its action as those ten times as costly.

Washington, U.S. GIMEL.

CALCULATING WAGES.

[4851.]—THIS little table (let. 4788) would also be suitable for cases where odd half-hours were worked, if the pay ended with 6d. Thus, suppose 41½ hours were wrought, and the wages for a full week's work to be 25s. 6d., how much is to be paid? Adding, considering the 6d. as a half, we get 67. Opposite this in the table is .... 20s. 9¼d.
Subtracting, we get 16. Opposite this is...... 1 2

19 7¼

The difference of these two sums gives the wages to be paid. The table would be useful for calculating or verifying ready reckoners. PHILANTHROPIST.

MARINE AQUARIUM.

[4852.]—WHILE acknowledging "Cuprum's" kindness (let. 4761) in communicating the result of his experience to the readers of the ENGLISH MECHANIC, I would point out that his plan is somewhat complicated, and to dwellers at a distance from the sea rather impracticable, and in regard to the expense is very little cheaper, unless made by the owner. A glass aquarium, flat sides, to hold ten gallons, can be purchased for 10s. 6d. A less troublesome plan is to employ artificial sea water, which from the accurate knowledge which chemical analysis supplies us can be made to answer every purpose from the following formula:—
To every 100 parts of the solid ingredients, common salt 81 parts, Epsom salts 7 parts, chloride of mag-

nesium 10 parts, chloride of potassium 2 parts; add water 2,900 parts. Of course any quantity in these proportions can be mixed up. The mixture should be allowed to stand a few days for the impurities to settle, it may then be poured off; no living creatures should be put into it except weeds and plants for a few weeks, the water will thus become oxygenated; carefully stocked and its contents well looked after, it will retain its pristine purity for a length of time. The above formula costs in preparation about 10½d. per lb., and where sea water direct from the sea is unattainable (where probably the majority of our fellow-readers live) is just the thing. TINTUB.

BOILER INCRUSTATION.

[4853.]—HAVING noticed in the MECHANIC for some time back articles on the subject of the formation and deposit, and the induration of the material, on the surface of the steam boiler plates, and the great difficulty of removing the same, whether the said material was lime, magnesia, or iron, or, which frequently happens, a combination of all the three bodies. We for years had great difficulty in removing the scale, in fact, we could only remove it by absolute chipping, and that very slowly and indifferently; we tried greasing the plates, gas tar, both acids and alkalies in abundance, and all without the least effect. I thought I would try an experiment with pigeon dung, and knowing it contained when fresh a considerable quantity of ammonia as well as other bodies we threw a quantity, about half a bushel of fresh pigeon dung, into the boiler—the first time about a year ago, and have done the same each time it has been empty ever since, and have not had since then one particle of scale adhering to the plates since. The matter is thrown down, and when the boiler is let off is mere slutch at the bottom, which during the night dries into a powder, such as you find inclosed in this note. A CONSTANT READER.

OUR MATHEMATICAL COLUMN.

[4854.]—I AM glad to see in our "answers to correspondents" that one of our contributors has invited our attention to the question of a mathematical column. It would, no doubt, be "a boon to many." Only yesterday a young friend of mine, who has read my MECHANIC for a twelvemonth or more, confessed to me his difficulty in understanding the figures used in the scientific papers. "To illustrate my meaning," said he, "I cannot tell what is expressed here (p. 578) by specific heat 0·250; atomic weight 16·; atomic heat 4·" Now, my impression is that there are scores of readers of the ENGLISH MECHANIC in a like predicament. Half the information it is capable of affording is lost, because every one does not learn decimals at school, nor is every one capable of teaching himself. If, then, you should conclude to act upon Mr. Biggs's suggestion, I have no doubt you will see the advisability of beginning at the beginning, so as to lead the minds of tyros up to the mathematical problems, and not to take it for granted that all readers of the ENGLISH MECHANIC are perfect, or even amateur, mathematicians.

H. G. W.

COAL IN IRELAND.

[4855.]—PERMIT me to correct "Philanthropist's" (let. 4274) statement in one particular—viz., as to the Leinster coal formation: the coal of counties Carlow, Queen's, and Kilkenny, being all the anthracite or stone coal, nor do I recollect that any of the bituminous sort is found in that province. When I was a lad, 40 years ago, very little other coal was used in my native town, and that (called sea coal) was confined to sitting-room fires. Of later times I cannot speak positively, many of the old pits having been worked out or abandoned, and I do not know if new ones have been discovered or opened. At the time to which I refer, on a certain day in the week, housekeepers used to go to the coal market and purchase a load of coals just as they would hay or any country produce, but alas! like many other Irish industries, that is now a thing of the past. It would be a blessing to that land if the present excessive price of coals roused the people to utilise the bounties of nature lying just at their feet.

A CARLOW MAN.

The Pathology of the Chignon.—M. Lindeman continues (says the *British Medical Journal*) his investigation of the parasitic bodies (Gregarinidæ) found on the false tresses and chignons commonly worn by ladies. They are to be found at the extremity of the hairs, and form there little nodosities, visible, on careful examination, to the naked eye. Each of these nodosities represents a colony of about fifty psorosperms. Each psorosperm is spherical; but, by the reciprocal pressure of its neighbours, it is flattened, and becomes discoid. Under the influence of heat and moisture, it swells; its granular contents are transformed into little spheres, and then into pseudo-navicellæ—little fusiform corpuscles, with a persistent external membrane, and inclosing one or two nuclei. These pseudo-navicellæ become free, float in the air, penetrate into the interior of the human organism, reach the circulatory apparatus, and produce, according to this author, various maladies—"cardiac affections, especially valvular affections, Bright's disease, pulmonary affections." M. Lindeman calculates that, in a ball-room containing fifty ladies, forty-five millions of navicellæ are set free; and he concludes that it is necessary to abolish false hair, which often proceeds from unclean persons.

REPLIES TO QUERIES.

. *In their answers, Correspondents are respectfully requested to mention, in each instance, the title and number of the query asked.*

[12311.]—**Hydraulic.**—I have a rainwater tank collecting the water from the roof of my house. It is 5ft. deep; the water enters the suction pipe of the pump by a tube 6in. long at right angles to the pipe, and 6in. from the floor of the tank. A plentiful collection of soot is found on cleaning the tank once a year, sometimes forming a layer of dirty water 4in. deep, but not a drop of this sooty water is pumped up.—WILSE BROWN.

[12348.]—**Spanish Pronunciation.**—I wish Mr. Wray would not insist on dubbing me "our learned friend." I know nothing of the Oriental alphabets, and cannot in the least say whether the *heth* (also spelt *cheth* formerly, and now commonly transliterated by *hh*,) is considered equivalent to the German and Scotch *ch* and Spanish *j*. I have seen a statement, in some grammar, that only one English word, *alcohol*, has the *h* made usually equivalent to the latter. The Sanscrit letters represented by *kh*, and *gh*, are said (as well as all those expressed by a consonant and *h*, as *bh*, *dh*, &c.) to be really double sounds, that, in a "perfect language," would only have needed a single character for *h* inserted between the mute and the following vowel. It is an interesting question what was the sound of the old English letter (always used till printing began) that has become *y* in a few of our words, as *you* and *yet*, while in the great majority it has become a silent *gh* (*might*, *though*, &c.) After throwing away the letter to make foreign type available, we have plainly lost the sound utterly.—E. L. G.

[12359.]—**Sulphurous Smell after Thunderstorms (U.Q.).**—Does not this arise from the conversion of the oxygen of the air into ozone? as in a room in which electricity is being developed and the spark passes through the air, this smell is very sensible.—S. BROUGHTON.

[12394.]—**Fret Saw (U.Q.).**—In what way is your fret saw mounted? if in a bow, your bow must be very weak, or you must have some back lash somewhere that wants taking up.—JACK OF ALL TRADES.

[12402.]—**Grease on Leather Bands (U.Q.).**—I know of no process that will make them look new, but a great quantity of grease may be got out by soaking in hot water and scraping, and the stains may be removed to a great extent by sponging with oxalic acid and water when damp. The above is a deadly poison.—JACK OF ALL TRADES.

[12405.]—**Boiler for Model Steamboat (U.Q.).**—The worst of these things is not being able to get heat enough, because you cannot get them fired well, or a draught up the flue. A boiler of the locomotive type would look and be best, and as large as you could conveniently get it in proportion for these things, if you wish to work them is out of the question. You could not do with less than a 2in. barrel, chimney end 1¼in., fire box 2¼in, and about 3½in. deep, and about six ⅜in. tubes through the barrel.—JACK OF ALL TRADES.

[12408.]—**Brass Moulding (U. Q.).**—I know of no process but mixing the lead and zinc, then adding to the copper.—JACK OF ALL TRADES.

[12410.]—**Chemical (U. Q.).**—This is a thing not come at as yet; copper, zinc, and Muntz metal do not do it, although they clean themselves to a certain extent by the chemical action of the salt water by exfoliation, but do not keep a clean bottom by any means.—JACK OF ALL TRADES.

[12418.]—**Resistance of Steel Plates to Air Pressure (U.Q.).**—This will depend upon the size of chamber. If I recollect right this was tried upon the Epsom line by some foreigners in 1846-7 after the atmospheric tubes were tried and found wanting.—JACK OF ALL TRADES.

[12422.]—**Steam Power (U.Q.).**—Work your steam more expansively; a counter shaft with a pair of pulleys may assist you, making a slight difference of one-third or two to one.—JACK OF ALL TRADES.

[12425.]—**Piano (U.Q.).**—I should advise you to have a fresh board put in.—JACK OF ALL TRADES.

[12426.] — **Unsound Pianoforte.**—If "A Subscriber's" piano has become a "rattletrap," which suffers the "rattles" to escape out of the trap simply in consequence of its soundboard being what many of us are, to-wit "a we bit crackit," this evil may be remedied two ways—First, by boring a small hole a little beyond each end of the crack, and widening the latter by running a common key-hole saw down it, thus preventing its sides from rattling against each other; secondly, by doing what my friend "Fiddler"—in common with many other fiddle fanciers—has, in all probability, often done—viz., introducing rather thin and very hot glue into the crack, and thereby making a sound joint, which, by the way, is not a very easy thing to do. Indeed, the attempt is almost hopeless, unless you thrust the edges asunder by a wedge while you introduce the glue, and warm it afterwards, for which purpose a hot smoothing iron serves very well, if not held too near the wood. Of course, the edges of the crack must be brought together and retained until the glue is dry. As an open slot in a soundboard is said to diminish the loudness of the sounds, you may—after widening the crack with a saw, and smoothing them with a thin file—glue in a slip of wood. The fiddle's belly—I mean the piano's—then becomes, for all practical purposes, at least as good, if not—like the ancient coat offered for sale by the Israelite, not without guile, who at once "sold" Old Clo' and his customer—"better than new." Should the soundboard have sank under the downward pressure of the strings, the only remedies I know are first to reduce the downbearings by introducing some packing between the strings and the string plate—or the fillet of the bent side—when they rest on it. If, however, the downbearing be not excessive, say not more than from 1 to 2 per cent. of the tensile force in the bass, from 2 to 3 per cent. from tenor C to pitch C, and from 3 to 5 or 6 per cent. in the higher trebles, the one thing needful is to make the soundboard more rigid. The best methods of effecting this are to block up the soundboard until sufficiently arched, and, having "shot" the backs of the belly-bars, to glue on more wood so as to make them deeper. Also, if needful, to "fit" additional bars to the back or under side of the belly, and glue them on securely, inserting a few screws (about No. 6 or 8) from the front. See my article on "Bellying," printed in No. 377.—THE HARMONIOUS BLACKSMITH.

[12444.]—**Day and Night Telescope.**—The only "speciality" I know of in the construction of day and night telescopes is that an eyepiece of low power is—or should be—provided for use when but little light is available for them. Much amplification cannot be allowed with small apertures say 1½in. to 2in. A 4in. astronomical (achromatic) serves exceedingly well for a night-glass with a power of about 12 to 30, according to the amount of light, but not so very much better than a non-achromatic glass, because at night there is but little colour to be corrected. I once made a night-glass—I don't mean a glass of grog employed for a night-cap—out of a 6in. plano-convex lens ground out of a piece of plate glass. The focus was about 100in. This was supported in a cell formed out of a piece of wood 3in. thick, with a recess 7½in. diameter (and a hole 58/10in. diameter), formed in it by turning out the material in the lathe—a wooden ring which fitted the recess being employed to retain the object-glass in its place. The tube was formed of four pieces of ⅜in. seasoned American pine wood, and the tube carrying the eye-pieces fitted into a hole about 1½in. diameter formed on a similar rectangular block. With this instrument—which, I fear, "F.R.A.S." would designate a "rough"—I could see "far into the night," sometimes too far for my peace of mind, for with it I have seen things which strongly impressed me with the notion that all my fellow Christians—notwithstanding. I was then "young" myself—were hardly so modest as—THE HARMONIOUS BLACKSMITH.

[12457.]—**Geometry.**—"Bobo" will not find any triangle in which my procedure does not produce an equal-sided rhombus; but perhaps the problem is to inscribe a rhombus whereof no angle shall be at an angle of the triangle, but one at a given point on its base, as S in the figure (p. 546). The proposer did not say "a given point," but simply a point of the base, which I assumed might be one of its ends. The problem is possible, however, with any point, as S, though not so easy. As for "P. W. H. J.," he merely describes how to make a rhomboid, but the engraver has made a trapezium.—E. L. G.

[12483.]—**Rewiring Old Piano.**—From the, now, very unusually short compass of "H. W.'s" piano—only five octaves—I presume it is even older than myself, for few pianos were, I believe, made with a compass of less than five and a half octaves after the year of grace A.D. 1799. I have had some little experience in "rewiring" old pianos, and experience has quite convinced me that it is my duty to quote, for "H. W.'s" behoof, Punch's good advice to persons about to commit another act of folly, "don't" use thicker strings, unless you are willing to incur the trouble and expense of making your ancient-keyed dulcimer stronger. Most ancient square pianos have but one pin in their belly-bridges for each string to press sideways against, consequently their bridges—and soundboards—are pushed in one direction (*i.e.*, backward) with a force equal to the total side pressures of all the strings resting on them. The common effect of this is to raise the soundboard in front and depress it behind the bridge; but this very great defect may be remedied by double pinning the bridge and moving the strings (at their ends, which are on the hitch-pins) to others which are in a continuous line with these parts of the strings between the bridges. Probably, a few additional hitch-pins will be required in the bass. I hope the wrest-pins of "H. W.'s" piano are not at the right-hand end of its case, but distributed on the back block, *à la* Broadwood. If "H. W." determines to "rewire," I should strongly recommend him to have his wrest-pins drilled. This costs but a trifle, and so greatly facilitates putting on the strings that Messrs. Kirkman had it done to some harpsichords they restored, in which wire as small as from No. 1 to about 16 is used. Unless the frame of "H. W.'s" piano be strengthened, it would be very imprudent to use wire more than one or two sizes larger for all the bichord notes which usually extend throughout the compass of old squares. I have, however, seen a foreign one (made during the last century) which had three strings down to fiddle G. Did "H. W.'s" piano belong to me, and I was afflicted with an irrisistibly insane desire to improve it, I should do the same to it as I once did to a 5½ octave square by Tomkisson formerly in my possession, to-wit, make the instrument unichord for the lower two or two and a half octaves in manner following:—Having double-pinned the belly-bridge, and also the wrest-plank bridge for about two octaves in the treble (where the side-bearing is usually insufficient to keep the strings steady enough for anything approximating to pure tone), using bridge-pins about four sizes larger than the old ones, and about 1/12in. diameter on the wrest-plank, I proceeded to strengthen the frame by introducing an iron bar above the highest treble strings, and another below the lowest F in the bass, notching the name-board to allow space for it. The trebles from C down to G were then strung with No. 12 instead of No. 9, after which Nos. 13, 14, and 15 wire, was used in nearly equal proportions, the F below fiddle G being strung with No. 15 wire, very lightly loaded by thin covering wire wound on it in an open spiral The same size was employed down to tenor C, which was the first string with its covering wire coiled closely on it. The B string was covered on No. 16, which size extended down to the lowest F. I forgot to mention, I blocked up the soundboard at the top, and down to pitch C, and strengthened it by glueing on a belly-bar 1in. × ⅜in. within 2in. of the bridge at the top C, and about 5in. distant from it at pitch C; it being tapered off to about three-sixteenths thick at each end, one of which rested on the fillet of the soundboard, and the other was about 6in. distant from the pitch C strings. This enabled me to give the strings more downbearing in the treble to the great amelioration of its tone, which was afterwards yet further improved by substituting a metal bridge on the wrest-plank for about an octave and a half. What all this cost, I am ashamed to say, but it is some excuse that I was then "young" as well as "green," which, no doubt, I yet am (more or less). The next thing to do was to improve the action; I deepened the touch, originally only ¼in., to full five-sixteenths of an inch, and made all the hammers about double their original weight, yea, even three times as heavy in the lower bass; they were then re-covered, the high treble hammers being made more pointed, and the bass hammers somewhat flatter. The tone was not only far more powerful than it originally was, but also of much finer quality; in short, the experiment was very "satisfactory," (except pecuniarily), especially after I had raised the pitch of this old instrument, so that the A keys produced sounds in unison with C of our philharmonic pitch; but then, alas, transposition by shifting its keys being quite beyond its capabilities, the singing men and women complained it was a trifle too sharp for their vocal organs. By the way, I found not many of them could play music written in C on the keys of the scale of A, so after greatly improving the old family piano, I had to re-write all the songs a minor third lower; rather small consolation for my brain and handwork, but was comforted by the reflection, "it might have been worse," for "ye practical man" prophesied the piano would be spoiled. Let me caution "H. W." against the use of brass wire, which is a delusion and a snare. The tone is, doubtless, very fine, but it won't stand in tune with steel strings. There is no difficulty in using covered steel wire in lieu of brass for old square pianos, and other instruments which have but one belly-bridge, in proof of which I may mention I once had some strings of only No. 10 steel wire covered (open) with No. 00 copper for the lower notes of the octave-stop of a harpsichord. "What man has done, man can do." If "H. W." will inform me the maker's name and date of his venerable piano, I might possibly give him further information, some of which he might possibly obtain by reading my rather long paper on the possible improvement of old pianos, published in "our" journal under the title of "How to Convert Good Old Pianos into New Ones." I have often thought if I had possessed sufficient "gumption" to have spent the time and money which was expended on the old "family" square on such an instrument as the Stodart grand therein mentioned, which sold for only 31s., the musical results might have been something more valuable; however, "H. W." may take "heart of grace," for after all his venerable piano can hardly be so old as those by Steen at Potsdam, nor even Mozart's square piano which, is yet extant; perhaps not so old as the "Zumpe" A.D. 1770, now in the possession of Messrs. Kirkman, which is, I believe, one of the most ancient pianofortes extant made in England.—The Harmonious Blacksmith.

[12502.]—**Nevill's Bread.**—No special formula for the manufacture, I believe. It is merely baked in hot-water ovens.—E. M.

[12504.]—**Sketching from Nature.**—The great requirement for correct sketching is an accurate and well trained eye. All mere mechanical contrivances have a tendency to weaken the self-relying powers of the eye, just as the constant use of a note-book weakens the memory. All that any one who has an eye sufficiently trained to be competent to commence sketching from nature should require, is to get his principal objects properly placed. This may always be done by the following simple means, which only require a little practice to become quite easy. As soon as he has ascertained, by holding his paper at a proper distance, the space his drawing is to take in, let him take the paper in one hand and a pencil in the other, then holding the former so as to cover the view exactly, let him lower it gradually, and as each principal object in turn cuts the top of the paper, let him make a dot on the edge. The same may be done at each side of the paper in turn, and thus, by drawing your pencil down and across (without marking lines on the paper), you get the exact place of each principal object on precisely the same principle as that suggested by Webb and others, while you dispense with the mechanical contrivance and gain training for your eye, which is, after all, the most important of all qualifications. When you have got the principal objects successfully placed, the minor ones are easily filled in. I have adopted the above method for many years, and while I will yield to no one in accuracy of outline, I will undertake to have my drawing all placed by the time the man with the frame and lines has adjusted his apparatus.—G. Nash.

[12510.]—**Camera Obscura.**—The dimensions are immaterial, so long as they are suited to the focal length of the lens. The ground glass is placed "flat," and a piece of tracing-paper on it if you want the drawing on paper. Ascertain the focal length of the lens, as directed on p. 494, Vol. XIII., and make the box accordingly with a little play either way. The only essentials are placing the mirror at an angle of 45°, and in the focus of the lens.—Tages.

[12523.]—**Lacquer.**—You can buy a blue lacquer for the purposes mentioned. The directions for applying it are given with it.—E. M.

[12524.]—**Holtz Electrical Machine.**—It would be quite possible to substitute a varnished tin plate for the small glass disc; but *cui bono?* I think the glass would give the best results.—Tages.

[12528.]—**Hay Asthma.**—This complaint is caused by the pollen of flowers of any sort. I have seen a lady unable to bear a glass full of garden flowers in a room. In 1850, a friend, liable to the disorder, came to shoot grouse on my moor in Teesdale on August 12. The heath was then in bloom, and he felt the effect of the pollen the moment he set foot on the moor.—Wilse Brown.

[12532.]—**Republican Months.**—The correspondent who answered this query on p. 571 omitted to give the complementary days, of which there are five in ordinary years and six in leap year. They commence Sept. 17.—Deeside.

[12537.]—**Compressing Air.**—By all means let "Mechanical Equivalent" publish the rest of his experiments. There are none, I believe, since Dalton's in 1800.—E. L. G.

[12539.]—**House-fly.**—There are two sorts of house flies, which so nearly resemble each other that few people ever think of distinguishing them. They are, however, really quite distinct species. One, the common house-fly, does not bite, having no apparatus for the purpose; the other, which may be distinguished by the wings being wider apart at the tips, and by its having the biting prong protruding from the front of its head, does bite, and when it does, makes itself felt pretty sharply. It does not often bite, however, in this country, but in Australia, where both species are also found, I have often both felt them myself and have seen the blood running down the legs of horses from the pertinacious attacks of these small tormentors. It was there I learnt to distinguish them from the common fly. The real mosquito is also common enough in this country, but it, too, seldom bites, except in particular localities, generally near the sea-coast, where there are drains or marsh, as in Lincolnshire, for instance.—G. Nash.

[12539.]—**House-fly.**—A little black pepper, a little brown sugar, mixed with water in a saucer, is a deadly poison to flies.—Wilse Brown.

[12550.]—**Seaweeds.**—I have repeatedly arranged specimens on a plate with a little water in it. The plate being gently shaken, gives the plant a good spread; begin the trimming and flatting out at one side, using a long pin, or wire, a hairpin does admirably; overlapping sprays must be nipped off with a thumb-nail or finger-nail; by gradually raising the plate, the water drains away, and leaves the seaweed behind, quite ready to be laid aside for a day or two to dry. To remove, loosen it gently with a pin or blunt knife. The very delicate species are better laid in the same manner on pieces of paper, and afterwards pressed between fine cloths, such as clean pockethandkerchiefs, &c.—H. O'B.

[12555.] — **Packfong, or Chinese White Copper.**—Several recipes having been given for this metal, I beg to send a formula I came across recently. It varies from the others which have been given, but they are all different. It consists of copper, 10·4; nickel, 31·6; iron, 2·6. As to the mixing, I know nothing, but I imagine the nickel and iron should be first melted, and the copper added afterwards.—Saul Rymea.

[12566.]—**Bees.**—The rule is for the owner of a hive to follow a swarm which leaves his premises. If he can keep it in sight—sometimes no easy matter—he can hive them, and take them home from his neighbour's land. Bee-keepers ought never to leave an empty hive in their gardens. It serves as a trap to a swarm, for bees are always in search of some habitat at swarming time, whether a hollow tree, or an empty space in the roof of a house, and will certainly fly to an empty hive.—Wilse Brown.

[12598.]—**Age of Trees.**—This is a strangely neglected question, on which something really ought to be ascertainable without refined science, if colonists could only be induced to remember it, when opportunities occur; and if the writer of the first and very ridiculous reply on p. 598 can succeed in spreading his notion that we have here a compendious and easy way of smashing up parsons, "theological myth," or anything of that sort, there will be a chance of eliciting somewhat of "visible fact" in a matter where all seems as yet the vaguest conjecture. His "reply," together with that of "M. A. B." would convey the impression that some Californian tree has been felled in which somebody has counted 3,800 or 3,900 rings (one for each year since "Abraham was a boy") and that other trees, a baobab and a deciduous cypress (it is not said where) have been felled in which somebody counted 5,150 and 6,000. Now, it would be extremely interesting to hear of any piece of wood wherein *one thousand* were ever counted, and still more, if any museum could exhibit a bar of wood, say 3in. or 2in. wide and deep, cut radially from the face of a stump, extending from the bark to an inch beyond the axis, and displaying any number above 1,000 layers. How easily might those who fell any remarkable tree (say the Californian pine whose bark stood up ten years ago, inclosing a winding stair, in the burnt wing of the Sydenham Crystal Palace, how vastly more easily and cheaply than all that cargo of bark), might they have sent us this little "visible fact," in the compass of a moderate breechloader case; and which would have been safe, in all probability, from any such conflagration! Most assuredly we may be grateful for any "facts of extraordinary longevity of trees," but not to correspondents who merely "add *other* facts" according to this disciple of Sir Richard Phillips's notion of "facts." By all means let us have *some* facts first, and then "add *other*." The test distinguishing "one fact" from "a million myths" would seem to be whether the thing happened to get copied into this thrifty bookseller's note-book, who, by the way, besides being knighted for happening to be alderman at some pageant, was the "Hampden" of his day! The Phillippian "system of the universe" was going to smash up Newton and gravitation all to shivers. Is our correspondent aware that all the trees these particular calculations referred to, the baobab of Cape Verde, the deciduous cypress of Oaxaca, the dragon tree of Teneriffe, are still each a "visible fact," standing and flourishing? Who are the clairvoyantes poor Sir Richard got to count him the rings in a living tree? Of course, though all very old trees are hollow, there is little doubt these have *had* some thousands in their day, but whether 3,000 or "5,150" or 6,000, De Candolle (from an early work whom the figures are copied and recopied) in his latest work ("Geographie Botanique," pp. 1063—5) finds no evidence for calculating, even to a millennary. Between 3,000 and 4,000 he assigns to the Oaxaca cypress (*taxodium*) if a *single* tree; but as its diameter is fully thrice that of any other known specimen, he thinks it more likely to be four or five, "soudées" like the trunks of the famous hollow chesnut tree of Etna. We must further observe that in this and most tropical trees, to prove 6,000 years age requires 12,000 rings counted, as they are semi-annual, one formed at each rainy season, in nearly all the few tropical trees that have visible rings at all. In the greater number they are indistinguishable as in mahogany; and scarcely one in 100 of tropical species have probably (like the Jamaica cotton-tree), such an annual interruption of functions as to mark single annual layers like our timber. The baobab above mentioned (*Adansonia*), is a close relative of this *eriodendron*, and like it, certainly fast-growing and short-lived, though both, at a couple of centuries old, are the monarchs of their respective woods. I have assisted at the felling of an eriodendron whose girth was 32ft. at 30ft. from the ground; the rings were about 90, and negroes present remembered it a sapling.—E. L. G.

[12598.] — **Age of Trees.** — Why cannot "A Believer that One Fact is Worth a Million Myths" (answer to query 12598) speak of the ascertained age of certain trees without indulging in a gratuitous sneer at what he calls a "theological myth"? What it has to do with the trees I cannot well see; they may have been growing for millions of years instead of thousands for all that theology says to the contrary, provided it is not at the same time asserted that they are younger than Adam. The reason why naturalists' statements have not always received implicit credence is due to no such absurd prejudice, but to the difficulty of obtaining an exact estimate of the number of zones in the wood by an outside measurement of the tree. So many causes may operate on a tree, particularly when young, to make it grow faster or slower, or more or less irregularly, that we cannot speak with anything like certainty as to the age until it is felled and the rings carefully counted. Measurement and calculation can only give an approximation. As theological discussions are excluded from the pages of this journal, correspondents should be careful to avoid giving provocation by making statements and allusions which others are not allowed to answer, and above all they should not, as in this case, sneer at the views of their opponents, without being quite sure that they know what those views are.—Vertumnus.

[12608.]—**Bookbinder's Press.**—"Dublin Subscriber's" question refers to a bookbinder's press, not a bookbinder's plough, as illustrated and answered by "Jack of All Trades" this last number.—Zeta No. 1.

[12613.] — **Excessive Perspiration.** — In the Brompton Hospital for Consumption they give tincture of zinc three times a day. Any chemist on reference to a Pharmacopœia, will tell you the dose. Buy threepenny worth, and find how many drops in water to take, if expense is an object. Wear flannel, but not in bed.—Zeta No. 1.

[12631.] — **Fixing the Bloom of Scarlet Runners.**—The falling off of the bloom of scarlet runners is very general this year. Some assign the cause to excessive heat. Fuchsias in the open garden also drop their petals. Give water freely; liquid manure if possible, and the later blooms of scarlet runners will pay for the trouble.—Zeta No. 1.

[12638.]—**Fleas in Dogs.**—"Countryman" will find common sweet oil, poured down the middle of the back of dog, a safer remedy than sulphurous acid. A solution of stavesacre flowers answers equally as well, and of all the dog soaps advertised, the best is the Japan soap, prepared by Rackham, of Norwich. An owner of upwards of eighty dogs, of various breeds, has tried them all, and ought to know something.—Zeta No. 1.

[12639.]—**Worms in Pony.**—Get an areca nut or two from a chemist, grate it on a nutmeg grater, and give it twice a day, in any kind of food, or made up as a pill. For a pony about as much as will cover a shilling, for a dog one-third that quantity. The cost of nuts are 2d. each, large size, and have proved very sure on all cases I have tried and elsewhere.—ZETA No. 1.

[12642.]—**Ice Cream.**—Put into a bucket 1lb. of ice broken rather small, throw two handfuls of common salt upon it, and leave it in a cool place. Put the cream into a pewter ice-pot, or an ordinary pint or quart milk can, with a tight-fitting lid, will do. Immerse it in the ice, and draw the ice round the pots so as to touch every part, then commence spinning the can round in the buckets by means of the handle on the lid. Every few minutes take a spoon and stir the cream so that it may freeze equally—stirring quickly increases the cold. As the ice in the bucket thaws, fresh should be added, and the water thrown away. The cream for iceing is thus made:—New milk one quart, yolks of six eggs, fine sugar 4oz., mix, strain, heat gently, and then cool. To this may be added any essence or flavouring you think proper.—E. R. WIGAN.

[12648.]—**Dictionary of Scientific Terms.**—There is a small one by Dr. Nuttall, published by Strahan and Co., 56, Ludgate-hill, about 5s. in price. There is also a more comprehensive one by Dr. Stormonth, published by Blackwood.—N. S. HEINEKEN.

[12649.]—**Kites.**—I send the description of a bird-kite which can be very easily made. The only materials are some stout glazed calico, a lath, a couple of good sound canes, some wire and string. Cut the calico to the shape of a hawk with outspread wings; omitting all minor details, and aiming only at the general outline. 2ft. 6in. from head to tail, and 4ft. 5in. across the wings, is a very good size. The canes, which should taper at the ends, should be 2ft. 10½in. each, and are inserted in the hem of the upper edge of the wings. At 9in. from the end of each cane a hole must be drilled, through which a stout wire pin, bent into a ring at the top, is placed, which itself fits into a hole made at 9in. from the top of the lath. It would be safer to tie a piece of tape to the pin, with which to wrap round the place of joining. A flat piece of wood 11in. long, and nearly 1in. wide, run through a broad hem at the bottom of the kite, will serve to keep the tail stretched out. The tail proper is composed of wire hoops, to which are attached conical cups, in the manner described by "Q Yorke," five of which are quite sufficient. If these directions are not intelligible enough, I shall be glad to answer any questions.—C. N. W.

[12653.]—**Poultry Keeping.**—A young woman, daughter of an innkeeper near Liverpool, was left alone one evening. She heard a noise in the poultry-yard, took a pistol loaded with small shot, went to the fence round the yard, and saw two men catching the birds in the dark. A scream from one of the men followed the report of the pistol, and both dropped their game and bolted.—WILSE BROWN.

[12657.]—**Cutting Cylindrical Glass.**—Heat a stout iron wire or thin rod to redness. Heat the neck of the bottle in a gas flame, and touch the hot part with a drop of water, which will produce one or more cracks. Then guide the crack in the desired direction by applying the red hot iron. The crack will follow the course of the wire, and the glass can thus be cut in any manner.—ALFRED H. ALLEN.

[12663.]—**Sunrise.**—The "Ephemeris," published by the Astronomer Royal at Greenwich, will give all the information "Delta" requires.—WILSE BROWN.

[12664.]—**To Stereotype Brass Blocks.**—When I get a new block cut, some customers want their printing done in black and some in metal leaf, so that if I could take an impression of the brass block I could have three or four working at once. They would cost but little, whereas if I must get three or four more brass blocks it would come very expensive. If I could cast them in brass it would be much better.—J. B. SHARPLEY.

[12665.]—**Sea Sickness** can be prevented by the voyager getting all strings, straps, and buttons loosened, and berth-gear put on whilst the vessel is still; keep the head on a low pillow, "screwed down," as a friend of mine once said, and determinately maintain the one position, not raising even a finger, not moving a limb, the whole time the steamer is in motion. "What man has done man may do," and I have tried and been successful.—H. O'B.

[12665.]—**Sea Sickness.**—Repeated small doses (10 grains) of chloral hydrate are said to have a marked effect in preventing sea sickness. I have myself avoided it when nearly every other passenger was ill, by sitting between the paddle-wheels (or as near the centre of the vessel as possible, not only from end to end but side to side), and carefully avoiding a view of the waves by reading an interesting book. A game of chess has answered the same purpose very effectually.—ALFRED H. ALLEN.

[12665.]—**Sea Sickness.**—Do not eat for two or three hours before going on board. Swathe the abdomen tightly with a broad bandage from ribs to hips; take 10 drops of chloroform on sugar or peppermint water as you go on board; lie down at full length as near centre of vessel as possible, and with head to vessel's stern, but not close to engines, as the oily smell and heat often sickens, and go to sleep.—M. A. B.

[12665.] — **Sea Sickness.**—Moderate doses of "hydrate of chloral" taken immediately on going aboard with an assumption of the recumbent position effectually preserved a party from sickness when crossing the Great Belt, from Denmark to Norway, and *vice versa*, although the passage was rather rough and vessel small. Recently, I prescribed doses of 15 grains in orange flower-water to a friend going to Quebec, and he writes that he was the only passenger free from sickness in the ocean steamer. The chemist prepared the doses in a graduated bottle, and my correspondent felt no discomfort whatever.—P. F.

[12665.]—**Sea Sickness.**—Eat a hearty meal of good plain food before starting, that the stomach may not be empty. When on board, avoid a hot rich dinner in the saloon, but have bread and cheese and ale on deck. Take brandy with you, but only use it as a last resource, and then drink a little, as nearly neat as you can bear it. Have some dry biscuits with you, to be eaten slowly if the feeling of sickness comes on. During the voyage, if the vessel pitches or rolls, do your best to stand; face the breeze and watch the motions of the ship so as to understand them and overcome all fear with respect to them. Above all, resolutely determine not to be afraid. Do not start, as I believe some people do, thinking about sea-sickness, expecting to be sick, wondering whether it is rough enough, and when you ought reasonably to be expected to begin. Go with the full confidence that you will not be sick and don't mean to be, but to enjoy the voyage instead; and then I think that with the precautions I have named you ought to get through your day comfortably, unless you are an exceptionally bad sailor, or the weather is unusually rough.—CERVUS.

[12665.]—**Sea Sickness.**—A light bandage pressing gently across the stomach I have proved to be a great comfort in heavy weather. If sickness should come on, avoid "brandy and soda," the stomach is irritated enough already. A little ice or iced water is good. And to bring the stomach round, nothing can do it more effectively than to eat very slowly; and well masticate a small plain hard water biscuit, taking also a small cup of strong tea without sugar or cream (sip this gently). If you can lay this foundation, supplement it with some beef tea. Twenty-eight years of sea journeying have convinced me that attention to diet will tend more to prevent sickness than the 101 nostrums vended.—JOE.

[12671.]—**Dressing Jack Line.**—"J. D." had better not use any waterproof composition for his lines. After years of experience as a salmon and trout angler I have come to this conclusion:—I have tried numbers of recipes—varnishes, plain boiled oil, &c., and the result invariably was the speedy decay of the line on the one hand, and increased weight on the other, so that the light cast, when the tail-fly should first touch the water, is not easily attainable. For a different reason I object to the staining of salmon or trout gut. The angler forgets, that although the plain gut appears very white to him when he looks down on it in the water, if he could look upwards through the water he would fail to see the gut-line, except by its disturbance of the water, the gut when wet being nearly transparent; but if he wishes to stain it, his best plan is simply to steep the gut-line a few minutes in lukewarm tea-water that remains in the pot. The reel-line I used was a thin one of plaited green silk. I had it in constant use for five years, and a bit that still remains I could not break by a fair pull. Of course, it was only used in fresh water; many a salmon I held with it, and the only precaution I adopted was to reel off the entire line immediately on my return from fishing and hang it on pegs to dry. "J. D." would require a powerful rod for pike, and I recommend him to adopt the one-splice rod; the best made either of pitch-pine or well-seasoned ash, from a tree that has grown in poor soil; and the top of lance wood. My rods were made thus, of 18ft. and 16ft. Those pretty toys of screw rods would soon come to grief with a 15lb. salmon. The best colours for salmon flies in August are a rich deep blue, and a claret nearly black; for September, the latter colour and plain gray bodies, each with fiery brown hackle at shoulder, and later in the month a blue jay's hackle.—E. J. D.

[12671.]—**Dressing Jack Line.**—"J. D." had best use indiarubber dissolved in bisulphide of carbon. If he had not rubbed it with wax I would have recommended steeping in a solution of catechu; solutions of shellac are good, but make the line too stiff, increasing the liability to "kink."—SOUTH LINC.

[12674.]—**Plant Boxes.**—I have seen Dutch tiles make a very pretty bordering for windows; the tiles are about 5in. square and ¼in. thick. It is merely a front and two ends, there being no bottom or back; the front is made like a picture frame, the depth of the tiles and length of the window it is intended to go in. It is placed on the window ledge before the flower-pots, and a screw in each end to keep it firm. If a back and bottom were put to it it would answer instead of pots.—F. S. M. W.

[12676.]—**Book-Keeping.**—The money invested in furniture, machinery, &c., must be considered as capital, and entered to credit of capital account, not to debit of profit and loss; only current expenses should be posted to the latter, such as rent, wages, packing materials, &c. All expenditure on work increasing the value of the plant, &c., is, or should be, capable of being realised again as cash or capital, and, therefore, should be considered as such; subject to a yearly deduction for depreciation in value, which latter item only should be carried to profit and loss.—LOACH.

[12676.]—**Book-Keeping.**—I suppose that "Book-keeping" charges his outlay for machinery to furniture account, and if he has a large expenditure for machinery carried quarterly or half-yearly to capital account, no wonder that his capital will appear to be diminishing. I would suggest that a "machinery account" should be kept and not closed, into which it would be quite legitimate not only to debit outlay for machinery proper but repairs—writing off a certain per centage yearly for "wear and tear." The balance of this account would then be an asset, and very properly so. This is the plan adopted by a Spinning Co. (Limited), whose books I audited at Christmas.—SENECIO.

[12680.]—**Darkening Graduations on Scales.**—First well clean your scales with turpentine or spirits of wine, and a piece of cotton wadding, then take a saucer and hold over a lamp or candle flame, and collect the carbon upon the same, next get a few drops of copal varnish and mix it up with your finger end and well rub it into the scales, and wipe it off clean with the palm of your hand, put by to dry for a day, then you may clean your face thoroughly with a piece of cloth and elbow grease.—JACK OF ALL TRADES.

[12681.] — **Is the Interior of the Globe Vacuum?**—From experiments made on the attraction of the earth, by observing the length of the seconds' pendulum at the top of a mountain or the bottom of a mine, it has been ascertained that the earth's specific gravity is about six, roughly, therefore its interior must be composed of much heavier matter than that which constitutes its surface. A pendulum vibrates more slowly at the top of a mountain than at the surface of the earth, because the attraction is less, the distance to the earth's centre being greater; it also vibrates more slowly at the bottom of a mine, as the attraction of the portion of the earth above the pendulum opposes to some extent the attraction of the rest of the earth. (There is an error in the query; the core, if possible to exist, would be 6,900 miles in diameter, not 5,000.)—PHILANTHROPIST.

[12681.] — **Is the Interior of the Globe Vacuum?**—I extract the following from Ansted's "Physical Geography," for the benefit of "Balcairn:"—It has been calculated by Professor W. Thomson, Glasgow, and Mr. W. Hopkins, Cambridge, that the crust of the earth must consist on the whole, and to an enormous depth, of some kind or condition of solid material more rigid than steel. If it were not so the height of the tides and the amounts of procession and nutation would be smaller than they are found experimentally to be. . . . . It seems that at least half the distance from the surface to the centre must be solid and rigid, to enable our planet to preserve its figure and allow the tides of the ocean and the movements of the earth to remain unchanged." The numerous volcanos and geysers sufficiently answer "Balcairn's" question about the heated interior. — RASSELAS.

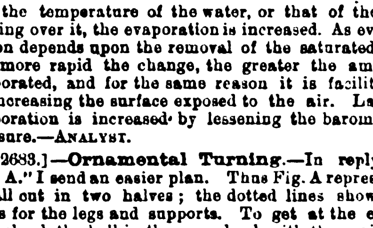
[12681.]—**Is the Interior of the Globe Vacuum?**—Mathematicians, as a rule, I believe, are inclined to favour the theory that the globe is solid. I would advise "Balcairn" to read what Thomson has to say upon this subject. I think his views are published in the Edinburgh "Philosophical Transactions." I have not made this branch of science a study, and would prefer to hear the opinions of "F.R.A.S.," Mr. Proctor, "E. L. G.," or J. H. Smith, upon the subject. At any rate, I fancy, that at the end of a discussion upon the question some of us would hold one opinion, and some the opposite. I doubt, too, whether it can be brought forward in a popular manner—*i.e.*, without the aid of higher mathematics. A large question, there is plenty of room for the mooting of theories, but will the ultimate good be sufficient to compensate for the space occupied?—C. H. W. B.

[12682.]—**Evaporation of Water.**—"Tintub" gives insufficient data. I think the question involves temperature, motion of atmosphere, &c.—C. H. W. B.

[12682.]—**Evaporation of Water.**—The rate of evaporation of water depends upon (1) the temperature of the water; (2) the temperature of the air; (3) the barometric pressure; (4) the more or less rapid removal of the air saturated with moisture. By raising the temperature of the water, or that of the air passing over it, the evaporation is increased. As evaporation depends upon the removal of the saturated air, the more rapid the change, the greater the amount evaporated, and for the same reason it is facilitated by increasing the surface exposed to the air. Lastly, evaporation is increased by lessening the barometric pressure.—ANALYST.

[12683.]—**Ornamental Turning.**—In reply to "T. A." I send an easier plan. Thus Fig. A represents a ball cut in two halves; the dotted lines show the holes for the legs and supports. To get at the exact line chuck the ball in the cup chuck with the grain of the wood across the chuck, with the corner of the chisel

FIG. A



mark a circle at C, then at D, and at E (of course the lathe must be in motion); next with a pair of compasses mark three dots with point of the compasses at equal distance apart; chuck the ball in the cup chuck in such a manner that one of the points marked shall revolve true as a centre—that is to say, the dot shall represent the centre; then bore the hole with the bits as described before, the holes should be quite through the ball, and so with the other two holes. When done, if care be taken, the six holes will be equal distance apart on each line; if the legs are required to stand wide apart, make the circle C and E nearer the centre of the ball; if to stand closer, farther from the centre. Any further information I will send if required. —SAMUEL SMITHER.

[12692.]—**Deliquescents.**—Sulphate of lead and nitrate of ammonia, muriate of lime and nitrate of soda, acetate of lead and sulphate of zinc, citric acid (in crystals) and carbonate of potash, carbonate of ammonia (3 parts) and sulphate of copper (2 parts). Powdered and rubbed together in a mortar.—T. P. H.

[12696.]—**Atmospheric Pressures.**—The Board of Trade's "Barometer Manual," price 1s., contains tables applicable to small heights, up to 500ft. from the sea level, and the formulæ for extending similar calculation to all heights. The rate of decrease upward varies greatly with temperature. The warmer the atmosphere, the higher must you ascend to reach a given diminution of pressure.—E. L. G.

[12696.]—**Atmospheric Pressures.**—The following table is copied from Brooke's "Natural Philosophy":—

Height above Sea Level.	Height of Barometer.
0 feet	30·0 inches.
5000 ,,	24·797 ,,
10000 ,,	19·000 ,,
15000 ,,	16·941 ,,
3 miles	15·00 ,,
6 ,,	7·50 ,,
9 ,,	3·75 ,,
15 ,,	1·00 ,,

—ALFRED H. ALLEN.

[12696.]—**Atmospheric Pressures.**—I know of no book giving such a scale as J. M. Taylor requires. It is not difficult to ascertain the pressure at any given point, and I have no doubt that if Mr. Taylor mentions any particular place some of your correspondents would give him the pressure. Why not make a table himself?—C. H. W. B.

[12698.] — **Vermin.**—Let "Sleepless" get six pennyworth of oil of rue in a small bottle with a cork (not a glass stopper), and wrap the bottle in his night-shirt when he gets up. I think he will not be plagued with fleas after the first night. Proved.—J. R., Jun.

[12699.] — **Onions.**—"Giant rocca" or any other "winter onion" requires no frame. Now is the time to sow in well-manured ground; if in a warm situation, so much the better; dig deep, and tread the top firm. I have just gathered a splendid crop of "giant rocca" sown this time last year.—SOUTH LINC.

[12700.] — **Bees.—Removing Supers.**—I have tried a number of ways for the last twenty years with varied success. My greatest difficulty often arose from having to leave the supers or glasses before I could get the bees out. An apiarian friend, Mr. Richard Aston, has invented a bee trap attached to a board. I simply place the super or glass on the board, and leave them. A bright day from nine in the morning to three in the afternoon is the best time for removal. You may place your bees thus removed to almost any part of your garden, covering glasses to make them as dark as possible, the entrance of the trap facing the light. Your bees will quickly pass through the trap, but cannot return, joining the parent hive as if nothing had happened. By this means I have removed about 20 supers and glasses this season, and only once had trouble with the queen; on which occasion I got the queen into any empty glass, placed a piece of zinc over the glass, inverted the glass, and placed it on the top of the hive, carefully withdrawing the zinc. We have 25 stocks at present in our apiary and garden, and I find it a great relief to be able to leave my glasses as long as I like, and attend to other pursuits.—APIARIAN.

[12700.]—**Bees.—Removing Supers.**—Choose shortly before sunset, and with a thin bladed knife remove the propolis by which the super is fastened to hive. Push a piece of sheet zinc under the super, remove to a short distance, place on its side upon the ground, and if the super is of glass cover with a cloth. After ten minutes remove the zinc, and the bees will in a few minutes go to the hive. Watch for this, and remove the honey, or the bees will return and deposit it to the main stock.—JANNIFRED.

[12703.] — **Fuchsias.**—There are several things that will cause this: sudden removal to a colder atmosphere; letting them suffer from drought; their being in too small pots, and becoming pot bound, so that the rootlets come in contact with the pot, and suffer from the heat of the sun when exposed to its rays; watering with too cold water, more especially if watered when the sun is broiling them, and sometimes from the pot being badly drained.—JACK OF ALL TRADES.

[12704.] — **Maple Veneers.** — Get a perfectly smooth bench or board on ditto, and plane them with fine set smoothing plane or tooth plane, a little each side till you get the ridges off. If you are going to veneer mouldings, you must get it nearly as thin as writing paper. Fix with hand screw to board or bench, and plane *from*, not *to* your fixing.—W.

[12704.] — **Maple Veneers.**—"Old Hatter's" veneers must not be up to much, or they would not show the saw cuts. I cannot see any better mode than well damping them with hot water on one side, then glue, and lay them immediately. If the veneers are very stout, tack them down, and use a plane carefully on them, or a scraper; when dry, finish off with a moulding plane or a steel scraper; be careful not to knock out the bird's eyes; although, I doubt if they will see any worse than before, if you do so.—SAMUEL SMITHER.

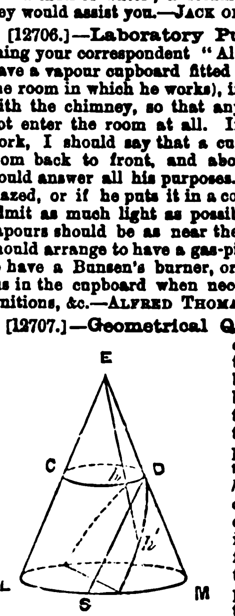
[12706.]—**Laboratory Purification.** — Never open the door of your laboratory. If you want a current of air, open the window at the top, and also at the bottom—the nearer the ceiling and floor the openings are the better. If you choose to assist the exit of noxious fumes and vapours, the following is an excellent plan. You have, doubtless, seen those circular ventilators in the tops of windows which revolve very rapidly when the heated air in the interior passes out. They are made similar to a marine screw-propeller. Fix a cord over a bobbin attached to the centre of the ventilator, pass the cord round a large wheel and fasten up; you can then turn the wheel. The ventilator spins round with great velocity, and sucks the foul air out of the room in a twinkling.—JOHN HOPKINS.

[12706.]—**Laboratory Purification.**—The best ventilator you can have is an Arnott's valve placed (as near the ceiling as possible) in the chimney breast—but noxious gases should as far as possible only be liberated in a gas-closet, which is simply a closet fixed beside the wall with openings top and bottom into the external air, and a glass front with sliding doors to enable you to see and regulate the operations conducted therein.—WILLIAM PARKER.

[12706.]—**Laboratory Purification.**—Let some air-bricks into the wall at foot, and ventilate into some chimney. Much may be done by a box of quicklime and a tank of water; a steam jet up a shaft or chimney would assist you.—JACK OF ALL TRADES.

[12706.]—**Laboratory Purification.**—The best thing your correspondent "Alastor" can do will be to have a vapour cupboard fitted up in his laboratory (or the room in which he works), in direct communication with the chimney, so that any obnoxious gases may not enter the room at all. If he does not do much work, I should say that a cupboard 24in. long, 18in. from back to front, and about 24in. to 30in. high, would answer all his purposes. Three sides should be glazed, or if he puts it in a corner, only two sides to admit as much light as possible. The outlet for the vapours should be as near the top as possible, and he should arrange to have a gas-pipe near so as to be able to have a Bunsen's burner, or other heating apparatus in the cupboard when necessary for evaporations, ignitions, &c.—ALFRED THOMAS JENKINS.

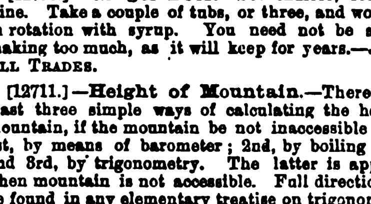
[12707.]—**Geometrical Query.**—Let ELM be a cone, CD a circular section of it, the circle to be projected into a parabola, E the position of the eye, DS a section of the cone made by a plane parallel to EL; this section is a parabola. Let h be any point on the circle, join Eh and produce it to h'; h' is its projection, and so, for any other point, the cone should be produced indefinitely in the direction towards LM.—PHILANTHROPIST.



[12710.]—**Ginger Beer.**—See indices, for ginger wine. Take a couple of tubs, or three, and work them in rotation with syrup. You need not be afraid of making too much, as it will keep for years.—JACK OF ALL TRADES.

[12711.]—**Height of Mountain.**—There are at least three simple ways of calculating the height of mountain, if the mountain be not inaccessible itself—1st, by means of barometer; 2nd, by boiling water; and 3rd, by trigonometry. The latter is applicable when mountain is not accessible. Full directions will be found in any elementary treatise on trigonometry—*e.g.*, Todhunter's "Smaller Trigonometry," or Hamblin Smith's, &c., &c.—C. H. W. B.

[12711.]—**Height of Mountain.**—Observe the elevation at two points, A and B, in line with the summit of the mountain, and measure the distance AB. Let the observed angles be a and β respectively. Angle



ACB $= \beta - a$; whence, by the rule of sines, BC $= \text{AB} \times \dfrac{\sin. a}{(\sin. \beta - a)}$; but FG $= \text{BC} \times \sin. \beta$; $\therefore$ FG $= \text{AB} \times \dfrac{\sin. a \times \sin. \beta}{\sin. (\beta - a)}$; and similarly F B $= \text{AB} \times \dfrac{\sin. a \times \cos. \beta}{\sin. (\beta - a)}$. P C, added to height of observer's eye, gives the height, and FB gives the distance of the mountain.—W. AIREY.

[12711.]—**Height of Mountain.**—Your best plan would be to ascertain first the distance of the mountain by means of a base line and quadrant; the height can then be calculated in the usual manner.—ALASTOR.

[12712.]—**Linseed Oil.**—Take spirits of turpentine.—JACK OF ALL TRADES.

[12714.]—**Echo of Sound on Water.** — The velocity of sound in water is about 4,708ft. per second, or more than four times the velocity in air. Therefore, a listener on the banks of Lake Simcoe, five miles from the discharge of the guns, would first hear the sound conveyed by the water, afterwards the more tardy air would produce a second impression. If "Gillem" was stationed at the end of a long iron pipe, while I struck the other end with a hammer, he would first hear a loud rap transmitted by the iron, and after a time a second faint rap transmitted by the air. —JOHN HOPKINS.

[12714.]—**Echo of Sound on Water.**—In the absence of data as to the elevation of the guns when fired, the state of the atmosphere, proximity of mountains, and the surroundings of the town and lake, it is almost impossible to answer the query satisfactorily. The sound would scarcely be carried by the water, although the latter is an excellent conductor, for sound seldom passes from one medium to another, unless they are of nearly equal densities.—ALASTOR.

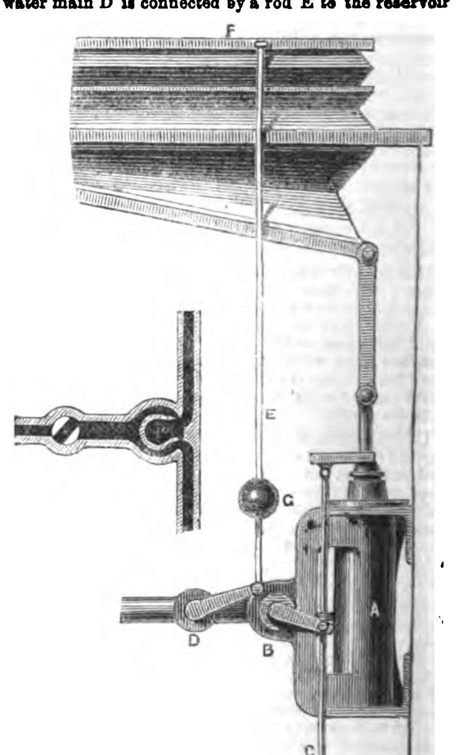
[12716.]—**Watch Drills.**—Get some silver steel wires and file them near the size required. Heat them in a candle and plunge them in the tallow; it is a rare thing to over heat them that way; grind them either on a stone or glazer, and point them on a Turkey or Arkansas stone for use; these I use without tempering.—JACK OF ALL TRADES.

[12719.]—**Medical Coil.**—Yes, Daniell cells do first rate for use with coils, and will do very well to work a clock, but are expensive to keep going.—WM. PARKER.

[12719.]—**Medical Coil.**—It will not be preferable to abandon the Daniell cells for a quart bichromate battery. I have used Daniell cells to work a medical coil, and would prefer three-pint Daniell cells to one-quart bichromate any time. You must only consider your cells three-pint Daniell, not four-pint cells. Leclanché's cells are preferable for clocks on account of their constancy.—JOHN HOPKINS.

[12720.]—**Medical Coil.**—"No. 170" is mistaken concerning screwing down the contact breaker to get a continuous current, he would simply get no current at all by these means except a momentary one. He doubtless means a current in one direction only. In most coils, the current is one way and then the other on each break of contact. If his coil is one of these he must be satisfied with one kind of current, and if not, he must purchase another coil which gives currents in one direction, or backwards and forward according to arrangement.—JOHN HOPKINS.

[12721.]—**Hydraulic Machine for Blowing an Organ.**—A is a cylinder similar to a steam-engine, B a valve moved by tappets on an adjusted rod C; the water main D is connected by a rod E to the reservoir



of wind F at such a position that when the reservoir descends by the exhausting of the air, the cock D is opened by the weight G, and the engine is set in motion. Cannot say what would be the cost of one. There is one of these machines at the Temple Church, Fleet-street, London.—J. B. CLAY.

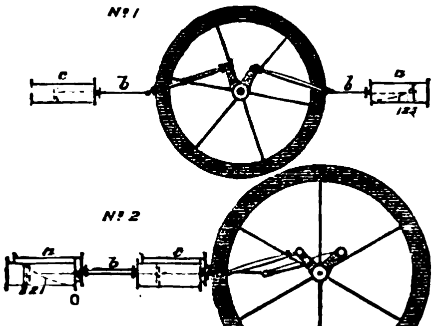
[12722.]—**Coal Getting.**—We have now two styles, one after that of a man hewing, and another after that of an elliptical saw, sawing or scraping the coal out. I have reason for preferring the former.—MECHANICAL EQUIVALENT.

[12722.]—**Coal Getting.**—There are some very good descriptions of coal-cutting machinery, with illustrations, in Vol. I of ENGLISH MECHANIC, Nos. 4 and 10, showing how compressed air is conveyed to the workings, and other valuable information.—W. BAKER.

[12723.]—**Compressed Air.**—I hope some of our friends will enlighten us upon this subject, as I have seen a patent apparatus with the six pumps worked by a twelve-horse engine labouring very hard for some hours to get a pressure of from 4lb. to 6,000lb. per square inch, but failed; the tremendous heat generated prevents the pumps from getting a full feed; but it is my belief that between 70 and 80 per cent. of that is generated by the friction of the pistons against the pump barrel, and not by the compression of the atmosphere. I hope some one will tell us a little about this, as I believe it will be a better way of ventilating the mines, as well as making a difference in price of coal in more than one way—viz., by cheaper working, and enabling us to get at and work coal that cannot be worked by any other means.—JACK OF ALL TRADES.

[12723.]—**Compressed Air.**—The best air-compressing machine is an ordinary steam cylinder and piston, the slide-valve of which works in opposite direction to slide-valve of the steam-engine by which it is driven. The air is then taken into the cylinder by the exhaust-pipe, and discharged after being compressed through what would be the supply steam pipe into the vessel prepared to receive it. Various other methods have been tried with engines without fly-wheels, but they do not appear to do so well, not being so steady.—COLLIER.

[12723.]—**Compressed Air.**—I send diagram of an engine, or rather compound engine, for compressing air, which is at present working as a commercial success (No. 2 engine). *a* are the air compressing cylinders, *c* the steam cylinders, and *b* the piston-rods, the air escape valves are weighted to 45lb. per square inch, consequently the air is being compressed to four atmospheres, the effective working pressure being three atmospheres. The dotted curved line in the air compresser shews the ratio of compression as the piston traverses the cylinder. It will be seen that the terminal pressure is not reached till the piston has accomplished three-quarters of its journey. Consequently, if the cylinders of the engine utilising this compressed air are of equal capacity, and worked non-expansively, the engine compressing the air will have to make four strokes, while the engine utilising it makes but one stroke, or otherwise, we must have reservoirs of compressed air, so that while the engine utilising the air is worked intermittently, the compressor can work continuously. I here take no notice of the loss of power by the generator of heat in the compressing cylinder when this heat is afterwards

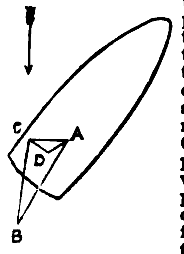


lost. One fact, however, is very important to notice—viz., the comparatively little opposing pressure of the air being compressed during the earlier part of the stroke. The maximum resistive force being the terminal pressure during the last quarter of the stroke, this necessitates the use of double engines when by the alternate action of the engines, and the momentum of the moving parts, accumulated during the earlier part of each stroke, the power thus accumulated is in practice found sufficient to urge forward the piston forward through the latter part of the same stroke, and even to compress the air to a tension greater than that of the steam. With single engines this is impossible, because the maximum power is required at the latter part of each stroke, causing a jerking motion to the engine, of an injurious nature. By a different arrangement this may to some extent be avoided even with a single engine, by having the cranks set at an angle of 60° instead of 90°, the general plan of which is apparent by an inspection of No. 1 engine. Our editor has a plethora of communications, so I had better conclude. If "Inquisitive" desires more information, I will either send it or communicate privately.—MECHANICAL EQUIVALENT.

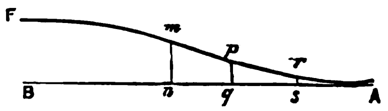
[12725.]—**Fused Chloride of Silver.**—From the description given, I fancy "Argentine" has in some way got the chloride converted into metal. The heat required for the fusion is very moderate—below redness—and the operation must not be performed in a metal vessel. Did "Argentine" use an iron pot or ladle?—ALFRED H. ALLEN.

[12726.]—**Motion of a Sailing Boat.**—When a boat is sailing, no matter whether close to wind or not, she moves from the point on which the wind presses most; but it must likewise be taken into account that a sailing boat is so constructed as to move easily ahead or astern, but with difficulty broadside ways. When a boat sails close to the wind's eye there is more pressure on the aft than the fore part of the sail, therefore she goes ahead. As a proof of what I say, run her up to the wind, and three or four points more, and keep her so, and then she will sail astern, because the most pressure is then on the fore part of the sail. A slate sinks zig-zag in water, because, although the attraction of gravity is equal the resistance is unequal, it being easier to sink edgeways than broadside first. A perfect globe of metal will sink straight.—DAVID CHRISTIE.

[12726.]—**Motion of a Sailing Boat.**—Let the accompanying figure represent the boat, the direction of the wind being indicated by the arrow, the direction of one of the sails is A B (the mainsail, &c.). Let C B indicate the force of the wind in direction and magnitude, it can be resolved by the parallelogram of forces into the two forces C A and A B respectively perpendicular and parallel to the sail; the latter has no effect, the former gives the pressure on the sail. It may be resolved into the two forces C D and D A respectively perpendicular and parallel to the vessel's keel; the force C D produces lee way, but the shape of the vessel adapts her to go forward much more easily than sideways; the force D A propels her. As to a slate, &c., sinking in an oblique manner or zig-zag in water, the centre of gravity does not coincide exactly with the centre of pressure.—PHILANTHROPIST.



[12728.]—**Wave Pattern.**—A body moving under the influence of a uniform accelerating force, such as gravity, describes spaces varying as the squares of the times taken to describe them. Let A *r p m* be a portion of the water line of one side of a vessel, A being the bow, and A *s q n* B a line passing through the middle of the vessel at the water line; A *r p m* and *m* F are two parabolas meeting so as to have a common tangent at *m*. Now, if we take equal distances A*s*, *s q*,



q n, along A B and draw the perpendiculars *s r*, *q p*, *n m*, these vary as the squares of the distances A *s*, A *q*, A *n*, and thus the water is separated as it would be by a uniform force. A *n* is one quarter of the vessel's length at the water line if *m* be the point where the two parabolas have a common tangent. A vessel constructed in this manner raises hardly any wave at any place. Bourne, in his work on the screw propeller, a rather dear book, describes this matter fully. More explanation if desired.—PHILANTHROPIST.

[12729.]—**Breech-Loaders.**—If "Faber" could get the Proceedings of the Mechanical Engineers for 1871, I think he would find therein no less than sixty-nine drawings of breech-loaders, details, &c. Unfortunately, these Proceedings cannot be bought, but may be borrowed, if "Faber" has a friend belonging to the association. I have often spoken of this exclusiveness of societies, and would again strongly urge attention to it. They profess a desire to disseminate information, yet refuse to let the public buy their reports. You must join us or go without, is the cry. Personally, I am greatly interested in this *Journal* of the Mechanical Engineers. I want to see all the numbers I can, yet hitherto have been unable to obtain a sight of more than the one above mentioned. Is any mechanical engineer willing to assist me in this matter? If thought desirable, I will make tracings of these drawings, so that, at any rate, readers of the ENGLISH MECHANIC may snatch this information from the hands of the few.—C.H.W.B.

[12730.]—**Weir's Sewing Machine** cannot get out of order. Probably the mishaps of which "H. E." complains are because he has not the proper tension. "H. E." should alter the tension nuts only a quarter or half a turn at a time.—T. P. H.

[12730.]—**Weir's Sewing Machine.**—Has this been taken to pieces? If so, the wheels have been misplaced, and want readjusting. The needle must descend and return to form a loop before the hook or retainer can enter it. There may be one of the small wheels shifted upon the shaft from the set-screw getting loose, or from dragging the work. The needle may have damaged the needle-plate, and made it rough. The looper underneath may become choked with shoddy, if stuff has been worked, and the consequence is the under part is hampered. This is caused sometimes by the needle acting like a pair of shears by its coming in contact with the needle-plate and shearing the stuff; more especially if the needle has come in contact with the needle-plate, blunted the needle, and roughened the plate, it will every now and then shear the cotton off as well.—JACK OF ALL TRADES.

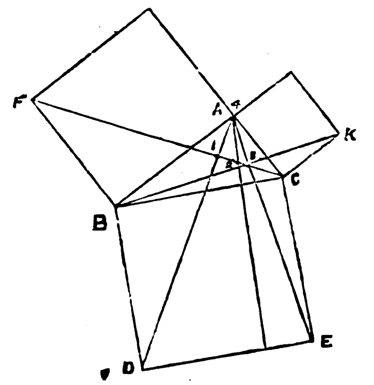
[12731.]—**Hand Pad.**—The handle must be hollow, and a brass head fitted to it, in which are two set screws, pressing not on the tool, but on an intervening piece of metal. The tools must, of course, fit accurately.—BRANCA.

[12736.]—**Cement on Postage Stamps.**—It is dextrine, or British gum, made by ex osing starch to a high temperature in presence of a very dilute acid or diastase for some time, and then baking. It is innoxious.—WM. PARKER.

[12736.]—**Cement on Postage Stamps.**—An article once appeared in "Household Words" on the above, headed "The Great British Gum Secret." The following is the substance of it:—A little westward of Dublin, on the banks of the Liffey, stood the village of Chapelizod. In 1821 it contained a large starch manufactory. The use of potatoes in this manufactory caused great discontent among the people, and one night it was set on fire. Great efforts were made to save the building, but with little success. The starch, mixed with the water used in quenching the fire, covered the streets and ran into the Liffey. A journeyman block-printer had assisted in putting out the fire, but being rather the worse for liquor had several times fallen among the liquid starch; and, next morning, on awaking, found his clothes completely gummed together. This led to a consultation with some of his shopmates, who had been in a similar condition, and the result was a visit to the ruins of the manufactory. They took some of the soft gummy substance that still lay in the streets, tested it in their trade, found it to answer, bought starch, burnt it brown in a frying-pan, added water, and discovered that they had a substance as good as gum arabic and many times cheaper. The block-printers did not keep their secret long. They sold it to a gentleman in Lancashire, from whom it passed to another English gentleman. This gentleman suffered a great amount of persecution, and was the object of a large number of spies. His secret at last oozed out. When the penny postage system came into use British gum was adopted for the labels. Some time after a rumour became prevalent that the cement on postage stamps was a hurtful substance. The secret was then spread far and wide. "The public was extensively informed that the postage-label poison was made simply of—potatoes."—TUB.

[12737.]—**Size of Globe and Speed Rate of Rotation.**—The motion of the earth round the sun is much faster than its motion of rotation on its axis. The earth goes more than 1½ millions of miles in the day in its motion round the sun. The query is not very clear.—PHILANTHROPIST.

[12739.]—**Geometrical Theorem.**—In the accompanying figure the angle BFC equals the angle BAD (as shown in the demonstration to Prop. XLVII., Euclid, Book 1). Also the angle ACF is equal to the angle CFB (Prop. XXIX). Therefore, angle ACF = angle BAD. But BAD and IAC make up a right angle. Therefore, IAC and ICA also equal together a right angle. But all the angles of a triangle together = two right angles, therefore the remaining angle at I is a right angle. The intersection of the lines AEBK may, in the same manner, be also shown to be at right



angles. Now, on reference to Euclid, Book 3, Prop. XXII., I find as a deduction to that proposition that "if two opposite angles of any trapezium be (equal to) two right angles, a circle may be described about it." Join points 2 and 4, and the line of junction being bisected gives the centre of the circumscribing circle.—C. P. E.

[12740.]—**Lever Escapement.**—By all means put new escapement. Look on the back of pillar plate, and you will see the size of the movement either 16, 18, or 20; send to a good tool shop, or to an escapement maker, for the size stamped on the plate. Your escape pinion (if not worn) will do again, and very probably the collet also; if your pallet-staff is true, and polished pivots, they will do again most likely. Pivot in your balance staff, have roller right height and firm, fit pallets and lever on its staff, pitch cross depth, bank and set pallets in angle, drill pallets and lever, finish off, poise balance, spring, and time. If the watch keeps the same time lying as hanging, pass it, but if not, do not put your balance out of poise.—CONVERSION.

[12741.]—**Leather Machine.**—Try a spokeshave, such as saddlers use.—TOIVO.

[12741.]—**Leather Machine.**—This is a very difficult job, as the leather differs so much in texture—some places are so tight, others so loose; cut your leather in strips, and pass it through a spokeshave. I have seen a good job made of it, but it requires a little practice.—JACK OF ALL TRADES.

[12743.] — **Essence of Wood Smoke.**—If "Anxious One" wants to know how to smoke his hams and bacon, he cannot do better than follow the instructions laid down some time back in these columns. But this I know, the men in the east of London smoke haddocks, kippers, bacon, and other goods, in a smoke-hole built on a certain plan, and use oak, mahogany, and other sawdust. Butchers prefer mahogany turnings for that purpose, but the fish smokers prefer oak sawdust. I formerly sold my turnings for that purpose, and at the present time can get a high price for oak sawdust.—Samuel Smither.

[12743.]—**Essence of Wood Smoke.**—Pyroligneous acid, I suppose you want. It can be purchased very cheaply. Unless you have a chemical plant that you can work out all your products, and that upon a large scale, it will not pay.—Jack of All Trades.

[12743.]—**Essence of Wood Smoke.**—A very dilute solution of carbolic or phenic acid in water, and put the ham into a bath of it, will give the ham a smoked flavour, but makes it taste sodden.—W. M. Parker.

[12743.]—**Essence of Wood Smoke.**—This is simply the crude or empyreumatic acetic acid of the wood-acid or pyroligneous acid works. It is obtained as one of the products of the destructive distillation of wood in close chambers or retorts. It has a brown colour, and a very strong smoky smell and flavour, but in other points resembles ordinary acetic acid of the same strength. The article commonly sold in bottles, at high prices, under the names of "Essence of Smoke," "Essence of Wood Smoke," "Cambrian Essence," "Smoking Fluid," &c., is commonly thickened and darkened by dissolving about two or three ounces of spirit-colouring (caramel) in each pint of the crude acid; but this adds nothing to its antiseptic and smoke flavour qualities, although it improves the colour of things prepared with it. The cheapest way of procuring the above is to buy it, of any wholesale or large druggist, under the name of "Crude (Smoky) Pyroligneous Acid." Price, wholesale, about 4d. per pound, or 2s. 8d. per gallon. (I think my last hogshead cost 2s. 4d. per gallon.) It is used either by brushing a little over the meat or fish, or by mixing a little with the brine. Some persons steep two or three drachms of the best wood-tar in each pint of the crude acid, with brisk agitation and slight warmth for one or two hours, and then, after repose, decant the clear portion for use. This is, however, quite unnecessary, as the acid itself is smoky enough; but the treatment slightly modifies the flavour and is in a manner relished by some persons. I cannot agree with "An Anxious One" that the old plan of curing by exposure in appropriate chimneys or smoking-houses is "unsatisfactory." In no way can such an excellent and refreshing flavour and odour of the kind be given to meat, fish, &c., as by direct and lengthened exposure to the attenuated smoke or fumes of a slow wood or turf fire. Some persons attempt to impart a smoky flavour to hams and bacon by the addition to the brine of a little creosote (previously dissolved in strong vinegar); but this is expensive, and the effect is not very satisfactory, as the food then gets a crude whisky flavour, smoky certainly, but devoid of the characteristic brown colour, rich flavour, and fragrance, of a prime smoked ham or flitch.—Arotes.

[12744.]—**Martini Rifle.**—See reply to 12729.—C. H. W. B.

[12744.]—**Martini Rifle.**—The extractor in the Martini-Henry rifle is shaped something like the letter L, moving on a pivot at the bend. The vertical arm of this bell-crank is formed like a fork, one of the prongs being at each side and exactly fitting the rear of the cartridge when "home." When the breech-block is depressed, it catches the horizontal arm of the extractor, forces it down, and consequently brings the vertical arm away from its place against the barrel, thus throwing out the cartridge case. There is no spring about the extractor, only this little bell-crank and the pin it works on. The bottle-neck cartridge has to be used with this rifle, owing to the manner in which it is loaded. The cartridge has to pass along the curved slot on the breech-block, and for this reason the ordinary cylindrical form of cartridge would not do.—Artillery Captain.

[12746.]—**Screws for Woodwork.**—This requires some space to illustrate as well as to engrave plant, for they are cut with dies.—Jack of All Trades.

[12747.]—**Roasting Jacks.**—Take a sheet of steel the thickness required, and cut strips the width required in the length, as that would be the way of the grain. Punch a hole in both ends and lap up on a mandril, harden, and blaze off with tallow. Put the spring inside a drum, and drive off the drum.—Jack of All Trades.

[12749.]—**Punching Holes in Sheet Brass.**—This depends upon the thickness and size, if light and small, a lever press, the same as the endorsing presses, might do.—Jack of All Trades.

[12749.]—**Punching Holes in Sheet Brass.**—Look at a punching machine and apply the same principle—that is, with a punch and die to fit each other and the punch to fall exactly into the die. This is the best method of punching.—Mutual Tom.

[12752.]—**Nervous Excitement.**—Your correspondent "Tremolo" ask for a remedy for the above ailment. I know of nothing better than that advised by Dr. Johnson, namely, the hydropathic treatment. In my last on constipation, I omitted to mention another proof given by Dr. Johnson that excitement arrests the secretions, and that cooling the body restores them. Let us take the case of one addicted to drink. In the evening he has excited the system with strong stimulants. In the morning he wakes with all his secretions arrested, mouth and throat dry, his nose dry, skin dry, his bowels costive—that is, dry also. Now let him get up, take a cold bath and go out into the cold air. The saliva returns to his mouth, moisture to throat and nose and skin, and soon after this, his bowels (if he be not habitually constipated) will be relieved. But if instead he remains in bed, the secretions may be many hours before they return. With those whose daily occupations render it impossible to take the hydropathic treatment, the doctor advises that one of Mead's Anti-Constipation Plaisters be worn, which is seldom known to fail to relieve the bowels daily, and also to use daily cold ablutions.—P.S.—Every nurse knows that one of the first and best signs of the subsidence of the excitement of fever is the return of the natural secretion to the nose and skin.—T. L. V.

[12755.]—**To "Jack of All Trades."**—How you manage to make rosin and shellac adhere to curd soap is something more than I can understand. You may blister it if the heater is too hot. Take the two—viz., soap and finely-powdered French chalk, and prepare some unglazed paper for the purpose, like whitewashing it. Use when dry.—Jack of All Trades.

[12766.]—**Fiddles and Fiddling.**—The bow must be well cleansed with soap and water, then rosined till white as snow, taking care not to use the refined specimens of rosin sold at music shops, but get a good piece of ordinary rosin from your chemist, and always use it before you play. Do not play too near the bridge, unless your position is a high one on the finger board. Do not attempt anything difficult until you can make clear tones. Place your bridge exactly in the centre, between the *f* holes, and try, try again.—Fiddler.

[12771.] — **Colorado, U.S.** — 1. Allan line *viâ* Baltimore. 2. Meals on cars are very expensive. Buy a basket at Baltimore, and fill with four days' supply of bread and corned beef. Coffee is to be had at all stations at any time. 3. As near to Denver City as practicable. 4. As good as the best. 5. Yes; can be had of Messrs. Reid and Keim, 36, Finsbury Circus. 6. Take no tools, but good warm and strong clothing, thick boots, pair of blankets, and indiarubber sheet. 7. With the qualities named, "first rate" and "independence."—R. H. Leese, Lt.-Col., U.S. Consul, per W. H. Coffin.

[12784.]—**Libraries.**—If "A Librarian" will get a set of brass figures with handles (say, one of each up to 10) he will be able to print all the books in gold at a very small cost. One book of gold at 1s. 3d. will print 700 or 800 books, and the numbers will last as long as the book. The figures will cost about 5d. or 6d. each. Make the figures hot in gas (not too hot), rub the face on a piece of cloth with a few drops of oil on, apply a little powdered rosin where you are going to print, then pick up the gold leaf with the figures, and hold it on about two or three seconds. After this rub it with a soft rag with a few drops of oil and turpentine on, and it will give a beautiful bright gloss. If you want any more information I will give it with pleasure.—J. B. Sharpley.

[12779.]—**Lightning and Thunder.**—1. "Sheet lightning" is merely the glare of a flash, reflected from cloud, sky, or other objects. However near a flash be, if our back is turned to it we can only see "sheet lightning." The varieties in the form of the flash itself are forked or unforked. The latter, by far the commonest, sailors very well name "chain lightning." It is more like a chain than the ribands (or strokes of uniform width) drawn by painters. It is commonly far less crooked in the general course, but with innumerable short crooks and dot-like raggedness. 2. The sound starts simultaneously from every point of the chain. If its form were a circular arc, with your ear in the centre of curvature, you could hear but a single gun-like explosion. But if you are a mile farther from one part of the chain than another, the peal must last 5 seconds; if 2 miles, 10 seconds; and so on. I do not believe in echoes from clouds, or any echoes contributing to the thunder, except those from mountains and precipices, which give it quite a distinct character from what it has over flat countries or sea. 3. What blasts a tree is simply its own sap suddenly made steam; and the instantaneous vaporisation of confined moisture, or of soot, will equally explain the demolition of the chimney witnessed by M. Paris, p. 620. Without having seen a large tree the day after its destruction, one can hardly form an idea of the tremendous force exhibited. I had such a view of a beech tree that was probably one of the largest in England, and may be remembered as standing before the elder chalk-pit west of Caversham, Oxon. The trunk, about 6ft. in diameter, and perfectly sound to the heart, had been cleft, and, except the lowest yard or two, had fallen with the limbs in all directions, with most of its wood in minutey separated fibres like over-stewed meat, and seeming fit to go into a paper-mill, and with very little more pounding form pulp. The fibres were also bleached whiter than parts that had been out of the lightning's track.—E. L. G.

UNANSWERED QUERIES.

The numbers and titles of queries which remain unanswered for five weeks are inserted in this list. We trust our readers will look over the list, and send what information they can for the benefit of their fellow contributors.

Since our last S. Broughton has answered 12359; "Jack of All Trades," 12394, 12402, 12405, 12408, 12410, 12418, 12422, 12425.

12493 Grove's Gas Battery, p. 496
12497 Horizontal Escapement, 496
12498 Green Shade, 496
12508 Eloby, p. 497
12509 Chemical, 497
12521 Value of Locomotives, 497
12522 Length of Pendulum, 497
12536 Speculum Grinding, 497

QUERIES.

[12801.]—**Hygrometer.**—Will some correspondent kindly show me how to find the dew-point and degree of humidity by Glaisher's tables, adapted to Mason's hygrometer, when the dry and wet bulbs indicate a fraction of the same degree—*e. g.*, 39·6° and 39·1°? Other indications, such as 39·6° and 38·1° I can manage.—Clitus.

[12802.]—**Length of Pendulum Springs.**—Would "Seconds' Practical Watchmaker" kindly give me his opinion as regards the length of pendulum springs, for best timekeeping?—D. C.

[12803.] — **Mainsprings Breaking.** — Would "Seconds' Practical Watchmaker" explain the cause of mainsprings breaking when the spring is the right height and strength, and the arbor the right size? One will last a week and the other for years; both best springs and fitted to the same watch by the same workman, and kept in the same temperature.—D. C.

[12804.]—**Fixing Photographic Prints.**—Can any one tell me the cause of my prints (after toning and when in the fixing bath) losing all their tone, and becoming a leathery brown colour?—One in a Fix.

[12805.]—**Photography.**—Can any reader give a process for sensitising paper, so that it may be kept without injury for two or three days? I believe such a process is in use.—C. B.

[12806.]—**Boat Building.**—I wish to build a small pleasure boat, say from 14ft. to 15ft., by 2ft. 6in. to 3ft. beam, yacht shape, principally for sailing, but also of a light build to row. Would any kind reader favour me with some practical information, or name a book from which I could get all practical information and dimensions? I have been trying to obtain a suitable book through booksellers' agency, but without success.—Another Paddler.

[12807.]—**Darkening Pale Mahogany.**—Will any subscriber kindly inform me the easiest way to darken the colour of pale mahogany, so that it will match that of a darker colour?—A. D.

[12808.]—**Enlargements on Zinc Plates.**—Will any of your numerous correspondents kindly furnish me with a method of taking enlargements on zinc plates direct or by transfer?—Sam Weller.

[12809.]—**Economy in Fuel.**—I want to know if there is any liquid that will bind ashes together, so as to burn them over again. I have wetted them with water and made it like clay, but when dry it crumbles. I should like to make it lumpy to burn like coke. I have put a lot of wet ashes in an American kitchener; it burns very well, when it gets dry, on the top of coke. The liquid must not be expensive, otherwise the economy will be lost.—Duplex.

[12810.] — **Electro-Magnet.**—I should be glad to learn how to construct such an electro-magnet as would be advantageously excited by 10 cells of Daniell's (quart size). Also what weight such a magnet would probably sustain. I find it much easier to coil the wire upon two brass tubes than to coil it directly upon the arms of the iron core. Will the currents induced in the tubes by the primary current appreciably diminish the magnetic intensity of the core?—Beta.

[12811.]—**Lamps.**—I have a quantity of good lamps, the brass bottoms of which have become tarnished or "shopworn." I should feel obliged by any one informing me how to get them up again like new.—W. S. C.

[12812.]—**Water for Aquarium.**—Will any of your correspondents kindly inform me which water is best for aquariums—whether rain-water from off tile roofs or that supplied by water companies?—Norwich.

[12813.]—**Circular Saw Bench.**—Can any of "our" subscribers tell me what size circular saw a 4 horse-power engine will drive, and what size pulley to fix on the same? Fly-wheel of engine, 4ft. 10in. Also what kind of teeth are best for cutting ash, oak, &c.?—Constant Subscriber.

[12814.]—**Contracted Muscles.**—Would some one kindly advise what could be done for a lad—twelve years of age—who is afflicted with a contraction of muscle in the neck, directly under left ear, which holds the head on one side. Can the muscle be developed?—Parent.

[12815.]—**Fusing Brass.**—Will one of your readers kindly describe to me the method of fusing brass? I have tried and failed. Would it require blowing with bellows?—Branca.

[12816.]—**Sepia.**—Sepia ought to be made from the inside of the cuttle fish. Can any one tell me how it is really made?—G. S. E.

[12817.]—**To Chemists.**—If sulphate of quinine is dissolved in sulphuric acid, and a few drops are mixed with water, it turns the water a blue colour. Will any of "our" chemical readers state the cause of this and oblige—William H. Bey.

[12818.]—**Postman's Duties.**—Will some brother reader kindly tell me the distance a walking postman may walk out of the highway? I live about 70 yards out of the highway and he says I shall have to pay extra for every letter.—H. W. F.

[12819.]—**Stains in Wood.**—Can any correspondent tell me of a substance which will take stains caused by nitrate of silver out of wood, and its price?—T. V. B.

[12820.]—**Churning.**—Is the separation of butter in churning caused by any chemical in addition to the mechanical action of the process, and if so what is the whole chemical action that takes place? An answer from "Sigma" would oblige—M. F.

[12821.]—**Soluble Glass.**—Referring to letter on Soluble Glass, p. 590, letter 4765, will your correspondent "G. J. H." kindly inform me how to prepare a soluble glass as a coating for brick or stone perfectly transparent and colourless?—Ajax.

[12822.]—**Extracting Opium, &c., from Poppies.**—How is opium obtained from ordinary poppies? How is the red colouring matter extracted? What is its name? Is anything else obtained from poppies? If so, what are their names and how are they obtained?—G. S. E.

[12823.]—**Cochineal Blue.**—I made a decoction of cochineal by pouring boiling water over the dried insects. I poured some of this into a clean tumbler, and added some acetate of lead in water, when, to my astonishment, it produced a light blue precipitate which remained suspended for some time in the water. What was the cause? Could not wool be dyed thus?—G. S. E.

[12824.]—**Magnesium.**—How is magnesium obtained from its salts and made into wire?—G. S. E.

[12825.]—**Insects in Leather Trunk.**—I have a large box covered with leather, with partitions and trays inside, and fitted with straps outside after the manner of a portmanteau, which has been unused for six months or more. On looking at it a few days ago, I found one of the wooden ribs at the bottom to be completely riddled by what looked like small worm holes—doubtless the work of some insect. The wood, on being touched, crumbled into dust in many places. It is an easy matter to replace the damaged rib, but I find that the box is eaten into in about two dozen places on the sides where it is covered with leather and on the bottom beyond the ribs. The holes are of the thickness of a knitting needle or thereabouts. If any reader of the ENGLISH MECHANIC will inform me how I can arrest the progress of the destroyer, he will confer a favour upon your constant reader—T. A. H.

[12826.]—**Panning and Non-Panning Tea.**—Some planters adopt the system of panning (frying) the leaf before it is finally dried, saying it excites the juices, whilst others, myself amongst the rest, dispense with it as being extra labour involved to no purpose. Could any reader inform me what actually takes place, or what chemical action takes place (if any) in the leaf whilst being panned, and which is dispensed with by being non-panned, and what effect it would have on the manufactured tea, whether making stronger, weaker, brisker, more pungent, &c.?—MELVILLE PIKE, Mohumpore, E. I.

[12827.]—**Blight to which the Tea-plant is Subjected.**—I send you a dried shoot of a tea-plant blighted. This disease, if so it may be termed, comes on principally and more severely after excessive and continual rain, and increases when rain falls more like a mist than rain proper. It is to be seen on plants in all positions, open or confined, barren or rich soil, and at all the bearings of the compass, N. S. E. W. Before it makes its appearance perceptible, the plants, I have observed, show a reluctance to shoot, and when they do shoot, the bud at the end of the shoot is affected, thereby causing a stoppage of growth, together with the three or four new leaves which compose the flush; some old leaves are also affected. In some cases, if the stalk or shoot be nipped off, a black spot will be seen in the centre (where the pith is in trees) of the shoot to varying depths according to the severity of the disease. I have seen portions of gardens looking as if a fire-blast had passed over them, and from which no leaf can be expected, unless the shoots are plucked off below the black dot in the centre of the shoot, and then it is doubtful. Could and would any kind readers give me their views on the subject, so as to enlighten me a bit? I wish to know what causes it, and why, and whether it cannot be prevented, and if not, if it can be cured by any means different to what I have already said (plucking off the shoots, &c.)? This complaint is very prevalent in Hylakandy, a sub-division of Cachar, and is scarcely known in Assam, North Cachar, Darjeeling, &c., the other tea districts.—MELVILLE PIKE, Mohumpore, E. I.

[12828.]—**Apothem in Tea.**—What is it composed of, and which would be the simplest and most certain way to extract it; and what is the test for it?—MELVILLE PIKE, Mohumpore, E. I.

[12829.]—**Theine in Tea.**—What is it composed of, and which would be the simplest and most certain way to extract it; and what is the test for it?—MELVILLE PIKE, Mohumpore, E. I.

[12830.]—**Carbonate of Iron in a Tea Soil.**—This is a component part of the Assam tea soil. What important part does it perform in relation to the growth of the tea-plant?—MELVILLE PIKE, Mohumpore, E. I.

[12831.]—**Charcoal for the Desiccation of Tea.**—It is asserted by the home (tea) trade, as also by some tea planters, that the fumes of charcoal alone, from its peculiar properties, are only adapted for the drying of tea; for one or two experimentalists have tried the drying of tea in pans, &c., but have arrived at very unsatisfactory results, such as the leaf not being good in appearance, the liquor relatively very much worse than the leaf, and, although not burnt, it had a peculiar flavour, classed by the trade "flat and odd." Would some kind reader inform me whether the fumes of charcoal have any chemical effect on the tea, if so, what effect, and how does it act? Cannot some substitute be suggested; hot air has been tried, but the tea is not as good as tea dried over charcoal fires.—MELVILLE PIKE, Mohumpore, E. I.

[12832.]—**Manufacture of Charcoal.**—Would any kind reader inform me the simplest way to manufacture charcoal, from all woods light or heavy, close grained or not, so as not to lose a grain, so that all may go to the designed end? I have been making about 65 tons yearly, and wood is becoming difficult to obtain. The method must be one understood by a coolie, a native labourer, whereby about half a ton can be made at once.—MELVILLE PIKE, Mohumpore, E. I.

[12833.]—**White Ants and Wood.**—Some time back there was a controversy in the Indian papers (the *Englishman*) regarding the destructive habits of these insects on green wood, which a Mr. P. Saunders confuted by saying, as I do, that they do not touch green wood to destroy it, but that they may, and do, climb up and go along it in search of dead wood or injured wood. Would any kind correspondents (Indian or otherwise) give their experience relative to these insects eating and destroying green wood? As this subject is of interest to many planters (tea, coffee, &c.) in remote districts and abroad. I would be glad to see it discussed and well ventilated in the ENGLISH MECHANIC.—MELVILLE PIKE, Mohumpore, E. I.

[12834.]—**Queensland.**—What are some of the best recent works on Queensland?—A. B. M.

[12835.]—**Unequal Timekeepers.**—Would a thorough practical workman explain to "our" readers the cause of one watch keeping much better time than the other—both Geneva watches, same size, and same maker; both have the same action, and the same number of turns in the hairspring; both have plain balances and same number of beats per minute?—CONVERSION.

[12836.]—**Light and Glass.**—How is it that shop lights, seen through the glass of an omnibus, produce an appearance of concentric fibrous circles in the glass?—A. B. M.

[12837.]—**Tobacco and Electricity.**—I was shown, the other day, some tobacco in a very mouldy state, and said to have been thus changed in one night through electricity in the atmosphere. Is this a known effect? Should any one wish to examine the tobacco microscopically, I can send him a little.—A. B. M.

[12838.]—**Testing Milk.**—Will some one kindly give me full directions how to use my lactometer in testing milk?—J. G. W. R.

[12839.]—**Prismatic Compass.**—Will some reader kindly give a short description of this?—DEESIDE.

[12840.]—**Watch Jobbing, &c.**—Does any reader know of a work from which a novice could learn to repair jewellery and watches and clocks, and the art of gilding?—W. W. BACARROUGH.

[12841.]—**Canal Steamboats.**—Having been informed that there are steamboats running on the canals between London and Derby, I should be greatly obliged if some intelligent subscriber would inform me, through your columns, whether such is the case. If so, please answer the following questions:—1. Whether the engines are worked on the high-pressure principle, or whether they are condensers? 2. Whether they use the ordinary canal water, or whether they carry filtered water with them? 3. What weight of coal they usually carry, and whether the coals do not sink one end of the boat deeper than the other? 4. What is the usual diameter of the boilers? 5. What is the saving effected compared with horse-power? In addition, I should be very much obliged if I could see a drawing of a boat and engines, or any information relating to any of the above questions.—J. P., Walsall.

[12842.]—**Vineries.**—Would "Saul Rymea" or any other reader give a few hints regarding the construction of vineries, and the most profitable vines to grow?—SODA.

[12843.]—**Blue Pipe-Clay.**—Would "Jack of All Trades" or any maker inform me how to make blue pipe-clay, and say the quantity of blue colour and vitriol used to the cwt. of pipe-clay, also the price per cwt. of blue colour?—CLAY.

[12844.]—**Cleaning Bones.**—Will some correspondent kindly inform me of the best way to clean thoroughly very dirty bones and small skeletons without injuring them in any respect?—VOIX.

[12845.]—**Fossils.**—I wish to know how to extract fossils from hard and soft rocks without injuring them. A few hints as to collecting, cleaning, and preserving fossils would be very acceptable. A list of places within (say) twenty miles of London suitable for geological excursions would, I think, be useful to many besides myself.—VOIX.

[12846.]—**Rowing.**—What lever (1st, 2nd, or 3rd order) does the motion of an oar, in rowing, constitute?—VIELLENT.

[12847.]—**Cleaning Steel, &c.**—What is a good preparation for cleaning and polishing steel and brass?—VOIX.

[12848.]—**Log-House.**—Will any one kindly give a sketch, with some particulars, of a four-roomed log-house, such as is usually erected by settlers on grants of land in the Western States of America on 160 acres of land? 1. Cost where timber is easily got. 2. Whether two or one story. 3. Height, length, breadth, slant of roof, doors, windows, and general out-houses. 4. How is a handy man to go about building his own shanty for self, wife, and child?—EMIGRANT.

[12849.]—**Separating Lenses.**—Will one of the clever contributors to "ours" kindly tell me how to separate the compound lenses forming object-glass of field-glass, as some liquid has partially penetrated between, and of course interferes with its clearness? Also, if after separation I can safely re-cement them together. I am desirous of doing it myself if I can manage it without damaging the glass.—R. HOWSE.

[12850.]—**Joining Manganese Cells.**—I inserted a query some time since, to which an answer was returned that the carbon must be soaked in paraffin, and the wire soldered in the carbon. The cells are now charged, covered with wax on the top, and the pores of the carbon are saturated with sal ammoniac. Must I first pick off the wax I have tried, uncharge the cells, and soak the AmCl out with water, join the copper wire by solder, and then soak with paraffin, or paraffin first and then solder into the hole? What paraffin do I use, paraffin oil or solid paraffin? and if the latter, how is it liquefied, and how long must the carbon be soaked? I suppose it would not do if I saturate with paraffin without freeing from the AmCl?—T. H. SOMERVILLE.

[12851.]—**Policeman's Lamp.**—Will any of "ours" kindly offer a few suggestions towards improving the present form of policeman's lamp? The leading features to be desired are small size, great reflective power, to be easily turned on or off, and to be easily taken to pieces and cleaned. The present forms are large, cumbersome, heavy, and impossible to take to pieces to clean. I think an improved form might be made with a flat wick instead of round, as at present, and when the light is turned off it might be made to turn the wick down at the same time, thus causing a great saving of oil, heat, and smell, which is anything but pleasant for a man to have under his nose the whole night long. Perhaps "Jack of All Trades" will kindly render assistance to the 40,000 men comprising the police and constabulary forces of Great Britain. This question was asked by "Phœnix" in last volume, but no satisfactory answer ever came.—W. H. H.

[12852.]—**Slide-valve Rod.**—Will some one kindly inform me of the best way to connect the slide-valve rod to the eccentric rod, the steam-chest being on top of cylinder? Diagrams will oblige.—J. W.

[12853.]—**Eyepiece.**—"F. R. A. S.," in his "Astronomical Notes" for this month, speaks of an eyepiece invented by the Astronomer Royal, for rendering objects free from prismatic colours when at a low altitude. Will Mr. Oldfield or some other reader kindly describe this eyepiece?—K.

[12854.]—**Dressing Corn.**—Will you or any brother reader of the MECHANIC inform me which is the best way of preparing Egyptian and Californian corn for grinding, as we are greatly in need of such an apparatus at our firm?—A DUSTY MILLER.

[12855.]—**Table Claws.**—Several readers as well as myself, wish Mr. Smither would, in his next letter, send a design for claws to match the table leg, inserted in No. 386.—H. COOK.

[12856.]—**Carbonic Acid Engine.**—Could any of "our" correspondents kindly give me some information about the construction of a carbonic acid engine? Are chalk or whiting and hydrochloric acid the best substances for generating the gas? Would it be possible to lead the gas as it escapes from the cylinder into a tank containing lime hydrate, so as to form carbonate of lime? Would a sufficient quantity be formed to be used to generate gas in the boiler? I should be very glad if I could get some hints as to the construction of an engine of this kind, and what success experimental ones have met with?—JUVENIS.

[12857.]—**Rust.**—Living amidst chemical manufactures the gas from them rusts all steel and iron. A preventative wanted.—MUTUAL TOM.

[12858.]—**Caustic Soda.**—Will some correspondent afford me an explanation of the gradual deepening of colour from a pale straw to a deep brown, consequent upon the evaporation of a solution of caustic soda.—A. K. C.

[12859.]—**Sand Wheel.**—I shall feel obliged if one of your readers can tell me what is the right speed for a sand wheel for planing or polishing wood. Also if the glue should be thinly brushed on, and the best way of getting the sand to stick on.—C. E.

[12860.]—**Dr. Carpenter and Geometry.**—In Dr. Carpenter's address before the British Association at Brighton, reported recently in the ENGLISH MECHANIC, this passage occurs which puzzles me:—"The whole fabric of geometry rests upon axioms, which are incapable of demonstration." Surely it is possible to show that "the whole is greater than its part?" Perhaps one of "our" mathematical correspondents would be kind enough to throw some light on this point.—TYRO.

[12861.]—**Bricks from Sand, &c.**—Is there any satisfactory process (and the rationale of the same and cost) for making bricks for building from fine sand or fine sandy river mud? Will concrete building answer for walls and beds of furnaces as well as brick, and what character of concrete is preferable? Is it an easy method to make a fair cement from fine river mud and other materials, and what are the materials and cost?—IGNORAMUS.

[12862.]—**Envelope Making.**—Can any reader say the size paper envelopes are cut from, and how many of each size (envelopes) will a sheet cut? If the sheets are different sizes, please state size of each. An answer will oblige—D. H. GDMN.

[12863.]—**Schroter's Telescope.**—In let. 4783, p. 574, "R. C." makes mention of the telescope of Schröter, as being 10ft. long, and only 3in. aperture. Will "R. C." oblige by making known the construction of the above, as to the steadying of such a whipstick of a tube on a stand, also as to the glasses made use of?—YOUNG GLASGOW.

[12864.]—**Sour Ginger Wine.**—I have some home-made ginger wine which has become sour or tart. Is there any way of removing this sourness and rendering the wine wholesome and agreeable again?—W. M.

[12865.]—**Sympathetic Clocks.**—Among the applications for letters patent during last month is one for improvements in sympathetic clocks. Can any fellow subscriber enlighten me as to the nature and application of this ingenious piece of mechanism known as a sympathetic clock.—CRUX.

[12866.]—**Quality of Cloth.**—Can any one give some useful suggestions in the choice of cloth, &c.? There must be a mode of distinguishing good from bad material, but though at the time of selection I carefully unravel numerous patterns and study the relative length and strength of the fibre, I have signally failed to discover the secret of stability. The most durable cloths within my experience were described to me at the time of choosing as Venetian cloth and double corded Scotch tweed respectively. Is there any way of recognising these materials and insuring a profitable investment with your tailor?—CRUX.

[12867.]—**Lightning Conductors.**—I am thinking of protecting my house. Will some kind reader inform me if it is necessary to put a conductor on each chimney, of which the house has four, three in gable ends of the house, and one near the centre? The distance between is, greatest 23ft. nearest, 11ft. Has it ever been ascertained what distance a conductor will protect (say if it projects 3ft. above the chimney). I should feel obliged if any one would inform me who publishes a book on the above subject.—J. G. T.

[12868.]—**Gyro Pigeon.**—How is this made and propelled?—PHILANTHROPIST.

[12869.]—**Water Power.**—Will some of your numerous readers, acquainted with water power, say what power a wheel of 4ft. diameter, supplied with water with an easy flow through a circular opening of 5in. will have, applied upon the overshot principle? and if the turbine with 4ft. 6in. of fall will be equal to the wheel?—AQUA.

[12870.]—**Stringed Instrument Maker.**—Can "The Harmonious Blacksmith" or other reader of "ours" oblige me with any information as to the status of one John Pitts, S. Paul's Churchyard, 1694? I have a very old viol de Gamba bearing above upon an almost obliterated ticket.—JOE.

[12871.]—**Burning Wood Pulp.**—Will some of our readers kindly inform me what I can mix with wood pulp that when it burns it will burn its own ash with little smoke.—ONE AT A STANDSTILL.

[12872.]—**Electro-Gilding.**—In electro-gilding some articles, I was called away, and left the solution on a stove, and on my return found it boiling. It was all right before, but after, it would not act. Is the gold precipitated, and, if so, must I use more cyanide, or is something wrong?—W. BAKER.

CHESS.

All communications intended for this department to be addressed to J. W. Abbott, 83, Loughborough-road, Brixton, S.W.

We have received the August number of the Dubuque *Chess Journal*, now recognised to be the leading organ of American chess players. The number is embellished with a protrait of the Rev. A. B. Skipworth, with some selections of his games, a large number of problems by American composers, and the advanced sheets of the late Congress at Cincinnati. We shall take an early opportunity of placing a few extracts from the *Chess Journal* before our readers.

ENIGMA III.—By A. W. Cooper.

White.

W K on Q 3; W R on K R 2; W Kts on K Kt 4 and K R 4; W Ps on Q 4, K B 3, K B 4, K Kt 6.

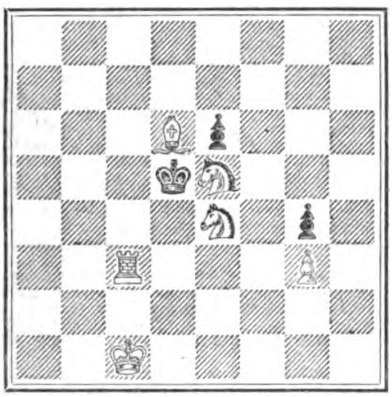
Black.

K on K R 4; B Ps on K R 3, K Kt 2, and Q 3.

White to play, and mate in three moves.

Problem XIV.—By P. T. Duffy.

Black.



White.

White to play and mate in three moves.

Solution to Problem XII.

White.	*Black.*
1. Q to Kt sq.	1. Anything.
2. Mates, acc.	

Solution to Enigma I.

White.	*Black.*
1. Q to Q R 8	1. Anything.
2. Mates, acc.	

D. M. (Norwood).—Problem XI. is quite correct, and admits of no other solution but that given by the author. If, as you suggest,

(1) $\frac{\text{P to Q Kt 8 (a Q) (ch.)}}{\text{K to B 3}}$ (2) $\frac{\text{Q to Q R 8}}{\text{Kt (interposes)}}$,

how can you mate next move? 2. The rule you quote is still in force. 3. There is no difference except in name.

S. H. Thomas (Plymouth).—Your problem is hardly difficult enough for publicity. Send us a few more specimens of your composition. We agree with the remarks contained in your letter on the construction of problems.

Argo (Yarmouth).—The problem is still faulty—*e.g.*,

(1) $\frac{\text{Q to Kt 2}}{\text{anything}}$ (2) Q to Kt 8,

and play as Black may, mate follows in two more moves.

G. C. Heywood.—We shall communicate with you on the subject of your last letter.

F. Owden (Hoxton).—Study the compositions of Healey, Duffy, & Campbell for six months, at the end of that period you may be able to produce something of your own.

D. A. (Maldon).—A forced move is when a player has but one legal move at command.

R. H. (Bristol) and A. B. C.—Look at the problem again, and you will find you are mistaken.

Correct solutions to Problem XII. and Enigma I. have been received from G. C. Heywood (Great Torrington); J. Bray (Langport); R. Lines (Cinderford); H. Cherry; W. Nash (S. Neot's); J. C. U. (Leicester); J. C. S.; A. R. Moleson (Swansea); W. F. (Manchester); Edeography (Leicester); W. N. P.; W. Airey (Worsley); Fritz (Bradford); G. T. F. (Croydon); A. W. Cooper; Argo (Yarmouth); C. J. L. (Portsmouth); S. H. Thomas (Plymouth); and Alchemist. All others are wrong.

Heated Bearings.—Dr. Mayer suggests the employment of a layer of iodide of mercury to test whether journals or other parts of machinery become heated by friction. A thin layer of the red-coloured salt is sufficient, and it becomes black when the temperature reaches 70° C. (154° Fahr.)

ANSWERS TO CORRESPONDENTS.

. *All communications should be addressed to the* Editor *of the* English Mechanic, 31, *Tavistock-street, Covent Garden, W.C.*

HINTS TO CORRESPONDENTS.

1. Write on one side of the paper only, and put drawings for illustration on separate pieces of paper. 2. Put titles to queries, and when answering queries put the numbers as well as the titles of the queries to which the replies refer. 3. No charge is made for inserting letters, queries, or replies. 4. Commercial letters, or queries, or replies, are not inserted. 5. No question asking for educational or scientific information is answered through the post. 6. Letters sent to correspondents, under cover to the Editor, are not forwarded; and the names of correspondents are not given to inquirers.

The following are the initials, &c., of letters to hand up to Tuesday morning, August 27, and unacknowledged elsewhere:—

H. Waters.—C. Bullock.—E. Tutte.—E. S.—G. C. Price.—E. Erasmus Wilson.—J. B. Ward.—F. E. Guinness.—Cox and Co.—Aurora.—Wm. F. Denning.—N. B.—T. W. J.—J. W. D.—J. W. Fennell.—K.—Rob Roy.—Bobo.—Old Ploughman.—L. E. E.—J. L. H.—Arid.—J. G. Rowe.—C. Bethel.—Kelby.—R. W. Barber.—D. G. W.—E. L. G.—Alfred H. Allen.—E. Stanford.—C. J. Harcourt.—E. A. Hodges.—J. Binchin.—J. F. Stanistreet.—Le de Fontainemoreau.—A. Felton.—Barnes Richards.—J. J. Reddell.—James Verity.—J. H. W.—John Manning.—J. Hebb.—Columbia.—An Engineer.—Logan.—P. C. E.—E. T. E.—M. Paris.—A., Liverpool.—J. M. N.—S. E. C.—J. T. R. Gorett.—Peacock.—Afflicted Subscriber.—Leonard N. Gill.—C. N. Abbott.—E. G.—H. Highton.—W. R. Birt.—Nathan Mutch.—Paul Greggor.—G. A. C.—Caledonia.—N. G. N.—Smoked Out.—Horosupus.—F. E.—Ignoramus.—Cervus.—Hypo.—J. Steward.—R. A. Huntley.—Tantalus.—J. S. Sharpe.—R. A. Proctor.—J. Frost.—The Harmonious Blacksmith.—Edward Hunt.—A Benefitted Reader.—F.R.A.S.—Dr. A. W. Blacklock.—P. R. S.—S. W. D.—C. B. A.—Old King Cole.—R. Dixon.—S. W. Burnham.—John White.—Rev. A. B. Kerins.—B. H.—Sarah.—Tai.—A Lancashire Beekeeper.—Joseph Gadsby.—Equator.—F. S. M. W.—A Turner.—T. Stewart.—J. H. Crillin.—Cumro Bach.—Xenophon.—High.—A Constant Reader.—John Watson.—Brym.—Experimenter.—Leander.—S. Ibbotson.—Inchicore.—Hone Ko Io.—H. T. Ward.—Apprentice.—B. C.—R. W. P.—Percival Norton.—C. M. B.—Aroma.—U. S. A.—J. H. Whistle.—Calico.—John McIntosh.—Tag.—M. F. P.—Q. Q.—L. C.—Zax.—J. T. C.—W. M. Parker.—Young Beginner.—A Young Jobber.—Mutual Tom.—James Tresise.—J. M. B.—Sigma.—Jack of All Trades.—Plymouthian.—James Odgen.—W. R. Butler.—A Plumber.—S. B. H.—An Expert.—R. W. P. Jun.—B. F.—James Gaze.—E. W. T.—R. A.—Rat-Tat.—H. M. M.—R. R. W.—Saxmundham. Dr. Hall.—Eyepiece.—James Ramsden.—O. P. Q.—Optician.—Tyro.—Anxious.—J. H. J.—Cumberland.

M. A. B.—Your "sheshee" is nothing more than crystals of magenta, and as you bought it in India is probably that prepared from indigo.

Bel Demonia.—We cannot help you.

Hy. Clark (Derby).—The "note" you have sent is not a copy of your rejected letter. You write as if we were under an obligation to insert all the letters sent to us, whether they are good, bad, or indifferent. You make a mistake. Your letter on phrenology was certainly, however, not good, and it was consequently rejected.

F. D. asks our readers to suggest something that will destroy those "horrible pests, beetles." He surely cannot be a reader himself, or he would know that "suggestions" were given so recently as last May, pp. 209, 235, &c., of the present volume. If he will also refer to Vol. XIII., he will find several replies on the same question.

C. Swale.—The "useful hints on French polishing" which you require, will be found in both Vol. XIII. and XIV., see indices. Look at p. 468, Vol. XIII. Anything you do not understand, if you will put it in the form of a definite question, will be inserted; but we cannot repeat information recently given.

T. Hatton.—Spitting of phlegm is a case for a medical man. If he says your lungs are sound, there is nothing seriously the matter with you. Take open-air exercise, and throw the paregoric "to the dogs."

Hugh Parr.—Consult a medical man.

J. H. Sutherland (Kingston, Jamaica).—You say you have "discovered the quadrature of the circle," and you want to know whether there is any particular society or department in Great Britain to which you can make your discovery known. We know of no such "society" or "department." Are you sure your discovery is not a "mare's nest"?

F. P.—Advertise for Newton's "Principia."

Bay Window.—We are not sufficiently acquainted with technical law to give you any reliable advice on the matter.

Warming Greenhouses (4774).—"Atmospheric Burner's" plan of a burner appears good. Why does he not make and advertise them in the Mechanic, that amateurs might experimentalise on their power?—Cheltenham.

Albert Lyon, Edinboro', Duplex, Limbo, J. K., J. A. T., S. Hill, E. T. E., J. B. Harris, Definition, E. C. G., Engineer, E. S., Scarboro', A. S., Good Intent, Horatio, C. H., are referred to indices to back volumes.

James Starum.—See let. 4761, p. 589, for information on marine aquarium.

J. Hampden.—Your outrageous letter is forwarded to Mr. A. R. Wallace, to be disposed of as he may deem advisable. Probably you may once more calculate on his mercy.

T. B. C., J. Harland, and Calico Printer.—Consult medical men.

K. L., Jacobin, Pro Bono, and R. W. Bruce.—See Hints to Correspondents.

A. B. C. (Lanark).—Nothing new in your method of warming rooms. See also article on "Healthy and Comfortable Houses," p. 577.

G. T. Kremlett.—For a practical treatise on harmony, see pp. 8, 50, 75, 123, 173, 273, 278, 324, 423, 503, 553, and 606, Vol. XIII. Second question write Secretary of Society of Arts.

H. Cook.—They were reprinted by Trübner and Co., Paternoster-row.

J. Gunn.—We have no room at present for attempts to trisect angles.

S. A. Z.—Private communication with contributors can only be made by means of advertisement.

H. T. B.—Don't trouble yourself about the matter.

Unit.—Can you not ask your question without an engraving? Benzoline lamps would hardly yield sufficient heat for a vinery, 33 by 15, unless they were employed in a very inconvenient if not injurious number. It has already been stated in our columns that these lamps are not injurious to plant life if properly trimmed, so that your pipes would be a needless expense. Better keep to the hot-water pipes you have.

Edward Gardner.—The technological examinations of the Society of Arts to which we recently referred are not actually in work, but there is little doubt the recommendations of the committee will be adopted. The plan of the scheme and the nature of the subjects in which candidates will be examined were sufficiently indicated in our article, which we shall supplement by further and complete information when the details are definitively settled. In the mean time you and others can study the subjects mentioned, for even if the scheme falls through, which is scarcely probable, you will obtain ample reward. The proposed examinations will commence with the technology of the paper and cotton manufactures, for either of which you can "go in."

Jas. Gray.—Yes; price according to length, from a few pence upwards.

C. Carter.—The only "book" on carpentry and joinery which descends to such rudiments as the methods of "holding the tools," is the English Mechanic (see the Amateur Mechanic's Workshop, Vols. VII., VIII. and IX.). For the rest, get "Tredgold's Carpentry," or the "Practical Carpenter and Joiner," by R. Riddle just published.

Chemicus.—A "good, cheap, and simple galvanic battery" depends upon what you want it for. At any rate you will find how to make the various cells detailed in back numbers.

W. W. Bacarrough.—Articles on watch repairing are in course of publication in our columns. Information on repairing jewellery and gilding will be found in previous volumes. We know of no work embracing the whole of these subjects. Query inserted.

J. C.—You will find the whole art of gilding in pp. 51, 66, 145 of Vol. X. Your query is too indefinite, and would involve two or three columns for a reply which might be given in a few lines. You should at least say what kind of frames you wish to gild.

J. Rhodes.—There are many brick making machines, made on different principles.

Sigma.—Your letter and replies next week.

J. E. Austin.—Consult Bradshaw's "Railway Guide."

Philanthropist.—Copy of your reply on "Chess" has been mislaid: the drawing is engraved.

THE INVENTOR.

APPLICATIONS FOR LETTERS PATENT DURING THE WEEK ENDING AUGUST 2?, 1872.

2404 A. M. Clark, Chancery-lane, for improvements in looms for weaving. A communication.

2405 P. McKinlay, New Broad-street, City, for husking, hulling, or shelling, and for cleaning and preparing rice and other grain.

2406 B. Hunt, Serle-street, Lincoln's Inn, for an improved refrigerating apparatus for ships or vessels, for railway carriages or cars, or for other structures or places. A communication.

2407 C. Randolph and C. R. Harvey, Glasgow, for improvements in and connected with tramway carriages to be propelled by steam or drawn by horses.

2408 J. Horton, Glasgow, for a new or improved mode and means of cooling the tools for turning and planing metals.

2409 J. Pinches, Oxendon-street, Middlesex, for improvements in presses for embossing, stamping, perforating, or punching, and an improved die and counterpart for embossing and perforating.

2410 G. W. West, Edinburgh, for improvements in machinery for ginning cotton. A communication.

2411 T. B. Daft, Failsworth, Lancashire, for improvements in indiarubber manufactures and in tools and machinery employed therein.

2412 U. Green, Cassland-road, South Hackney, for improvements in apparatus for washing and separating ores and other minerals. A communication.

2413 T. Thomson, Southampton-buildings, for improvements in anchors.

2414 G. Haseltine, Southampton-buildings, for an improved holder for scrubbing-brushes and other similar implements. A communication.

2415 W. B. Chapin, Southampton-buildings, for improvements in fastenings for railway fish-joints.

2416 S. Chandler, sen., S. Chandler, jun., and J. Chandler, London-road, Southwark, for improvements in dip pipes for regulating the seal in hydraulic mains used in the manufacture of gas.

2417 F. D. Blyth, Fenchurch-street, City, and A. G. Southby, New Inn, Strand, for improvements in the process and apparatus for treating wood for the manufacture of pulp for paper.

2418 H. Crawford and J. Crawford, Beith, Ayrshire, for improvements in machinery for finishing thread and yarn.

2419 T. B. Rossiter, Bristol, for improvements in sewing machines.

2420 J. Riddale, Tufnell-park, West, for improvements in lamps.

2421 J. J. Blackham, Birmingham, for improvements in stoves.

The English Mechanic

AND

WORLD OF SCIENCE AND ART.

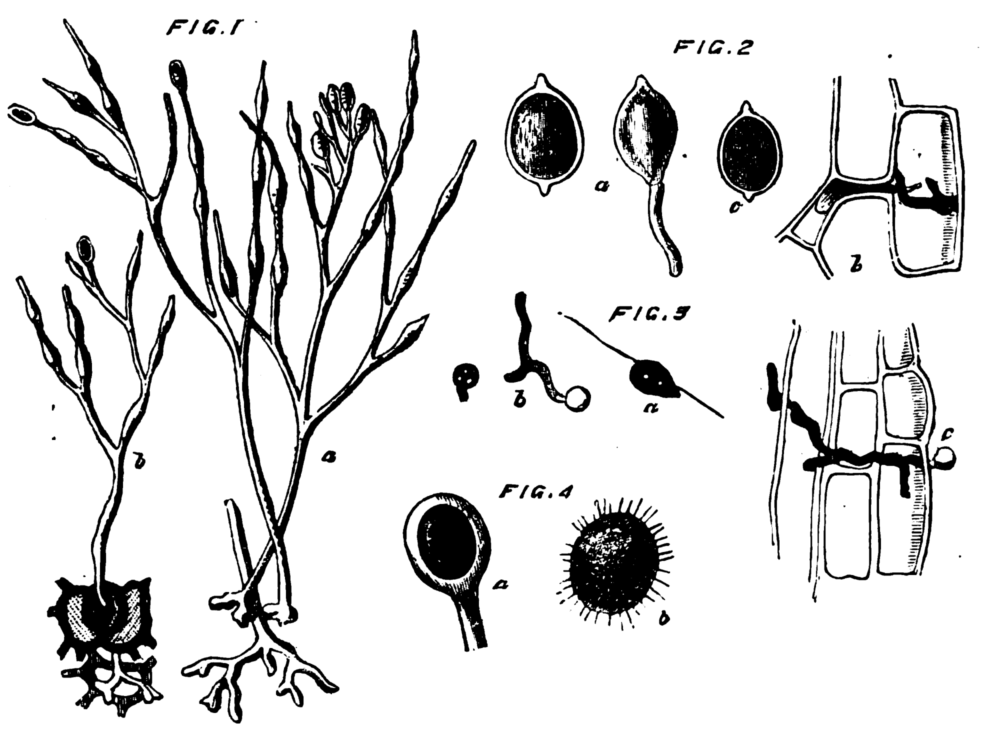
FRIDAY, SEPTEMBER 13, 1872.

ARTICLES.

THE POTATO DISEASE.

REPORTS from all parts of the kingdom represent the potato crop as being only about half the average yield; and there is only too much reason to fear that the reports, allowing for the usual amount of exaggeration, are true. To ascertain the magnitude of this loss, and estimate its effects on our food resources, a few figures may be serviceable. It is stated, then, that about 1,630,000 acres were this year planted with potatoes, and supposing each acre to produce 4½ tons (many produce more than double) we have 7,335,000 tons, representing at usual prices no less a sum than £30,000,000; so that if half the crop is diseased, there is a loss of £15,000,000. It must be acknowledged that under these circumstances it is not to be wondered at that the *Times* has opened its columns to the truly-vexed question of the potato disease and the means of preventing it, for no one talks of curing it, or doubts that the cause is involved in obscurity.

But, as a matter of course, we have had the usual flood of opinions—some from persons who probably never grew a potato or examined the ominous spots on its leaves; others from those who have some pet variety of the *S. tuberosum*, or some special method of planting and cultivating it, to which they attribute the immunity from disease hitherto obtained by themselves in its cultivation. It may interest many of our readers if we make a short digest of the letters which have appeared in the *Times*, steering clear of that peculiar disease which at this season of the year exhibits itself in leading articles—viz., newspaper science. The letter of Dr. Hooker, suggesting the utilisation of the starch, which we reprinted on p. 621, opened the discussion, and, of course, came in for criticism—one writer considering that the act of grating potatoes into a tub of water was of "rather too scientific a nature" for the agricultural mind! As a matter of fact, however, this plan is successfully carried out in places where the diseased tubers are not used for feeding pigs, and Dr. Hooker has done well in making it more widely known. But to return to the disease itself: there seems a general concurrence of opinion that it is connected in some way with the "electrical state of the atmosphere," and the fact that the disease is more prevalent when thunderstorms are most frequent is well established. But the potato blight does make its appearance even in seasons peculiarly free from electrical disturbance, so that the "post hoc, ergo propter hoc" style of argument does not fit in well with any of the theories yet broached. All that can be fairly asserted is that the blight is more wide-spread and more rapid in its action in a direct ratio with the number and severity of thunderstorms. So firm a hold on the agricultural mind has this idea obtained that various remedies have been proposed having for their object the arresting or turning aside of the electric "fluid" by planting some taller-growing specimen of the vegetable kingdom between the rows of potatoes. One gentleman, who claims the theory as his, recommends the planting of broad beans, the stalks of which "act as natural conductors and carry off the superabundant electricity." It is possibly not worth while inquiring who first started the "electrical" theory, but it is well to mention that the veteran Mr. Glenny years ago saw that lightning had something to do with the disease, and promulgated the only palliative that has ever been found worth practising—viz., cutting off the haulm directly the spots are seen, on the economic principle that it is better to have small and sound than full-grown diseased tubers. The bean-stalk notion has been tried and found wanting over and over again. The various nostrums recommended from time to time—the sulphur and iron, the soot and lime, night-soil, blood manure, bone dust, rape dust, and the numerous special compounds—have all failed in their turn; and planting wide or close, deep or shallow, earthing or not earthing, have yielded equally negative results. In short, scientific men, as well as the practical cultivators, have found themselves completely baffled by the insidious nature of this terrible blight; that is, as far as preventing its ravages is concerned, for the life-history of the characteristic fungus which is generally accepted as its cause amongst students of science is tolerably well known.



Potato-growing seems gradually becoming a lottery—a mere game of chance. Sorts that turn out healthy and good croppers in one district are often the most seriously affected in others; and although much has been done, solely by the enterprise of our large seedsmen, in improving the stock, imparting vigour and early maturity, there is ample room for much greater improvement in a direction now generally acknowledged to be the most likely to lead to the stamping-out of the disease.

It is doubly unfortunate, too, that the blight should have appeared in such force this year, for if the reports are to be relied upon, there is no doubt the potato crop of 1872 would have been the most abundant known for many years. But although the damage is in many cases over-stated, there is, as we said before, too much reason to fear that a heavy and irretrievable loss will be the result when the accounts are made up. A Cambridgeshire farmer, writing to the *Times*, says:—"The results of my examination this day of many varieties of potatoes grown on my driest and best soils, which are noted for being, as a rule, freer from disease than any in this district, show an average of disease of from 30 to 80 per cent. It is worthy of remark that the most prolific varieties seem to be most liable to disease. There is, however, one most striking exception to this rule, and that is Sutton's red-skinned flour-ball. This is the most abundant cropper I ever grew, and yet I did not find among them one diseased tuber. This is all the more remarkable since, as I use it as a dividing line between all the other varieties—it being so strong a grower and so distinct in colour of tuber—each root, tested in every part, was growing side by side with the roots of the others showing so much disease." If similar results are obtained with this variety in other parts of the country it will speak volumes in its favour, and at the same time dispose of the idea of contagion, or the spreading of the blight from one tuber to another while in the ground. It is satisfactory to turn from an account which shows an average loss of more than 50 per cent. to one furnished by the rector of a Devonshire parish, who says that Mr. Randle of Ringmore, in the South Hams of Devon, reports that "never in his life have his potatoes turned out so well as this year," the yield, moreover, being so abundant that the money value would purchase the land on which they grew. This letter is especially valuable in connection with the "electrical" theory, for the rector informs us that there have been less than six thunderstorms during a period of more than 12 years, and that during the present year there has been far less electric disturbance than in other parts. Among the more sensible of the preventatives proposed by the writers to the *Times* is one from Mr. Hallett, of Brighton, who describes his own plot as yielding three heaped bushels per rod and "no sign of disease." He thinks that disease is as hereditary in plants as in man, and that so long as unhealthy seed is planted so long will the potato be liable to disease. Acting on this view he has carefully selected his seed potatoes for years, rejecting the whole root when only one tuber was tainted, or even suspected of being tainted, and the result has been an almost complete immunity from disease.

But the experience of Dr. Wallace, of Colchester, who has been a cultivator of the potato for some years, and whose letter is more valuable than any which have yet appeared, is directly opposed to this, for he says that he has had most excellent crops from seed saved from infected plots. Dr. Wallace considers there are only three theories of the potato disease which are worthy of credence—first, that which attributes it to the operations of an insect (*e.g.*, Smee's *Aphis vastator*); second, the fungus origin; third, the atmospheric. In these three causes, taken conjointly, Dr. Wallace is convinced the true origin of the disease is to be found. He considers that the error of former observers lies in their having found but one link of the chain; but there are three links, any one of which being absent the disease does not appear. The following is a brief summary of his theory:—

Towards the end of June or in July, if any one approach growing potatoes and strike the haulm gently with a stick, he will see numerous small green flies, or midges, dart away. These are named *Eupteryx picta*, *E. viridis*, and other varieties, and are common in our gardens. If he proceed to examine the haulm and leaves, he will find numerous white specks, and, looking closely, will find small green insects without wings—the larvæ of the Eupteryx. There are also two or three other species, one a bug, and other aphides, which prey similarly on the potato. These white specks are made by the larvæ, which have consumed the chlorophyl on the under surface of the leaf; the haulm, also, to some extent, is similarly affected. These specks increase in size and coalesce, and as the weather gets warm become discoloured, and form a brown blotch, chiefly at the tip of the leaf; any injury to the cuticle—as a bruise—will create a similar blotch. This is the first link in the chain, the primary or predisposing cause of the disease. The haulm and leaf are punctured in many places, and their juices withdrawn by insects. An effort is required from the plant to heal the wounds; an exudation arises. All this weakens the constitution of the plant. Should fine weather continue, the blotches merely dry up, the haulm in due season dies down, the tubers ripen, and are turned up free from disease. And this is a good season. But should rainy weather (the second link in the chain and exciting cause of the disease) supervene in July and August, just when the wounded stems and leaves are healing up (the critical time), when the potatoes are nearly at their full size or just about to ripen, and more especially should electrical discharges, with heavy rainfall, supervene, saturate the ground, and induce for several days a muggy condition of atmosphere, then a fungus (the third link in the chain), *Botrytis infestans*—the true potato disease—is developed with marvellous rapidity. A white film of mould appears on the under surface of the brown blotch—not, indeed, on the dry portion, but where the exudation has been poured out at the edge of the green portion of the leaf—a rapid development of mycelia and spores ensues, and in another 48 hours, if the atmospheric conditions be favourable, the mycelia will spread with marvellous rapidity, attacking the haulm and leaf at numerous points, descending through the stem to the roots and tubers (those at the top are generally the first affected), and thus the three links of the chain are completed.

The first appearance of disease in the tubers is a brown discoloration, generally commencing at the eye attached to the haulm, and the only remedy with which the doctor is acquainted is that mentioned above—pulling out or cutting off the haulm. It seems that this theory is due to the late Dr. Maclean, of Colchester, who explained it some years ago to Dr. Wallace, and gave him an account of the experiments which confirmed him in his opinion. These experiments were made by planting potatoes in pots, and covering the haulm with gauze supported on sticks. From one series all insects were excluded, but the Eupteryx was purposely introduced to the other; the result being that in the first case every tuber was sound, in the latter every tuber was diseased.

The more generally accepted theory of the disease is that which originated, we believe, with Dr. Julius Kühn, who stated that the "cause" of the blight is a parasitical fungus called *Peronospora infestans* (Fig. 1),* the spawn or mycelia of which penetrates the tubers, and communicates the disease from one to the other. This theory is held by the Rev. M. J. Berkeley, the highest English authority on mycology, who says that the first appearance of the blight is indicated by the presence of brown spots on the upper surface of the leaves. If the reverse of these spots be examined, it will be found that the brown colour has been produced by the action of a parasitic mould, which gradually extends in the circumference of the spots, destroying the tissues as it proceeds, and ultimately gaining extensive possession of other portions of the plant. The genus Peronospora consists of some forty species, all of which are parasitic on living plants, but the species known as *infestans* was not observed previous to 1844. The mould bears abundance of spores on the tips of the branches (Fig. 1, *a*); the mycelium burrows amongst the cellular tissue of the leaf (*b*), and causes rapid decomposition, while the vertical threads, carrying the spores, find their way through the stomates, or leaf-pores. The spores, falling on different parts of the plant, germinate and penetrate the tissues, producing a brown tint in the parts infected. Some of these spores undergo a peculiar process, and are divided into a number of cells that ultimately produce a multitude of zoospores, which are exceedingly active so long as there is sufficient moisture to enable them to change their position by means of the thread-like processes shown in Fig. 3, *a*; these also germinate and penetrate the tissues in the same way as the simple spores *b c*. Scientific inquirers are not quite certain that the potato Peronospora possesses the perfect form of fructification, called resting spores—that is to say, they are not certain it has been observed, for there can be little doubt that the fungus has some means of surviving the winter and propagating its species under suitable conditions. Dr. Montague figured a genus discovered in spent tubers by Dr. Payen, to which he gave the name of Artotrogus, which there is reason to believe is the resting spore of *Peronospora infestans*.

* The illustration is copied from the figures by Mr. Berkeley in the *Gardeners' Chronicle*.

Von Schultzenstein, however, is of a different opinion; he considers the cause of the blight to be a withering or dying of the cellular tissue and the vessels, and states that it is only along with the chemical decomposition of the decayed parts at a later stage that the fungus makes its appearance. It is, too, asserted that fungus growths rarely if ever appear on healthy organisms; but this notion has been often refuted, and can scarcely be held as true. A curious fact has, however, been recently mentioned, which shows that after all there may be something in Von Schultzenstein's theory. A number of potatoes were left on the ground exposed to the sun, as it was thought they were all diseased. On examining them a few days afterwards about half were found to have been acted on by sunlight in the usual manner, being turned a dark green, while the remainder, submitted to exactly the same influence, retained their pale and sickly hue. This would seem to show that some great change had been effected in the constitution of the tubers; and on examination those which had greened were found sound, but the others were all diseased.

The different results obtained in similar experiments in potato culture, the diverse and conflicting opinions of those who have studied the matter, together with the utter inability to point out a a remedy of those who have the best right to our attention, have involved the whole subject in obscurity. Few of us can believe that if the disease and its cause were really understood we should fail so lamentably in grappling with it. There is good work in this direction for the Royal Agricultural or the Royal Horticultural Societies. Cannot they try experiments in raising new sorts, by crossing *S. tuberosum* with another member of the Solanaceæ, and so mayhap impart some property which will make the potato proof against the attacks of the fungus? There is hope that something may be accomplished by this means towards stamping out the disease, for the instance of the red-skin flour-ball mentioned above, and the new American sorts, which have hitherto been but little affected, give an earnest that if as much skill, care, and enterprise are brought to bear on the potato as have been lavished on florists' flowers, we may eventually obtain a tuber as greatly improved in hardiness and healthiness, as the flowers are in beauty.

DESCRIPTION OF ILLUSTRATIONS.

RAILWAYS OR NO RAILWAYS—THE BATTLE OF THE GAUGES CONTINUED.

NARROW gauge railways and the Fairlie locomotive are facts too well established in different parts of the world to have needed the triumphant "apology" for their introduction issued by Mr. Fairlie. Engineers of the 4ft. 8½in. standard seem to be as much chagrined at the successful and economical working of a narrower gauge as Brunel may be supposed to have been when he discovered that his magnificent innovation found few imitators; and the Fairlie type of locomotive has met with opposition of a character and to an amount which could scarcely have been expected by its inventor. Mr. Fairlie has, however, told his tale well in the little book whose title we give below, and has met the arguments of his opponents at every turn. If he has failed to convince them of their mistakes, they have at all events not succeeded in carrying his position. The question of narrow gauge does not, of course, affect this country to any extent, where all the main lines † are of the standard gauge ordered by Act of Parliament and only a few local and special lines are of a different width; though there is ample room in this latter direction for the introduction of cheap narrow gauge lines for suburban traffic around large centres of industry, and for special purposes in different localities. But in many of the more sparsely populated countries of the globe—in those, in fact, where railways are especially necessary to their development—the difference between the so-called broad and narrow gauge is in reality the difference between a "railway and no railway." On this point of the question there can, we should think, be little discussion, whatever there may be on the broader ground on which Mr. Fairlie has taken his stand when he contends that a broad gauge means costliness with extravagance when compared to the economy with efficiency of the narrow gauge. In a country like India, requiring long lines of permanent way, embankments, bridges, cuttings, and engineering achievements of a more or less costly character, the question of expense is of the first importance, and a saving of even £100 per mile a consideration not to be lightly thrown aside. The argument that has been used with regard to the Indian railways—that they should be constructed with a view to Imperial purposes, such as the speedy conveyance of troops in emergencies—should not be allowed to weigh in the balance, unless a complete network of lines is to be at once constructed; for it is obvious that, even taking this argument into consideration, three narrow gauge lines would probably be more advantageous than two broad ones. Mr. Hawksley spoke at his inauguration as President of the Institution of Civil Engineers of the new gauge of absurd dimensions which had been introduced into India at the instance of some unknown crotchetty person, which would inflict all the evils of break of gauge, and all the inconveniences of inefficient accommodation, in a country in which a magnificent system was being constructed. But, as Mr. Fairlie points out, the Indian railways are too magnificent, and the few miles (comparatively speaking) yet built, have cost an enormous sum, and earn but a small income. In Australia, too, the broad-gaugers are straining every nerve to burden with costly constructions a country which wants cheap railways.

But it is in the United States that the problem of the efficiency and economy of narrow gauges, when tried in actual work on a large scale, will first be solved, and it is mainly in reply to the Hon. Silas Seymour's review of the report of Gen. Buell, the engineer of the Texas Pacific Road, that Mr. Fairlie has written this book. The subject seems to have been treated in a much better manner in that country than it has here, for the opponents of the narrow gauge do not appear to have sought out all the minute and apparent defects, but have argued earnestly and ably against it, pointing out what they considered its disadvantages. The advantages claimed by Gen. Buell in recommending a gauge of 3ft. 6in. for a railway of 1,500 miles, were a saving of 30 per cent. of the cost of the narrow gauge road-bed, &c., 45 per cent. of the cost of the super-structure, and 50 per cent. of the cost of rolling stock; while the proportion of dead weight to load would be ·47, as compared to ·75 on the broad gauge, and a speed of thirty-five to forty-five miles an hour might be attained with safety. These estimates were reviewed by Mr. Seymour, who objected that the difference in cost of the road-bed would only be the value of a longitudinal slice 1ft. 2½in. wide, taken out of the centre of the ordinary track (single line); this, of course is absurd, for the wide gauge is necessarily constructed to withstand the heavy weights passing over it, and in estimating the cost of the road-bed for the narrow gauge, it should be remembered that the "true practice permits a closer adaptation of grade to the natural surfaces than is attained on the broad gauge," requiring lower banks and shallower cuttings, less formation width, because the running weights are less; sharper curves are also permissible, thus avoiding tunnelling as a rule, and executing that description of work more cheaply where necessary. As a matter of fact, this question had been already settled in Norway, where the first railways cost £11,000 per mile, an outlay which M. Carl Pihl has brought down to an average of £4,347 for three lines of narrow gauge railway, one of which at least was carried across very difficult country. Mr. Fairlie can also point to the narrow gauge lines of Russia, Canada, New Zealand, and other parts, where the actual cost is well known to be considerably less than for the broader gauge. With Mr. Seymour's other objections, which were of a similar nature, he deals in an equally conclusive manner, and quotes the tables prepared by Mr. Fowler to show the

* Railways or no Railways. By ROBERT F. FAIRLIE. London: Effingham Wilson.

† The Great Western is, we believe, in course of alteration throughout its whole length.

difference in cost of a "light" 5ft. 6in., and a 3ft. 6in. gauge for India—viz., £5,397 as compared with £4,543, or a difference of 16 per cent. Now, allowing the heavy charge of 3½d. per ton for shifting merchandise, this is but a small item when we remember the saving in first cost, and the smaller amount of dead weight to be hauled, with the consequent saving in hauling-power. The advocates of broad guages will here find the case against them fairly stated; we shall be curious to see if they as publicly and conclusively answer it. As might be expected in a work on narrow gauge railways, several pages are devoted to combating the adverse criticisms of the now well-known Fairlie locomotive. Our own pages have contained statements of opinions on the advantages and disadvantages of this type of engine, but it must be acknowledged that its opponents have failed to make out a case. But it is principally in reply to a report against the principle of the Fairlie engine by Mr. Ramsbottom, the well-known able engineer of the London and North-Western, that the author brings what we consider conclusive arguments to bear. Mr. Ramsbottom reported upon three engines sent out to Queensland to work upon the 3ft. 6in. gauge, which were condemned as useless and reshipped to this country. It is unfortunate that the examination of these engines should have been made the foundation for an attack upon the *principle* underlying the peculiarities of the Fairlie design; for it appears that Mr. Fairlie never saw these engines till they reappeared in England, when he found that they "were not constructed in any measure" upon his designs. Independently of this fact, the engines had not a fair trial, for only one was put together and worked in Australia. Mr. Ramsbottom alleges that a serious defect of the Fairlie engine is to be found in the bogie frames, which are not free to move *vertically* as well as horizontally; but Mr. Fairlie disposes of this objection by stating a simple fact that in the Fairlie engine proper the bogie frame is free to move in both directions. With the view of testing this part of the arrangement in the returned Queensland locomotives, Mr. Ramsbottom had a portion of a temporary road raised so as to form an apex with two opposite inclines of 1 in 100, and he asserts that the result of passing the engines over the summit of the gradient was to reduce the weight on the leading wheels so materially as to show that the engine was unsafe for travelling over such a road. This is his chief objection to the Fairlie engine, and Mr. Fairlie demolishes the whole argument by a few diagrams. Assuming, he says, for argument's sake, the two bogies of the engines in question to be held perfectly rigid vertically, like a girder—a thing utterly impossible—yet, under such conditions the alleged effect when the engine was standing on the crown or apex of a reverse gradient of 1 in 100 could not be produced. Mr. Fairlie takes, by way of argument, two reverse inclines of 1 in 50, and shows that even then, when the engine is crossing the apex, there is the weight of the leading wheels, axles, and boxes on the rails, assisted by the down pressure of the springs. But it is impossible to explain this question thoroughly without the diagrams, which are drawn to scale, and with the description clearly show the fallacy of Mr. Ramsbottom's argument. But it was not to be supposed that Mr. Fairlie would submit to this sort of treatment of *his* engine without putting his opponent's to the same test, and he clearly shows the absurdity of the argument by illustrating the position and action of an ordinary six-wheeled goods engine in passing over the "apex" of the inclines of 1 in 50, when the weight would at one time be supported entirely on the centre wheels with the leading and trailng wheels 1in. from the rail—a see-saw, in fact. Besides this, he does not fail to point out the advantage of his own arrangement in securing a stratum of water over the fire-box in ascending and descending inclines of any possible gradient; while in ordinary engines, with the fire-box at one end, in descending inclines the water naturally flows to the lower end, leaving the fire-box uncovered, or partially so. Mr. Fairlie, after meeting and demolishing the arguments of his opponents, appends the following note:—"Such a thing as an apex being permitted to occur on any line is unknown to my experience; what I mean by an apex is that rails are never so laid on a grade up and down as to form a distinct angle, but its introduction in Messrs. Ramsbottom and Marshall's report only shows how far the opponents to the principle of the double bogie engine will permit themselves to be carried in order to find some excuse to damage it." With the other objections urged against the Fairlie engine its designer deals in an equally satisfactory manner. The steam-joints *are* found steam-tight in practice; the repairs are not excessive; and the engine is not too powerful for properly managed traffic. To the absurd argument that it is too powerful for the coupling chains of ordinary wagon stock, and that, consequently full advantage could not be taken of their capacity, Mr. Fairlie replies, that one of the principal causes of coupling chains breaking is want of power in the engine; "because these engines can only start their trains when the wagons are coupled up loose"—*i.e.*, with from 6in. to 12in. between the buffers, so that the locomotive is in motion before the whole weight of the train is brought upon it. These jerks and snatches frequently part the chains, while the tendency of the hinder wagons to overrun the front ones when speed is suddenly slackened or the road is uneven often causes the link to be lifted off the hook. Now, the Fairlie engine being so powerful enables the wagons to be coupled up tight, preventing jerks, broken chains, and consequently accidents. The book contains some heliotypic illustrations of Fairlie engines and stock constructed for different lines, with much interesting matter for the careful consideration of directors and shareholders; and some facts, figures, and arguments, not easily overthrown or disputed by the advocates of the broad gauge and the prejudiced opponents of the double bogie locomotive.

NOTES OF COMMUNICATIONS TO THE ACADEMY OF SCIENCES, PARIS.*

PHYSICS.—ON THE CURRENTS OF INDUCTION DEVELOPED IN THE INSTRUMENT OF M. GRAMME.

1. M. Gramme employed a long bar of soft iron in his instrument described to the Academy in July, 1871. On the bar was coiled an insulated conducting wire, presenting a straight permanent magnet to this, and moving the magnet parallel to itself, maintaining a constant distance from the bar; magnetism is developed in the bar and helix as long as the permanent magnet is in motion, the polarisation in the bar changing with the motion of the magnet. M. Gaugain, when analysing these inductive actions, placed pasteboard between the bar of soft iron and the coil to enable one to slide freely on the other, and with this arrangement met with the results detailed below.

2. Placing the bar and the magnet at right angles, the latter towards the middle of the former, on sliding the helix in the direction of its axis, without moving the bar, an induction current is obtained which cannot be set down to the account of a change in the magnetic state of the bar, but depends exclusively on the displacement of the helix, by rapport with the magnetic pole developed in the soft iron by the magnet.

3. If the helix be stationary, and the bar moved in the direction of its axis, the relative positions being maintained as in No. 2, a similar result is produced by the alternate magnetisation and demagnetisation of the latter.

4. From the two following facts it results that when the bar and helix are moved together the resulting induced current arises from different causes; the one is the movement of the helix in presence of the pole developed in the bar; the other from the successive changes the magnetic state of the bar undergoes. This applies to M. Gramme's experience (No. 1) with the inverse movement of the magnet in presence of the immovable bar and helix.

5. I proceed to point out the results of the experiences yielded by the first of these two causes. Taking a bar of steel regularly magnetised, placing on the middle of it a helix formed of several spiral turns, and putting the helix in communication with a galvanometer, on making the helix slide rapidly towards one or other of the poles of the bar, an induced current is obtained, the direction of it remaining the same whichever pole the helix may be pushed towards. An inverse current is obtained when the helix is brought again from either extremity of the bar towards the centre. This fact, known long since, accords with the theory of Ampère and the law of Lenz, and we will now see if we can here connect the theory with the experience of M. Gramme.

6. Placing together in succession two bars of magnetised steel, as identical as possible, opposing them with like poles, a double bar is obtained. Passing from one extremity to the other there is first a simple pole; suppose it to be N.; then follows a neutral region; then a double S. pole; then a second neutral region; finally, a second N. pole, placing upon this double bar a helix formed of some spiral turns, and connecting it with the galvanometer, on sliding it from one extremity to the other of the bar we obtain at first, in passing from the first N. pole to the first neutral region, a current moving inversely to the molecular current which, on the theory of Ampère, constitutes the magnetism of the first bar; let us consider this current negative. It will change its direction and become positive on passing the helix from the first neutral region to the double pole, and remain so whilst passing to the second neutral region, becoming again negative on the helix being moved to the second N. pole. Thus, when the helix is moved constantly in the same direction, the inductive actions developed in the space between the two neutral regions are opposed to the actions which develop themselves in the spaces situated out of these neutral regions, and, as the sum of the first is equal to the sum of the second, it results that the sum total of the forces developed in the whole extent of the bar is *nil*. The author has verified by direct experiment these consequences of the theory.

7. Now suppose a bar of soft iron be placed in presence of a magnet in the position indicated in No. 2, this bar will assume, under the influence of the magnet, a magnetic state analogous to that of the double bar of No. 6; only that each of the neutral regions in the double bar finds itself at an equal distance from the double pole and the adjoining single pole, whilst in the bar of iron magnetised by influence the neutral regions approach nearer to the double pole than to the single. On placing a small helix on the iron bar, and moving it from one extremity to the other, the current will yield the same changes as in No. 6.

8. If in place of a helix of eight or ten turns one is employed embracing the whole space between the two neutral regions, and encroaching a little beyond, it is very clear that the induced currents resulting from the displacement of the helix will be all of the same kind, so long as the extremities of this helix be not sensibly removed from the neutral regions.

9. If, on the contrary, a helix be employed covering the whole length of the bar, the sum of the inductive actions will be *nil*, after No. 6; for it is clear that if this helix be displaced to the extent of one turn of the spiral there will be the same result as if we operated with a single turn of wire and that this were moved from one end of the bar to the other.

10. This last case is precisely that of M. Gramme in No. 1, and, consequently, the induced currents which manifest themselves in that experiment ought to be attributed to the second of the causes mentioned in No. 4, since the actions arising from the first cause in No. 4 naturally neutralise themselves.

11. This conclusion does not apply to the instrument of M. Gramme, in which a ring of soft iron, surrounded by an endless helix, turns between the two poles of a permanent horseshoe magnet. The disposition of this machine is such that one gathers exclusively the currents developed in the intervals which separate the two neutral regions; the apparatus finds itself in the conditions examined in No. 8; then, as we have seen, all the conducting actions resulting from the displacement of the helix by rapport with the double-developed pole in the soft iron act in the same way, and, in consequence, this displacement of the helix contributes to the production of the current obtained. The author is even of opinion that it contributes to it for the greatest part.—M. J. M. GAUGAIN.

TERRESTRIAL PHYSICS.—OF THE MAGNETIC CURRENTS AND SOLAR EXPLOSIONS THAT ACCOMPANIED THE AURORA OF THE 7TH JULY.—1. *Magnetic Phenomena.*—Very pronounced magnetic perturbations showed themselves upon the telegraphic-wires of Brest suddenly at 5.2 p.m., by energetic positive emissions, and a strong adherence of the armatures in all the apparatus. As in all other analogous cases, the intensity of these currents was greatest on the longest lines, and those directed from W. to E. were most affected. The following are deviations of the galvanometer (of 12 turns) at this first characteristic period:—

h. m.		h. m.		h. m.	
5 2	+ 18°	5 15	+ 40°	5 23	+ 28°
5 5	+ 25°	5 20	+ 30°	5 25	+ 25°
5 10	+ 40°	5 22	+ 25°	5 28	+ 0°

*Translated and abstracted for the ENGLISH MECHANIC.

The following are subsequent deviations out of sixty-five observations :—

Maxima Negative Deviations.		Return to Zero.	Minima Negative Deviations.	
h. m.		h. m.	h. m.	
5 32	− 12°	5 33	5 48	+ 30°
5 40	− 20°	5 41	...	...
5 55	− 20°	...	6 57	+ 27°
7 02	− 16°	7 06	7 20	+ 28°
...	...	7 47	7 50	+ 18°
8 08	− 22°	7 55	...	...
8 55	− 15°	...	...	...
10 00	− 20°	10 45	10 50	+ 10°
10 51	− 10°	10 52	...	...
11 00	− 20°	11 45	...	...

From 5.41 to 6.10 there were several negative waves; from 6.10 to 7.1 several positive. The most remarkable wave of this period was from 6.57 to 7.2, which passed zero at 7.1. From 11.0 to 11.72 the needle remained immovable at − 20°, the most prolonged period of contact. There was a very prominent maximum in the terrestrial currents when the aurora was at its height. From 11.12 to 11.24 the intensity diminished gradually from + 20° to + 10°. At 11.45 the luminous and magnetic phenomena ceased at the same time. On the 8th July there were magnetic perturbations all day, until 8.50 p.m. Sky overcast.

2. *Solar Phenomena.*—M. Le Verrier is of opinion that this magnetism is of the same nature as ordinary magnetism. The theory which I had the honour to offer to the Academy on 15th February last, placing the origin of it in the explosions or great commotions that occur at the surface of the sun, acquires a character of probability from the observations of Father Secchi. On the 7th July, independently of the solar spots observed for several days even with the naked eye (one of them 2' 24" diameter), he witnessed at 3.30 p.m. a violent solar explosion. At 2.40 there had been at the same locality only a small luminous jet. The interior movements of the incandescent vapours, amongst which he recognised hydrogen and the unknown matter which has yet only been seen in the sun, were so intense that the luminous clouds changed form to the eyes, and at 1.15 their height was ten times greater than the terrestrial diameter. This spectacle remained at its height for two hours. At 7 p.m. the appearance had become the same as at the beginning. On the 8th another eruption was seen by the same observer near the locality of that of the evening of the previous day. An aurora was perceived at Madrid the same day. Violent magnetic disturbances were noticed on the 7th and 8th at Rome, and in other observatories.—M. H. TARRY.

PALÆONTOLOGY.—ON THE FOSSIL CROCODILE OF AMBOULINSATRE (MADAGASCAR). — Amongst the animal fossils of Amboulinsatre are found bones of the hippotamus, epiornis, and a reptile of the crocodile family. The two former have ceased to exist in Madagascar, but crocodiles still live there. The following is a comparison of the extinct with the living species. The former is only known by disjointed but well-preserved bones, a certain number of which are from parts of the skeleton important enough to admit of a sufficiently complete knowledge of the animal. This animal was of great length, and stout; the bones are thick, with prominences well-accentuated; the teeth and alveoli are enormous. Without doubt it should be classed with the genus *Crocodilus*. The teeth, to the number of nineteen of the upper jaw and fifteen of the lower, show well the customary form in this genus. The snout would be short. A first very strong caudal vertebra is fifty-six millimetres long. The examination of the whole remains shows sufficiently that this crocodile is absolutely different from the only species still existing in Madagascar, *Crocodilus Madagascariensis*, Grand., which approaches *C. vulgaris*, Cuv., above all to the variety *Suchus*, remarkable for its gracefulness and elongation of its snout. Thus this fossil crocodile has disappeared like the animals it accompanies. As to crocodiles in other parts of the globe, it can only approach *C. bombifrons*, Gray, of India, or *C. Niger*, Latr., of Senegal, but with the former the first inferior teeth penetrate the intermaxillaries, and in the latter, the five last teeth, according to Owen, are in a simple groove without separation by transverse partitions of bone, characters which fail in the crocodile under consideration. The authors propose to name this *C. robustus*, adding that it appears to have affinities with the Senegal species. —MM. A. GRANDIDIER AND L. VAILLANT.

CHEMISTRY.—ON THE INSTANTANEOUS OXIDATION OF ALCOHOL.—We have here a simple example of the direct conversion of alcohol into acetic acid and aldehyde without the medium of any other agent than oxygen modified by electricity. If into a demi-litre flask filled with concentrated and moist ozone be inserted about ten cubic centimetres of absolute or hydrated alcohol it is sufficient to agitate the flask strongly for some seconds, when the neutralised, and, so to speak, inodorous, alcohol manifests to turnsol paper a strong acid reaction due to the vinegar formed,* and develops an odour of aldehyde, the presence of which is shown by the reductive influence the liquor exercises upon an ammoniacal salt of silver. But the most curious fact of the experiment is the simultaneous formation of quantities, relatively considerable, of oxygenated water. Some cubic centimetres of the alcoholic liquor strongly colours blue the mixture of chromic acid and ether. In operating with ordinary oxygen—that is, with oxygen from the same source before the gas has undergone obscure electrisation—nothing like this is observed. Even after twenty-four hours' contact the alcohol is left neutral, inodorous, and without action on the salt of silver, as upon the chromic acid. Ether undergoes from concentrated ozone under the same conditions an analogous and yet more rapid oxidation with production of oxygenised water. On comparing these effects of oxidation with like effects that alcohol exhibits in oxidising bodies, as chromic acid, the mixture of sulphuric acid and bichromate of potash, &c., one cannot misunderstand the deep analogy that seems to exist between free ozone and oxygen in combination. It is, indeed, that analogy which, for a long time, made the author suppose that ozone can only be the primitive state of oxygen.† Whatever it may be, it is shown by these experiments that concentrated ozone, which can now be easily produced by his ozonising tubes, is an oxidising agent, at once simple and energetic, the use of which may be useful in researches in organic chemistry. It is necessary to use ozone with great caution, as even a small quantity will cause rapid inflammation of the mucous membranes that will give rise to a spitting of blood.—M. A. HOUZEAU. JOHN J. LAKE.

* After the action of the ozone the alcohol, being saturated with limewater and evaporated to dryness, leaves a residuum which disengages acetic acid on contact with diluted sulphuric acid.

† There is more in it than this. See the translator's paper on the subject, *Polytech. Rev. and Mag.* Vol. II., 1845, page 260, and article "Ozone" in *Supplemen. Pen. Cyclop.*

THE TEMPERATURE AND PHYSICAL CONDITIONS OF INLAND SEAS.

IN the paper by Dr. Carpenter, on the "Temperature and other Physical Conditions of Inland Seas, considered in Reference to Geology," read at the meeting of the British Association, he stated that the earlier experiments with thermometers in ascertaining the temperature of deep soundings could not be depended upon, on account of the pressure having interfered with them. Recent soundings, recently taken under the equator with protected thermometers, at two thousand fathoms, gave a temperature of about thirty-two and a half degrees. He thought that, if they went deep enough in sounding equatorial seas, they would invariably find the temperature to be glacial, which must exercise great influence in dwarfing animal forms. This cold could not be understood except by supposing the cold water from the poles to creep along the sea-bottom. Dr. Carpenter then pointed out the ridge which arose from the Mediterranean floor, and so shut it off from the Atlantic, making it an inland sea. In consequence of this the cold water flowing at great depths along the bottom of the Atlantic could not get into the Mediterranean, and soundings at the greatest depths of the latter showed a uniform temperature of 51° to 56°. This exception could only be understood on the theory of a general polar circulation in open seas like the Atlantic. The fact that no circulation could take place in the Mediterranean had an important bearing on its animal life. They expected, when sounding, to come on an abundant fauna, instead of which the dredge brought up nothing but mud. The blue colour of the water in the Mediterranean, and also in the Lake of Geneva, was due to the minute diffusion of fine particles of mud. This fine mud had borne on the distribution of marine life in the former waters, as it choked them, so to speak, and thus prevented their multiplication. The organic matter at the bottom of this sea used up most of the oxygen when decomposing. This organic matter was poured into the Mediterranean by the rivers. Turning his attention next to the physical conditions of the Red Sea, Dr. Carpenter showed that its upper waters had a very high temperature. Even at a great depth there was a general temperature, even in winter, of over 70°. There was no large amount of organic matter poured into it, and hence he thought that an abundant fauna would be found along the Red Sea floor, simply because there was no decomposition of oxygen by organic matter. This was proved by the abundance of corals in that sea, as these forms cannot live except in purer water. He thought that the reason why reef-building corals could not live at a greater depth than 25 fathoms was entirely due to the temperature. Wherever the colder sea currents kept up a temperature of less than 68°, coral reefs could not grow, in fact, that these animals could not live where the temperature was less than 68°. Hence the limited vertical distribution of coral-reefs. If this was true, then they ought to find reef-building corals at greater depths in the Red Sea, where the deep temperature was so much higher, and he ventured to prognosticate such would be found to be the case. In the sea, shut out by islands, &c., the temperature was the same as that of the neighbouring ocean, but it had not a lower temperature than 51°. He thought the fissures in the barrier rock allowed water of that temperature to flow in. In conclusion, he showed how different would be the animals entombed in the deposits of these different seas, and the large bearings the question had on geological deductions.

Prof. Phillips then referred to the movements of the atmosphere as illustrating the circulation of water in the ocean. He thought Dr. Carpenter's theory about the vertical distribution of reef-making corals being due to temperature would throw great light on geology, and enable geologists better to ascertain the physical conditions of ancient seas. He thought nothing had been read for many years before the section which would prove so suggestive to geologists.

In reply to Mr. Balls, Dr. Carpenter remarked that all rivers contained a large amount of organic matter—a sort of dilute protoplasm. In the Black Sea the specific gravity varied according to what was poured into it by rivers, and the conditions of life were the reverse of those of the Mediterranean. The doctor stated, in conclusion, that he did not himself lay any claim to being the author of the theory of general oceanic circulation.

FRAGRANT BISULPHIDE OF CARBON.

IT will be a matter of interest to some of our readers, says the *British Journal of Photography*, to know that the usually offensive liquid, bisulphide of carbon, can be obtained free from unpleasant smell, and this as an article of commerce. The value of the liquid as a solvent for resin and other purposes is very well known, but its extremely unpleasant odour had hitherto greatly limited its use, notwithstanding the fact that it is very much cheaper than ether, and can be employed for many of the purposes to which ether is at present solely applied.

We do not know by what process the commercially purified bisulphide is prepared; but, on a small scale, the following plan succeeds very well :—Shake up about one per cent. by weight of corrosive sublimate with the liquid bisulphide, and allow the two bodies to stand for several days with repeated agitation. Some sulphur compounds appear to be removed in great part or decomposed by this treatment, for the mercury salt is rendered nearly black, owing to the formation of sulphide of mercury. This treatment so far reduces the unpleasant smell that, in distillation, a comparatively sweet-smelling liquid is obtained; but a much better product is prepared if the bisulphide, after the treatment with the corrosive sublimate, be mixed with one-third of its volume of almond oil, and then distilled after the mixture has rested for some time. Of course the bisulphide only distils over, since the oil is not volatile, but the former is now found to possess a rather agreeable ethereal odour. It is probable that the oil acts in somewhat the same way that fat or oil does in retaining the perfumes of flowers. In the south of France this power is taken advantage of for the extraction of the delicate odoriferous principles of some flowers; but we employ the oil, in the case of the bisulphide, to remove a very unpleasant smell. The treatment is in both cases effective, whatever its rationale may be, and we can convert bisulphide of carbon into a liquid of agreeable ethereal odour. Now that the purification has been effected on a large scale, we hope to see the bisulphide employed for many photographic purposes for which its use has been hitherto greatly limited.

New Microscopic Slide.—At a late meeting of the Biological Microscopical Section of the American Academy of Natural Sciences, reported in the *Philadelphia Medical Times*, Dr. Hunt called attention to an ingenious slide invented by Mr. D. S. Holman for exhibiting infusoria, especially under the gas microscope. These slides are made by grinding a deep depression in a thick slide, and then making a very shallow circle all round the deeper central cavity. If the shallow depression be filled with the organisation in water which it is desired to study, and covered with a thin glass, in a short time the shallow circle all round the margin will be filled with minute bodies, often zoospores or other objects in the life-history of the object in the deeper cell. The pressure of the atmosphere retains the cover in position.

THE WATCH, AND HOW TO REPAIR IT.

By "SECONDS' PRACTICAL WATCHMAKER."

(*Continued from page* 581.)

THE former remarks in connection with the horizontal escapement are intended as a popular description of that particular arrangement. Proceeding further to consider it, we refer to Fig. 9, which represents the horizontal escape-wheel tooth in action with the cylinder C, both lockings and impulses being shown, the lockings at M N, the impulse at O O H L'; the wedge tooth L is represented as just having fallen from the outside impulse F on to the inside locking M, the point of the tooth there resting during the motion of the cylinder, in common with the balance in the direction P; so far, then, a dead or repose of the train of wheel-work until the return vibration of the balance, which would permit the point of the tooth L to escape from the locking M, and continue to press onward the section of the cylinder M N, till it assumed the relative position as at I H; the wedge having gradually pressed onward the cylinder C until L' had slipped from the curved face of the cylinder C N, and would have advanced so far, and fallen from the cylinder at H, and thus have that portion of the outside of cylinder presented to the succeeding tooth of escape-wheel, in order that when that tooth had fallen it would rest upon that part of the cylinder marked I; therefore the angle of escape is shown by the dotted portion of the diagram marked O O, for during the advance and pressure of the wedge tooth on the edge of the cylinder, it gradually advances and presses forward the cylinder till it escapes from it, and when the point of the tooth falls either on the outside or the inside, the fall of such tooth causes the "tick" which is recognised when heard. The "tick" is caused by the escape-wheel teeth falling alternately upon the outside and inside of the cylinder.

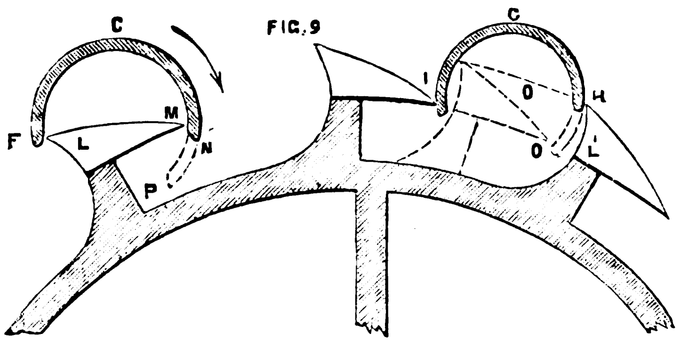

FIG. 9

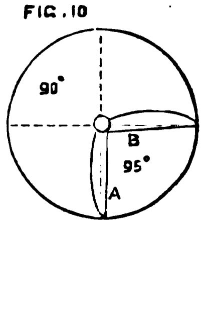
Therefore it is important that the distance that the teeth fall upon the cylinder should be equal; there is, therefore, a rule by which examiners judge the quantity of "drop" (as it is termed) necessary. When the watch is held firmly, and the balance fixed by a thin wedge of cork, and the escape-wheel tooth inside the cylinder as represented at L M; when the wheel is pressed by a nicely-cut peg the tooth should have appreciable shake as freedom; and also when the cylinder is brought into the relative position as represented at I L H, the escape-wheel should have exactly the same amount of shake or freedom as in the former instance. If all the teeth are tested in this manner, and the point of the escape teeth pass over the centre of the cylinder lower pivot hole, the cylinder and its depth may be considered correct. The angles of the teeth, as shown in Fig. 9, are somewhat in excess of those usually adopted in the early watches by Graham and others of that period, which produced scarcely half a turn of motion of the balance, but since the time of Professor Robison the angle of the teeth has been greatly increased, until our foreign neighbours have produced the present form of escape-wheel teeth, which in practice is found to be all that could be desired to produce the great end in view—namely, steady and good timekeeping of the watches to which such escapements are applied. But we are compelled to remark that there are many Swiss watches, even at the present day, with escape-wheels having teeth of various angles, some even similar to Graham's, but they are rather to be catalogued as ironmongery than as watches.

Having thus far followed the escapement of the horizontal watch, we have to be equally familiar with the "verge" escapement, because, although an old-fashioned piece of mechanism, it is to be found in every part of the world, and it is supposed (and not without cause), that very few minds are attracted toward it in such a way as to obtain for it the best result, for when all its parts are thoroughly worn out, and the escapement is in its worst possible condition, the verge watch will continue to tick, and that state of things occasionally satisfies; but if the best result is required, a deal of thought may be bestowed upon it, and it will be found that the verge escapement requires as much thought and care as any which has followed.

It is very important that the angle of the verge should be attended to, also that the balance-wheel should be hung so that its teeth are equal on each pallet, and that the drop of the teeth on the verge pellets should be as nearly equal as possible. We will first notice the angle of the pallets, which will, perhaps, be better understood by the diagram 10, and must be considered as the most important part of the escapement. By the term "angle" is meant the relative positions of the upper and lower pallets one to the other as regards their angular opening. For instance, holding the balance (with its verge secured thereto) in the left hand, and the lower pivot upward, look down from it toward the upper pallet, and observe whether the face of the lower pallet and that of the upper one form nearly a right-angle triangle, *i.e.*, about a quarter of a circle. By this term "quarter of a circle" I intend to direct the mind's-eye in a popular manner to the subject, and thus follow more in detail. Fig. 10 will assist in further describing the verge escapement. The circle represents 360°, divided into quadrants by dotted lines of 90° each; therefore, by laying down upon the circle the faces of the two pallets, it will be observed that the opening of the pallets in the diagram represents rather more than a quarter of a circle, and thus it should be in practice. Their angular opening is about 95°. If the opening of the pallets were only 90°, and the escapement otherwise good, the backs of the pallets would strike the banking-pins, if banked inside, and whether banked inside or otherwise, when they were made free the verge would hang on its bankings, and no remedy could be devised to alter it; such a defect, it is well known, would cause very irregular going of the watch. See, therefore, when looking down at the verge "angle" that the pallets stand similar to 95°, as marked in the diagram. If so place the escapement together, leaving only just freedom of balance-wheel as regards end shake. If holes are good size, and the verge not worn, proceed to try the "drop" of balance-wheel teeth on the verge pallets. Therefore hold the upper-plate in the left hand, keeping the balance steady by means of the fore-finger, then with the point of a nicely cut peg press the balance-wheel by its pinion so as to impel the wheel forward. If the teeth drop the same quantity upon each pallet, that part of the escapement may be left without further alteration; but then, before deciding whether the "drop" is in excess, the hanging of the wheel upon the verge body should be seen to; that is to say, the teeth of the balance-wheel should be the same distance from the body of the verge at the upper-pallet as they are at the lower one, which may be seen when the verge is turned round, so that the pallets are from the teeth of the wheel, in which case the wheel can be turned round and easily determined. The next procedure will be to see that the balance-wheel teeth are not too close nor too far from the body of the verge. The general rule will be to have the teeth of balance-wheel just free of the verge, in which state it is termed "'scaped" full close; that is, it cannot be 'scaped closer; at the same time the balance-wheel must have no end shake. Then follows the trial as to the quantity of drop of wheel on the pallets, and this leads to ascertaining the breadth of the pallets, for if the pallets be narrower than they should be, the balance-wheel teeth will fall sooner than they would were the pallets broader, and consequently the teeth will have greater drop on to the other pallet. It is, therefore, necessary to keep the verge pallets as broad as possible for the sake of gaining advantages of leverage, and also to reduce to the smallest limit the drop of the balance-wheel teeth on the pallets. To test the breadth of pallets allow the tooth of wheel to drop from the lower pallet to the upper one, keep the balance perfectly steady at that precise instant, then turn the balance the least bit possible back, so that the *edge* of the lower pallet is presented to the back part of the balance-wheel teeth, and then try if the wheel has perceptible shake or freedom; if so, it would be right; if not, narrow a trifle, but be mindful to keep the edge rounded from the back of pallet, because that shape permits free motion between the backs of the balance-wheel teeth and verge pallets. If the wheel has excessive shake or freedom on the pallet's edge that pallet is too narrow, and no remedy is at hand but another verge, if the wheel is the proper depth on the body. In trying the drop of wheel on the pallets the angle of the verge has to be kept in view; for instance, should the pallets be very open, the drop would be greater than when the angle is correct, so that although the wheel may be 'scaped quite close, yet with open angle of verge the wheel will have excessive drop which cannot be avoided unless the pallets are closed. By a little practice the verge angle may be altered, either opened or closed, in the following manner. Some verges are very highly tempered; but if so, in most instances, the pallets may be closed without breakage. Having fixed in the vice a brass stake, and holding the balance firmly in the left hand, place the lower part of the verge on it with the edge of the pallet somewhat raised from the stake, then with a hammer, such as might be used for ordinary work, strike the edge of pallet downward with little force at the first trial; should it not yield, then make another trial with a little more force, and in this way the angle may be formed at pleasure; be sure that the verge lies fairly level on the stake, else there is danger of it breaking. Thus far we have before us a few of the leading principles connected with the verge escapement, but although there are many other points to be considered relative to it, they more specially belong to the jobbing department.

FIG. 10



Having left the escapement as complete, it is necessary to try its correctness; and, therefore, when the watch has been cleaned, put together, and ready for the balance to be pinned in, it will be found of great service to have the watch going without the pendulum spring; therefore mark where end of the spring lies, then remove and clean it. Screw in the verge and balance; having seen that the verge holes are of the proper size, wind the watch a little, and observe the amount of vibration of the balance (half a turn is considered fair motion) when acting on the lower pivot; then, when it is acting on the upper one, and probably the two actions will be similar. Next hold the watch so that the follower is downward, the frame being held vertical; observe the balance motion in that position, for this is a test whether the upper pallet will catch or hang on the balance-wheel teeth, and is a very general fault with verge watches after repairs. Trying thus without the pendulum-spring saves a deal of trouble, because the tension of the pendulum-spring assists the pallet to pass the teeth of wheel, provided a slight catch only existed, and hence this kind of slight defect causes many watches to be complained of as either frequently losing a great deal, or at times stopping. This part of the trial being disposed of, reverse the frame, and hold it so that the follower is upward, and the motion of the balance when in that position will test whether the lower pallet is perfectly free. When such conditions are obtained from a verge watch, and the balance-wheel teeth have very little drop on the pallets, there need be no fear as to the watch going fairly well. Our next article will introduce to us the patent detached lever watch.

Oxyhydric Light.—"The entire town of Buffalo, U.S.A., is now lighted by hydrogen gas, extracted from hydrate of lime, carburetted, and burnt with the oxygen extracted from the atmosphere. The cost of the hydrogen is about a penny per cubic metre; that of the oxygen varies with the price of coal, and is estimated at the value of six kilogrammes (18lb.) of coal, say 2d. to 3d. The oxygen is nearly pure, containing only about 3 per cent. of azote." So says an old established "magazine." Will any of our American correspondents kindly inform us how much (if any) of the above statement is true.

LESSONS ON CHEMISTRY.*

By SELIMO R. BOTTONE.

(Late of the Istituto Bellino, Novara, Italy.)

(Continued from page 579.)

215.—WE have seen that sulphur can be made to unite directly with oxygen in two different proportions—viz., to form sulphur *dioxide* SO_2, and sulphur *trioxide* SO_3 (163). Placed in contact with water, both these sulphur oxides form sulphur acids, and it is of course essential to be able to distinguish them by the name. The mode in which the distinction is made is as follows:—The acid formed by the union of an element with the smallest number of atoms of oxygen takes the termination *ous;* thus, sulphur*ous* acid. The acid containing the larger number of atoms of oxygen is known by the ending *ic;* as sulphur*ic* acid. It sometimes happens that after two acids of a self-same element have been discovered and named, others are discovered; in such cases prefixes are used to denote whether the new acids contain more or less oxygen than the old ones. The acids formed by chlorine will be found to exemplify this matter very clearly. In this series we have:—

Chlorous acid.
Chloric acid.
Hypochlorous acid (from *hypo*, under or less).
Perchloric acid (from *per*, over or more).

216.—With regard to the names of the salts formed by the union of acids with bases, it is only needful to note that those acids, the names of which terminate in *ous*, form salts, with names ending in *ite;* thus potassium united to *chlorous* acid, or to *hypochlorous* acid, will form a potassium chlor*ite*, or hypochlor*ite*. Acids, the names of which terminate in *ic*, give rise to salts, with a name ending in *ate;* as potassium sulph*ate*, potassium chlor*ate*, and potassium perchlor*ate*, for compounds in which potassium is in combination with sulphuric, chloric, and perchloric acids, respectively.

217.—Perhaps the most vexed question of modern chemical nomenclature is the one concerning the correct application of the word *acid*. While some chemists maintain that no real *acids* can exist without the presence of the *elements of water*, others uphold that these hydrated bodies, usually called *acids*, are in fact only the *hydrogen salts* of the true acid; and regard as the real *acid*, the body which is usually known as the *anhydride*.

In order that the reader may be in a position to judge somewhat of the merits of these rival opinions, it is necessary to throw a glance at the progressive steps made in our knowledge of the constitution and properties of acids.

Until the time of the discovery of oxygen, little or nothing was known for certain of the constitution of acids; and no attempt had been made to theorise on the reason of their acidity. Lavoisier, basing his ideas on the limited number of acids then known, came to the conclusion that the acidity† of the bodies in question was derived from the oxygen they contained, and in accordance to this view gave the name oxygen, from *oxys*, "acid," and *gennao*, "generate," to the newly-discovered element. But it was not long before it became known that many acids existed which did not contain oxygen as a constituent. Hence it was evident that oxygen was not *the* acidifying principle. Chemists then divided acids into two groups—viz., (1) such as contained oxygen, and (2) such as contained no oxygen. The latter were known as *hydracids;* the former as *oxyacids*. As it was found that those oxidised bodies which played the part of acids when combined with the elements of water had no action on litmus, and did not combine with bases, unless water were present, it became necessary to include these elements of water in giving the composition of the true acid; while the body which formed the acid on admixture with water was designated by the term "anhydrous acid," or more recently "anhydride." The following table of a few of the oxyacids and hydracids will serve to illustrate the two groups into which these bodies were divided:—

Hydracids.

Hydrochloric acid, HCl.
Hydrobromic acid, HBr.
Hydriodic acid, HI.
Hydrofluoric acid, HF.
Hydrosulphuric acid, HS.

Oxyacids.

Nitric acid, HO,NO_5.
Sulphuric acid, HO,SO_3.
Carbonic acid, HO,CO_2.
Chloric acid, HO,ClO_5.
Perchloric acid, HO,ClO_7.*

A cursory glance at this table at once shows that no point of resemblance exists in the constitution of these two groups when expressed in the above manner. Yet in their physical properties, in their behaviour towards bases, and in their general chemical reactions, the greatest similarity was found to prevail. When the so-called hydracids acted on metallic oxides (bases), water, and a salt of the acid employed, was formed. The same was found to take place when an oxyacid acted on a base; and, notwithstanding the exact correspondence of the reaction in both cases, it was customary to express these changes in two different ways, as the following equations will show:—

For hydracids.—The action of hydrochloric acid, &c., on potassium oxide, &c.:—

$$KO + HCl = HO + KCl.$$

For oxyacids.—The action of nitric acid, &c., on potassium oxide, &c.:—

$$KO + HO,NO_5 = HO + KO,NO_5.$$

The incongruity of this view soon led to a more rational method of viewing the constitution of acids, and it was soon shown that all these bodies might be ranged under one head—viz., that of hydracids.

The following formulæ and equations, illustrative of the composition of the acids and their action on potassium oxide, will prove how much this view simplified the comprehension of the subject:†

(1) Hydrochloric acid, HCl.
Hydrobromic acid, HBr.
Hydriodic acid, HI.
Hydrofluoric acid, HF.
Hydrosulphuric acid, HS.
Nitric acid, HNO_6.
Sulphuric acid, HSO_4.
Carbonic acid, HCO_3.
Chloric acid, $HClO_6$.
Perchloric acid, $HClO_8$.

(2) Action of hydrochloric acid, &c., on potassium oxide, &c.:—

$$KO + HCl = HO + KCl.$$

And in the case of sulphuric acid and potassium oxide, &c.:—

$$KO + HSO_4 = HO + KSO_4.$$

This view, with the addition of the changes in quantity, which the new atomic weights have necessitated, is the one which now meets with the general approbation of chemists. Hence we may define an acid to be "the hydrogen compound of a radical, in which the hydrogen can be replaced by a metal." The radical may be an element, as in hydrochloric acid; or it may be a compound, as in sulphuric acid. The only difference in the formula of the above and other acids will be that necessitated by the view that the relative atomic weights of hydrogen and oxygen, &c., are as 1 to 16. The annexed is a tabular view of the constitution of the above bodies, as expressed in the modern notation:—

Hydrochloric acid, HCl.
Hydrobromic acid, HBr.
Hydriodic acid, HI.
Hydrofluoric acid, HF.
Nitric acid, HNO_3.
Hydrosulphuric acid, H_2S.
Carbonic acid, H_2CO_3.
Chloric acid, $HClO_3$.
Sulphuric acid, H_2SO_4.
Perchloric acid, $HClO_4$, &c.

218.—This is the view which we have ourselves followed in the course of the lessons. It by no means follows that the above formulæ represent the exact position of the various atoms in the molecule. It does not appear probable at present that we shall ever know the mode in which the atoms are arranged. But we do know that in some instances a compound splits up in one way, and in others in a mode quite dissimilar; and it is always well to bear in mind the various groupings to which these various modes of decomposition point. As examples, we may quote the different results of the decomposition of sulphuric acid, according to the method employed. When sulphuric acid is distilled along with phosphoric anhydride, this latter body seizes on the oxygen and hydrogen contained in the acid in the proportions to form water, leaving sulphuric anhydride, thus:

$$H_2SO_4 + P_2O_5 = H_2PO_6 + SO_3.$$

From this reaction it is evident that we may consider sulphuric acid as being constituted of one molecule of sulphuric anhydride united to one molecule of water,

$$H_2O.SO_3. \quad \text{(See 165.)}$$

By the aid of heat alone sulphuric acid splits up into sulphurous anhydride, water, and oxygen,

$$H_2SO_4 = SO_2 + H_2O + O.$$

In this latter case we may suppose the constitution of this acid to be:

$$SO_2 \begin{cases} HO \\ HO \end{cases}.$$

219.—Those who give the name *acids* to the bodies which we have hitherto termed *anhydrides* do so from an idea that these bodies are the radicals of the salts formed on union of the acid with a base; but a moment's consideration will show how fallacious this application is. It is admitted on all hands that in the bodies usually termed acids, the hydrogen contained in them plays the part and holds the place of any metal with which the acid can combine; thus, in sulphuric acid H_2SO_4, the hydrogen holds exactly the place of potassium in potassium sulphate, K_2SO_4. But it must be remembered that the majority of these acids, or *hydrogen salts*, as they are sometimes called, are sour, corrosive, redden litmus paper, &c., and that these *acid* properties disappear in exact proportion to the amount of hydrogen replaced by a metal. Hence it is evident that the name *acid = sour* is more appropriate and more applicable to these bodies, as a class, than to the anhydrides, which do not exhibit any of these distinctive properties, unless placed in contact with the elements of water. But the anhydrides (generally speaking) are *not* the radicals existing in the salts, any more than the metallic oxides are the bases; for instance in the presence of potassium oxide, sulphuric anhydride is changed as follows:—

$$K_2O + SO_3 = K_2SO_4.$$

Now, if it be really desirable to limit the term *acid* to the radicals of the salt, it is evident that the real acid in the bodies H_2SO_4 and K_2SO_4 must be the compound SO_4, and not SO_3, &c. The fact is, the terms *acid* and *base* are in the highest degree unscientific and unsatisfactory; and it is much better to use the terms *chlorous* and *basylous* for the negative and positive radicals of a compound than to continue the employment of the words acid and basic in any other than an adjective sense.

† Acidity, sourness, capacity for combining with metals, &c.

* These formulæ are all according to the old notation, taking the atomic weight of oxygen as 8.

† For the facility of comparison these formulæ are also given with the old notation.

NEW SAFETY LAMP FOR MINERS.

AT the recent meeting of the Iron and Steel Institute at Glasgow, Dr. Irvine introduced to the notice of the members a new safety lamp, based on the now well-known phenomenon of the singing flame. He stated that when a mixture of any inflammable gas or vapour with air in explosive proportions passed through, and was ignited on the surface of, a disc of wire gauze of such mesh as to prevent the passage of flame, and a suitable tube or chimney was placed above, and surrounded at its lower end, the disc preventing the admission of atmospheric air to the chimney except through the wire gauze, a musical sound was produced, varying in pitch, &c., with the size of flame and dimensions of the chimney. In this, as in other flames singing in tubes, the sound was caused by the vibration of the flame determined or intensified by the current up the chimney, and communicated to the column of air or gaseous fluid within the chimney, whose length commanded and timed the rapidity of the vibrations, so as to produce a given note, just as the flutter of the air originating at the embouchure of an organ pipe was commanded by the length of the pipe. The conditions under which this flame was produced differed considerably, however, from those of other singing flames. The hydrogen jet, for instance, was burned in an open tube, to which air was freely admitted at the lower end, and it was necessary that the tube inclosing the jet should be lowered more or less till the singing point was found. In Dr. Irvine's singing flame, the tube was not open at the bottom, and no admission took place except through the wire gauze, and the note was produced when the flame was at the lower extremity of the tube or chimney. These were the conditions which gave to this flame its applicability to the purposes for which he (Dr. Irvine) employed it. The fact of the combustion of an explosive gaseous mixture on the surface of a material impervious to flame (viz., wire gauze, originally employed by Sir Humphry Davy in the construction of safety lamps), suggested the possibility of employing this flame for the purpose of giving warning by sound of the presence of an explosive atmosphere, or elsewhere, by means of a lamp suitably constructed. Accordingly, he had had lamps made for giving light, which, while the atmosphere was not contaminated by fire-damp or other inflammable gas, burned in the usual way, but which, as soon as such a gas mixed with air in explosive proportions entered it, appeal to the ear by a loud musical sound, as well as to the eye by its effects on the appearance of the flame in the lamp—just as in the "Davy." In one form of the lamp, which was more particularly adapted for the use of the viewer or wasteman of the mine, the air entered near the top of the lamp, obviating the necessity of turning the instrument on its side, as it was frequently necessary with the "Davy," when but a thin layer of fire-damp was floating at the ceiling of the mine. In another form the lamp was adapted to the use of the working miner, and a superior light was obtained by the use of paraffin oil. In a third form, specially constructed with the object of being a warning apparatus as well as a stationary light, the sound was given forth when an atmosphere of gas and air under the explosive point entered it. Dr. Irvine had thought of a variety of applications of this singing flame besides safety lamps, but he brought only one more to the notice of the meeting —viz., its use as a fog horn, which on account of its portability, simplicity, and cheapness, might take the place of a costly apparatus, and would be highly suitable for railway junctions, or other situations of danger.

The merits of the new lamp have been freely discussed at the various meetings of those interested in collieries which take place at this season, and a great diversity of opinion has been expressed. At the meeting of the South Midland Institute of Engineers, Mr. Bromley said he thought the invention was one of considerable merit as an alarm lamp, to be hung up at the end of the workings, there to indicate when danger existed. In that shape it would be a tell-tale more likely to prove effective than were the instruments now in use. As a lamp for the every day use of the miner, he did not think the invention was of great value, because when the gas reached a certain point the lamp ceased to afford light to the workmen. The impracticability of such an invention in the North Staffordshire pits would appear when he stated that at that hour there were many miners at work, in that division of Staffordshire, with the gas burning upon their lamps all day long. —Mr. Glennie thought that as the lamp did not begin to sing until the gas and air had arrived at a stage at which the mixture became highly explosive, the fact of its ceasing to give light to the workmen would be an advantage. If he mistook not, the Government Inspectors and other official personages regarded the existence of gas in such a degree as calling for a cessation of labour. No doubt many mines were carried on in a loose way, and perhaps considerable risk; but what would be the position of a mine manager in the event of a fatal explosion occurring at a pit worked under the circumstances mentioned by Mr. Bromley? He thought that although the lamp might not be of so much practical utility as to supplant other lamps at present in use, yet that it was an invention of great value, to which the attention of the Institute might well be given with great deliberation.—The Secretary said that Dr. Irvine had visited Birmingham with a view of making some business arrangements with a lamp-making firm, for the bringing of the lamp into the market as an article of commerce. So soon as two lamps were ready the Dr. had promised to send them to the Institute; and he (the secretary) would take care that they should be in a position to experiment with them. He explained that the lamp, which was fed by paraffin at the bottom, and did not require the removal of the top in order that it might be replenished with oil at the same time that it went on burning, was one from which much practical good might be looked for. After the adoption of such a lamp, miners would have no excuse who exposed the naked flame of their lamps for any purpose. This brought up the question of the practice of miners smoking in the pits; and an expression of a favourable opinion as to the lamps that the Institute had seen in use in North Staffordshire, which could be locked and unlocked only by a powerful magnet.—The Chairman concurred in the testimony borne to this lock lamp by the other members, but observed that Mr. Heath had himself remarked that if miners were determined to smoke in pits, it was next to impossible to prevent them. This, however did not stop either Mr. Heath, or any other colliery proprietor from doing their utmost to impose obstacles in the way of a practice so greatly to be deprecated.

At the meeting of the same Institute held at Stoke, a modification of the lamp was shown, in which the sound was given forth before the proportion of gas was so great as to make an explosive mixture. The use of such a lamp, which is not intended for workmen, would be to indicate the presence of a small quantity of gas, the approach of danger, and the necessity for looking to the ventilation. The working of the principle was also shown in its application to a fog horn. Dr. Irvine further exhibited a paraffin safety lamp which gave forth a brilliant light, and the flame of which, on the entrance of an explosive mixture, "sings" like his ordinary oil lamp. The paraffin lamp is so constructed that the workmen can take out the reservoir and refill it without interfering with the flame, which continues to burn with undiminished brightness, notwithstanding the temporary removal of the reservoir. Mr. W. Ness said, as a practical miner, he considered Dr. Irvine's lamps were perfect, and the paraffin lamp of very great value, because it removed from the miner the temptation to take off the top of his lamp in order to get more light. Mr. Udall and other gentlemen recognised the ingenuity of the invention, but opinions were nevertheless divided as to its practical value.

VIENNA UNIVERSAL EXHIBITION.

HER Majesty's Commissioners for the Vienna Universal Exhibition have obtained answers to a series of questions of importance to exhibitors.

Machinery and apparatus specially adapted to the requirements of the exhibition may be supplied by exhibitors, as, for instance:—Boilers for the production of steam for engines. Steam-engines for driving the main shafting. Gas and water-power engines, for driving single machines and groups of machines. Large and small pumps for waterworks and fountains. Travelling cranes, with normal gauges of 1·5 metre (4ft. 11in.) Overhead travelling cranes, with winch and moving gear, with a gauge of 10·5 metres from rail to rail. Hydraulic lifts for raising persons. Portable engines for service outside the Machinery Hall. Exhibitors supplying such machines and apparatus, intended for special service during the exhibition, will enjoy special privileges. If British makers lend cranes, hoists, boilers, engines, &c., for use of British exhibitors, no fees will be levied by the Imperial Austrian Commission for the use of the same by British exhibitors. But if British exhibitors lend such machinery for the use of foreign exhibitors, arrangements will be made by the Austrian Director-General to indemnify British Exhibitors for the use of their machinery.

The power required to set machinery and main shafting for driving machinery in motion will be supplied by the Austrian Commission, and exhibitors will in no case be charged for motive power supplied by the main driving shafts. The moving force will be transmitted by two horizontal shafts of a diameter of about 4·39in., and at 120 revolutions per minute. Exhibitors supply the pulleys for the main shafts, as well as any other gear and driving bands, at their own cost. The preservation, cleaning, and oiling of the main shafts will be attended to by the Austrian manager, but exhibitors will have to attend to the preservation and oiling of the gear supplied by them, as also to the security of their straps.

Brickwork foundations in the Machinery Hall must be built at the cost of the exhibitors, and be finished and ready for receiving the machinery by the 15th of March, 1873; but the brick foundations and the stonework for engines and steam boilers, &c., employed for setting in motion the machines exhibited, will be constructed by the Austrian Commission, according to the plans of the exhibitors. The main lines of pipe for water, steam, and gas will also be laid by the Austrian Commission, and the exhibitor has only to supply the connecting-pipes with his machines.

Coals from the best Austrian and Prussian coal mines, and feeding water for boilers, &c., will be supplied by the Austrian Commission free of expense. Stokers will also be provided for the steam boilers lent for service in the exhibition, or, if the exhibitor should prefer to employ his own people, the wages of the latter will be paid by the Austrian Commission, according to the fixed tariff.

The whole exhibition ground will be drained by a system of drainage-pipes, carrying water and liquids to the Danube, and every measure has been taken to have a sufficient supply of water in all parts of the exhibition. Water will be furnished at a pressure of about 24ft. at low pressure, and about 120ft. at high pressure. Gas will be furnished by the Imperial Continental Gas Company at the usual pressure.

Steam pressure generally at five atmospheres, but in foreign boilers is not limited, although they will be subject to the Austrian laws and regulations. Single boiler-houses are erected at the rear of the Machinery Hall, about 40ft. distant, but a special boiler-house for British boilers will be built by the Austrian Commission.

Traction engines, locomotive steam carriages for ordinary roads, steam omnibuses, and similar kinds of self-propelling vehicles, will be allowed to run about during the exhibition, in some parts of the park and the exhibition grounds. In fact, traction engines, road rollers, self-propelling steam carriages, steam omnibuses, and steam pleasure-carriages, will be very welcome. There will be some work of importance to be done by steam road-rollers, and, in case of any work performed for the installation by traction engines or road-rollers, all expenses will be paid by the Austrian Commission.

In case of railway locomotive engines and carriages being sent to the exhibition, the rails for them to stand upon must be provided by the exhibitors, and it is very much desired that rails from England should be sent to Vienna as exhibition articles.

There will be competitive trials with steam fire-engines, and the jury and exhibitors are invited to send special engines for this purpose. Such engines will be considered as objects of exhibition, and, if lent for use, fuel and care will be at the charge of the Imperial Austrian Commission.

There will likewise be special trials held with agricultural machines and implements in fields in the neighbourhood of Vienna, or in such places as can be easily reached by the Exhibition Railway. Agricultural machines will be exhibited in a pavilion specially built for that purpose. All machines, &c., intended for the exhibition will be admitted to the Machinery Hall from the 1st of February till the 15th of April, 1873, inclusive, and must be set up by the 25th of April. Machines and apparatus arriving in pieces, and consisting of heavy and bulky parts, must be set up by the 15th of April.

Slate is particularly desired to be sent to Vienna to the exhibition; the slate will stand a chance of being sold at a good price at the close of the exhibition, the Austrian slate being only fit for roofing.

It is also desired by the Director-General that fittings, show-cases, cloth for the covering of walls, window-glass, &c., should be sent from England to Vienna; these would be considered as exhibition objects, and could be sold at the close of the exhibition.

The Director-General has also made special arrangements for storing "empties," which he offers gratis to the foreign commissions.

INSECT METAMORPHOSIS.

THE following lecture was delivered by Professor P. Martin Duncan, F.R.S., at the meeting of the British Association:—Everybody, whether learned or unlearned, is aware that insects undergo changes in their shapes and habits. Great numbers of popular works on natural history have made the description of these changes or metamorphoses familiar to the public, and others have informed the scientific world upon the anatomical and minute changes of structure which accompany the wonderful varieties in form and in method of life. The array of facts is enormous, and yet with all this vast amount of sterling knowledge very little progress has been made towards recognising the cause and meaning of metamorphosis in biology—in the science of life. The facts and details of the subject have been accumulating, but the nature of its philosophy has been studied by very few naturalists, and it is only of late years that Lubbock and Fritz Muller, and a few others, have been stimulated by the light of the theory of evolution to examine into it. Believing that the subject is increasing in interest, and that its consideration bears upon some of the most important theories respecting life, it is proposed to devote this lecture to a description of the different kinds of metamorphoses in insects, and to a consideration of the biological meaning of the phenomena. Let me recall to your recollection two instances of what may be called perfect and complete metamorphoses.

Butterflies and Caterpillars.

When the tenderest cabbages are growing in the early summer, a number of very small caterpillars or larvæ may be seen upon the leaves, devouring them in a regular and systematic manner. Avoiding the leaf-veins as indigestible, they nibble the juicy leaf, and consume daily more than their own weight. These pests of the gardener have small heads and ends, and the body is greenish, and striped with yellow bands, being at the same time hairy. At first very small in size, the caterpillars do not attract much attention, and especially, as after living for a few days, they hide up out of the light, and look shrivelled and ill. After a short time, the caterpillar in retreat bends its back violently, and splits the skin of one of the rings or segments of the part nearest the head, then a vigorous struggle enables the legs and the head to be withdrawn through the crack, and the larva is noticed to have attained a new skin within the old one. It crawls on to its favourite plant and makes up for lost time, grows rapidly, and really may be said to live to eat. It cares not for its fellows, nor for any other leaves; it is content with its own cabbage, and has no ambition and no desire to quarrel or to move away. During growth the powers of mastication and of digestion increase, but they are checked several times by the larva having to pass a period of quietude whilst a new skin is finished under the old, and whilst this is cast off. These skin sheddings have a definite relation to the increasing size of the insect, but they are not simple changes of skin because the old one has become too tight for its rapidly growing possessor. They accompany certain important changes within the insect, and not only is the outside skin shed, but the mucous membrane of the digestive organs and of the air tubes which enable the creature to breathe, suffers also. They are really important elements in the metamorphosis, which term includes the sum of the changes of shape, habit, and instinct. When full growth has been attained, the caterpillar crawls off his cabbage and wanders restlessly about, even to considerable distances, in search of a dry sheltered spot. After having discovered such a locality, it fills up the space between its hind legs with silk, and attaches this part of the body to the wood or stone as the case may be. The larva then hangs head downwards, and forthwith begins to bend its head backwards, upwards, and then from side to side, until, after a little practice, it is enabled to touch the solid substance to which it is hanging on either side of its body. Then some silk is secreted, and by applying the mouth to the spots touched one after the other, a fine sling of silk thread binds the insect down and prevents it from being swayed to and fro by the wind. This is the last act of the larva which shows any evidence of will. Then it begins to look shrivelled, shorter than before, and broader behind the head, and after a time the skin splits, and is shed with greater or less wriggling. A sticky, varnish-looking moisture covers the very different looking thing which now presents itself, and dries rapidly, and forms a case over the skin of the pupa beneath. The alterations within and without the insect at this time, that is to say, during three or four days after leaving the cabbage, are carried out with great rapidity, and the future butterfly is well foreshadowed at this period in the structure of the chrysalis or pupa. Hanging as a chrysalis or pupa in a perfectly immobile condition, neither seeing, hearing, nor tasting, and losing very little weight from the exhalation of its moisture, the insect lives on for many months, and until spring has nearly ended. Then the dark case splits, and a tender white butterfly crawls forth, and, under the influence of warmth, and the sun, becomes dry, stretches, and unfolds its crumpled-up wings, walks feebly upon long legs, trails a short body, moves a curious flexible trunk in front of its head, the result of the modification of its former jaws, and takes to flight. The common white butterfly, whose solitary flight is so zigzag and wandering, and whose flight in company is so tumultous, ascending, and vibrating, lives for love. It has a soul above cabbages, and rarely condescends even to sip or suck the daintiest nectar from flowers. After a longer or shorter existence, it begins to lay eggs, and places them in the immediate neighbourhood of the favourite food of the larvæ, which are to come from them.

The Life Cycle of a False Wasp.

Another familiar example of perfect metamorphosis may be studied in the instance of one of the false wasps *Odynerus parietum*. This small wasp-like insect may be seen on the other side of the Channel in great companies on lucerne and clover when in full flower. It is a solitary kind, and the male and female care nothing for their companions, who rush and tumble over, in, and about the flowers, sucking their sweetness, and squabbling and flying for the freshest corollas. Day after day this buzzing, busy crowd may be seen leading a life of happy enjoyment, feeding, playing, and flirting, but after a while an unusual excitement is noticed amongst a large number of the insects. These extend their flight beyond the favourite field, and seek the neighbourhood of sandy, clayey banks close by. They may be observed digging their heads into the sand with great assiduity, and pulling out sand grains, and gradually forming a hole. Each wasp works independently of its neighbours. As soon as the hole is large enough to admit the wasp's body, the legs remove, by a process of brushing, the particles loosened by the jaws. After a short time the wasp will be found to have made a tunnel, and the constant out-pour of sand and clay indicates that excavation is still proceeding out of sight. Soon the Odynerus perfects two or three chambers deep in the bank and opening into the tunnel. She (for it is the female who does the work) carefully pounds the insides of the cavities and removes all roughness from them, and leaves them as commodious hollows, water-tight, and not likely to fall in. This is not all. On coming back into the light the wasp seizes cylindrical pieces of earth and moulds them, more or less, into shape with her jaws, and places them in front of each other, and side by side, so as to form a hollow tube which sticks out from the bank, and opens into the tunnel. The free end of this ante-chamber is left open, and the pieces of which the whole is formed are gummed together and pressed. The tube is extremely fragile, and the pieces of it are not in contact everywhere. Nevertheless, the Odynerus passes along it readily enough, but no other insect of its size can do so. All this work is carried on whilst the wasp appears to be in an intense state of excitement, and when it is completed the insect flies off to the flowers again; but not to return to its former habits. On the contrary, the purposeless tumbling about of flowers, and the occasional sip of nectar, are forgotten, and the flighty little vegetarian becomes a ferocious and ardent huntress of prey. She seeks the small larvæ of a species of weevil which abound about the plants, and seizing one, digs her sting into it so that a weak venom is introduced close to the nervous system of the victim. The larva is paralysed at once, but not killed; on the contrary, it remains motionless but lives. She then flies off with her prey to the bank, enters the tubular antechamber, traverses the tunnel, and reaches one of the chambers. Here she deposits her insensible victim, and lays one egg close to it. Returning again to the field, she seizes another larva, stings it, and carries it off to deposit it close to the first. This procedure is repeated as many as thirty times, and the chamber becomes full of insensible weevil larvæ and one Odynerus egg. The other chambers are filled in the same manner, and an egg is laid in each. Then the wasp comes out of the tunnel for the last time, breaks down the tubular antechamber, so as to hide the entrance to the tunnel and chambers, flies off, and dies. She never sees her offspring, for which she, a vegetarian, has provided animal food in abundance. The egg is soon hatched in each chamber, and a small, legless, and extremely delicate larva crawls forth, and fixes upon the miserable victim close to it. So tender is the larva that the least roughness of the sides of the chamber would destroy it, and the least struggle on the part of the poisoned weevil grubs would kill it; but all this has been made safe, and the little thing eats into its living prey, and when one is finished it attacks another, until all are eaten up. This is the life of the larva; it is incapable of walking any distance, and simply leads a life of gormandising on the flesh and juices of weevil grubs. It never emerges from the chamber, and when it has no more to eat spins a cocoon of silk around itself, and sleeps therein during the late autumn, the winter, and until the spring. Then a change in form ensues, and a pupa, which greatly resembles the perfect insect, appears under the skin which is shed. In the course of a few weeks the perfect false wasp escapes from the pupa skin, digs its way into the world, and emerges to enjoy the destiny already described. Many other false wasps which belong to the same group of insects as this Odynerus have a corresponding life cycle, and choose many curious kinds of prey, but the formation of the safeguard of the tubular ante-chamber places this kind in advance of all others. It is, then, an example of very perfect metamorphosis with high instinct, and like all other instances of what is termed perfect metamorphosis, there is an intermediate stage of a quiescent pupa between that of the larva and imago, both of which are able to lead independent and distinct sorts of lives, and to take food.

(*To be concluded next week.*)

MECHANISM.*

(*Continued from p. 633.*)

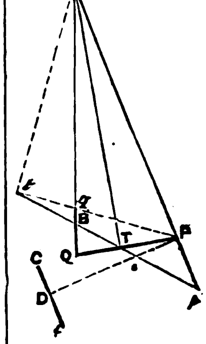
"MOTIONS produced by links," which is the title of this evening's lecture, is a phrase expressive of the leading branch of it only. Mechanicians may have a very clear idea of the meaning intended by it, but to others very varied may be the ideas which the title conveys. Practical mechanics, by the word "links," may have entered the room with an impression that they were about to listen to a discourse upon the elemental pieces of which chains are made. Social science enthusiasts may be anticipating a discussion upon friendship, and even marriage and upon the proclivities of individuals to walk "linking." Antiquarians' thoughts will probably turn to those ornamental extinguishers high above the railings at the doors of aristocratic houses, by means of which, during the last century, "link" boys extinguished their torches. Landowners may be thinking of estates, from the fact of there being generally so many "links" in an acre. A Scotchman's thoughts may revert to one of his country's rivers, and the grounds called "links" lying along its windings; and Americans, if there be any present, may not unreasonably be expecting some description of London sausages, for sausages are called "links" in America. All these expectations must be disappointed. "Link," in an antiquarian's view, is from a Greek word which signifies a lamp; but we have nothing to do with that. In the other sense it is from a German word which signifies "a joint," and it is in the simple sense of a piece joining two pieces, and by which the motion of one may be conveyed to the other, that the word is generally used by engineers. Such a link is either rigid, as in the case of wood or metal, or flexible, as in the case of rope or wire; and it is a means by which the motion of one moving piece is transferred to another. Thus employed, it truly comes under the ordinary definition of "a connecting or joining piece."

A link, therefore, is now to be regarded simply as the connecting piece of two movable pieces; the form and the material are not in any way concerned. Contacts in rolling and sliding cease when we deal with links—flexibility, as in cords, is neither an essential nor a hindrance. It may be well, therefore, to take a preliminary example of a link, for those who have not given the subject attention may be informed that the complexities of link movements far surpass the complexities of cam movements. On the board are a couple of pieces of wood joined by a link, quite sufficient to illustrate the general idea. These two pieces are capable of motion about two drawing pins as centres. A third piece, connecting these two, is the link. If now this third piece be connected with the two movable arms at varying distances from the centres of motion, the paths of the driver and follower will be very different, the variations depending entirely upon the relative lengths of the arms. Sometimes an oscillatory motion of the driver will communicate a circular one to the follower. Sometimes these relations will be reversed. Under other circumstances a continuous communication of motion is impossible, in consequence of a locking of one or other of the arms, owing to the rigidity and length of the connecting link.

The first question to be solved by those who deal with link movements is, what is the law which governs the motions of the two arms when they are under the influence of a link? The law is a very simple one; simple in expression, but complicated in result. It is one of those simple laws that produce very singular consequences; it depends upon the inclination of the link to the line joining the centres of motion of the arms.

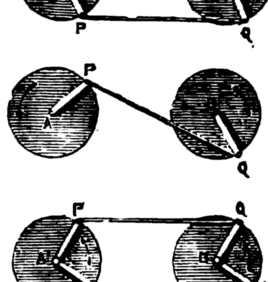
Let A P and B Q or B *q* (Fig. 29) be the arms, movable in the same plane about A and B, P Q or P *q* be the link, then the link will cut the line A B. either in T or (produced if necessary) in *t*. Wherever it cuts, whether between or beyond the centres of motion A B, this law holds good that the velocity ratio of one arm is to the velocity ratio of the other arm inversely as the segments into which this line of centres is divided by T or *t*. Or take it in another form (one more convenient probably in some respects), the velocity of P is to the velocity of Q, as a line drawn from A square upon the link is to a line from B drawn square upon the same link. Observe for a moment the nature of these motions. Assume the shorter arm to be the driver, that driver therefore conveys a very small motion to the driven and longer arm, in certain positions it ceases to convey any motion. For example, in this position, viz., B Q and Q P in one straight line, it cannot convey motion. Putting it in other positions will show the relations more plainly. Observe how slight the motion is upon one arm, and now that the perpendicular from B upon the link is passing from one side to the other, the directional relation of motion also is changed. This is a serious question with links; there is a continual change of the direction and velocity ratio. Through a small motion of either arm there may be what is, for all practical purposes, a communication of uniform motion. This is the case when the direction of the links being produced and meeting as in K, the line joining K and T is at right angles to the link.

FIG. 29



On the table are a number of examples of links; let us follow the action in this one. A and B are the centres of two equal wheels, P and Q pins near the circumferences, P Q the link. If slow motion be communicated to A, then through the intervening link, P Q, a motion will be communicated to B. So long as by the hand or otherwise, P Q moves parallel to A B, then clearly whatever be the motion of A it will be repeated in B. This is the principle on which the ordinary parallel ruler is made. For, in this case of parallelism, the link never cuts the line of centres, the ratio of the velocities of A P and B Q will be constant and equal. You may observe that the motion is apparently communicated with great regularity. In truth it is not so, for the link cannot be left to itself. The hand by which the link P Q has been hitherto supported and guided, is now withdrawn, and you will notice a failure of motion takes place when the pin, P, is in the same line with A B. In fact, there are then two paths which this link, P Q, may take; it has the choice either of ascending or descending, and it will probably take sometimes one course and sometimes the other. The nature of the motion is thus changed, sometimes there will be a complete revolution communicated to B Q, and at other times an oscillating motion only. Conse-

FIG. 30

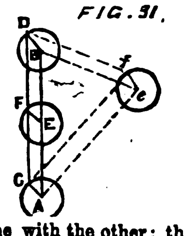


* By the Rev. ARTHUR RIGG, M.A., being the Cantor Lectures delivered before the Society of Arts.

quently, to place a link upon two arms and leave it freely to act, is a matter that is quite hopeless if continued systematic action is required. The second and third parts of Fig. 30 illustrate, by the position of the link and directions of the arrows, what takes place. There must, therefore, be some plan by which this link shall not have a choice of paths.

There are three modes of doing this. In the one case, if we place a third equal crank, and connect it to the others by links, observe the way in which it acts. A C, B D (Fig. 31) are the original cranks, E F (or e f), is a third crank. The link, C, F, D, cannot now leave the prescribed course. A fourth or fifth crank may be added, in fact we may take any number, and we obtain a system of bars capable of a very regular motion one with the other; they move parallel to each other. On the table there are bars so arranged. The link connecting those arms is not free to move, being bound by another arm, and the links are parallel in all positions of the cranks.

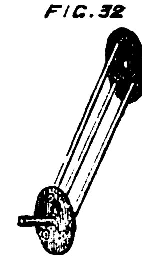
FIG. 31.



There is another mode of preventing an uncertainty in the path, by putting an additional pair of cranks and a second link. Observe, there is now no longer any freedom of position, for each link is compelled by this second arm to retain a preordained course, and the consequence is we have uniform motion in these arms. This is the most simple mode of overcoming the difficulty of variableness in the direction of the link, and it is the plan adopted in all locomotives. You see a link generally on each side of a locomotive, the object being to prevent the accident that has been described, which is sure to happen when there is only one link.

There is still a third plan, viz., to multiply the links. Here (Fig. 32) are two shafts parallel to each other, but the ends are not vertically one over the other. If you look at this yellow bar [the three sloping bars in Fig. 32 were painted three different colours in the model] you will see it is in reality acting as a link. If there was only one bar it might assume a cross position. Owing to the other bars being constrained to follow the path that has been allotted for them, the yellow bar cannot take a cross position. Hence this mode of transferring motion by links from one shaft to another as freely and uniformly as though they were straps. The motion is not very old, having been invented in 1834, when the Society of Arts awarded a silver medal for it. It is mentioned in the "Transactions" for the year 1834, p. 83, and "the silver medal was presented to M. Victor Baum, member of the Royal Chapel of Munich, for a method of communicating rotary motion, a model of which has been placed in the Society's repository."

FIG. 32.



With these three contrivances, links can be safely carried over what are called their centres. These centres are peculiar, and the laws of them are important. You have seen that when a link is in a certain position there is an option of two paths. Both of those paths cannot be followed. Owing to there being, as it were, no decision on the part of the driver, and, in fact, at that particular point, no motion communicated by the driver, it has been called a "dead centre," simply because there is no living motion in it. Mechanics have tried in various ways to overcome a difficulty which, under the influence of a fly-wheel, is more theoretical than practical. On the table is one plan. Here is a section of the vertical cylinder of a steam-engine. When the piston is at the lower part of the cylinder it cannot move the crank, but when it has risen a short distance it is capable of acting upon the crank. This very short additional cylinder causes the double action of another link. By allowing steam to operate in this very small second cylinder, at the instant that the crank reaches a dead centre it is thrown over, and thus the crank of the engine is placed in position for the continued action of its own piston.

On the table are some peculiarities of link motion. Multiplicity of links leads to multiplicity of arrangements and results. [The lecturer here referred to models, which consisted of cranks or arms, acting under the influence of connected links. They were produced to show how rapidly motions could be multiplied by means of links. In one contrivance there were three links and four arms. These caused eight movements in one pointer, consequent upon one rotation of the first crank. In another grouping of links and arms one revolution of the crank produced at the two extremities of the combination alternate rest and oscillatory movement.]

LETTERS TO THE EDITOR.

[We do not hold ourselves responsible for the opinions of our correspondents. The Editor respectfully requests that all communications should be drawn up as briefly as possible.]

All communications should be addressed to the Editor of the ENGLISH MECHANIC, *31, Tavistock-street, Covent Garden, W.C.*

All Cheques and Post Office Orders to be made payable to J. PASSMORE EDWARDS.

"I would have every one write what he knows, and as much as he knows, but no more; and that not in this only, but in all other subjects: For such a person may have some particular knowledge and experience of the nature of such a person or such a fountain, that as to other things, knows no more than what everybody does, and yet to keep a clutter with this little pittance of his, will undertake to write the whole body of physicks: a vice from whence great inconveniences derive their original."—*Montaigne's Essays.*

THE FLOOR OF PLATO.

[4856.]—THE darkening of the floor of Plato, as the sun rises higher above its level, is a phenomenon of so much interest and importance (if fully established) that Mr. Birt will probably not be unwilling to explain certain points in connection with it.

I wish particularly to know whether he has by any test *proved* the darkening to be *absolute*. The determination of the comparative brightness of different regions is so uncertain that one can scarcely tell what reliance to place on observations going no farther. Plato is so much larger than any region of similar extent in the neighbourhood that I find it difficult to understand how the relation in question has been demonstrated.

Another difficulty which presents itself on a perusal of one of Mr. Birt's papers is connected with the curves by which he indicates the sun's altitude and the luminosity of Plato. Having drawn a curve to indicate the sun's altitude in lunar latitude 50° at the equinoxes, and having assumed a very light tint of Plato (0·80 of his scale) to correspond with solar altitude 0°, and a very dark tint (0·70 of his scale) to correspond with solar altitude 40° (this corresponding closely with observation), he says of the resulting curves "one very remarkable feature is that the chromatic curve lies almost wholly within that of altitude, from which it may be inferred that the full effect of the sun's influence is scarcely attained, &c." But so far as I can judge from Mr. Birt's paper, the selection of the relation between the two scales—that of altitude, and that of tint, is altogether arbitrary. Why should not a medium tint, 0·60, for example, have been associated with the solar altitude most nearly corresponding? This, with tint 0·30 for altitude 0°, would have altered the scale. Again, why should not the curve of altitudes be replaced by the curve of sines of altitudes, since the sun's illuminating power on a surface varies as the sine of his altitude above the surface?

I merely submit these points so that I may have Mr. Birt's explanation. I have doubtless misapprehended him in some way or other.

I must confess I cannot accept as decisive Mr. Birt's reasoning (*Monthly Notices*, Vol. XXXI., p. 81) that the want of agreement among the curves of visibility for different spots is at once conclusive that *all* the variations in visibility are not dependent on extraneous circumstances, such as solar illumination, alteration of position on the moon's disc by librations, &c. Much would depend on the nature of the surface. Take half a dozen or more spots on the moon, each a few miles long and broad, and suppose one to be a surface covered with sugar-loaf hills, another covered with domed hills, a third covered with saucer-shaped hills, a fourth covered with saucer-shaped hollows, a fifth with relatively minute walled craters, a sixth with hemispherical depressions, and so on; then these spots would be very differently affected by variations in the sun's altitude above their mean level. As we see these spots, even with the best instruments and under the best conditions, as we should see a terrestrial surface two or three hundred miles away, it is not easy to tell what the structure of their surface may be. (Of course I am not for a moment supposing that the spots are actually covered as above. But, on the other hand, it seems unsafe to suppose that they are all alike as to the general confirmation of their surface.)

RICHARD A. PROCTOR.

THE MOON.

[4857.]—I VENTURE to point out a slight error in the remarks of "F.R.A.S." (let. 4823, p. 639) on this subject. He says that the motion of the perigee is direct when the moon is in conjunction, and retrograde when she is in opposition. There is, however, no necessary connection between the moon's age and the motion of the perigee. The motion is direct (on the whole, during the lunation) when the perigee is in or near conjunction or opposition, and retrograde when the perigee is in or near quadrature. But during the progress of any lunation the motion is sometimes direct and sometimes retrograde, its character when the moon has any given age depending on the position of the perigee with respect to the sun.

Having thought it desirable to go through the calculations respecting the moon on which the numbers given in my answer to W. L. Brown (let. 4790, p. 614) were based, I detected a slight error. The mean advance of the perigee from the node is accomplished at the rate of 60° 1′ 49·4″ (not 59° 58′ 4·8″ as stated in that letter) *per annum*, or almost as much over 60° as the former estimate was under. The mistake arose from my writing in one place 346·667 instead of 346·607 for the mean interval between successive conjunctions of the sun and the moon's rising node. The value now given is the final value, as it is to be entered in my book on the moon.

It follows that the mean interval between successive conjunctions of rising node and perigee is 2190·348 days, or about $1^{1}/_{9}$ day less than six years.

I need hardly say that for 18 years 110 days, I should have written 18 years 11 days for the length of the Saros. I probably wrote 11·0 days (which, be it noted, is not exactly the same thing as 11 days). I may take this opportunity of mentioning that having had occasion to examine the values given in our books for the moon's mean and maximum librations in latitude and longitude, I find slight errors. The computers seem, so far as I can judge from their results, to have overlooked the consideration that the inclination of the moon's orbit cannot have its maximum value at the time of maximum libration in latitude; and, again, that the eccentricity cannot have its maximum value at the time of maximum libration in longitude. The difference is slight, however. Thus I get 7° 45′ instead of 7° 55′ for the maximum libration in longitude, and 6° 44′ instead of 6° 47′ for the maximum libration in latitude, giving 10° 16′ instead of 10° 24′ as the absolute maximum libration. But a more important error has been made as to the extent of the moon's surface brought into view by libration. Instead of a seventh, very nearly a sixth of the farther hemisphere is brought into view, without taking into account the diurnal libration, which raises the proportion to about $^{8}/_{15}$ths. In Klein's "Das Sonnensystem" the invisible part of the moon is set at 0·4248 of the whole surface. This is much better than Arago's estimate; but with the accepted value of the librations (which Klein adopts) should have been 0·4183, without taking diurnal libration into account.

RICHARD A. PROCTOR.

THE MOON'S LIBRATION.

[4858.]—THANKS to Mr. Proctor for pointing out the mistake in my paper (ENGLISH MECHANIC, No. 330, July 21, 1871, p. 424), which most probably arose from my not noticing, at the time of writing, the different directions of the apsidal and nodal revolutions. Although it does not alter the general reasoning, it necessitates a correction of the passage in which it occurs, which should read thus: "As the moon moves from the point of mean distance to that of her greatest distance (apogee), the point of intersection of her equator and first meridian approaches the centre of the apparent disc, and as the period of her motion with respect to the line of apsides is not coincident with that between her passages of the ascending and descending nodes, but is of *longer* duration, the equator *at the epoch of apogee is south* of a line at right angles to the first meridian, which crosses the apparent disc from north to south. When the moon is in apogee under these circumstances, the libration of the centre, which at perigee, was nothing in latitude and longitude, is nothing in longitude, but a measurable quantity in latitude; in other words, the line of libration no longer cuts the centre of the apparent disc at the point of intersection of the equator and first meridian, but at a point having *north* latitude, or *north* of the moon's equator; so that when the moon *arrived* at her descending node the first meridian *was still eastward* of the centre of the apparent disc. [Note.—The *italicised* words indicate the corrections to be made.]

May I be permitted to offer a remark on that part of Mr. Proctor's letter (4790) in which he states "that the interval between successive conjunctions of the perigee and rising node is slightly greater than six years"? From this I apprehend the reader might infer that the three-yearly interval between mean libration occurs alternately with ascending and descending nodes at perigee, so that at the end of every six years from any given epoch of mean libration the returns would be in the same order. Beer and Mädler give the following formula for finding the interval. Half the revolution of the line of apsides = 4·42 years; half the revolution of the line of nodes = 9·31 years, therefore

$$\frac{4{\cdot}42 \times 9{\cdot}31}{4{\cdot}42 + 9{\cdot}31} = 2{\cdot}997 \text{ years,}$$

which is slightly less than three years. In 1865, as stated in my paper, mean libration occurred on October 4, moon in perigee, and descending node. Six years after, epoch of mean libration October 4, moon in apogee and ascending node. In this year, 1871, the perigee coincided with the descending node, not the rising. In 1868 mean libration occurred on October 12, moon in perigee, just past the ascending node; in 1874 it will occur on October 11, just past the descending node. The alternations are, therefore, as follows:—1865 Perigee: Descending node. 1868 Perigee: Ascending node. 1871 Apogee: Ascending node. 1874 Apogee: Descending node. Longitudes of ascending node:—1865, October 8, 201° 12·7′. 1868, October 7, 143° 18·6′. 1871, October 8, 85° 11·4′. 1874, October 8, 27° 9·1′. Time—3,287 days, being less than half a revolution of the line of nodes, and greater than one revolution of the line of apsides. Mean libration on or near October 4, perigee: Descending node and apogee: ascending node. Interval, six years, nearly. Mean libration on or near October 11, perigee: Ascending node and apogee: descending node. Interval, six years, nearly.

From the above it appears that the conjunctions of the perigee and rising node alluded to by Mr. Proctor, attended with a state of mean libration, take place at intervals of twelve years (nearly). Mean libration at the intermediate six yearly interval occurring, with the apogee and descending node. W. R. Birt.

LUNAR ATMOSPHERE.

[4859.]—The following extracts from Mr. De la Rue's address to the Mathematical and Physical Section of the British Association are of interest in connection with the question of the moon's atmosphere:—

"The vaporisation of even solid bodies at low temperatures suggests that a mass of matter in space will ultimately surround itself with its own vapour, the tension of which will depend upon the mass of the body (that is, upon its gravitating energy) and the temperature. If the mass of the body is so small that its attractive force is insufficient to give to the enveloping vapour its maximum tension for the existing temperature, the evolution of vapour will be continuous until the whole mass is converted into it. It is proved by analysis that such a mass of gas or vapour in empty and unlimited space is in a condition of unstable equilibrium, and must become dissipated by continual expansion and consequent decrease of density. It follows that celestial spaces, at least within the limits of the stellar universe, must be filled with matter in the form of gas."

"Professor Zöllner finds, by calculation, that the density of air forming an atmosphere round the moon must be $\frac{1}{10^{334}}$ of that of the air of the earth's surface."

The different tints indicative of the different reflective powers of the materials composing the moon's surface are conclusive as to the *variety* of such materials, and from this it follows that the moon's atmosphere cannot be strictly homogeneous, but must contain vapours given off from each material. The question now for solution is the possibility of the condensation of such vapours in the *immediate* neighbourhood of the moon's surface. W. R. Birt.

LUNAR OBJECTS FOR OBSERVATION, OCTOBER, 1872.

[4860.]—October 5.—Picard A and B of Beer and Mädler with other craters in the interior of the Mare Crisium (*a*). October 6.—Fabricius (*b*), Metius, Steinheil. October 7.—Theophilus; the central mountain is a fine study if coming into sunlight. October 8.—Ariadæus, Silberschlag, Hyginus. October 9.—Cassini, Sulpicius Gallus, Menelaus, Manilius. October 10.—Craters and mountains between Archimedes and Plato. October 11.—The Alps and wedge-shaped valley, the interior of which may be examined for craterlets. October 12.—Plato; the Hartwell ledge on the S.W. border is visible as a fine streak of light fringing the shadow of the mountains on the S.W. of Plato for 48 hours only; if not detected on the 12th, look for it on the 13th. October 13.—Horrebow, its interior wall dividing the crater. October 14.—Hippalus, its divided interior, diverse floors, and included craters. October 15.—Wargentin, Schiller.—October 16.—Full moon, aspect of the interiors of craters, particularly of Maginus and Geminus.

(*a*) A decided instance of change has taken place in the Mare Crisium. Formerly, about 10 or 11 years ago, I *constantly* observed under a high illumination a large white cloudy patch west of Picard; it was larger than the crater, and on its side under a low illumination, I detected a small pit-like marking, very distinguishable from the rest of the surface by its whiteness. Subsequently, two small craters were discovered by Mr. Knott in this pit-like marking, and of late years the cloudy patch has been much reduced in size. 1872, August 18, about the time of full moon, when the light spots on the surface are very perceptible, I observed the locality, and made the following record: "The large cloudy spot west of Picard is not present; its locality is marked by a very faint light spot." The phenomena lately ascertained as characterising Plato render this instance more interesting than it would otherwise be.

(*b*) On the south of Fabricius is a large depression with an elongated central elevation which stretches from the south border of Fabricius. It is proposed to name it Janssen.

Attention is especially directed to the region SS.E. of the Mare Serenitatis, containing several dark spots, among which are Julius Cæsar, the Boscovich of Schröter, and the Boscovich of Lohrmann.

W. R. Birt.

THE AUGUST METEORS, 1872.

[4861.]—I read with much interest the communication from Mr. W. Davenport, which appeared in your last number, having reference to these phenomena, and hope that some further observations may be supplied by any of your subscribers in whose localities the weather was sufficiently favourable. The sky was almost entirely overcast at Bristol on the nights of August 9, 10, and 11, and at Weston-super-Mare, where I was then staying, clouds also interfered with observation. On the 8th, however, several meteors were witnessed, but they were very insignificant objects, and not brighter than stars of the 3rd mag. One bright one was seen on the 12th at 10h. 15m. It passed down the western sky and left a trail of light, which endured but for a moment. Another brilliant meteor, equalling, or even exceeding in magnitude, any of the brighter stars, came under my observation on the 19th at 8h. 50m. It was visible in the E.N.E. part of the sky, and was very star-like in appearance. It did not leave any train of light marking the path it had traversed, and it was of a blue colour. On the 20th I saw another at 9h. 40m. It was rather bright, but its duration was very brief. It passed through Ursa Major.

The Rev. S. J. Johnson, F.R.A.S., of Crediton, Devon, says, in a letter to me, "I only saw three meteors on the 8th up to 11h. 30m., though with clear sky. 9th, a densely-clouded night. 10th, windy. Partly clear at intervals. Watched from 10h. 45m. to 12h. The first meteor glanced through a break in the clouds at 11h. Between 11h. and 12h. I observed twelve. 11th, watching from 10h. 50m. to 11h. 30m., with a clear sky, I saw eleven meteors only. One on the 10th and one on the 11th equalled 1st mag. stars."

Referring again to the letter of Mr. Davenport, it will be seen that he found the radiant point of the meteors which came under his observation was somewhere near 22 Andromedæ. The majority of those meteors which I observed in August last year appeared to emanate from B Camelopardi, or from a point in close proximity to that star. I noticed several meteors distant only two or three degrees from the place I have indicated, and from their paths it was evident that a radiant point existed at B Camelopardi. Each of these meteors had very short paths, and were faint objects, enduring but the fraction of a second. Several other radiant points of the August meteors have been determined. Prof. A. S. Herschel writes:—"The chief radiant point of the August meteors, as observed last year, was certainly northwards from χ Persei (about 3° or 4° towards ι Cassiopeiæ), and it will be interesting to watch if it remains in this position, or returns to a more southerly place, near η or γ Persei, or to B Camelopardi. The position of the radiant point in Pegasus was most imperfectly indicated by the many meteor tracks from the southern constellations, which were recorded among the unconformable meteors noted in last year's shower; but its position seemed at last to be quite distinctly fixed about 3° north of α Pegasi (at R.A. 346°, N.D. 17°) with two other contemporaneous radiant points, one at least of them producing as many meteors as the radiant point in Pegasus, and very definitely marked at R.A. 342°, S.D. 32° (close to Fomalhaut), agreeing remarkably with a radiant point at R.A. 338°, S.D. 28, observed on the 28th of July, 1865. The agreement of the positions is complete (although quite independent) from the observations of both dates, and it will be interesting to trace the return of this radiant point if it should occur again among the unconformable meteors noted in this year's August shower." Unfortunately, however, there have been but few meteors seen during the past month, in consequence of the generally cloudy state of the atmosphere. At some stations, perhaps, the weather may have been more favourable; and if so, the observations made might tend to an augmentation to our knowledge of the radiant points, &c., of the meteor shower of August. There is no reason to suppose that during the last few years the August meteors have become less numerous than formerly; on the contrary, it seems probable from the number seen last year that they have increased.

In regard to the solar observation made by Mr. J. H. Whistle (let. 4792, p. 614), it is not unfrequently the case that the umbra of a solar *macula* is encroached upon by a luminous vein or spot (facula). Previously to the dissolution of all the larger spots, streaks of bright light may be observed encroaching upon the penumbra and umbra. This was particularly the case in regard to the immense spot of September, 1870, as will be seen by a reference to some sketches of its appearance on p. 25, Vol. XIII. of the English Mechanic. It is not, however, very often the case that an isolated bright spot is detected in the centre of the umbra of a spot, and it is probable that if your correspondent had used an instrument of greater power, he would have probably seen that the luminous appearance which came under his observation was connected with the edge of the spot by a thin vein or streak of light. Still, observers have noticed occasionally bright spots within the penumbræ of maculæ, and quite possibly Mr. Whistle has made a similar observation. In the immediate neighbourhood of all large solar spots or groups of spots, the faculæ always exist in abundance, and it is not surprising that they should sometimes be observed upon the umbræ or penumbræ of the darker spots when we consider the disturbed condition of the solar surface in which they are situated.

On observing the sun to-day with a 4in. metallic mirror reflector, I saw several conspicuous spots, but none were of great dimensions. They were situated on the eastern portion of the disc. There have occurred lately several exhibitions of the Aurora Borealis. On August 3 and 8 I witnessed the phenomenon. Neither of these displays were exceptionally brilliant, though several well-marked streamers were visible at times, enveloping the stars in Ursa Major and Auriga. A strong auroral glow was also strikingly manifest on both evenings of observation.

Bristol, September 2. William F. Denning.

INTERIOR OF THE EARTH.

[4862.]—"Philanthropist" (answer to qy. 12681, p. 647), is quite mistaken in the reason he assigns for the slower vibration of a pendulum at the bottom of a mine. (In the Hartley Colliery experiment the pendulum vibrated more quickly at the bottom of the mine; but that is a detail.) The portion of the earth above the pendulum (that is, all the matter further away from the earth's centre) cannot under any circumstances oppose the attraction of the rest, but must always (in the case of a mine) tend to increase that attraction. Whether the increase is sufficient to make up for, or more than make up for, the reduction in the actual mass lying nearer to the centre than the pendulum does (as compared with the mass so situated with respect to a pendulum at the surface), depends on the shape and extent of the mine.

Richard A. Proctor.

PROCTOR'S SMALLER STAR ATLAS.

[4863.]—Referring to Mr. Proctor's letter (4699, p. 560), will he please to say if this contains as many objects as the larger atlas? He speaks of each being a companion to a different work. Smyth's "Cycle" is in the hands of very few amateurs. Webb's work is possessed by every one, but it contains many objects not in the "Cycle." T. T.

GULF STREAM AND MAP PROJECTIONS.

[4864.]—To speak of "a map" as "solely intended to give true areas" (let. 4755, p. 583), and having "no occasion whatever to illustrate forms" (par. 2), would strike most people, I think, as mere paradox. The proper means of doing this would surely be a *table* of mere numbers and names, as Mr. Bottone's chemical one on p. 578; and I regard the grotesque figure that Mr. Proctor conceived to illustrate his excellent "Gulf Stream" criticism rather as an awkward table than a map, good or bad. The essay could hardly be said to need any graphic or tabular illustration at all, beyond such a mental one as most people who have atlases or globes, or have been to school, would carry in their eye. The present deluge of misapplied Mercator charts, however, infects us all with monstrously false ideas of the relative areas of the arctic and tropical regions, whether lands or seas, and was doubtless a main cause of the ridiculous theories he wanted to expose. By the way, he surely does not suppose there was anything newer in his views on the cause of the Stream than in my remarks on different map projections. In what book, or how I first heard of the "Gulf Stream," quite passes my recollection. Probably it was at some lecture; but wherever learnt, I certainly, at a first Atlantic voyage at the age of 20, had precisely the same view of the circulation, its rationale, and its independence of all wind action, as now. Constant evaporation from the hot latitudes, only very partially made up by rain and river returns in the same climates, or indeed anywhere, but mainly by the melting of polar ice, must needs cause a predominant set of the surface waters from the cold latitudes to the warm. On a globe without land, this would be the universal surface motion; but its rotation must make any such currents easterly ones, because each particle, going from a lesser to a larger circle of latitude, carries the slower motion due to the former into a quicker moving zone, and is thus constantly left behind by the ground over which it is arriving; or, in other words, must be constantly moving (relatively to the ground) westward, like the trade winds. Within the range of those winds, then, the surface of sea, and lowest layer of air, have each, independently of the other, a set in the same direction. Were the sea frozen, the winds would, for aught that appears, be the same; and were there no air, the surface water would equally have this set—namely, outside the tropics nearly due westward, but within them turning more and more meridionally, as the westing diminishes, by the successive parallels and their rotative speeds growing less unequal in approaching their maximum. If the currents either of air or water, from the two tropics, continued sensible to their very meeting, at the warmest parallel (which shifts according to the seasons, from about 12° N. to 5° S.), their encounter would be direct, one due N. and the other due S., when meeting at the equator, and equally opposite when at any other parallel. But, in fact, they cannot ever be traced to within some degrees of this line of theoretic meeting. Between them is the zone of "doldrums," at the borders of which, becoming imperceptible, their last traces are still, in the case of the winds, NE. and SE.; and if we suppose any general momentum impressed by either these or the water-currents on the belt of warmest water, its direction must be westward. I am not aware of any such predominant set being observed either in the equatorial air or water; and should rather, in a map of currents, leave the "doldrum" zone blank, as a kind of vast backwater, whose evaporation is the main exciter of the currents of both hemispheres without itself participating in either. Among all the cases of drifting to great distances, I never heard of anything carried from the southern hemisphere into the northern, or *vice versâ*; and therefore should not, like Mr. Proctor, carry the current lines across the equator, but regard our North Atlantic circulation rather as a distinct self-contained system, that would probably be not sensibly different were it made a real lake, by a barrier of land (instead of still water) closing it southward between Guinea and Pernambuco, and a closing also of Behring Strait, or even exclusion of the whole Arctic sea by lands joining Scotland to Greenland. In any such great lake, extending across our north temperate zone, it is easily seen there would be a necessary circulation in the direction of the hands of a clock; and if it were in the southern hemisphere, in the contrary direction. The locality of the origin or exciting cause could only be said, in either case, to be the whole eastern coast of such lake or basin; and in our case, the whole trend of the European and African coasts, from Norway to Cape Verde, being south-westward, like the current the sun would excite were there no land, this tends to confine and regularise the motion, and to throw the whole ultimately on the Brazilian and Guayana coasts. These can, by their form, only deflect it north-westward, into the great central American recess; whose coast-line for some 4,000 miles, from the equator to the Florida

Strait, is so formed as to gather and intensify the whole motion into a current constantly more confined and more rapid, up to its maximum at the escape between Cuba and Florida. The islands south of Porto Rico are too sparse and separated by deep water to present any obstacle; and Hayti and Cuba, meeting the westward set of surface-water about where its westing (to judge by that of the wind) is strongest, repeat in their coast-lines the very trend of the Brazilian coast, in a latitude where the mainland has ceased to do so, and thus contribute in conducting the whole of the inter-tropical currents into the singular trap formed by the Mexican Gulf, for detaining, heating, and concentrating them. Mr. Proctor is certainly wrong in carrying the lines northward past this Strait, for navigators have many tales of the two contrary currents always occupying it, the westward one along the Cuban coast, and the stronger "Florida Stream" proper, confined to the northern half of the channel. In fact, as we have no drop of blood that has not, within a few minutes, been through the heart, there would seem to be no water in the North Atlantic that has not recently made the Mexican tour, and been expelled past Florida, this gulf acting the part of boiler to the whole self-contained system. Without the long detour, under a hot sun, that the peculiar form of the Mexican coasts obliges it to make, this whole ocean and its surrounding lands, especially north-eastward, would certainly be colder; and, in fact, we and Scandinavia have the warmest climates, for our latitude, in the world.

For a map to illustrate any of this (or, indeed, anything else), its main concern is surely with forms. In regard to areas, all it needs is not to exaggerate uselessly the polar regions. Now, Mr. Proctor's wonderful caricature does, to all intents, more than double them. He has to explain that it includes the *whole* polar circle, but as this is converted into a sector, less than a semi-circle, the fact of its equalling in area the whole true circle makes it equivalent to an exaggeration of that circle to the full size of that whereof the sector is a part. For no mind, however practised in maps, is adequate to realising that the sector means a whole circle, and two lines nearly as widely separated as possible are "one and the same meridian," when, if joined, they would obviously make the map a tall extinguisher, instead of any approach to part of a globe. Continuity of surface is before any correctness of either forms or areas. I will venture to say that, whatever way Mr. Proctor may define "the purposes he had in view in constructing the map," the very first plate of Phillips' "Library Atlas" presents two constructions, each fulfilling them far better. There are three pairs of hemisphere maps, each differently divided, and each also on different projections, but none with other than circular curves. The large pair, divided by a meridian (as usual through Iceland) are on the fancy projection made by dividing each of the four radii equally and the circumference also equally, and making every meridian or parallel an arc through three of the points thus determined. It may be called a compromise between the equal-surfaced and equal-angled (or stereographic) methods, and inferior for any one purpose, I think, to either. A smaller pair are divided by the equator, and another, of the same size, by the horizon of London; and these exhibit the two rational methods in their purity, the former that of true areas, the latter of true angles and therefore forms, its linear scale at the extreme margin being just double, and therefore scale of area quadruple, of that at the centre (not double, as I inadvertently called it, p. 566). Even this variation of scale I do not call "monstrous," but rather trifling compared to what is now everywhere thrust upon us by the lazy Mercator mappers; and a care to mark all the parallels (not the meridians) to single degrees, either on the water or land (whichever is least written on) would quite obviate any false impression, by thrusting prominently on the dullest eye the fact, and precise degree, of such variation. Now, either of these two projections would have given Mr. Proctor the whole contents he has indicated, in less space than on p. 499. From the first of them, the equal-surface map, with pole in the centre, all that is north of the equator might be directly *traced*; and from the other, the stereographic with London in the centre, the meridians and parallels would be unchanged, but the places shifted 40° eastward; for it happens, oddly enough, that the latitude of London is exactly the middle parallel he required. He goes southward 10° beyond the equator, say 62° from this parallel, and northward 23½° beyond the pole, giving also 38½° + 23½° = 62°. Only two extreme points are beyond 60° from the centre, and at this distance the stereographic increase of scale is but as $\sqrt{3}$ to 2 lineally, or 3 to 4 in area; few maps that include more than one country having so little variation. With degree parallels marked as above said, I should call it perfectly "immaterial," or incapable of misleading, even if involving the making 3,000,000 square miles in one part equivalent to 4,000,000 in another; which "monstrous" difference, however, to which Mr. Proctor leaps, could by no means exist; for it is only in two extremities that, perhaps, thirty square miles at the utmost are swelled to the area of forty at the very centre. From the other map of Phillips, however, he had only to trace one rigorously equal-surfaced, if that was his crotchet.

If this or any of the maps to which I have seen his name are fair specimens of the "thousand" alluded to, p. 588, I venture to say that he thinks quite erroneously he has "a much wider practical experience of all modes of projection than 'E. L. G.'" Not that I mean to imply his experience may not have extended to some reasonably well-planned maps, but that it includes far too many bad ones. There is one set of his star maps which, though bad in style of figuring and almost every matter of detail, are in reality the best projection for their purpose, the twelve gnomonic circles circumscribing 12 pentagons; the same I had begun in a much better style of execution years before, but was assured there was no public for any fresh star maps. In another dozen, however, his planispheres for each second hour, on the horizon of London, the construction is as ill-chosen as possible. The stereographic (in this case the easiest by far) was the only right one, not only because alone giving each constellation its true form, whether high or low, but having a peculiarly happy adaptation to this purpose, by its enlarging their scale towards the horizon exactly as our common error of judgment makes them seem larger, as noted in the recent letters on Perspective (Mr. Proctor's, 4706, p. 560, &c.). As we grow older, this fancied difference of scale between the same object when isolated high in the sky, and when adjacent to terrestrial objects, diminishes; but I well remember, as a boy, estimating the lineal scale of the constellation Lyra, when at the zenith or the north horizon, to differ as 1 to 2. Now, this is the precise difference that a stereographic projection of the whole visible sky (the only one preserving the *form* identical in both positions) actually gives. There is no kind of map, terrestrial or celestial, about whose right projection there could be so marvellously little doubt, as this wherein the "wide practical experience" wandered so hugely astray.

E. L. G.

[4865.]—IN "Oceanic Circulation" (p. 500, *ante*) there is a quotation from Maury containing statistics which appear to me to be capable of a different interpretation to that educed by Mr. Proctor, who follows Captain Maury's line of reasoning in the particular sentence referred to. Writing of examinations of log-books, Maury says:—"The results show that within these latitudes—and on the average—the wind from the north-east is in excess of the wind from the south-west only 111 days out of the 366. Now, can the north-east trades, by blowing for less than one-third of the time, cause the Gulf Stream to run all the time, and without varying its velocity either in force or prevalence." If the wind blew from the north-east only for 111 days in the year, the deduction would be logical that it blew from that point for less than one-third of the time; but this is not how the quotation reads. As it stands, we may reasonably infer that the wind blows during 255 days equally from north-east and from south-west—that is to say, half that time from each point; and that, besides this, it also blows for 111 days entirely from north-east, for are we not plainly told that the wind from the north-east is in excess of that from the south-west for 111 days? so that it may blow but 127½ days from the south-west, 127½ from the north-east, plus an excess—viz., 111 days, also from the north-east, or 238½ from the latter point, and not 111, or "less than one-third," as Maury reasons, unless he states what he does not mean. As an approximately correct knowledge of the intertropical wind currents is so important in any inquiry into the origin and maintaining cause of the Gulf Stream, no doubt Mr. Proctor will speak to the point, as he is always so competent to do.

F. D.

"E. L. G."

[4866.]—IT has been to me a source of wonderment that no notice appears to have been taken of that extraordinary communication of our "roaring lion" (let. 4630, p. 511). Obviously it is the interest of any body (heavenly or earthly) to avoid colliding with a comet whose vapours are pretty certain to condense, upon contact, into a diluvial torrent of adverbs, substantives, and adjectives, but, notwithstanding and nevertheless, in the interests of social and moral progress, I desire to say a few words on the subject-matter of the letter under review, without wishing to enter into the vexed discussion on co-operative stores.

A gentleman of the order of mind of "E. L. G." should hardly need reminding that the bare announcement of mental deductions, decidedly in advance of the time, on any subject upon which the world at large almost universally holds opposite views is just time lost, and the labour expended in hammering in repugnant ethics into unprepared minds is, like trying to drive a wedge wrong end first, a simple waste of energy; something like attempting to teach a schoolboy the principles of geometry by beginning at the tenth book. Such a course is fatal to the successful propagation of any new theory, more especially when it comes recommended by such language as "polluting debasements of soul;" "such damning and unalterable truths as the essential defilement of the touch of all 'trade' as now understood." What can the uninitiated make of all this sort of talk? Where is the close and orderly sequence of argument to convince their sceptical minds? Language admittedly loses weight and force from a superfluity of big words, and especially when thundering maledictions are hurled broadcast at what people have, in their ignorance, come to regard as just and proper things, however much such things may merit bad names—for, until the public mind is educated up to the requisite point to see the fitness of the denunciations, the only effect of such strong language as quoted is to cause its author to be regarded as an enthusiast or a fanatic by the ordinary reader. Teach the public scientifically—by which, I mean begin at the beginning, and teach the science of trade or "equitable commerce" as "Sigma" teaches of electricity, &c., or as S. R. Bottone teaches chemistry—by grounding the learner in first principles, and presenting to his mind a coherent and intelligible system, and then some one may give attention to the subject, but, until then, it will just be the old complaint—"We have mourned unto you and ye have not lamented." I believe one mind out of a thousand cannot tell what "E. L. G." is driving at, and the mercantile mind—on whom the fire is directed—is quite capable of taking up the defensive attitude against such sweeping principles, coming as they do, recommended by averments like this:—"Every one who is not combining to supersede butcher, baker, &c., by establishing shops and shopkeepers of their own, had better for mankind not have been born." And they sadly need enlightenment as to the meaning of "competition in righteousness, instead of dark pelf filching." Is the above meant to do away with private enterprise for all future time, and am I a rogue and swindler because I don't entertain the public with a schedule of my profits, every item of which would be, of course, unquestionably true? This is how the majority of readers understand the argument and reason upon it. There are also men in the religious world sufficiently captious to consider as an attack on Christianity — and not without apparent reason—such indoctrination as that "combination against the trade class, and for the restraint of 'trade' as now defined [how?] is the only religious act possible to us English of these days, the only worship of the Almighty." This is one way of setting about the education of the masses of us poor ignorant readers into sounder commercial and Christian principles. But, if I may venture to generalise, the chances are a thousand to one that those anxious to do what is right are deterred by such a passage as last quoted from giving the assertions which appear in the same company a second or serious thought; they will conclude, probably, that much learning hath made him mad, and perhaps this is the correct explanation of the fact that no one seems to have taken the trouble to notice them. At any rate, a topical treatment of so large a subject as that "E. L. G." touches upon, interspersed with such smart sentences as instanced, is nothing short of injurious to the cause the author has in view—whatever that may be—and, as a sad waste of the precious space of "our" journal, is, I think, to be deprecated.

F. D.

CHANGES OF LEVEL IN LAND AND SEA.

[4867.]—THE "Antiquity of Man," quoted by "Saul Rymea" (let. 4819), is the only one of Lyell's books that I can say I have thoroughly read, and I did so at its first appearance, having till then been in as complete fog as Mr. Taylor and others complain they now are on this interesting question; for how long, before the great revolution of fifty centuries ago, can traces of man be carried back? Cuvier, while irrefutably proving the date, simultaneity, and vastness of that event, was ignorant as to whether man existed before it, and even Mantell and Buckland seem to have been without positive evidence on the point. Since their day it had been placed beyond doubt, by antediluvian human traces, both in Europe and America; but whether going back one or ten thousand years earlier I was quite in the dark. Now Lyell's book, though purely negative, seemed to settle the absence hitherto of any evidence for men above a few centuries before that catastrophe, because nothing can be plainer than his great desire to make out an extreme antiquity, unless his complete failure to find such evidence beyond 60 or 70 centuries back. If "Saul Rymea" would read the book through, he would find, I think, the most striking and novel feature to be the vain attempt I noticed, to make a geo-chronometer of what is the most utterly uncertain and unfit of all known motions for such a purpose, the insensible rise or fall of land; on the assumption of *either* moment always averaging the present mean rise of the centre of Norway (which is rising most at one end, and slightly sinking at the other!). Raised beaches rather testify a long former resting at a certain level than a raising by jerks. But at all events, let books, and Lyell's particularly, be examined for *facts*, and not for *opinions*, or with any such superstition as that "there must be" something "enabling geologists to arrive at an opinion," this or that; which is the essence of Mediæval grovelling and obscuration. On the same principle there "must be" proof of astrology.

E. L. G.

MONOLITHIC BUILDING.

[4868.]—I HAVE been much interested in the letters that have appeared in "ours" on this subject, and hope that any subscribers who can give any practical hints or details of working, cost, &c., will not fail to send them for publication. I am about to erect a small residence for myself in the neighbourhood of Birmingham, and would like to have some idea of what it ought to cost; as not being burdened with a superabundance of "siller," I want as much good, substantial work as I can get, in these high-priced times, for my money. The sort of house I fancy is one with two living rooms, each about 16ft. by 18ft., kitchen about 12ft. square, four decent sized bedrooms, and all necessary offices. The rooms about 10ft. high, walls of concrete, floors and ceilings of rolled light iron girders with concrete arches, or rather arched slabs, the girders about 6ft. apart, the stairs also of concrete. With the object of saving coal, and promoting comfort, I think of heating by means of hot-water pipes from a boiler in the kitchen, running a 4in. pipe round the rooms with a coil in some convenient place in the room. Ventilation by means of a pipe carried from the ceiling of each room into a shaft kept warm by being placed contiguous to the kitchen flue. The roof I should have flat, or with only a very gentle slope for drainage, and a parapet round, so as to form a promenade, or site for an arbour wherein to enjoy the fragrant weed, and take a look around. Any remarks, suggestions, &c., on the above will be gladly received, I dare say, by many others besides

BRYM.

GYROSCOPIC MYSTERIES.

[4869.]—I beg to offer the cases of a wheel or hoop trundled along a level surface for the consideration of those who are perplexed with the subject of rotary motion, as affording instances under different conditions to those given by the spinning-top; with rapid motion such bodies are stable, and they fall as the velocity of rotation diminishes. No doubt clear mechanical ideas are requisite for comprehending gyroscopic mysteries—more definite than are usually imparted by a course of "popular" reading, and it is in this sense that I understand Mr. Proctor to state that it is impossible to give a popular explanation of gyroscopic motion, and not that a man must be versed in the subtleties of mathematical analysis, including "polhode," "herpolhode," "couple of impulse," "ellipsoid of gyration," "reciprocal surface of the momental ellipsoid," &c., to account for individual cases. This I should think is practicable in the same way that Airy has in popular language explained the lunar theory and brought it within the compass of those who have little more than a "popular" knowledge of geometry and mechanics. Gyroscopic motion is no doubt a more difficult subject, but need not, I should think, be considered beyond the pale of those who have not mastered the principles of rigid dynamics. A man may understand why a ball flies furthest from the blow of a bat, that does not sting the hand, without a mathematical demonstration respecting moments of inertia or centres of percussion. I may have misunderstood Mr. Proctor, or I may be wrong, but I apprehended that for individual cases there are clearer (or I should say simpler) methods of explanation than the process of interpreting a general mathematical solution of the question.

I speak with diffidence, for I have read neither Poinsot's or Routh's treatise on the subject, and it is truly said that one thing becomes very clear to the unprejudiced inquirer after truth—viz., the amount of his own ignorance. This remark may apply in my own case to the following sentence quoted by "R.A.P." from Routh. I do not know to whom the italics are due. "In the game of cup and ball any motion caused by a wrong pull of the string *or by gravity* will not, if the ball is spinning round a vertical axis, produce so great a change of motion as it would have done if the ball had been initially at rest." By spinning the ball the verticality of the spike hole is no doubt secured against the disturbing effect of a side pull, or if the spike-hole be slightly inclined, it is steadied by rotation of the ball from the effect of any upward vertical pull, but I cannot see how the action of gravity is modified by the rotation of the ball, unless the conical form of the hole is taken into consideration, which would affect the homogeneity of the ball, and to a very slight extent in certain positions its motion as affected by gravity, &c., but these positions are excluded by the supposition of the verticality of the ball's axis, so that there only appears to remain for consideration the parabolic motion of the ball, which is independent of its rotary motion and uninfluenced by it. M. A.

THE BRITISH ASSOCIATION, AND THE MECHANICAL EQUIVALENT OF HEAT.

[4870.]—The British Association appointed a committee to investigate the subject of the mechanical equivalent of heat. That committee has been appointed now three years, and has drawn money for its expenses, but has not made public a single word by way of report, or given any reason why it has not done so. I sent in a paper on the subject to the Mechanical Section, but they said that as a committee had been appointed to investigate the matter, they thought it better to send on the paper to them. In the Chemical Section I took an opportunity of denouncing that part of the theory which makes −278° C. to be the absence of all heat, or absolute zero, and I could not find a single member to defend the point. On the contrary, one of the most eminent authorities on the subject of heat took the same view of the subject as myself. From an article in the *London Quarterly Review*, it would appear that Joule himself has in some way modified or given up his theory, but the writer, though authorised by Joule himself to say what he says, speaks rather ambiguously.

Putney, Sept. 2. H. Highton.

DR. CARPENTER AND GEOMETRY.

[4871.]—The axiom that "the whole is greater than a part" referred to by "Tyro," qy. 12860, p. 651, cannot be demonstrated, because we cannot experiment on *every* whole and *every* part. It can only be illustrated by example. Nothing can make it more obvious than it is in itself. Nor can we *prove* in any way that two straight lines cannot inclose a space. Our conceptions of a straight line alone render the axiom obvious to us.

By the way, Professor Clifford, following several eminent German and English mathematicians, holds in the possible non-universality of the truth of certain geometrical axioms. See his address in last number of English Mechanic. Their hypothesis is that as conceptions relating to space of two dimensions are inadequate to deal with the relations of space of three dimensions, so our common ideas relating to space of three dimensions may not be true with respect to possible space of four dimensions or more.

Richard A. Proctor.

THE PLANET JUPITER.

[4872.]—Now that this planet is receding from the sun, and will soon be favourably situated for telescopic examination in the morning hours, the two following sketches of his appearance (made in the early part of the present year), may be considered interesting, and may also be found valuable for comparison with other drawings of the planet that will be made during the ensuing winter months:—

Fig. 1 represents the planet as observed January 5, 1872, at 15h., by Mr. E. B. Knobel, who employed an 8¼in. silvered glass reflector, power 212. Fig. 2 was made on the following evening at 10h. Mr. Knobel says:—"I should call attention to the curious slanting streak in the S. hemisphere, which has been most persistent. I observed it first on January 5, 1872, and also saw it on the evenings of January 6, February 2, April 11, 16, and 28. This slanting streak is shown in Mr. Birmingham's sketch in the *Astronomical Register* for February, and is also mentioned in the March number as having been observed by Mr. Gledhill on February 2, but I can find no notice of it by any observer prior to January 6. In my sketch of Jupiter made on January 5, the slanting streak is not shown so extensive as on the following evening, and it would be interesting to know whether my drawing of January 5 is correct, or whether the streak was observed, prior to that date, as fully developed as in my sketch of January 6, or Mr. Birmingham's in the *Astronomical Register*."

In Fig. 1 a well-defined, circular, dark spot is delineated near the E. limb and just S. of the equatorial belt. This object was the shadow of satellite 3, which entered upon the surface of the planet at 14h. 39m. on January 5. Mr. Knobel adds it is necessary to mention that the belts and dark spaces in the equatorial zone of Jupiter as represented in the sketches are somewhat too dark.

Bristol, September 3. William F. Denning.

FIG. 1

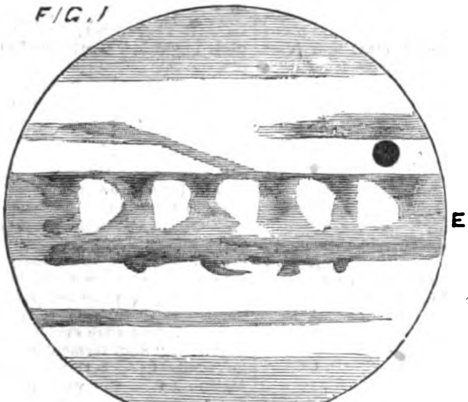

FIG. 2

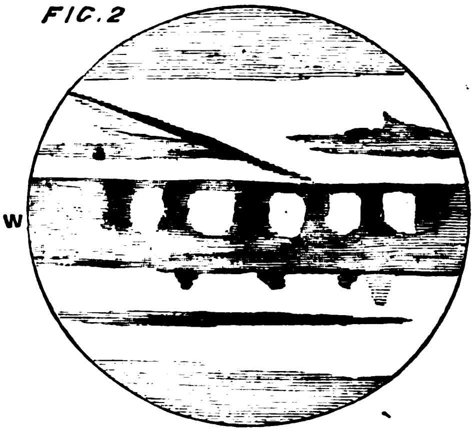


PERSPECTIVE.

[4873.]—Mr. Proctor (letter 4802, p. 617) considers that further reasoning would be thrown away upon me because I spoke of "plumb-lines converging in the zenith," but Mr. Proctor himself, in letter 4621, p. 509, states that the "vanishing point of any plumb-lines is the zenith," so that I fail exactly to see wherein I have so grievously erred. I take it that if two plumb-lines were placed a few feet apart the convexity of the earth would not prevent their appearing to vanish in the zenith. In another letter Mr. Proctor intimates that I am making two parallel straight lines inclose a space optically; that is quite possible, just as it is possible for two parallel straight lines to meet in a vanishing point.

I grieve to state that it is many years since I limped over the "Pons Asinorum," and therefore I may forget my Euclid. I cannot remember any proposition in which there was a plane parallel to a given line, and I am sorry Mr. Proctor has not favoured us with a diagram showing this case of parallelism. I have, however, carefully looked through all the portion of Euclid he recommends so touchingly to his youthful protégés, but have failed to see how it supports the following monstrous assertion, made, not exceptionally, in a well-known work on perspective: "Perspective is said to be the art of representing an object, or combination of objects, on a plane, such as a sheet of paper or canvas, as they would appear to the spectator looking through a sheet of glass or window interposed between himself and the objects to be delineated. This sheet of glass or window is a most important feature in perspective drawing, and though views are more frequently taken in the open air than from a room, an intervening sheet of glass, or transparent plane, is always supposed to exist between the spectator and the original objects, and this supposed intermediate plane is called the plane of delineation." Now, I think I have proved that this sheet of glass will show convergence in the tower, and therefore we cannot use it as above advised as a guide to pictorial representation. In fact, the glass would delineate what we see, while our paper or canvas must from one point of view exhibit what we do not see, in order that we may by means of this opaque plane of delineation produce the required effect. I have not maintained that the tower must be made to converge on the canvas, but that, considering the way a picture is generally viewed, the artist may, if he thinks fit, make it do so. The question is an artist's and not a mathematician's. M. Paris.

P.S.—I do not profess to be a mathematician, but I venture to doubt the assertion that two planes must intersect if one plane be parallel to a given line in the other, because the two planes may be themselves parallel. Mr. Proctor undertook an impossible task, and has egregiously failed. His letter is quite in the style of Buzfuz to that stupid witness, Weller. If we had lived in dome-shaped houses we should never have heard of a plane of projection or delineation. It is a purely technical matter, and adopted to meet the exigencies of flat mural decoration. In this question there are three things to be taken separately into consideration, the tower, the teacher's sheet of glass, and the sketcher's paper or canvas. The lines passing through the glass, if fixed, would not coincide with those drawn by an artist on an opaque plane, assuming perfection of work and the position being the same; therefore, even if Mr. Proctor's rider held good for the paper or canvas, it would not for the glass, so that all writers on perspective, as far as I have studied them, are simply misleading the student. I cannot see that solid geometry is involved in this matter; we are dealing with a superficies, *i.e.*, the face of the tower.

M. Paris.

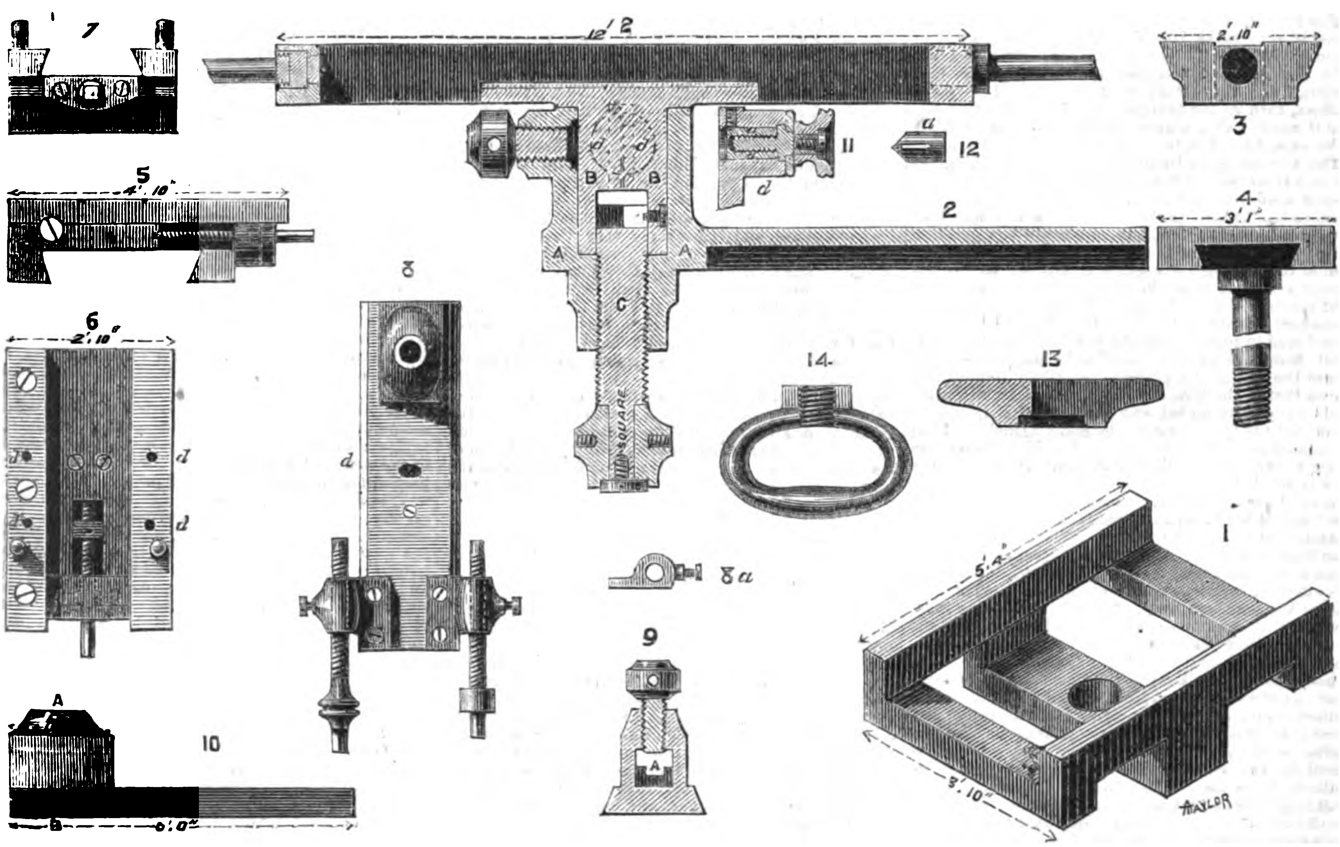
[4874.]—Mr. Proctor (let. 4802, p. 617) misquotes me, and places his misquotation in inverted commas. I did not say that a vertical line should be represented by a curve. An optically vertical line should, of course, be represented vertical; but such vertical line must, to appear vertical, be in the exact position to which the axis of the cone of vision is pointed. Let this vertical line be A, let there be two other naturally vertical lines B C at equal distances on each side of A, let all three lines be produced to the vanishing point in the zenith, then A, though it must be represented by a vertical line, will in nature appear to bend over the spectator in a curve; the lines B and C will also in like manner bend over to the zenith, and being both convergent to A, they must appear to reach the zenith in curves in the same plane as A.

As to Mr. Proctor's sneer about "that singular curve," it is quite beside the mark. I meant the word singular in the colloquial sense of curious or remarkable, not as solitary or unique. Bobo.

[4875.]—There have been lately several letters upon this subject, and plans to enable a person to draw correctly. They are all troublesome, more or less. I beg to send a description of a small affair I made to enable a person who can draw but cannot sketch to do so. It consists of two pieces of thin wood, about 8in. long and ½in. wide, jointed about 2in. from one end, so as to open and shut. To use it you fix upon one perpendicular line, or any straight convenient line, and apply the inner edge of one long leg so as to be parallel to it; and then move the other leg so as to be parallel to some other part of the object, then lay the nstrument down upon the paper and mark the two ines, and so you go on. I have now before me a drawing very nicely done by a young lady for whom I made one, and who could not sketch at all, but who at once succeeded when using my instrument. The picture is painted in sepia, and is a view of part of a village containing trees, animals, houses, church, and so on, so that there was a good deal of work in it, and shows how easy the instrument is to use. E. T. S.

ORNAMENTAL SLIDE-REST.

[4876.]—I SEND the drawings and description of the long promised slide-rest:—Fig. 1 represents the cradle of slide-rest, drawn isometrically to avoid three views of one rectangular object, and will be understood at once. Fig. 2 shows the whole of the principal parts of the slide-rest taken in section through the middle of Fig. 8, which shows the shape of either end of the slide; this upper piece is cast open the width of the dotted lines in Fig. 8, except at the part shown in section forming the connection with the stem B B. A A is the socket in which the stem is carefully fitted; the lower part at right angles is grooved on the under side in the usual way of a T rest, to carry the head of holding down bolt; the breadth of this piece is shown in Fig. 4, where the bolt is shown in position. I shall return to these two pieces later on. Fig. 5 is side view of the slide which travels on the face of Fig. 2; Fig. 6 is plan view, and Fig. 7 end view of the same; Fig. 8 is plan of the tool-holder slide, Fig. 10 side view (adjusting screws removed), and Fig. 9 end view in section through A B Fig. 10, this slide, of a (Fig. 12) is tapped to carry the screw, retained in position by a small plate bearing against a shoulder on the screw, and fastened to the stem by three small screws (not seen); the end of cylinder is shaped like a V, and the stem of the rest has two similarly shaped grooves cut along the whole length at right angles to each other, one of these is shown dotted between *d d*. Now, if the tightening screw is slacked, and the cylinder is in the position shown in the drawing, the rest may be moved about its centre in any direction, but if it is wished to set the rest to either of its right angled positions, it is readily done by moving it round a quarter circle (by estimation), and then by turning the milled head on the end of the screw the small cylinder will force its way into the groove, and set the stem fast in the required position; the end of the small screw seen bedded in the thickness of the stem works in the little groove on the upper side of the cylinder (Fig. 12), and keeps it in proper position. The lower end of socket A A is extended downward, and tapped to receive the screw C, of which the upper cylindrical part is accurately fitted to a hole bored up in B; on the lower end of the screw a boss is fitted, with holes drilled round the circumference for turning the screw with a lever. For the purpose of causing the screw to draw the slide down, as well as push it up, a recess is turned away near the top to the depth of the dark shading, and to it is fitted a steel ring cut in halves, and kept from revolving by the points of two split-headed screws which bear in a shallow hole drilled in each half ring. There is nothing in the construction of the upper slide calling for any particular explanation, beyond that the shaded piece A seen



course, fits into Fig. 6 and 7. Fig. 8*a* is an end view of one of the pieces into which the adjusting screws are tapped. This rest differs in two essential points from those in general use; one is, the means furnished for raising the slide above the centre, the other, the plan for setting the rest parallel, or at right angles with the bed of the lathe; these I shall explain later on. To return to No. 1, this piece is cast solid, and fitted between the bearers of lathe by its mid rib, if the heads of the lathe fit internally; or, by the outer strips, if outside fittings, in which case the end strip is separate and screwed on from the underside, and set up to its place by the adjusting screws, of which the corners are just seen in the drawing. To this the parallel tail piece of the rest is fitted, and held down by the bolt clip 13, and handle 14. The clip is circular, and has a slot of the diameter of the bolt cut out from circumference to centre, to admit of its being slipped on or off the bolt, which enables the whole apparatus to be lifted off the lathe bed without disconnecting the cradle. The long slide has its screw and nut as usual, but the ends of screw are carried through the rest, and the cranked handle fits both ends; the right-hand end of screw fits against the flat end of slide with a boss, divided on its circumference into fifty divisions, which read against a scratch on the upper face of slide, which is divided from end to end in inches and tenths, so that the 500th of an inch is easily read off. The socket A A has two circular projections at right angles to each other, one carrying the tightening screw as seen to the left, the other *d d*, shown in section *d d* Fig. 11, and supposed to be broken off to show its construction, which is merely that of a miniature cylinder poppet head; the cylinder in the mouth of the pent house (as we call the tool-holder in Fig. 9) is a loose piece planed to fit the width and height to centre of the ornamental turning tools usually sold in sets; the two pillars standing up in Fig. 6 and 7 are the stops for the adjusting screws of Fig. 8; *d d d d* in Fig. 6 and *d* in Fig. 8 are respectively the holes and oblong slot in which a forked lever works when the slide is disconnected from its drawing screw. A friend who made a rest of this pattern, and who had ½in. more to spare in the height of his centre, improved on the upper part by putting an additional slide over the one shown (supposing the pent house cut away) pivoted in front, and secured at the rear end by a milled headed screw working through a quadrant; this enabled him to set the upper slide to an angle without moving the stem of rest. The description of this tool has reached a very unexpected length, and will appear tedious to some of your readers, but it must be borne in mind that I am writing for the information of such as may be inclined to try their hands at making the tool, and who may not have any opportunity of inspecting one, far less of pulling it to pieces. In conclusion, the pent house tool-holder, as will be seen, can only take a drilling or cutting instrument of rectangular form which can slide through it from one or other end, therefore, if it is proposed to use the ellipse or rose cutting frames, which have tangent wheels on the end, another form of tool-holder, called the receptacle holder, must be substituted; in this the tool is dropped in from the upper side, and held in position by a pinching screw passing through a rectangular piece sliding in a recess planed out in the upper part of the holder. WAKENAAM.

SOUND OR UNSOUND THEORY.—To "F.R.A.S."

[4877.]—I TRUST if I again trouble you on the above subject you will attribute my doing so to my earnest desire for that knowledge of which I feel myself very deficient, and not a mere unworthy determination to have the last word.

It is on the fact that "a confined mass of air may be made to vibrate rhythmically" we build all our organ pipes and similar contrivances, but to enable this fact to augment the mere loudness of the sounds produced by vibrating bodies (be they tamburi, bars or plates of wood, glass, or metal, or even soundboards moved by strings) I have hitherto supposed it was an essential condition that the said masses of air should be of such dimensions that their vibrations must either be unisonous with, or bear some definite harmonic relation to, those of the vibrating body which causes their motion or communicates its motion to them.

When a tuning-fork or bell is employed to perform the function of the reed of an organ pipe—*i e.*, to put the air in a tube into sonorous vibrations—it is customary to adjust the length of the tube, often by pouring water into it, until its upper portion becomes capable of containing a column of air whose length is such that it vibrates in unison with, or harmonic relation to, the fork. Under these conditions the phenomenon termed resonance is powerfully developed, but not—so far as my experience extends—otherwise; and we do much the same thing by reverse means when we alter the length (and consequently its rate of vibration) of an organ reed until its vibrations become nearly, if not quite—it should be quite—synchronous with those of the air in the pipe.

In the instances of the harp and violin little or nothing of this kind is effected; truly, some very rough approximation is attempted in the former by making its "box" larger at the bass end than at the treble. Even this most primitive attempt at correct proportion is not carried out in the ordinary violin, excepting so far as it may be said to be done by making the cubic capacity of a viola greater than that of the violin, that of the "cello" yet larger, and that of the contra-bass of varying dimensions until it becomes "the giant" No. 204 of the catalogue of ancient musical instruments at South Kensington Museum. It would puzzle Apollo, although the god of music, and the Muses nine into the bargain, to make one organ pipe which should produce sounds whose pitches vary from fiddle G to E (not to say the F above in altissimo) without its length undergoing any alteration. Now, this is just what the one mass of air confined between the back and belly of a fiddle (whose volume is unvariable) must do if it really be resonant to all the sounds of different pitches which the varied lengths (and consequent varied rates of vibration) of its strings compel its soundboard to produce.

It will be understood the above observations apply only to loudness. That the included air may—probably does—modify the soundboard's vibrations, so that the timbre or quality of the sounds we hear differs considerably from that of the sounds we should hear, were the soundboard "naked, and not ashamed," as it would be, if both its sides were exposed. Perhaps the "'melioration"—as the old harpsichord makers were accustomed to express it—of the abominable sounds of that slightly unsavoury "man and brother," the nigger's very primitive banjo may partly be caused by its not being "backed up" as the lute, chitarrone, theorbo, and mandoline are; but the very different proportions of its strings, the different shape, material, and condition of its soundboard, seem to me quite sufficient to account for the superior quality of the tones of the guitar to those of its "black brother," without any aid from that "backing up" long since disused in the pianoforte.

As regards making my fiddle. I must quote the wise Frenchman, who said "let us wait awhile, so that we may make an end the sooner." No doubt "the proof of the pudding is in the eating," and no one could be more ready than the writer to report the result of experiment, even if unsuccessful, because like the announcement "Dangerous" on thin ice, it saves or should save others from being lost. It is my full intention to have this "pudding" made, but before doing so I should like a trifle more of "good advice," especially from Mr. P. Davidson.

THE HARMONIOUS BLACKSMITH.

THE PRIMITIVE CONDITION OF MAN.

[4878.]—SIR JOHN LUBBOCK, in a paper read before the British Association in 1867, attempted to show that the primitive condition of man was one of "utter barbarism," and in order to prove it endeavoured to establish the following propositions:—1. That there are signs and traces of a "stone age" in most countries, which prove the barbarism of their earliest inhabitants; 2. That there are signs of progress among savages; 3. That there are traces of early barbarism among civilised nations. Let us briefly examine each of these points in their order.

The phrase, a "stone age," is, of course, ambiguous, since it may mean either "polished stone age" or "rough stone age." Now, no one for a moment would hold that polished weapons indicated "utter barbarism," for they were used by ancient civilised nations, such as the Ethiopians, as Herodotus tells us; and it needs but a glance at the beautiful polished stone axes, figured in the recent work of Mr. Evans on "The Ancient Stone Implements of Great Britain," to see that their makers must have been very far indeed from a condition of "utter barbarism." It must be, then, to the "rough stone" or Palæolithic age that Sir John Lubbock refers, but here again the question arises whether it is the period of the bone-caves or that of the river gravels which is alluded to. If the former is meant, then the statement that these show that the primitive condition of Man was one of "utter barbarism" is simply contrary to fact, for pottery has been found in some of the oldest caves, and the oldest skull from the caverns (the Engis) might have contained the brains of a philosopher, while Dupont has shown that at the time of the bone-caves an extensive trade was carried on between France and Belgium. I know that the bone-caves are by many thought to be of the same age as the river gravels, but Mr. Flower has lately shown (*Anthropological Journal*, 1872) that the idea is refuted by palæontological and geological evidence. It must follow, therefore, that the "stone age" meant by Sir John Lubbock is that of the drift-gravels, but we cannot infer the barbarism of the men who made the drift "implements," because no traces remain of them except their weapons, and these alone are utterly insufficient to tell us how civilised or barbarous their makers were, for very rude stone weapons may exist among semi-civilised tribes. Thus the natives of New Caledonia have the roughest stone-pointed javelins, and yet Captain Cook says their plantations were well cultivated, their houses were of more than one story with carved door-posts, and they made pottery, which is in itself a sign of considerable progress in civilisation. If these rough weapons alone remained of the New Caledonians, how very fallacious would be the conclusion that these savages were "utterly barbarous." Mr. Evans says, of the river-drift implements, that of themselves they "afford but insufficient means of judging" of the civilisation of their makers (see "Ancient Stone Implements" p. 573), so that we may dismiss the first of the three propositions with the verdict of "not proven."

The second is—"There are signs of progress among savages," but here it is plain to all that unless these "signs of progress" can be proved to have originated from unaided efforts of savages, and not from foreign influences, they are utterly useless; when, therefore, we find this proof not attempted we may safely reject the so-called "sign of progress" as worthless. We are told that the Wajiji, of East Africa have just learnt to make brass, but, as Burton says they learnt this from the Arabs, the fact of it is of no avail for the theory. Then comes the statement that the Andamaners have "recently" introduced outriggers, but in order to make this good, it must be shown that they never before had them, and that they did not borrow the invention from others; neither of these is proved, and it is very curious that Sir John Lubbock says such a case as the above probably arises, not from invention of a new art, but from an oversight of early travellers; his words are "Suppose an early traveller mentioned the absence of some art or knowledge among a race visited by him, and that later ones found the natives in possession of it. Most people would hesitate to receive this as a clear evidence of progress, and be disposed to suspect that later travellers with better opportunities had seen what their predecessors had overlooked," and he shows in this way that the Ladrone islanders were not ignorant of fire, as was first supposed, but in the same way the Andamaners might have made outriggers, but early travellers might not have seen them. The Bachapins have recently commenced to work iron; but here again it cannot be proved that they did not learn this from others, as the Wajiji learnt to make brass from the Arabs. Lastly, the boomerang is said to be an invention of the Australians, as it is confined to them, but this is contrary to fact, for Denham found it in Central Africa, and the Bishareen Arabs use it to this day, while a convincing proof of the antiquity of the weapon is that it is found on the Egyptian monuments, and in the sculptures at Nineveh. Thus each "sign of progress" cannot be proved to be an original invention, and as all the "signs" might thus be shown to be wanting in this point, the argument from them completely breaks down. Concerning the non-progressive character of the Africans, Denham says "Every approach which the Central African has made towards civilisation is attributable to the intrepid Arab spirit, which has alone penetrated to any extent into the country of these before unenlightened savages" ("Travels in Central Africa," p. 331), and Captain Burton, in his "Mission to Dahome" is equally emphatic, for he says, "The so-called civilisation of the negro is from without; he cannot find it within. As an adult he is the victim of imitation, the surest sign of deference; he freely accepts foreign customs and manners however incongruous."

Further, if the weapons and arts of savages were all independently invented, then we ought never to find that the civilised tribes were ignorant of an invention possessed by their barbarous neighbours, but we do find this occurring frequently, and it is an awkward fact for the upholders of the "savage theory" to face. Thus, the semi-civilised Tahitians had no pottery, while the barbarous Pelew islanders and other western tribes had; the Tahitians had bad canoes, while the more savage Maories had good ones (although, strange to say, Sir J. Lubbock says bad ones—"Pre-historic Times," p. 475—contradicting his own previous statements); the clever Kaffirs had no bows, while the miserable Bushmen and Fuegians possessed them; lastly, the wretched natives of Easter Island cultivated yams, plantains, and sugar-canes, while among the more civilised Hottentots agriculture was unknown. Now, if the lowest savages had independently discovered agriculture, pottery, bows and arrows, and the making of good canoes, how comes it that their more civilised brethren had not found out these things too? They have had opportunity to do so, and the inventions would have been of inestimable advantage to them. Well may Sir John Lubbock say these are "most remarkable" facts, for so they are, and they are so very "remarkable" that they go a long way towards overturning his theory. We now come to the third point—"There are signs of primitive barbarism among civilised nations." The fallacy here has been pointed out by the Duke of Argyll: it is this, that whenever a barbarous custom is found it is at once assumed to have been primeval, whereas the custom may have originated in later times, and this glaring assumption is again and again brought forward. Rude customs may show that nations once passed through a savage state, but as the Duke of Argyll says, "They afford no presumption whatever that barbarism was the primeval condition of man, any more than the traces of feudalism in the laws of modern Europe prove that feudal principles were born with the human race." ("Primeval Man," p. 133.) As we know that savages have been corrupted by acquaintance with other communities, and as Sir John Lubbock seems to admit the unnatural customs were not primeval, we may, I think, reject the third point.

But if it cannot be proved that "civilised nations show traces of primitive barbarism" the counter-proposition is undeniable, viz.—"There are among savages indications of early culture and civilisation." Casalis has shown that among the Bechuanas he found in their language proofs that they were once more enlightened than at present. Among the Makololo; Livingstone found the agricultural implements wonderfully to resemble those of the Egyptians, and the same was found to be the case with the spinning and weaving of the natives of Angola; and in another place he says that the numerous hoes and baskets of the Maravi men were all so exactly alike that they must have come from a common source ("Zambesi and its Tributaries," p. 507). Dr. Krapf speaks of the ancient civilisation of Senjero in East Africa, while in Easter Island, and in the groups north of New Guinea, huge buildings and statues have been found which show that the early inhabitants were skilful and ingenious.

In the present condition of science it is our duty carefully to examine those theories which are so confidently and dogmatically brought forward; the time has long gone by when mere assertions were received without question, and it is useless for the maintainers of the "savage theory" to attempt to force their ideas on the public by reiterated assertions, mingled with sneers at their opponents. I trust your readers will fairly examine both sides of the question, and I feel confident that they will then reject the theory on the ground of its being supported by insufficient evidence, and opposed by insoluble objections. D. G. W.

WARMING RAILWAY CARRIAGES.

[4879.]—IN answer to let. 4816, p. 620, I beg to inform "Philo" that the warming of railway carriages described by me is quite new, and the coal is a purely chemical-prepared one. The only substances besides charcoal are only chemical, which give the time of burning and the degree of heat they shall develop. Both heat and time can be regulated by the manufacturer. No clay is used whatsoever. The invention is such a simple and convenient one that the Prussian Ministerium has recommended that all State railways shall be warmed in that way, and several other railways are preparing their carriages for this system of warming MENZ.

ENGLISH BLACK v. LIGURIAN BEES.

[4880.]—THERE seems a very strong desire in the minds of many of our bee-keepers to set in the foremost ranks a stranger from Italy, and put aside our old and long-tried friend the English black bee. Mr. F. Cheshire (let. 4629, p. 511) would have us believe that he obtains a full title or claim to the laurels of the first order. Now, as no one else has taken the trouble to defend the character of an old friend, I have humbly undertaken the task, as I have a swarm of the black bees that have no cause to blush when placed by the side of his ligurians. I see he received his swarm on April 28, 1872; I suppose they had swarmed at least one or two days before he received them, and they had placed or packed in his different rooms something like 110lb. of honey and comb; now this certainly looks something like being very sweet. Now. I will just compare things a little. My bees swarmed May 25, two days within a month later than the strangers. We had, like my brother bee-keeper, a week of very bad weather, but in about three weeks they had filled their stock hive, which contains about 60lb. of honey. I placed on a collateral or side box, into which they soon placed 38lb. I then put on a super, into which they literally crammed 37lb.; these two boxes I took for myself, amounting to 75lb., and left them the 60lb. for their winter supply, making a total of 135lb. I, like my joyous friend, gave a little soothing syrup, and I think they have amply repaid me for it. Another of my stocks, an old one, swarmed on the 23rd of May and cast five days later, and after that filled me a glass, containing (with the glass) [illegible] of honey. A LINCOLNSHIRE BEEKEEPER.

POTATO DISEASE.

[4881.]—IT may benefit some of my fellow readers to learn the plan very successfully used here by myself and many brother mechanics for several years past to arrest the destructive effects of the potato disease, which is simply to pull up all the haulms in our gardens as soon as any brown spots are seen on the haulms, and to put back and cover up any potatoes that are pulled, and there leave them to be taken up as required until the frost sets in, when they are pitted as usual.

Aberavon. PERCIVAL NORTON.

THE PROPER MANIPULATION OF CONCRETE.

[4882.]—I READ with much interest the account of the concrete bridge between Gloucester-road and Earl's-court-road stations on the District Railway given in No. 388 of the ENGLISH MECHANIC, p. 617, and am gratified at finding so effectual a step in the right direction. But I may, perhaps, be permitted to point out the inconsistency with the correct treatment of concrete materials indicated by the closing paragraph, in which it is remarked that:—"Nevertheless, the porous nature of even such good concrete as that used in the bridge is shown by the fact of rain passing through it in the course of a few hours." Now, in my practice I have always found that concrete properly manipulated was exceedingly impervious, and capable of much greater degrees of cohesion and strength than it is commonly allowed to attain. I have recently made a flat roof 6in. thick, one half of it chiefly lime and ballast (with the constructional details of my patent), and although exposed to the violent storms of the summer it has never once leaked. I inclose a statement of experiments and other matters connected with this system, which I trust may merit your attention.

PHILIP BRANNON.

"E. L. G." AND CO-OPERATION.

[4883.]—REALLY, I wonder such a letter as that of "E. L. G." upon co-operative stores was not consigned to your waste-paper basket, for the expressions of which it is full—"blasting the souls of wretched traders" with pennies, "pestilent hoards for furthering all iniquity," Satans, Armageddon, and all the rest of it, as well as the temper in which it is written, seem hardly consistent with the character of a scientific journal. Argument there is none. "E. L. G." simply lays down the law, says that such and such a man was made by the Creator, such another by the Prince of Darkness, that coin is a badge of conquest and slavery, which should be at once superseded by a complicated system of what he calls "labour notes," and all who differ from him are corrupting the nation and race, spreading moral pest, and doing all manner of horrible things, from which he, the high priest of the co-operative religion, is the destined deliverer. Surely, this is more suitable to the columns of the *Beehive*, the *Iconoclast*, or *Reynolds's Newspaper*, than for those of the ENGLISH MECHANIC.

His grand mistake in reference to the currency is that for a medium of exchange like coin, whose value is absolute and certain, or at any rate whose standard is only subject to slow and almost imperceptible depreciation, he would substitute a system of payment in labour—one of the most inconstant and variable things that can well be picked out. We all know the value of a sovereign, and what it will buy, but how many can as accurately estimate the result of an hour's labour? One sovereign is a sample of all, but is one man's labour always of the same value as another's? Does "E. L. G." mean to tell us that the labour of an ignorant, lazy, or unskilful man is worth as much as that of an honest, painstaking, and industrious one? Can he, for instance, give the exact proportion between a lazy man's hour at carpenter's work and a diligent man's hour at writing? In fact, for a simple and uniform standard of value, such as coin, we should have, not one, but a thousand standards, varying in relative worth from day to day as the dispositions of ilities of those by whom the notes would have to be leemed.

One of the notes quoted by "E. L. G." is apparently r house rent, which, therefore, we may conclude he inks equitable and just. But at the same time that allows it to be right for a man to let his house on re, he grows in a furious passion at the idea of his oing the same thing with his money. It is right, erefore, for me to spend a thousand pounds in building a house and then to lend it to somebody for fifty unds a year, but wrong in the highest degree to lend e thousand pounds for the building of the house, and receive fifty pounds a year for the use of the money. e does not seem to see that rent and interest are nvertible terms, entirely identical in principle, so at the fundholder is no more a "lower animal" an is the landlord. VERTUMNUS.

CO-OPERATIVE AND OTHER CRUDITIES.

[4884.]—REALLY "E. L. G." seems to find some of y remarks upon the frightful crudities he tries to rce upon us to stick in his throat like a fish-bone; least, I suppose so, from the way in which he keeps oking over them. But I must really correct him as his observations in let. 4803, p. 617. I never ob-cted to any space occupied by any efforts of his to stinguish plainly points he was, as he says, quite norant upon. Doubtless, the space occupied did ove that (or, at all events, the mode in which it was ccupied), but that was an accidental and unintentional sult. The object of "E. L. G." was to prove that he new all about the matter, and my objection was to eing so many columns wasted over mere guesses, any ridiculous, some amusing, and a few ingenious, t all mere guesses set forth as facts and argued from actual data.

It is exactly the same with the present subject of -operation; it is an important one, worth wise discus-on, and it is one on which I could very well say mething; the place, however, is occupied by E. L. G." in much the fashion in which a mad man ight amuse himself in a fireworks' store, and it is, erefore, useless for a reasonable and moderate person approach it.

It is really sad to see a person who has the ability guide others, so utterly waste his own and other eoples' powers as does "E. L. G." upon the various oints upon which he is afflicted with temporary in-anity (it is not monomania, because there are so many f them). Can he not see that when he begins raving, e renders argument impossible, and that he takes up position to assail which irony and ridicule are the nly possible weapons? What on earth can one say to man who asserts that when a poor honest man, who as saved a few pounds, sets up therewith a green-rocer's shop, and gets his wife to look after it while he at work, he is doing "something to blast the retched trader's soul, increase all degradation, and ile up pestilent funds" (say the savings for a trip to largate), "for furthering all iniquity"? There is nly one possible answer to such high-falutin' twaddle—iz., to laugh, and say—Bosh.

What argument is possible with a man who can ssert that money, that is, a certified value which ordi-ary people cannot otherwise estimate, is no more ne-essary than certified weights of cheese or soap which ny one can value, and which, furthermore, are com-only made up in just such certified values, or packets, y the salesman? If "E. L. G." wishes to convince thers, or to meet with any response except amused aughter or a pitying smile, he must really learn not nly to talk sense, but to talk it in a sensible manner. hen neither I nor any one will complain of any space e may take up. SIGMA.

HAIRSPRINGS.

[4885.]—HAVING dabbled in watch repairs as well as ther things, I will merely state my reason for coming o that conclusion; having purchased several reels of ire for the purpose of making my own pendulum prings, I had a job come in—viz., to put a spring in detached lever watch, the spring of which was very elicate. Upon turning over the stock, knowing I ad some, I found it damaged (*i.e.*, rusty), and therefore seless. I forwarded the number of reel and had the ounterpart sent me and did the job, &c. These reels vere numbered. Now if not gauged, why numbered? never saw a gauge. JACK OF ALL TRADES.

GRAPHITE BATTERIES.

[4886.]—IN reply to "H. H. G." (let. 4780, p. 593), he size and arrangement he proposes will answer ery well. I should advise the porous cell to be about 1½in. or 2in. across, and to come clear through the overing disc, having a separate cover of its own. The size of zinc is immaterial, ⅜in. rod is perhaps the best if cast; the graphite may be ⅛in. square, but a plate is better, as pieces may be packed between it and the cells, and thus more points of contact secured. It is not advisable to make holes in the porous cell, as the manganese may work through, nor do I think well of the graphite porous cell. I have used and much prefer an outer containing cell of graphite material into which the carbon and manganese are packed; this serves instead of the conducting-rod and gives large contact; the only objection to this is the cost.

As to the solution, chloride of ammonium gives the greatest force; with sulphate an extra cell or two might be required, but I am inclined to think that it would be more enduring and steady for bell purposes, as it would not, I believe, form crystals over the zinc and porous cell, which is a great nuisance and loss with the chloride. I should use a solution only three parts saturated, and of course no crystals. "H. H. G." must not omit the pipe for supplying fresh liquid, and must always take care to leave a small hole or pipe (a mere pinhole is enough) to allow the ammonia set free to escape; the best plan is to tie a piece of india-rubber over the mouth of a tube and slit it across, this forms an excellent valve; I rather think that this is really the one thing patentable in the Leclanché specification, and that one thing I do not remember to have seen ever used in a Leclanché cell.

The proposed connection with the graphite is not reliable, and there would be an action on the lead which would probably split the carbon, though very perfect saturation with paraffin might prevent this; it is better to cast a solid cap over the carbon, better still to electrotype on a copper cap, and perfectly saturate afterwards. SIGMA.

DISTANT SIGNALS ON THE MIDLAND RAILWAY.—To A. G. BOYD (P. 621).

[4887.]—THERE is not much advantage whether the distant signals are arms or discs, but I find that engine-drivers very much prefer the disc signal as shown on p. 541. Drivers tell me that at large junctions and sidings, where there are many signals, that where the distant signals are arm signals, they look just the same as starting signals, and that often drivers have been deceived, and taken the distant signal for a starting signal, and thought that it applied to the sidings, when really it was a main line distant signal, and frequently collisions occur through this error; but where the distant signals are discs as shown p. 541, no matter how many starting signals or junctions, a driver on the main line can always distinguish the distant signal, and since the alteration shown in my drawing p. 341, there is now no fear of a driver taking the back of a distant signal. The altered form of the disc on the Midland Railway is giving great satisfaction. There is also another advantage in distant signals being discs, as the semaphore arm signals at all places on the Midland are absolute "stop" signals, and every train must stop clear of them, not so the distant signals, which are only to protect a stopping train, and trains do not stop at them, but run cautiously by up to the place of obstruction (see Vol. XIV., p. 42, Railway Accidents, 36 lines from the top) where the use of distant signals is described. As the use of the distant signal, and the semaphore signal is so very different I think it is very important that there should be so much difference between them that a driver shall know at a glance which is which. This I am sure the disc signals do, as it is impossible to mistake them. C. E. S.

OBJECT-GLASSES.

[4888.]—MR. W. OLDFIELD (let. 4844, p. 643) is in error in supposing that I have ever recommended one form of object-glass over another, at least in the pages of the ENGLISH MECHANIC. If he will kindly refer to my letter he will see that I simply gave what Mr. Cash wanted, the proper curves for an object-glass on Herschel's principle, and that without saying one word in its favour or against it. I know very well that it is not the best form of object-glass, I also know why it is not the best form, and I have no doubt, too, that I could find out the very best possible form for any particular case if I wished, but the calculation would necessarily be so tedious that I have never yet had the courage to attempt it. It seems to me, too, that Mr. Oldfield has misunderstood Mr. Cash. I fancied myself that Mr. Cash was in doubt whether the thickness of his flint lens had not something to do with spherical aberration, having in his mind no doubt the quantity called the thickness in some of the formulæ for spherical aberration. I may tell Mr. Cash that the thickness of his glass does not alter that quantity in the least. I myself make use of a method I have discovered, I suppose I may say, by which the surfaces of an object-glass may be found without employing any of the formulæ for aberration, or once considering that confoundedly troublesome quantity. The whole of the computations may be performed in an hour or two, and with all necessary accuracy in the results. As a matter of course, like all other inventors, I consider it about the best thing ever done, and as the provisions for patents won't apply, intend to keep it a profound secret, but if Mr. Oldfield were a B.A., a F.R.A.S., or some learned gentleman, I might perhaps, by way of giving him an idea of the enormous research and ingenuity requisite, allow him to have a peep at (say) half a sheet of the computation. Why does not Mr. Oldfield write a little more carefully? Who on earth is to understand that part of his letter which commences with—"viz.," and ends "72in."? HENRY T. VIVIAN.

ON INTONATION.—To "FIDDLER."

[4889.]—IN your letter 4740, p. 567, you say "imperfect intonation has become—query, always was—so great a nuisance that you are surprised nothing has been done to remedy it. I beg to inform you and my other fellow readers that a great deal has been done with more or less success for the purpose of remedying this admitted evil in most musical instruments with fixed sounds. The thing has been done over and over again, but probably because we are descended from ancestors who less than a century ago considered one sound near enough to the required pitch to serve for FF and FF♯, it is one of those things which don't pay, at least in the pecuniary sense, and that is for all practical purposes the only sense.

Archicembalos—literally many harpsichords in one case, some of them having four or even six ranks of keys—have been constructed in Italy, and many patents obtained during the last century in England for improving intonation by various means, a favourite means being to vary the lengths of strings after the fashion of the pedal harp, *par exemple*, the telecohordon of Dr. Clagget, that being one of the earliest. Organs have been built which were also designed for the same purpose with many additional pipes, and others in which the pitch of the sounds produced by a single pipe could be varied, *par exemple*, by Liston's movable shades to organ pipes, notably the so-called enharmonic organ of the late Colonel Perronet Thompson. The same "awfully clevar party" also constructed an enharmonic guitar and a phonometer, all of which I hope to see added to the permanent collection at South Kensington, a collection all should help to render yet more complete.

If I am not greatly mistaken, all the contrivances you mention have long been used. Dr. Clagget, A.D. 1788, in his teleochordon, claims dividing the octave into 39 intervals by means of additional bridges (also applied to harpsichords and pianos) which were made to shorten the vibrating portions of their strings by pedal actions. D. Loeschman, A.D. 1809, divided the octave into 24 which was the number of keys in a spinett belonging to Dr. Pepusch, which my late friend J. J. Hawkins saw at Rome about 1832. I think, Thompson, A.D. 1862, carries this much farther, dividing the octave into 41 intervals, which he said would "afford, in just intonation, every major or minor scale in a series progressing upwards by fifths from C flat through C natural to C♯, or from 7 flats through C natural to 7 sharps to adopt the signatures generally used in music, with the chromatic and enharmonic of each," whatever those scales, or rather the latter one, may mean. Col. Thompson says the Greeks employed the term enharmonic simply to signify what we mean by the expression "being in tune."

Organ pipes with holes in their sides *à la* flute or bassoon, are very far indeed from being novelties. The French organ in the 1851 Exhibition had but one pedal pipe for 11 semitones, so of course one organ pipe may be made to produce two sounds differing so little as the major seventh does from the octave of its key note without altering its mouth, which is more than it well can be made to do in the instance of its producing 11 sounds differing in pitch from each other a semitone. The practical economy of making one pipe serve for two semitones is altogether another matter, concerning which our "Adept," if yet alive, could afford "Fiddler" some valuable information. No doubt the extraordinary luxury of sounding B and C together—to the writer this luxury is what Artemus Ward would have called an unmitigated "noosance"—is not often indulged in by "ordinary" composers who know it is "contrary to rule," which only "extra-ordinary" composers, alias "lunaticks"—with much method in their madness—such as Beethoven, can afford to disregard. To the writer the effect of sounding simultaneously the sharp seventh and octave of the key note is simply vile, "playing out of tune" with a vengeance.

Your proposal to make six strings in the piano do the work of twelve is similar to making one pipe of the organ serve for two sounds. It would, of course, serve for more melody. Your experience as a "fiddler" must render you familiar with the fact that one long string might be made to produce all the different sounds in the compass of the pianoforte, which would rival, if not surpass Paganini; but, *cui bono*. We want pianos capable of both harmony and modulation; neither can be facilitated by stringing them *à la* harp, even if the Erard double action be applied to them. In the harp, many strings are in the way of the fingers—the complex Welsh harp, to wit; but we can manage twelve (if not twenty-four) manual keys to each octave in the piano, &c.; probably because we are accustomed to twelve and not used to twenty-four. It is far easier to execute rapid chromatic passages on the piano than on any harp, Irish, Welsh, or French, even if provided with "double action."

That the costly piano, with all its strings oblique in one direction, you lately saw, was less powerful than another with all its strings nearly upright is just what might have been expected by any one who has mastered the elementary truth, that the soundboard is, for all practical purposes, the sound generator. Any instrument, be it virginal, spinet, or piano, whose strings are all nearly parallel, and situated obliquely to its keys, must have its strings crowded together on its belly-bridge. As a mere matter of course, the surface of its soundboard (between the strings of each note) must be smaller than in horizontal grand and ordinary upright pianos. I may, however, remark, *en passant*, that the obliquity of strings need not necessarily be accompanied by their parallelism. On the contrary, they may be radiated, or spread out, on the soundboard bridge over quite double the space parallel strings occupy, which is equal to that occupied by their keys and hammers. See my design for grand upright 8-octaves cottage piano in No. 235, and another which I will send shortly for a very powerful piano only 40in. high.

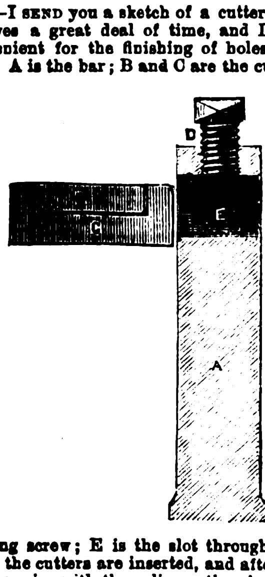
THE HARMONIOUS BLACKSMITH.

NEW SOUNDBOARDS.

[4890.]—IF I have understood the recent papers on soundboards rightly, it is a sine quâ non that opposite kinds of wood should be used close together. I have never seen a violin whose breast was made of hard and soft wood glued in two halves, and should very much like to know how it would sound. I do not see how it could be wrong, for is not the back made of hard wood, and by the soundpost connected with the breast, making a continuous soundboard with the sides, in fact, all round the violin? If it is a continuous soundboard, then Mr. Schucht is right, but why have a soundpost? would not the sides do by themselves? Yes, if the string is bowed on the side instead of on the top, but when bowed in the usual way a soundpost is necessary. We might understand this better if we could see in what direction the waves of sound move. Mr. Schucht in his diagram makes the vibrations wave along the surface of the breast from end to end, and continue round the back, and then I presume along the breast again; but is this the right direction? Might not the wave or vibration affect the air in just the opposite way, from side to side, and round the back, as though I twirled a hoop perpendicularly round the violin held horizontally. Now, I think, that if I pull the string by the action of the bow on the top, as is usual, I cause the wave to move in the same direction as the bow is drawn, and as the wave has to right itself by rising higher, so as to form a circle round the violin, the soundpost may have a tendency to direct the wave of sound in this position, not to remain there, but form almost instantaneous rills of sound as far as it is heard. But if I begin the sound by drawing the bow on the side of the string (near the top of the finger board), the wave commences in the proper direction, that is upwards, and then round the violin, and not requiring a soundpost to direct it into a proper position. If this theory is wrong, please say why a soundpost is not required when the bow is used on the side of the string, but is an obstruction to the sound, as any one may perceive if they will inquire? Again, if the vibrations flow from end to end, why have a wide soundboard? The same quantity of wood made into a long narrow soundboard would do better, either with or without a back; the four strings of the violin, or even a fifth, could be placed on the same sized bridge as the present, and the soundboard continued below the bridge, so that the instrument could be played as a violoncello is held, in front of the performer in the Turkish style. It may be asked. But how could the different sorts of wood be made to go in such a narrow soundboard? This would depend on the thickness of the soundboard; if thick, then in layers; if thin, then side by side. It is doubtful even if the waves run along the breast that the sound would be improved, because there would be so little for the tone to sound or be formed in. I think, then, a series of soundboards could be placed under the narrow breast, all of them being attached by their edges to the upper soundboard or breast, and hanging down, as it were, like inverted tuning-forks. It is certain that if these inverted soundboards were glued their whole length to the upper soundboard or breast, the whole affair would be too rigid or stiff; but this could be obviated by cutting one edge of each in a half circle, or, perhaps, in a wave line, so as to be attached by three or four points instead of their whole length, thus allowing fuller play to the breast. Or these extra tuning-boards might be fixed on the extreme end of the narrow breast in the same way that the metal projects from the bass vibrators of a musical-box. I think we have all heard of the genius who introduced iron into pianos, under the idea that the wires would sound louder if a number of tubes could be made to sound sympathetically or synchronously; the reason why he failed was, because the wire could only vibrate a soundboard, and had not sufficient strength to move the air in the tube so as to make the desired increase of tone. I am afraid the same cause will operate against all our funny fiddles and soundboards, unless we can bring them all into intimate connection with the vibrating string, and find a way of moving the soundboard more than is done at present. We want a stronger string (not wire) yet sufficiently elastic to be played on with a bow. May I beg a few suggestions from our numerous thinkers, for as the tone of the piano has been improved by imposing heavier steel wires, so I want to improve the violin by bowing a string that shall move the soundboard more, and a larger soundboard than is used at present? FIDDLER.

CUTTER-BAR.

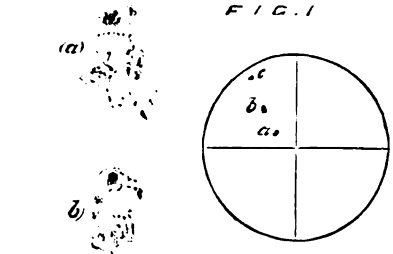
[4891.]—I SEND you a sketch of a cutter-bar, which I find saves a great deal of time, and I consider it very convenient for the finishing of holes of various diameters. A is the bar; B and C are the cutters; D is



the pinching screw; E is the slot through end of bar into which the cutters are inserted, and after being set to the proper size with the calipers the pinching screw D is tightened up to hold them in position; when they get so much reduced in size that the rymer has too much to do, unloose the screw E and take out the cutter a little; they will serve for finishing holes of various sizes. Of course, when one pair of cutters comes to be too small for the holes to be bored, you have only to insert a pair of larger ones, avoiding the necessity of going to the smithy to have your drills hammered out, which, after being done, if not carefully ground, may have to be taken back again to the smithy. I do not know if these are in use anywhere; if so, please say. JOHN KEARY.

SPOTS ON THE SUN.

[4892.]—IN the months of April, May, June, and July, I was able to observe the same cluster of spots during four revolutions of the sun. The telescope I used was of only 2¾in. aperture, with a power of 140. In Fig. 1, *a* is the copy (inverted) of a sketch I made of a cluster on April 24 at 5 p.m. On April 25, at 4.45 p.m., I made another sketch of the same cluster, which had changed considerably (Fig. 1, *b*). Its position on each date is marked in the circle on the right. *c* represents its position on April 28 at 6 p.m., when it was passing off the disc. On May 14 I saw the cluster again, but only identified it by the position it occupied on the sun's disc. In Fig. 2, *a* represents the cluster as seen on May 16 at 7 p.m., and *b* on May 20 at 5.30 p.m; *c* and *d* represent the largest spot in the cluster on May 21 at 6.30 p.m. and May 22 at 5.20 p.m respectively. The different positions of the largest spot on each occasion are shown on the right. In June I saw the spots again performing another revo-



lution, but had no opportunity for sketching them. On July 10, at 6.30 p.m., I observed them again on their fourth appearance, considerably within the disc (*a*, Fig. 3); it was too hazy for delineation. Fig. 3 (*b*) represents their appearance and position on July 12 at 6.15 p.m. The spots have since disappeared.

Bordyke House, Tonbridge. R. W. BARBER.

[4893.]—THE theory of "A." (let. 4453 and 4830, p. 640) accords well with one or two phenomena of the solar spots, but is negatived by many others. I should explain that in speaking of "broken umbræ," I did not mean to describe an appearance as though a dark region were broken *across*, but to describe that apparent "breaking in" of the boundary of certain spots at one side which is so familiar to the telescopist. A spot shall have its penumbra well defined for seven-eighths of its circumference, but on the remaining eighth it shall have no penumbra at all, but either appear as though the photosphere had here broken through to the umbra, or (more commonly) as though the umbra had broken through to the photosphere.

"T. H. B." (let. 4831) does not seem to have read my letter very carefully, since I explained in it why I did not draw the granulations. To have drawn all I could see during moments of favourable definition, in the spot-region actually pictured, would have required four good hours, and I had barely half an hour. Moreover, the great interest of the region depended on its general features. I think that the 2¼in. Dollond with which I drew the picture forming the frontispiece of my "Sun" would have shown all the features actually included in my sketch. I may notice that in the frontispiece to Schellen's German version of Secchi's "Le Soleil," a photograph of the sun shows the same great spots as my picture, and from a careful comparison of the successive enlarged photos. of this spot on the 23rd, 24th, and 25th of September, 1870, all the details of my drawing are justified.

I do not know what "T. H. B." means by a "much smaller telescope" than the $4^{7}/_{10}$in. instrument I used. The latter shows the granules all over the sun, as well as in the neighbourhood of spots. But a *much* smaller instrument cannot possibly do this, no matter how acute the vision of its possessor, or how favourable the atmospheric conditions. It is calculable that with an aperture below 3¼in. or 3⅜in., diffraction must cause the images of the granules to coalesce.

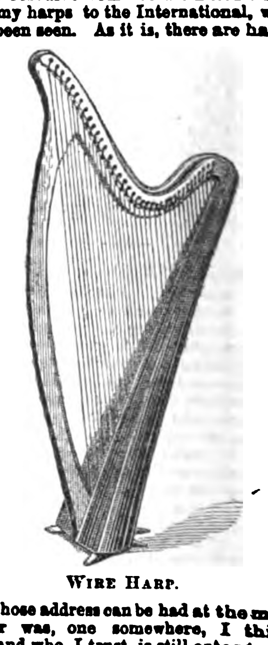
This case is quite different from that to which "F.R.A.S." refers (let. 4823, p. 639, 2nd column). It can scarcely be doubted that acuteness of vision is an essential circumstance in the recognition of minute points of light, faint illumination, and so on; so that while thoroughly agreeing with "F.R.A.S." that the 6th star in θ^1 Orionis cannot possibly be visible in the 3in. telescope, I wished to remove a misapprehension which might have suggested itself to some who read his letter on the subject. To say the truth, some of the feats of Dawes and Goldschmidt would have to be regarded as impossible, if a hard and fast line were drawn as to such observational tests as these.

Since I wrote my last I have tried 57 M. under favourable conditions. The faint light in the interior can readily be seen with three-fourths of the light-gathering power of the $4^{7}/_{10}$in. telescope.

RICHARD A. PROCTOR.

THE HARP.

[4894.]—I HEREWITH inclose the photograph of a wire harp, to which I trust you will kindly yield insertion. The original is of pleasing tone, and, although only capable of being played in one major key, or that of G with F♯, is calculated to realise very pleasing results. No one, I think, who should hear played upon it, as I have often heard played upon it, our old Irish, Scottish, and English airs, could listen quite unmoved. It is not so perfect as is the double or even the single action harp, but it is perfect as far as it goes, and vastly less costly in construction and maintenance than the more elaborate pedal harp. My idea was, and is, that the cheap wire harp might be turned to account in cases where the expense of the more costly and elaborate instrument could not be afforded. Half a loaf is better than no bread. If a double-action harp cannot be had, is the more humble and yet sweetly satisfying wire harp to be discarded? I was going along Paternoster-row a few days since as in one of the side passages a pedal harp, with flute accompaniment, produced music that might have graced many a drawing-room. For a small piece of silver, the performer played for me two or three of Verdi's divine airs more than passably well. As I listened to the poor fellow it set me a-thinking, and I asked myself whether it might not be possible to combine the gut and wire harp, and so arrange the gut-strings as by means of a simple pedal action to produce the half tones, the F and C regarded, and secure at pleasure the desirable modulation. This the wire string does not permit. We might thus, it strikes me, at least in a measure, cheaply combine the excellencies of both instruments, for cheapness with efficiency is, I submit, the great desideratum in the harp of the future, and the talent of the contributors to the ENGLISH MECHANIC is such that I am disposed to think that everything reasonably practicable is at their command. The Welsh harpers have multiple strings to secure the wished-for results. Half notes, to be sure, at least as regards the F's and C's, might be introduced into the Irish or wire harp, but it would considerably augment the number of the strings, and, after all, the resource would be a limited one. I wish I had sent my harps to the International, where they could have been seen. As it is, there are harp-makers



WIRE HARP.

in London whose address can be had at the music shop. There is, or was, one somewhere, I think, called Hafernack, and who, I trust, is still extant. Harps are to be seen in the shop windows of music-sellers in ever large town, and if inquirers and intending constructors would take the trouble of looking in when it would not interfere with the business of the day, few would be found so churlish as to refuse inspection. I only wish I could offer suggestions yet more available than the foregoing—suggestions calculated to bring, or tend to bring, within the reach of every one the refining solace, the almost unlimited gratification, which the music of the harp, when well played upon, is calculated to yield.

IXION.

THE HARP.—To "FIDDLER."

[4895.]—YOU say, let. 5497, "Wires would do for the treble, but be too twangy for the bass." Practically, wires will and have done for both (better or worse). They have "done" for the Irish harp, and would—in another sense—soon "do" for any harp with a moderately long scale, if as thick as those specified by "Ixion" for his favourite "green" instrument, for no ordinarily-constructed harp could bear a tension of (say) nearly 200lb. per string. "Cat—hys—gut" being much less heavy, and perhaps quite as elastic as steel wire, makes better harp, guitar, and fiddle strings, than steel, without any danger of "making both ends meet," which the enormous tensile force required for steel wire might possibly do in a very uneconomical sense, not to mention that a thick and tight steel wire would be rather difficult to deflect down to the finger-board, and to stop in tune. Steel wire is far more suitable for strings whose vibrating lengths are not varied—like those of virginals, spinetts, harpsichords, and pianos—than for fiddles, lutes, or guitars.

For the lowest bass strings of the harp steel wire, loaded by covering it with whitened brass wire, is now very generally employed, and the tone is both powerful and good in quality. There is no novelty in employing steel wire for the bass of the harp. As early as 1828 Deakin used fire-hardened and spring-tempered steel wire for harps and pianofortes. Even then it was not new, for the steel strings of the monster unichord grand piano (grand, in this case, certainly signifying great), constructed for Earl Stanhope, by Loeschman, had fire-hardened and tempered strings, some of which were about 8ft. long between their bridges, and one-sixth inch diameter—by the way, I should be very much obliged by being informed what has become of this "monster." Similar strings were afterwards used by M. Pape, and some one alleged such strings never went out of tune, which I take the liberty of doubting, whoever the "allegator" may be; no doubt, they would stand in tune exceedingly well, just as Horsfall's patent-hardened and (blue) tempered wire did, which, I am sorry to say, is now unpurchasable.

I have sometimes thought catgut strings, if thick enough, and sufficiently loaded, would produce finer sounds than those obtained by covered steel strings in the bass of the harp. They would more nearly resemble the sounds of the double bass where its open strings are pulled by the finger, which I consider the *ne plus ultra* of bass string tone. Some harps do produce bass sounds approximately to these. The clever harpist of the Christy Minstrels (who "never perform out of London") almost deceived me once into supposing a double bass string was being plucked, so fine and powerful were the sounds his Erard harp produced. Very thick—about No. 30 to 36—steel wire (say 8ft. between bridges, and heavily loaded, so that its tension is necessarily great), produces similar sounds in a modern pedal harpsichord, if its plectra be covered—on their acting surfaces—by thick doeskin leather: about a 10lb. touch is required for two strings.

THE HARMONIOUS BLACKSMITH.

ATOMIC PROPORTIONED ALLOYS.

[4896.]—IN "E. L. G.'s" letter (No. 4766, p. 590), chemical contributors are requested to mention any useful alloy having its more fusible component in excess, the writer expressing an opinion that the opposite rule—the less fusible metal to prevail in quantity—has the force of a law in useful alloys. The compositions of following everyday alloys are in direct opposition to "E. L. G.'s" supposed "law":—

1. Britannia metal is an alloy of 10 or 12 parts of the more fusible metal, tin, to 1 of antimony, with sometimes a little copper.
2. Pewter is composed of 4 parts of tin and 1 of lead, the latter being the less fusible metal.
3. Type metal, when of superior quality, contains 1 part of the less fusible antimony to 1 of tin and 2 of lead.
4. German silver contains at least 80 per cent. of the more fusible metals, copper and zinc, to 20 or less of the highly refractory nickel.
5. Silver coinage contains 92·5 per cent. of the more fusible metal, silver.

Alas! for the theory of "E. L. G."

ALFRED H. ALLEN.

THE ORGAN BUILT.—XI.

[4897.]—BEFORE going on with the key movement, I must point out an error in Fig. 2 in my last letter. The trackers from the rollers to the pedals are all shown at equal distances from each other, but they ought to be arranged to correspond with the pedals—viz., leaving a space between the fifth and sixth, twelfth and thirteenth, &c.

The next part to get out will be the backfalls for the great organ. Get a board as long as the windchest, and as wide as from the pullwires to exactly the back of the great organ keys; along one side of the board make a mark corresponding with the pulls, and on the other side a mark corresponding with the centre of the key. Now draw lines across from the first pull (CC) to the corresponding key, and go on, remembering that the second pull belongs to the third key DD, and the third pull to E, as six of the bass pipes are on the treble side of the soundboard. Now continue the marks until you come to the upper note, and then mark out the six bass notes, as if there were six more keys. Having carefully marked out the position of the backfalls, proceed to get them out as described in my last, with this exception, that separate centre wires are only required for the six at each end, and one length of wire for all the rest. Now get the rail out and fit the backfalls into the grooves; a little play should be allowed them, so that they will not stick fast in damp weather, and a very good plan is to blacklead that part of the backfall which goes into the groove of the rail. A roller board will be required to carry the movement from the six transferred pipes to their keys; one arm of the roller is over the key and the other arm under the proper backfall. The position of the roller board is shown at A in Fig. 1.

FIG. 1

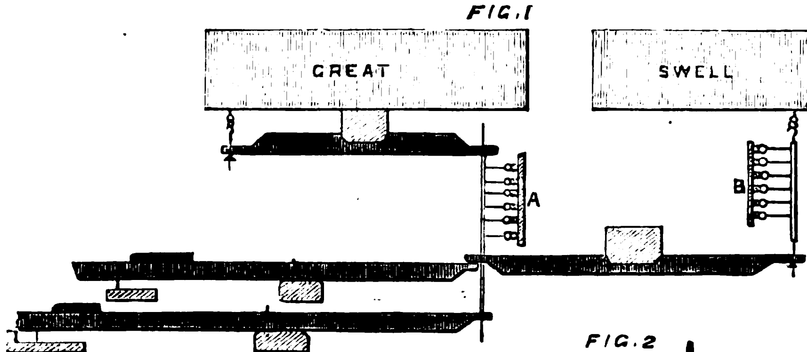


FIG. 2

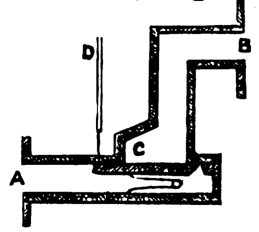
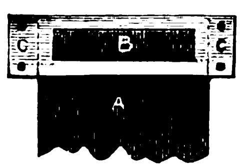




Backfalls for the swell organ will now require getting out: proceed in the same manner as for the great organ, only that the backfalls for the transferred pipes are to be placed over their proper keys, the other end coming between the pulls in the windchest, and pulling down the arm of the roller. This roller board is shown at B in Fig. 1.

The rails and backfalls having been completed, screw the great organ rail to the windchest so that the hole in the backfall is exactly opposite the pull, and to each pull attach a tapped wire, placing a leather disc between the two. The screwed end of the wire goes through the hole in the backfall, and a cloth washer and leather button placed on in the usual way. This windchest may now be put into its place on the frame; it is only laid on and kept from slipping by two dowel pins on each side, the dowels being fixed in the frame, and corresponding holes bored in the windchest, the front part of the windchest being level with the front of the framing; also put the swell windchest on the frame in a similar manner, and leave a space of 6in. between them. I am, of course, presuming that the swell may be tuned from the back, and am therefore putting the organ together in as little room as possible; but if that arrangement is impracticable, space must be left between the windchests for the tuner, and a board placed for him to stand upon, the backfalls and other movements being made to correspond. The great organ stickers are now to be got out; they are thin round rods of pine, ⅜in. in diameter, the length of them is the distance between the keys and the backfalls. The easiest plan to get them out is to use a ⅜in. beading plane, but they may be got out square and rounded with a smoothing plane. Stickers of suitable length go from the keys to the roller arms, and at the other end from the roller arms to the backfalls. The connection between the swell backfalls and the pulls of the windchest is by trackers, made as described in my last letter, a hook being used at the end near the windchest, and a screw wire at the other; in this case the rollers are attached by trackers to the backfalls at one end and to the pulls at the other end. The windtrunks are now to be made; they are flat tubes to convey the wind from the bellows to the windchests. The internal diameter of those to the great and swell should be 9in. by 2½in., those to the pedal organ 8in. by 3in., but a valve is to be placed in these two for the draw stop to move. A plan is shown in Fig. 2, where A is the entrance from the bellows, B the entrance to the windchest, C the valve which is pushed open by the sticker D, this sticker being moved by the stop knob. All the windtrunks are fastened in their places by flange plates, which are firmly glued and fixed to the trunk, and then screwed with four screws to the trunk band of the bellows or the windchest. These plates are generally made of 1in. mahogany, of such a size that they can have a hole cut of the size of the hole they are to cover, and leave a margin of ⅜in. at the top and bottom, and also project an inch on each side of the windtrunk. See Fig 3, which shows a flange plate on a trunk: A is the trunk, B the aperture the wind goes through, C the flange plate.

J. D.

INFLUENCE OF LIGHT ON ANIMAL LIFE.

[4898.]—IN a paper on this subject in the *Revue des Deux Mondes*, extracts from which were furnished by a correspondent, it is stated (p. 606) that "the phenomena of sunstroke arise from the action of light, not from elevation of temperature." In a recent number of the ENGLISH MECHANIC the opinion of competent medical authorities is quoted, which contradicts this explanation. Many years ago I noted cases of "sunstroke" without sun occurring frequently among stokers in the tropics, and I think I am correct in stating that the opinion of medical men in this country is decidedly in favour of the cause of heat-apoplexy being an increase of the temperature of the blood.

In the same abrégé it is stated that the Hindus of the Himalayas are nearly blind; this must, surely, be a misprint. Again, light cannot be the sole cause of the black skin of the negro, unless we are to believe an hereditary proclivity to blackness, originally due to solar light, exists. For, if so, the negro child born reddish, and clothed and living in temperate climates, would not blacken as it grew up. Far more likely does it appear that blackness was given to the skin of certain races to favour radiation, and that the amount of heat to be endured was considered in their creation. It is well known that the depth of shade does not correspond with the intensity of solar light, and, what is still more significant, the internal organs of the negro are melanotic or smoky-tinted.

M. PARIS.

OUR MATHEMATICAL COLUMN.

[4899.]—FOR a long time I have entertained the idea that a column devoted to the consideration and solution of mathematical problems would be of very great service to a large number of readers. Every now and then friends write to me asking for the solution of this or that problem, and continually the list of queries in the ENGLISH MECHANIC contains several problems for solution.

Now, to a great extent, problems, like words, may be divided into classes, and if the student can interpret this or that reasoning, he is able to solve a class of questions. Whilst problems are given indiscriminately amongst other queries, this classification cannot be carried out, and space is consequently occupied by the solution of similar (*i.e.*, belonging to the same class) problems. My idea is to assist students generally, the amateur as well as the professor. The explanation of a fraction or a decimal will be of as much value to one class of readers as the discussion of the simplest manner of "taking out strains" will be to a second class, or the discussion of chemical formulæ to a third.

No branch of trade can be carried on without some knowledge of mathematics, and, unfortunately, the major portion of the community is not before its requirements. It would, therefore, benefit many to have their difficulties solved quickly, easily, and cheaply. The aim of this column will be to serve the mass, and not those select few whose study is in the van of science and scientific thought. If, then, a number of problems are given, and solved weekly, and if to these be added short notices of new mathematical books, or papers read at the meetings of the various scientific societies, the wants of readers, we imagine, will be satisfied.

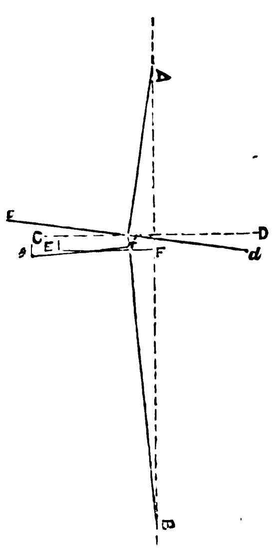
Personally, I should have preferred to have seen Mr. Proctor, or some equally competent hand, conduct this portion of our cosmopolitan journal; but, I fear, owing to his manifold engagements, we must be satisfied with what we can get from him in other ways. I know he will be only too pleased to give any assistance that he can, and I would appeal to all mathematical readers to endeavour to make this column as useful and interesting as possible.

C. H. W. B.

REPLIES TO QUERIES.

*** In their answers, Correspondents are respectfully requested to mention, in each instance, the title and number of the query asked.*

[11313.]—**Setting Lathe.**—In looking over some back numbers I noticed this query, and also "J. K. P.'s" answer to it on p. 48, as also his additional answer on p. 154, but neither give the desired information. It is rather late to answer a question asked the 22nd of last March, but I hope not too late to prevent F. Hume from spoiling his lathe by adopting any fixture or wedge device for setting his lathe headstock. The screw he mentions as fitting between the sides of his lathe bed is a very proper and necessary adjunct to any good lathe, particularly a slide lathe, which I opine F. Hume's to be. The proper way to set the headstock by means of this screw, is this:—First screw the large face plate on to the spindle nose—said plate must run dead true—then, premising that said face plate allows, as it ought to do, the centre to be placed in the spindle nose, which centre should also run dead true, get a piece of stout iron wire and bend one end into a ring which will jam tight on to the end of a mandril, the centres of which are good. The wire must then be bent at right angles to its length, and to the plane of the ring at its end at about an inch less than the radius of the face plate from the centre of said ring, and cut off about 2in. from the angle, and the extremity of the above-described contrivance must be then filed to a point. It must then be jammed on to the end of the mandril, and the two together set in between the centres of the lathe, the point of the wire, which should now be at a very little distance from—in fact, nearly touching—the surface of the face plate, upon being handed round to different points on the face plate, will show by its distance at those points which way the headstock is out of adjustment, as, if perfectly true, the point would keep an equal distance from the plate all the way round. So if the point of the wire is furthest from the plate at the front side of the lathe, the head wants setting back, and if at the back, then it wants to come forward. Perhaps the sketch I send, if worth the



trouble of cutting, will give an idea of what is required. The dotted line A B represents the true line of parallelism of the lathe. The dotted line C D, at right angles to A B, the (consequently true) position of the face plate. E F, the wire described fixed to the mandril (supposed) F B. The full lines represent in an exaggerated form the positions of the several parts when out of truth.—Hone Ko Io.

[12433.]—**Pie Heater (U.Q.).**—There are various ways of doing this: some are pans supplied with steam from the boiler used for general cooking purposes, whilst others are pans perforated, and heated by gas jet; a pipe conveyed from one corner of the tin is passed out either at one corner or out at the top of window; in some cases down in the cellar.—Jack of All Trades.

[12457.]—**Geometry.**—"Bobo" has himself fallen into two mistakes in finding fault with "E. L. G.'s" answer. "P. W. H. J.'s" method does produce a rhomboid, which "Bobo" would have seen had he read the answer. Also, "E. L. G." produces a rhombus, though not the rhombus required, he having overlooked the condition that one corner must coincide with a given point. I would like very much to see the true answer to this problem.—Xenophon.

[12460.]—**Four-Valved Cornet (U.Q.).**—I don't know, but should imagine the "four-valved cornet" would have the same fingering as the baritone euphonium, or bombardon, has with four valves; if so, "H." may first learn the scale as though the instrument had but three. The fourth is extra; it is equal to the first and fourth—*i.e.*, you may finger D below the first, or G below the second ledger below the staff (treble cleff) with the first and third or fourth (the latter is generally preferred); the same notes flatted, thus D flat and G flat, may be made with second and fourth, instead of first, second, and third, thus avoiding the use of one valve. Again, it is useful in shaking on C (on first ledger line below), using the fourth instead of first and third for D, the note above the shake. In instruction books they give the fingering of the scale chromatically down to C, making the compass of the instrument three octaves, but every note below G is too sharp.—L. C.

[12468.]—**Exhibited Inventions (U.Q.).**—I have seen the same in print, but know not where. Apply to the officials.—Jack of All Trades.

[12471.]—**Wheels.**—The face spokes of wooden wheels are those nearest the nose of stock or front side of wheel, so face arms would be those nearest front side of a metal wheel.—Zax.

[12472.]—**Electrical.**—1. If the wire of the galvanometer is short and thick, it will not be deflected, because the quantity of electricity transmitted by the induced direct and inverse currents is the same; but if the wire of the galvanometer coil is long and fine, there will be a deflection, because although the direct and inverse currents are equal in quantity, they are unequal in intensity, the direct current having highest tension. 2. Hedreder's is the best coil for medical purposes, but the ordinary so-called "shocking coil" does for passing the induced currents through the body for relieving rheumatism. Magneto-electric are useful in dispensing with all the trouble of battery, &c., and the currents can be obtained from them in similar forms to those of ordinary induction coils. 3. Daniell's is a good constant battery, but expensive. Smee's is a very useful battery when made with lifting gear (so that it may be dropped into the solution when required, and raised out again as soon as done with), is moderate in price, simple, and I think would suit your purpose well. The sulphate of mercury battery will keep in order from six months to a year, is also moderate in price, but not very powerful.—Zax.

[12504.]—**Sketching from Nature.**—I regret that I should have troubled any of your readers, especially a lady, to make further inquiries by my not being sufficiently explicit. I tender my apologies, and ask the fair "Julia's" pardon. I presume that the student having traced the outline on the glass proceeds to copy it on paper, and from time to time lays the glass over the same (the sketch) to see how he gets on. Next the gummed side of No. 1, on which the drawing is traced, is laid gummed side down on white paper. Over this glass No. 2 gummed side upwards is laid, and a charcoal tracing is made thereon; on this plate, No. 2, the drawing is laid, and rubbed on the back. Then it is removed, and the outline traced with lead pencil. I hope this is sufficiently clear. I would add, that it would be well to have several holes in a line towards the glass, made for the upright *a* to increase or diminish the size of the picture. A student who practises this method for a short time will soon be able to lay it aside and sketch freely without any mechanical assistance.—Old Boots.

[12528.]—**Hay Asthma.**—"Alfred S." (p. 622), is "sorry that I recommend the inhalation of creosote;" as "in any shape or form it will inevitably cause nervous twitching, and even paralysis!" How benighted, then, must have been the General Medical Council, composed of the foremost men of the United Kingdom, who, in 1867, issued the "British Pharmacopœia" with formulæ for "Creosote Inhalation," mixture and ointment—creosote in these various "shapes and forms," and yet not one word of caution as to "twitches and paralysis"! I have no objection, if "Kate" has not, to "Alfred S.'s" Epsom Salts. Eau de Cologne is as useless as it is expensive.—Lambda.

[12529.]—**Improved Machine for Making Aerated Drinks.**—I believe the gas for all aërated or mineral waters is produced from diluted sulphuric acid and whiting; it is for all the machines I have seen. I do not see any improvement in the machine "H. B. E." recommended, as I tried that principle years ago, and it was quite a failure.—L. W. D.

[12529.]—**Improved Machine for Making Aerated Drinks.**—I see you have many inquiries on this subject. I am one of the earliest makers of them in England, but gave up the manufacture many years ago. No one can make them properly without a machine. One made on the best principle may now be had at from £30 to £80, according to size. The principle on which all aërated waters are made is simply this:—A leaden retort is filled half full with whiting and water. Into this mixture a very little sulphuric acid is poured at once, which instantly liberates a quantity of carbonic acid gas. When that acid is spent, a little more is introduced, and more gas liberated. The gas thus liberated passes through water into a gasometer. Thence it is pumped into a metal cylinder containing water, or soda and water, &c., and very powerfully compressed, being well mixed by means of an agitator, or, as we used to call it, an "O'Connelliser," very rapidly revolved. When the liquor has absorbed sufficient gas, it is conveyed by pipes to the bottling machine, bottled, corked, and tied over. It is then quite ready for use. If requested, I shall be happy to send drawings and a detailed explanation.—Kelby.

[12537.]—**Compressing Air.**—At p. 622 there is given the result of some experiments on the compression of air and resulting temperature. The theory of a perfect gas, supposed to consist of free and perfectly elastic molecules in a state of motion, the mean square velocity of the motion being proportional to the absolute temperature, reckoning it from $-461°$ Fahr.—the zero of gaseous tension—gives the mutual ratio of change of pressure, density, and temperature when the gas is suddenly compressed or dilated. The rule for computing may be inferred from the following proposition:—$t \propto \sqrt[4]{p} \times \sqrt[3]{d}$, in which t is the absolute temperature, p the pressure, and d the density. As an example of the computation, take the experiment that lasted two hours, in which the valve was loaded with 45lb. to the square inch, making the whole pressure or tension of the compressed air to be $45 + 15 = 60$lb. Before compression we have $t = 461 + 42 = 503$, $p = 15$, and $d = 1$. After compression, $p = 60$, and d is less than 4, because of the rise of temperature, $256 - 42 = 214$, the absolute temperature being $461 + 256 = 717°$, so the density has to be reduced in the ratio of 503 to 717 (Dalton and Gay Lussac's law), or $\frac{503}{717} \times 4 = 2{\cdot}806 = d$. To find the theoretical value of the absolute temperature, t, the following is the proportion:—$\sqrt[3]{1} : \sqrt[3]{2{\cdot}806} :: 503° : 709°$, which is thus 8° less than the result of experiment. This may, perhaps, be accounted for by the heating of the cylinder, and consequently of the entrant air before it is compressed. In another experiment, with load of 58lb. on square inch—which was also continued for upwards of an hour—the same computation gives 277° Fahr., instead of 296°, or 19° less. From newspaper accounts, it appears that the Americans are applying compressed air to locomotion on tramways. It is to be hoped they will be successful, on account of the poor horses. In the economic application of such power, it is obvious that artificial cooling is required during the compressing or storing, and artificial heating during the expansion or delivery of the power.—N. S. N.

[12551.] — **Picture Framing.** — Errata.—For "springs," read spring bit.—A., Liverpool.

[12557.]—**Nickel Silver.**—May I request the attention of "E. L. G." to the extract from Montaigne's Essays which heads the correspondence in "Ours." The advice there given would be very serviceable to him in particular, and possibly some other of our friends who are sufferers from that distressing affection "cacoethes scribendi." In answer (No. 12557, p. 573), I explained the composition of German and nickel silver, and stated that pure nickel unmixed with other metals was never employed, while on page 623 "E. L. G." takes the trouble to contradict this statement and say that pure nickel is employed for coinage, mentioning the Belgian sous as the nearest example to hand. Now, as a matter of fact, the coin mentioned is not pure nickel, nor is there any coin in circulation that is composed of nickel only. The Belgian "sous" (or 5 centime piece) was formerly made of German silver, but is now composed of an alloy of nickel and copper, with sometimes a little iron. I have not analysed a piece quantitatively, but believe the copper to amount to about 30 per cent. of the coin. As "E. L. G." is evidently not a chemist, I may inform him that he can readily detect the presence of abundance of copper in the coins he erroneously took for pure nickel, by pouring on the piece a few drops of nitric acid (the coin is not defaced), allowing it to act for a minute or two, rinsing off with a little water, and dropping a small piece of iron (a tack or needle) into the liquid, when he will find a deposit of metallic copper will be speedily produced. Before "E. L. G." again contradicts a perfectly correct statement, he will do well to remember that it has a very bad appearance, and may induce his numerous admirers to pause more frequently before they swallow his many fanciful theories, from cometary deluges downwards.—Alfred A. Allen.

[12621.]—**Black Dye for Leather.**—If "Kendal Saddler" would give his recipe for dyeing leather black on a large scale, he would greatly oblige—Experimenter.

[12642.] — **Ice Cream.** — A cheap and effective mode for the above is to first make a composition of the following:—Beat three eggs with half a pound of loaf sugar, till well mixed, then add a pint and a half of milk, and bring to boil on a quick fire, keeping it well stirred. Add half a pint more milk and put it in a cool place, stirring it occasionally. To freeze the same pour the composition into the freezing-pot, which is a vessel made of either pewter or zinc, the latter being much the cheapest, with a lid having a handle over across the top, and watertight; place the pot in a pail, and pack a mixture of rough ice and coarse salt round the pot in the pail so as to bed it in, put a thin sprinkling of salt on top, then cover the ice round with an old flannel, and work the pot containing the composition backwards and forwards for a minute or two. Take the lid off, and scrape what adheres to the side, and again work the pot round and scrape with a wooden spoon, as before, continuing this process till it becomes the proper consistency, which should be as stiff as butter; a little vanilla added greatly adds to the flavour; then throw the melted ice and salt away, replacing with fresh, which will then keep it stiff for six hours. For 12lb. of broken rough ice put 3lb. or 4lb. of coarse salt. On no account let any of the ice mixture get in the composition in the freezing-pot or it will never freeze.—Louis.

[12650.]—**Government School.**—Candidates for engineer studentships must be between 15 and 16 years of age. They are examined every June and December by the Civil Service Commissioners at Devonport, Portsmouth, Chatham, and Sheerness. The examination is open and competitive: on this account it is competed for by large numbers of clever youths, which renders it very stiff indeed. "W. M." may, on application to the office of the Admiral Superintendent at either of the above-mentioned yards (surely "W. M." must have known that Woolwich yard was closed), obtain nomination papers and also papers containing all requisite information.—E. S.

[12653.]—**Poultry Keeping.**—I kept twenty fowls in an ordinary poultry house, and one night saw thieves at the door. I went upstairs and fired at them a revolver out of the window, they quickly disappeared, and have not come again since, but my poultry being valuable, and not wishing to trust to the chance of knowing when thieves might come again, I constructed a new poultry house of corrugated galvanised iron, which is perfectly thief proof. It is 4ft. wide and 8ft. long on the ground plan, and 6½ft. high at the back and 4½ft. in front. The house consists of five pieces, back, front, two ends, and roof, they are put together by bolts and nuts, the nuts being inside the house. Part of the front is the iron door; it is secured by a stout chain and padlock, the chain going through a hole in the door and a hole in the end of the house. At the other end a hole is made just big enough for the fowls to go in and out. To prevent the house being too warm in summer and too cold in winter it is lined with ½in. boards.—J. L. H.

[12667.]—**Organ.**—"W. Z." has not carefully read my letters on "The Organ Built," or, I think, he would not have asked such a question. Refer to letters three and four in "ours" of January 26 and February 9 of this year, and see if full directions for fixing pallets and guide pins are given. I think they are, but if "W. Z." still remains in a fog I will try to enlighten him. No covering board is placed over the paper on the bars.—J. D.

[12681.]—**Is the Interior of the Globe Vacuum?**—"Rasselas" has quoted an extract from Ansted's "Physical Geography," which indorses the views of Prof. Sir W. Thomson and Mr. W. Hopkins, Cambridge. M. Delaunay, the lamented director of the Observatory in Paris, has come to a different conclusion. According to that eminent mathematician and astronomer, in order that the reasoning of Professor Thomson might be entertained, we must admit in liquids an absolute mobility. But this does not exist, for all liquids are more or less viscous. When a sudden rotation is communicated to a solid, which envelops a liquid on all sides, the solid alone turns, the liquid remains behind, which it is easy to ascertain by observing sawdust which has been put in that liquid. But it is no longer so, when we turn the balloon slowly, in that case inertia makes the liquid adhere to the inside of the vessel, which carries it in its motion. The hypothesis of the central fire is not contrary to the astronomical phenomena, according to M. Delaunay, who pretends that the action of the sun and the moon is exerted on the whole mass of the globe, and that thus the phenomenon called precession is not an objection to the fluidity of the central part of the globe.—F. T.

[12684.]—**Canoe.**—In reply to "Aquarius," I have much pleasure in giving him the dimensions of a canoe which ought, I think, to suit his purpose. Length, 12ft.; beam amidships, 30in.; depth from rabbet of keel to gunwales, 10in.; depth of keel, 1½in.; sheer of gunwales, 5in. The well to be 32in. long by 20in. wide, the back of the well to be 21in. abaft the centre of the canoe. The deck to be of cedar or mahogany (the former preferable), and have about 3in. arch amidships; the stem and stern posts of oak or ash; the keel of same timber or American elm; the planking of oak if for travelling and knocking about much, otherwise of yellow pine, or spruce, or cedar, and the ribs or timbers of oak, or ash, or birch. Step the mast 3ft. 10in. from bow, and rig with a standing lugsail of following size: Fore leach, 8ft. 6in.; after leach, 7ft. 6in.; head, 5ft. 3in.; foot, 5ft, 3in. Rig a dandy also, abaft the well, of a jib shape, 3ft. 6in. leach and foot. I do not know anything of sheeting a canoe with zinc, but do not think it would suit at all. Any other information required by "Aquarius" I will be happy to give, if in my power.—CANOEIST.

[12696.]—**Atmospheric Pressures.**—The Board of Trade's "Barometer Manual," Stanford, Charing-Cross, price 1s.—E. L. G.

[12703.]—**Fuchsias.**—Fuchsias are very susceptible of change of place. I have known some affected to the falling off of leaves and flowers by being shifted from one room to another, nay, from one side of a room to another. It is but reasonable, then, that they will go to the bad when brought from a greenhouse or nursery, where they have been forced, perhaps, into premature bloom, and placed in an atmosphere many degrees lower. I have spoiled a magnificent plant this summer by putting it outside the window one day and inside the next, as I thought the weather suited; at last I put it in the ground to save it. It is now in full and luxuriant foliage, but it has not shown a bloom this year. Also too much water, or too little, will cause buds and leaves to fall off. In future all my fuchsias will go into the flower-beds in the spring, to be shaded by an awning (as is or should be done with tulips) from heavy rains and strong sunshine. I have some very fine fuchsias, but no greenhouse, and in that case my experience has convinced me that the plants do much better in the beds.—H. G. W.

[12705.]—**Extracting Vegetable Colouring Matter.**—The green colouring matter of leaves, known as chlorophyll, can be extracted by chopping up green leaves or grass with a knife, and digesting with strong alcohol. A deep green solution is produced, which is strongly fluorescent. If this solution be evaporated gently to dryness, a splendid red colour often appears on the edges of the residue, while comparatively pure chlorophyll is deposited in the centre. This red colour, found principally in autumn, and called erythrophyll, is an oxidation product, and may be extracted from the residue by treatment with water. On redissolving the purified residue in alcohol or carbon disulphide, the green colouring matter may be obtained almost pure. Analogous processes may be employed for most other vegetable colouring matters, comparatively few being soluble in water. Many yellow and orange colours may be separated by shaking the alcoholic solution with carbon disulphide, when the yellow colour becomes in a great measure dissolved in the heavier liquid which settles to the bottom.—ALFRED H. ALLEN.

[12706.]—**Laboratory Purification.**—Processes producing disagreeable fumes or gases are usually conducted in a glass case or "stink-cupboard," having an opening into a chimney, or, better still, into a separate flue. When the action is imperfect, it may be increased by lighting a gas jet placed under an iron tube which passes through the aperture into the flue. This tube may, with advantage, be made large enough to fill the hole, but as the latter must be nearly at the top of the case, the gas-burner must be raised accordingly. A small case can be constructed out of a large box or packing-case, fitted with sufficient glass to allow of the operations being watched from without. If sulphuretted hydrogen is the principal annoyance, it may be got rid of by always treating the solutions in a bottle fitted with tubes, so that the excess of gas can be passed into a tube or bottle filled with acetate of lead, sulphate of copper, or a mixture of ferrous sulphate and slaked lime, either of which will absorb it pretty completely. The last is the cheapest, and may be used over again after being turned out and freely exposed to the air.—ALFRED H. ALLEN.

[12706.]—**Laboratory Purification.**—Make an opening into a chimney, of course close to ceiling. The best way is to close in a recess with a sliding window; make the opening in this recess and carry on all offensive operations therein, closing the case as much as possible. In this way, and by using refrigerating tubes of my own device to condense the fumes, I sometimes keep acids boiling for hours at a time without making the laboratory itself unpleasant, while no fumes reach the rest of the house at all.—SIGMA.

[12707.]—**Geometrical Query.**—The projection of a circle is proved to be an ellipse at p. 326 of Todhunter's "Conic Sections." I will send the proof if required.—XENOPHON.

[12707.]—**Geometrical Query.**—The sole condition for having a circle projected perspectively as a parabola is, that the ray from one point of its circumference (and from only one) to your eye shall be parallel to the plane of the picture. There is an engraved interior view of S. Paul's, taken from under one of the diagonal arches of the central octagon, and as the circular cornices about the base of the dome have one point vertically over the spectator (the picture plane being also a vertical one as usual) all their lines become nearly parabolas. This view (unless as a cosmorama or peep-show) does not make a satisfactory picture, for the reasons I explained to M. Paris. Views within the Pantheon at Rome, similarly taken from the exact line of wall base, would make all the circular lines of the full diameter parabolas, and if the spectator advanced to (say) 50ft. from the centre, they, and all of more than 100ft. diameter, would become hyperbolas; one alone (that one in the dome whose radius is 50) being a parabola. But as views of this building, so far as I know, are always from the back of some recess, they project all the lines as ellipses. A view from the top cornice, or springing of the cupola, would make every line above that one circular, as in the stereographic map projection. A circle's projection can only be a conic section; a straight line, ellipse or circle, whenever the picture, indefinitely extended, would enable you to show the whole of it; and a straight line, hyperbola or parabola, whenever it could not embrace the whole.—E. L. G.

[12710.]—**Aerated Ginger Beer.**—Perhaps "Sodawater" uses too much essence of ginger; about ½oz. of good essence to 3lb. of sugar with tartaric acid to suit the palate is a firstrate flavour, and it will not make the water scarcely at all cloudy, but all essences will if too much is used. Perhaps the gas is not sufficiently washed, or not properly generated. If he will say how the gas is made for his machine, and what class machine, I could better say, and give him a more definite answer.—L. W. D.

[12711.]—**Height of Mountain.**—At A, take the top's angular altitude and angular distance from B; at B the same two relations to A; and measure the distance between A B (not less than a tenth its distance from either) and also their difference of level.—E. L. G.

[12718.]—**Potato Stains.**—If "Anti-Acid" will go to any oil warehouse, and purchase a piece of pumice-stone, and first rub a little soap on his fingers, and then rub with the stone, it will soon remove the stains without injury to the skin. Proved.—J. W. PEARSON.

[12720.]—**Medical Coil.**—These cannot give a continuous current under any circumstances. They can and ought to be made to give one in one direction only, and the way to do this is to connect the beginning of the secondary to the end of the primary wire. A bichromate cell will be found more convenient than the Daniell. The latter will also work to much less advantage than the Leclanché for a clock, or for any use requiring currents of small quantity.—SIGMA.

[12725.]—**Fused Chloride of Silver.**—"Argentum" has probably not dried his chloride before fusing. It should be well dried, and then it fuses with perfect ease over a Bunsen gas-burner or spirit lamp, and may be cast into rods or plates; the battery as made, however, is a very expensive toy.—SIGMA.

[12726.]—**Motion of a Sailing Boat.**—Everybody can understand how a boat can sail before the wind, but to sail with the wind on the side, or to make way against the wind, is far more difficult; in fact, persons unaccustomed to it often doubt the possibility of doing so. In explaining this we will consider the sails as quite flat, for the nearer they can be brought to flatness the better. Supposing the sails, then, to be flat, and the wind to strike them, part of the force is lost, as will be understood on mechanical principles, part of it presses against the flat surface of the sail, and perpendicularly to it, this, then, tends partly to drive the boat ahead, partly to drive the boat bodily to leeward, and if the boat were a box or a tub, she would go in a direction between the two, but as boats are constructed sharp at the fore end, the surface opposed in that direction is not more than one-seventh of the surface which the nearly flat side opposes. Thus the boat is driven easily ahead, but only a little to leeward. I cannot attempt to explain the latter part of the query without disregarding the advice contained in Montaigne's Essay.—CAMBRIA.

[12736.]—**Cement on Postage Stamps.**—British gum, made, I believe, by heating starch until it assumes a brown tint.—AROMA.

[12736.]—**Cement on Postage Stamps.**—It is dextrine, or British gum, made from starch by exposure to heat. It may also be prepared by the action of acids and diastase (a substance formed in malt), and by a limited fermentation.—SIGMA.

[12739.]—**Geometry.**—Let P be the intersection of A B and F C. Since the angle B A D equals B F C, and A P C equals F P B (i. 15), therefore A (1) P equals F B A, equals a right angle. Therefore the angle A (1)(2) equals a right angle. In the same way the angle A (3)(2) equals a right angle. Therefore a circle can be described round A (1) (2) (3).—XENOPHON.

[12756.]—**Etching on Stone.**—Very fine lines can be etched on stone. Instead of a grained stone it should be what is termed a polished stone, produced with pumice-stone, cake colours being used the same as water colours, and drawn with a lithographic pen. I have done the same myself for gold and colour printing.—JOSEPH WILLIAM FENNELL.

[12757.]—**Hand Railing.**—Templets being made for every pattern of bend or curve, planes most suitable for the same with paring chisels, gouges and rasps finish the same. See "Hand Railing," in *Building News*, which will furnish every particular.—JOSEPH WILLIAM FENNELL.

[12757.]—**Hand Railing.**—After the wreath has been truly squared there is nothing better than the two-handled draw-knife for reducing it nearly to the mould, then use routers of the spoke-shave pattern, but having for a cutter the plane-iron taken out of the planes, used for moulding the straight lengths of rail. Your ingenuity should devise the rest. No two men pursue exactly the same method.—OLD PLOUGHMAN.

[12758.]—**Socket Handles.**—By making a pair of hollow clams, to work by a screw or lever, the same as vice jaws, you could do them almost as fast as counting them. Make the plate to the proper taper, heat them, lay them between the jaws, and the mandril upon the top, and pinch up with either a screw or lever.—JACK OF ALL TRADES.

[12759.]—**Leaking Indiarubber Bottle.**—Get some indiarubber solution, and put a patch on the inside; it will require some considerable time to get dry.—JACK OF ALL TRADES.

[12759.]—**Leaking Indiarubber Bottle.**—Stick it together with indiarubber cement, and, if necessary, stick a new piece over leaky place with same.—ZAX.

[12760.]—**Bringing Slate to Surface of Quarry.**—Use a wire rope and horizontal drum, using two tramways and two trucks, the one going down whilst the other is coming up.—JACK OF ALL TRADES.

[12760.]—**Bringing Slate to Surface of Quarry.**—It is quite practicable to wind up the stone in the manner mentioned. If the weight of the load, including the weight of the waggon and friction, be 1 ton, the incline 1 in 6, and the height 60ft., it will require 4 horse-power to land each load in one minute, which would be a speed of about 6ft. per second, or about 4 miles per hour. These are all approximate numbers. It would be a question depending on further details of the situation whether a vertical lift would not be preferable to an incline. It would cost less.—C.S.

[12760.]—**Bringing Slate to Surface of Quarry.**—"A Poor Irishman" may bring slates to the surface of quarry with his present engine by fitting up a barrel for wire rope and laying down tramway; the barrel would require to be 3ft. diameter and 4ft. long, and make about fifteen revolutions per minute; it will require a sliding coupling on driving shaft for disconnecting from engine, and a brake on end of barrel for running down empty waggon, wire rope ⅝in. diameter; it will require small rollers or pulleys placed between rails 9ft. apart to prevent rope from rubbing on the ground; it will bring up a ton at a time. If the barrel cannot be placed in a line with tramway the rope can be guided to it with pulleys; it will work more satisfactory than a steam winch, and much cheaper.—P. C. E.

[12762.]—**Curve of Mirror.**—The surface of the concave speculum of a reflecting telescope must be worked to a parabolic curve. Various machines have been devised for producing this figure with certainty. Valuable information on this subject may be found in the columns of the ENGLISH MECHANIC, where the subject is fully treated by "Arcturus," W. Purkiss, &c. I should recommend "Zeta" to read carefully "Herschel on the Telescope," and the back numbers of the ENGLISH MECHANIC. I am using a mirror 5⅜in. diameter and 51¼in. focal length, which I made by hand only, without any machine whatever, and which is of excellent quality. It will divide 36 Andromedæ, π Aquilæ, and ι Arietis with a power of 250 diameters.—A. WOOLSEY BLACKLOCK, M.D.

[12762.]—**Curve of Mirror.**—The curve of the mirror of a reflecting telescope is a parabola. The mirrors are ground by a machine. The process is a very delicate one.—ALFRED H. ALLEN.

[12763.]—**Preparation of Carbon.** — Carbon may be prepared from sugar: 1. By the action of superheated steam; 2. By placing in a receiver with Nordhausen sulphuric acid H_2SO_4, or English acid $2H_2OSO_3$, or by the oxidising effect of nitric acid.—C. B.

[12763.]—**Preparation of Carbon.**—Heat the sugar to a red heat, without access of air.—ZAX.

[12765.]—**Sun Dials.**—A horizontal dial for 40° N. latitude can easily be constructed. The gnomon must point to the pole, its angle is thus equal to the latitude of the place, which should therefore be accurately known. The XII. o'clock hour-line should be fixed in the astronomical rather than the magnetic meridian. A true meridian-line can be found by equal shadows of a blunt rod, or by observations of stars having the same right ascension. The angles which the various hour-lines make with the XII. o'clock line are readily found. For 40° N. latitude they are as follows, being equal for hours equi-distant from the meridian:—

Hour-lines.		Angle with Meridian.	
XI a.m. and	I p.m.	9°	46′
X	II	20	22
IX	III	32	44
VIII	IV	48	4
VII	V	67	23
VI	VI	90	...
V	VII	67	23
IV	VIII	48	4
III	IX	32	44

The last three angles are of course on the opposite side of the VI. o'clock hour-lines. I shall be happy to supply "Emigrant" with any further information on this subject. The best treatise I know on the subject is one in the "Edinburgh Encyclopædia," article "Dialling," Vol. VII. Your correspondent will there find an excellent description of all kinds of dials, from the "Portable Dial on a Card," to the "Universal Dial on a Cross."—TAG.

[12766.]—**Fiddles and Fiddling.**—I have no doubt "H. H." will find the cause of his trouble is in the bow, the hair being greasy. If so, take a clean tallow candle and rub the tallow well into the hair with finger and thumb from end to end; then take a clean duster and rub the tallow off (be careful to get the hair perfectly clean); then take a little clean flour and rub it well in as before; then take a clean duster and clean the hair as before; then powder a little rosin, and rub it well in; then "rosin the bow" in the usual way, and you will find it will go as free and as beautiful as if it was new. And when clean, you should never touch the hair with your fingers.—C. M. B.

[12766.]—**Fiddlers and Fiddling.**—In answer to your correspondent "H. H.," requesting to know the reason his bow slips and makes "squeaky and offensive" notes, I would suggest it is the fault of "him that boweth," for if "H. H." will pay due observance to the rules which govern "fiddling," he will see that he must press his fingers very firmly on the strings, and next, he must hold his bow firmly, and pass it in a direct line between the bridge and the end of the finger-board. If the bow should deviate from that line, and wander too near the bridge, it will create the offensive notes complained of: or if the bow, on the other hand, be allowed to wander too near the finger-board, it will very likely slip, and squeaky notes be produced; or if the fingers are not pressed very tightly on the strings (never mind corns), the same disagreeable results will follow.—A. DEANE.

[12767.]—**Puddling Fishponds, &c.** — The thickness of the puddle should not be less than 8in., and if clay is plentiful, 12in. is a better thickness. Whatever the thickness may be it should be worked in two layers, so that the imperfections of either may not be continuous through the whole mass. Two inches thickness of lime is sufficient. The same thickness of smith's ashes will do instead. Mixing gravel with the clay tends to prevent the burrowing of rats or other vermin, but it requires to be carefully done, so that the mixture shall be uniform.—C. S.

[12767.]—**Puddling Fishponds, &c.**—You will need at least 2ft. of clay, use it as stiff as possible, and with a little water; well ram it down; if you can get a layer of cinders or ashes in your bottom, it will be better than lime.—JACK OF ALL TRADES.

[12770.]—**Boring for Water Jet.**—These wells have been in use, undoubtedly, for several centuries in the north of France and Italy, but it is not more than eighty or ninety years since they became known in England and Germany. In August, 1823, Mr. John Good, of Tottenham, took out a patent for "certain improvements in implements for boring the earth for water," but the first modern well of great depth (which drew public attention to well-boring) was that bored by Mulot for the city of Paris at Grenelle, commenced in the year 1832, and water rose after incessant labour, on the 26th February, 1842, from the total depth of 1,798 feet. The well at Passy was commenced by Kind, in 1856, and water was struck on the 24th September, 1861, at a cost of more than £40,000, the yield of water being 17,000 metres of water per day. There is a long account of it just published in the *Engineer*. I wish that I could give our valuable and valued friend, "The Harmonious Blacksmith," more information on this subject, but perhaps some talented correspondent will enlighten us both on this matter.—ZAX.

[12771.]—**Colorado, U.S.**—By National Line to New York, expense about £18 to Denver City, by steamer and rail; the cost of living I do not know. My information is derived from a friend who went to Denver with the same idea as "Emigrant." He writes:—"The country is completely overdone by emigrants, there are thousands living at the various ranches throughout the state, working for the farmers, and receiving their board and lodging only as pay. The soil may be good, but there is literally no water, and in summer if you succeed in growing anything the grasshoppers eat it. The climate, which is described as being the finest in the world, is tremendously hot in summer, and although the papers describe the winters as being so mild that cattle can be left to take care of themselves, at the time I write (the end of February), the ground is covered with snow 8ft. deep, and has been for six weeks; the thermometer is below zero. Cases of frostbite are frequent, and if I could get away, even at a loss, I should be glad." In fact (from my friend's statements), the country is written up by Yankee land speculators, who have lots they wish to dispose of to credulous investors. If you want to emigrate, why not go to Canada?—A CONSTANT READER.

[12771.] — **Colorado, U.S.** — "Emigrant" and others would do well to write to U.S. Consul at Liverpool to send them a copy of "Information for Emigrants," an official work, by Edward Young, Chief of U.S. Bureau of Statistics, giving the only complete and reliable information to be obtained about that country, and presented on a new plan by which one need not read more of the work than relates to the part in question. This will be sent to any one who will forward stamps to pay the postage. As to the best way of getting to Colorado I would recommend New York, as the fares are much less than by any other city. As I have never been in the western part of the United States I cannot inform him as to climate and expenses. I would heartily recommend him to go to New York by the White Star line of steamers, as they are by far the finest and best, as well as the cheapest, and whether "Emigrant" be a scientific man or an epicure, he will find abundant means of enjoying himself on this line, as I can testify. In case the consul at Liverpool cannot furnish him with the book, if he will publish his address, I will put him in the way of obtaining one.—U. S. A., Washington.

[12772.]—**Bee Keeping.**—Mr. Walton does not tell me the sizes of his hives, frames, or centre apartment inclosed by the movable partitions, consequently I am unable to give him other than general information. If his centre apartment contains sufficient for winter use I should certainly remove all the sealed combs from the collateral sides, leaving them quite empty; further I should overhaul the combs in the centre apartment, cut out all the sealed drone comb, and fill up the spaces with sealed worker comb cut from the collaterals, or from supers, although the former generally yield sufficient. The empty ends form comparatively dead air spaces, and may be made the means of drying, warming, or feeding during winter or spring. A hot dry brick or bottle of hot water will give a good deal of warmth, a lump of quick lime will dry the air in the hive, and a comb filled with syrup will form a ready means of spring feeding. I presume the hive is so made as to enable Mr. Walton to get at the collateral ends in winter without disturbing the bees, and if so they will form a capital means of ventilation; or the back of the hive may be raised, and the back of the cover or honey board raised also, or if the said cover be in pieces according to my own principle, the pieces should be set about one-sixteenth of an inch apart, after the bees have finished propolising, and a light sack or thin carpeting laid over it. I gave directions for transferring combs last week, and can give nothing more special on Mr. Walton's behalf, as he does not say anything of the relative sizes of his frames, to or from which he wishes to transfer the combs. The great feature to remember in transferring is not to undertake too much; get the upper part of the frames filled with comb, and fastened in by the bees, before attempting to fill up the lower part, then the lower part having firm bearing on the bottom bar cannot fall, and will require little attention except from the bees.—C. N. ABBOTT.

[12773.]—**Boot and Shoemaking.**—If "Harry" intends to go in for rivet work repairs the tools that he will require are a pair of lasts, a size or two sizes smaller than his boots, bottom iron plated, an iron foot, a shoemaker's hammer, ditto pincers, bradawls and sewing awls, and a closing awl and stabbing awl, a shoe rasp about 8in., knife, sole tacks, and hack knife. The thin edge of the worn leather is lifted by the hack knife after the nails are cut out, and the piece for repairs is thinned down to correspond and placed under, and all bradded down together.—JACK OF ALL TRADES.

[12774.]—**Harmonium Keys.** — "E. W. P." might purchase old piano keys for a mere trifle; these might be converted for the above purpose.—JOSEPH WILLIAM FENNELL.

[12776.]—**Gas.**—In our town (Macclesfield) we have formed a Gas Consumers' Association (membership free), and have held several public meetings to complain of the gradual increase of the gas bills during the last two years, since the introduction of collecting the bills quarterly, which now average double for the quarter what they were for the half-year, and to protest against the injustice of supplying poor gas for the high price fixed by our Act, 4s., which orders 18-candle gas. The increase in the bills is caused by the coal being exhausted too much, thereby making more vapour of a less illuminating power, leaving the coke unfit for household use, and the gas of so poor a quality as to need a larger consumption to get a light at all; in this way an immense amount of extra money is squeezed out of the consumers. The meters in most cases register perfectly correct, but we complain of being forced to burn more and to pay the same price per thousand for poor gas, when we need not consume so much if what we obtained was of good quality, which would be secured by taking the coal out of the retort sooner. It is a curious problem that some towns charge so little, and other towns are allowed by Government to charge so much—far in excess of the difference of the carriage or any rise in the cost of coals, and it is strange how few towns have a public photometer to show the quality of the gas supplied. Brighton is the only one I know of that has an official inspector and public photometer. Birmingham has a public photometer in its town-hall, and Leek is fixing one in the collector's office. Birmingham charges 2s. 9d. per 1,000, and allows 5 per cent. discount for cash Leek charges 4s. 2d., with 3d. discount for cash. Wolverhampton 2s. 9d., Plymouth 2s. 9d., Nottingham 3s., Manchester 3s. 2d., Warrington 3s. 6d., Derby 3s. 5d., Macclesfield 4s., London 3s. 9d., Diss 5s. 10d., Beccles 6s., Lowestoft 5s. 10d., Brighton 3s. 6d., Halesworth 5s. 10d.; Congleton lights its streets free. The above eastern counties towns look very much like a combination of gas companies, and much good would arise if each association will increase and diffuse what information they can gather. From the information we have so far gathered we find that wherever the gas is supplied by private companies much better satisfaction seems to be given, and wherever the gas works are corporate property every element of dissatisfaction appears to be introduced either from ignorance or from the illegal design of extorting extra money from the consumers for town improvements, &c., by supplying a poorer gas than the law allows, the gas committee knowing that the town possesses neither inspector or photometer to test the rubbish supplied. We desire to petition Parliament to appoint a public auditor of gas accounts qualified to test the gas at irregular times, and to allow the maker a certain margin (say 20-candle gas) and then give him a month's imprisonment whenever it is below 18-candle. The admission of the newspaper reporters to the weekly meetings of the gas committee would remedy much that is complained of, where the works belong to the ratepayers who are able to watch every other committee excepting this one, where there is the most danger of dishonesty and mismanagement. A correspondent made some capital remarks in a previous issue, regarding the different values of the different qualities of gas, but we ought to unite to obtain a really good quality, and then no one will object to pay a fair price.—R. A. HUNTLEY, Hon. Sec., Mac. Gas Cons. Assoc., Macclesfield.

[12776.]—**Gas.**—The illuminating power of gas is commonly ascertained by Bunsen's photometer, the result being expressed in "candles." Thus, if a sample of gas is said to be "16 candle gas," it means that when burning from an Argand burner of particular size, surmounted by a glass chimney of definite height, the rate of issue of the gas being five cubic feet an hour, the light given by the gas is equal to that produced by 16 sperm candles, each burning at the rate of 120 grains an hour. To perform the experiment, "H. J. W." would require a small dark room and some expensive apparatus. It is evident that unless the rate at which the gas burns is known, it is not possible to get comparative results. A very rough idea of the illuminating power of the gas may be obtained by a thin rod, such as a knitting-needle or pencil about a foot from a sheet of white paper placed against the wall; on adjusting the gas flame and a sperm or paraffin candle at such distances that the shadows produced on the sheet of paper shall be equally intense, the squares of the distances of the lights from the paper screen indicate the comparative intensities of the lights. Thus, if a gas-flame at 4ft throw as intense a shadow as a candle at 1ft., then $\frac{4 \times 4}{1 \times 1} = 16$; the number of times the light of the former is greater than the latter. There is much truth in "H. J. W.'s" remark that gas companies often produce bad gas and good dividends; but the transference of the concerns to Corporations or Boards of Health is usually attended with difficulty, and always with expense—two guineas a minute being a very common price for appearing before a Parliamentary Committee. The suggestions that the illuminating power of the gas should be a factor in estimating its value is a good one, but many people are guilty of wilful waste of gas and money by using bad or worn out burners. By paying attention to this subject, gas consumers may greatly improve their lights, and even reduce their gas bills.—ALFRED H. ALLEN.

[12778.]—**Printing Metal Leaf on Silk and Cotton.**—Let J. B. Sharpley try a varnish made of pint good methylated spirit and 1oz. shellac, about the same quantity of silver sand that has been washed clean and dried. Well shake it occasionally, and stand by to settle; when clear pour off the clear and add 1oz. of either gum sandarach or pale resin; when clear, fit for use, apply with a camel's-hair brush, and apply your metal leaf and heater. The cost will not exceed 1s. I prefer naphtha for the job.—JACK OF ALL TRADES.

[12779.]—**Lightning and Thunder.**—Question No. 1 is not clearly worded. Lightning is not necessarily forked because not sheet. We have zig-zag, sometimes nearly straight or curved, forked and sheet, also that very mysterious form called globular lightning. All these, even the last, I believe, have been imitated by the electrician. Real sheet lightning is, if it ever occurs, very rare; still it is possible. 2. The proper sound of the electric explosion is a crash more like the breaking of glass than anything else, *me judice*; the rolling is the effect of echo; however, the direction of the flash may prolong or modify the crash—still, as on lofty mountain peaks and in other favourable positions, the rolling sound is separated from that of the explosion by a wide interval, we hear the true sound. 3. Violent vibration of atoms or molecules, which is equal to saying we know nothing about it.—M. PARIS.

[12780.] — **Turning Spokes of Carriage Wheels.**—I believe that it is impossible to turn a single spoke at once in a common lathe, but two may be turned at once, over half the circumference of each, by fixing them side by side in a sort of metal chuck at each end, holding them firmly and having centres on the outsides, to be carried by point chuck and point of back centre in lathe; when both turned on the exposed sides take them out and reverse them in the fixings, and complete by turning the then exposed sides.—ZAX.

[12780.] — **Turning Spokes of Carriage Wheels.**—If "Amateur" looks over indices he will see that this thing has been treated upon and illustrated.—JACK OF ALL TRADES.

[12782.]—**Full Moon.**—The following are the dates of the full moons up to the end of next year:—

		h.	m.
1872.	September 16	17	5
	October 16	8	35
	November 14	17	8
	December 14	9	44
1873.	January 18	4	23
	February 11	23	33
	March 13	17	44
	April 12	9	51
	May 11	23	18
	June 10	10	1
	July 9	18	33
	August 8	1	52
	September 6	9	9
	October 5	17	31
	November 4	8	48
	December 3	16	20

—WILLIAM F. DENNING.

[12783.]—**Sash Planes.**—These are not exactly alike, and therein consists their value. The No. 1 must be used first, and should be set a little more "rank" than the other. When that has been worked quite down, take No. 2, which will take off about four fine shavings, and the moulding is finished. "Science and Art" might learn more about work and tools by working a few months in a shop than twenty years' reading. —OLD PLOUGHMAN.

[12783.]—**Sash Planes.**—If "Science and Art" planes down as far as he can with the No. 1 plane set rather coarse, he will find No. 2 will then take a shaving or two off, if set nice and fine; so No. 2 plane acts as a smoothing plane for No. 1, and leaves the work nice and clean.—PEACOCK.

[12783.]—**Sash Planes.**—The reason why they are numbered 1 and 2 is because No. 1 is used first, and takes off the greatest part of the wood to the shape required. No. 2 is then used, and is made to take two or three shavings more off, even after the other had worked quite down, so that it will keep sharp longer, and work finer.—JOHN WALTON.

["B. H." has also answered this query.]

[12784.]—**Libraries.**—I notice that some libraries have their names impressed on their books, &c., by a series of small perforations close together in the form of the letters, in the same way that bankers cancel their cheques with the date, &c., and Government is going to mark ballot papers, &c.—ZAX.

[12786.]—**Photography.**—1. Pack sensitised paper very tightly in an envelope that will exclude air as well as light. 2. A small quantity of carbonate of soda. 3. Place them face to face with a piece of millboard on each side of the pack, and wind a string tightly round. 4. Explained in replies to query 12656. 5. Use an ordinary copying camera.—J. W. N.

[12788.]—**Design for Marble Inlaid Table.**—If "M. and S." will have a really good and new design for a inlaid table let him only look on the numerous new church windows, and he will find all he requires. —MENZ.

[12788.]—**Design for Marble Inlaid Table.**—"Marble and Stonemason" has not said what sort of table, round or square, or probably I could furnish the design.—JOSEPH WILLIAM FENNELL.

[12789.]—**Staining Fanlight.**—The common or green glass is what is termed flushed glass, that is, the colour is flushed on one side of clear glass; if you eat the colour off by acid you will have the clear centre, or what part you please to operate on for your picture; you can paint or draft. Ample recipes you will find in back numbers.—MUTUAL TOM.

[12789.]—**Staining Fanlight.**—Perhaps "Kendal Saddler" means the glass done as follows:—A sheet of coloured glass is laid on a sheet of white glass, and melted together in a furnace. Then the surface of the coloured glass is covered with paraffin and wax, and smoked over a candle. The design is then drawn through the glass and eaten in right through the coloured glass by fluoric acid, which leaves the design in white glass.—C. B.

[12789.]—**Staining Fanlight.**—What "Saddler" speaks of are etched upon plated glass for the purpose by the action of hydrofluoric acid. The glass is to be got at the glass warehouses.—JACK OF ALL TRADES.

[12789.]—**Staining Fanlight.**—The glass alluded to is not stained (except the yellow), but is manufactured as coated glass, the chief part of its thickness colourless, but with a uniform coat on one side, of either the strongest red (miscalled "ruby") or the strongest blue. I have never seen it coated with green, or any colour but these two, nor with these in less than their fullest intensity, nor with both sides coated, though any such varieties would be more available. A third kind, however (yellow), is plain glass uniformly dyed over one side with the silver stain. Taking any of these, and covering its coloured side with Brunswick black, when this has dried you scrape it from the lines or forms that you desire to be white, and a "glass embosser" will then pour fluoric acid on it, which etches away the coloured coat where thus exposed. If a printed page or impression of a woodcut be applied with its face to the clean glass, and then the acid (either in gas or a weak solution), even the printing-ink will protect what is under it, while the paper will not, thus reproducing a *fac simile* with the colour for black. Gaseous acid leaves a perfectly dead surface, but the liquid a semi-polished one, less fit for a sunblind.—E. L. G.

[12792.]—**Tempering Needle.**—They are best as hard as they will go at each end, and can with care be easily soldered without softening.—JACK OF ALL TRADES.

[12792.]—**Tempering Needle.**—I think this extract from Brewster's "Magnetism" will answer the question:—"With regard to the best mode of hardening and tempering needles, Captain Kater found that when a needle is considerably hardened throughout, its capacity for magnetism is diminished. He found that the needle was susceptible of the greatest directive power when it was first hardened uniformly at a red heat, and then softened from the middle to within an inch of its extremities, by using a degree of heat which is just capable of making the blue colour, which is thus produced, to disappear." I should try coaguline as the means of attaching a weight to the needle, and not heat of any kind, which I think could not be applied with safety to a finished needle.—E. T. E.

[12792.]—**Tempering Needle.**—The harder steel is left for magnets the better it retains its magnetism, therefore leave your needle as hard as the circumstances will allow. The hot solder will, of course, draw the temper of the part it is applied to.—ZAX.

[12793.]—**Oil of Peppermint.**—Take your herb fresh gathered, when the bloom is just about to open, and place in a still with a quantity of water. Draw over one half, separate the oil from the water, and return the water to the still; take the old herb out, and replenish with more; put the still head on, and distil as before. You will need from five to six pounds of herb to get one ounce of oil.—JACK OF ALL TRADES.

[12794.]—**Ammoniacal Liquor.** — Twaddle's degrees of gravity are equal to 5 degrees on a hydrometer, in which water is 1,000. Thus, 1° T. = 1,005, 2° T. = 1,010, 5° T. = 1,025. In other words, to convert "Twaddle's" results into degrees of real gravity (with water = 1,000), multiply by 5, and add 1,000. If we divide the real gravity by 100, we obtain the weight in pounds of one gallon measure of the liquid. Thus, 1025 ÷ 100 = 10·25lb. for the weight of a gallon. "J. W." has now only a simple proportion sum before him. As 10·25 : 1 = 2240 : : 218·5; the number of gallons in 1 ton of the liquor at 5° "Twaddle."—ALFRED H. ALLEN.

[12796.]—**The Spanish Language.**—There is a Spanish "Ollendorf" published. I do not quite agree with "E. L. G." (reply 12348, p. 545) about the value of the four auxiliaries, and the Spaniards have well dropped the use of *tener*. The Portuguese, who, like the Spaniards, have *ser* and *estar*, still employ *ter* as an auxiliary. The correct use of *ser* and *estar* is a great nuisance to foreigners, and it appears to me very singular that *estar*, derived from the Latin *sto*, should be used to express a temporary condition. I do not believe there is any better way to learn a language than by grammar and dictionary, with a newspaper. Translate a part of it into English one day, and back into Spanish the next. *Experto crede.*—M. PARIS.

[12796.] — **The Spanish Language.** — I am acquainted with five or six Spanish grammars, and find the best to be Del Mar's, which I have successfully recommended to many.—PEDRO.

[12798.]—**Air Vessel on Suction Pipe.**—The pump barrel being so much as 20ft. above the water in the well one should know the speed of the pump-bucket in order to judge whether the air vessel is of use or not. At 20ft. above the water level the pressure of the atmosphere which forces the water up into the vacuum produced by the upward stroke of the pump-bucket, is reduced to about one-third of its normal pressure, or to about 5lb. per square inch. If the speed of the bucket be considerable this pressure may not be sufficient to cause the water to follow the bucket fast enough, and when is has arrived at the top of its stroke a void would be left underneath it, and before this could be filled by the rising water the bucket would have begun to descend again. This would both reduce the quantity of water lifted at each stroke and would cause a shock to the whole machinery when the bucket should come suddenly down and meet the water; but with an air vessel below the barrel the compressed air, expanding, assists to make the water follow the bucket more closely, and perhaps perfectly; the degree depends upon the relations which exist between the size of the suction pipe, the speed of the bucket, and the capacity of the air vessel. For these reasons it is best to place the working barrel of a pump as low down as possible; then the full or nearly full force of the atmospheric pressure causes the water to follow the bucket closely. But under some circumstances it may be well to place the working barrel, as in this case, considerably above the water level; but in that case an air vessel would be required to effect what I have pointed out. This is the way in which, it seems to me, the presence of the air vessel is to be accounted for.—C. S.

[12798.]—**Air Vessel on Suction Pipe.**—With a column of water of 20ft. by 6in. there would be a violent concussion consequent upon putting into motion and stopping suddenly at each stroke, which would probably burst the pipe but for this air vessel.—A., Liverpool.

[12799.]—**Speculum.**—The glass disc from which I worked my speculum was a piece of ordinary thick rough plate glass. After being smoothed it is now 1¼in. thick, so I suppose at first it was 1½in. It was chipped into a roughly circular form by the makers, and I finished the edge on a grindstone by hand.—A. WOOLSEY BLACKLOCK, M.D.

[12804.] —**Fixing Photographic Prints.** — "One in a Fix" either has his fixing bath too strong or keeps his prints in too long and not long enough in the toning bath. The strength of fixing bath ought to be—hyposulphite of soda, 1oz.; distilled water, 6oz.—NOTURB.

[12804.]—**Fixing Photographic Prints.**—All prints toned by chloride of gold change their purplish hue to a ruddy brown on immersion into the hyposulphite bath, but those which are sufficiently printed and toned in the first instance recover their proper hue between the fixing and washing operations. An acid condition of the toning bath, however, will produce pictures which are "flat, stale, and unprofitable."—S. BOTTONE.

[12812.]—**Water for Aquarium.**—The water must on no account be drawn from a well or pump, and, indeed, any kind of water that is used for drinking is unfit for the aquarium. The best water is that which is drawn from a river or pond. Ordinary rain-water will, however, answer all purposes, provided that it be clear, and that the butt from which it is taken has been provided with a cover. The water supplied by the water companies is filtered from nearly all animal and insect life, which constitutes the natural food of the fish, &c. Do not change or renew the water. A little may be added as evaporation takes place, but none must be taken away. Any further information required will be given with pleasure.—JAMES DICK.

[12817.]—**To Chemists.**—The blue colour is not due to any impurity, but is a peculiar action of the solution upon the light. If a quantity of quinine solution be viewed by the light which has already passed through a glass vessel filled with a similar liquid, no coloration is observed in the second quantity. The "fluorescence" is also destroyed by addition of an acid not containing oxygen—such as hydrochloric acid —while any oxygenised acid restores the blue coloration. The precise physical cause of the colour is that quinine (like turmeric, ivory, petroleum, &c.), has the power of changing the refrangibility of the ultra-violet rays of light, that is, lowering the number of vibrations per second, and so bringing these rays within the limits of our range of vision. The effect is made more visible by using light which has been deprived of the less refrangible rays by passage through purple-blue glass.—ALFRED H. ALLEN.

[12817.]—**To Chemists.**—The solution of sulphate of quinine is yellowish white by transmitted, and silvery blue by reflected, light. We can give no more satisfactory reason for this than we can for a rose being red, or grass green. The usually accepted explanation of the blue reflection from the surface of a solution of quinine sulphate, is the following:—"The highly refrangible actinic rays (usually invisible) become degraded into luminous rays of less refrangibility on striking the surface of such a liquid." Hence these rays, then, become visible. This peculiar property is termed "fluorescence," and is possessed by several liquids, among which the following are conspicuous:—Petroleum, aqueous infusion of horse chestnut bark (æsculine), tincture of Datura stramonium seeds, alcoholic solution of chlorophyll, and tincture of turmeric. Uranium glass is also highly fluorescent.—S. BOTTONE.

[12819.]—**Stains in Wood.**—Cyanide of potassium; very efficacious, but very poisonous; price, about 1s. per pound.—S. BOTTONE.

[12822.] — **Extracting Opium, &c, from Poppies.**—Opium is obtained from the white poppy, *Papaver somniferum*, by making incisions in the unripe capsule. A white milky juice exudes, which is carefully collected as soon as it acquires sufficient consistency to admit of its being scraped off. Poppy oil is also largely prepared from the seed of the above by the ordinary mode, viz., grinding, and pressing the meal thus produced between hot-plates in a hydraulic or other press. No use, that I am aware of, is made of the red colouring matter from the ordinary poppy, *P. Rhœas*. It may be extracted by alcohol.—S. BOTTONE.

[12823.]—**Cochineal Blué.**—It is a property possessed by colouring matters generally to form insoluble compounds with lead oxide; such compounds are technically known as *lakes*. The body in question has been studied by Preisser so long ago as 1851.—S. BOTTONE.

[12824.]—**Magnesium.**—Chloride of magnesium is prepared by dissolving magnesia or magnesium carbonate in hydrochloric acid, mixing the liquid with chloride of ammonium, evaporating to dryness, and igniting. Mix 900 grains of this product with 150 grains of fluor-spar, 150 grains fused common salt, and 150 grains of sodium cut into slices. The mixture is thrown into a red hot earthen or iron crucible, which is then covered and again heated. When the action has terminated, the fused mass is stirred with an iron rod to promote the union of the globules of magnesium. It is then poured upon an iron tray, allowed to cool, broken up, and the globules of magnesium separated from the slag; they may be collected into one globule by throwing them into a melted mixture of chlorides of magnesium and sodium with fluor spar. Do not heat too strongly.—ALFRED H. ALLEN.

[12846.]—**Rowing.**—Second kind of lever: the blade of the oar being the fulcrum, the power being exerted at the handle, and the boat being the weight acting at the point of contact of the oar and the boat. —LEWIS.

[12849.]—**Separating Lenses.**—Soak them for an hour or two in spirits of turpentine. Lenses are easily cemented together by pouring a few drops of the best Canada balsam into the concavity and gradually lowering the convex-lens into it, in such a manner as to avoid the formation of air bubbles. The lenses must be then clamped together until the balsam is dry. No difficulty attends this operation.—S. BOTTONE.

UNANSWERED QUERIES.

The numbers and titles of queries which remain unanswered for five weeks are inserted in this list. We trust our readers will look over the list, and send what information they can for the benefit of their fellow contributors.

Since our last "Jack of All Trades" has answered 12433, 12468; "L. C.," 12460.

12562 Tar Pavement, p. 521
12567 Brick and Tile Glazing, 522
12569 Consumption of Alcohol, 522
12575 Angles of Incidence and Reflection, 522
12580 Photo.-Lithography, 522
12583 Electro-plating and Coppering, 522
12585 Thermo-Electric Pile, 522
12587 Lamp for Blowpipe, 522

QUERIES.

[12873.]—**Overshot Water-wheel.**—An overshot wheel, 30ft. diameter and 11ft. wide, is now running 18in. deep in the tail water. What power would be gained, if any, by lifting this wheel entirely free from this tail water?—PERCIVAL NORTON.

[12874.]—**Decaying Wood.**—Will any fellow reader kindly advise what is best for the seats of a church (restored only five years ago) which are actually rotting? large patches of fungus appear indiscriminately on floors and seats, but always where there is a joint. It is almost confined to north side of church, where there is least sun.—CHURCHWARDEN.

[12875.]—**Sulphate of Manganese.**—Will some obliging reader give details of the manufacture of this salt as prepared for the calico printer, stating proportionate quantities of acid and oxide to be used, time occupied and heat employed? Also quantity obtainable from one ton black oxide of manganese?—TYRO.

[12876.]—**Electro-Plate.**—Could any of your subscribers inform me what is the composition of plate powder, and how does it act on the silver?—MECHANIC.

[12877.]—**Photography.**—Would some friend kindly tell me why the front portrait lenses are cemented together—mine having come apart? What cement could I put them together with? Are they cemented only round the edges of the glasses or all over, and does it matter if they are left apart?—PEACOCK.

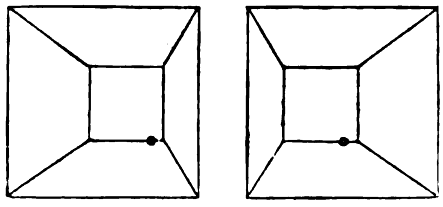
[12878.]—**Electric Bells.**—I am anxious to fit an electric bell in my bed-room to give notice if a window should be opened at night. Will any of "ours" learned in electricity, state what battery I should make, its strength, and how the bell is made? The distance between bed-room and window is about 10 yards.—H. MACKINTOSH.

[12879.]—**Curious Occurrence.**—A day or two ago, an ordinary tumbler that had contained water in which had been placed citrate of magnesia (but which at the time I speak of was quite empty), suddenly cracked with quite a sharp sound, and on my attempting to take it up, came in two. Could any one kindly give an explanation?—CARADOC.

[12880.]—**Oxygen Gas.—Substitute for Gas Bag.**—Would some fellow reader kindly give me an opinion as to the feasibility of the following idea to do away with gas-bags or gas-holders for the lime-light. Dentists carry their nitrous oxide in an iron retort about the size of a mercury bottle (1ft. long, 3in. diameter), into which (so a dentist has just told me) 100 gallons of gas is compressed by hydraulic or steam power. If 100 gallons of oxygen could be compressed in this way the gas could be used directly from the retort, and the pressure might, I imagine, be regulated by the stop-cock, and the supply would be sufficient for nearly four hours. The difficulty with me (in the absence of steam power and hydraulics) is how to compress. Could same be done in this way? Get a mercury bottle fitted with stop-cock, put in sufficient oxygen mixture to generate (say) 30 gallons of gas, turn off the cock so that no gas could escape, place over fire, leaving the heat to produce generation, and generation compression; the residuum of the mixture after generation occupies but a very small space. Would the experiment be a dangerous one; if so, how would be the best way to guard against such danger?—J. M.

[12881.]—**Condensing Engines.**—Would some obliging correspondent answer the following:—1. Why is the pump which withdraws the injection water, &c., called "air pump"? Is the name justified by the "small portion" of air (as engineers term it) mixed with the water, which, when meeting with the hot steam, is expanded, and thus requires a larger pump than would be required for withdrawing simply the injection water and condensed steam? 2. What is the quantity of air in water, is it about a 2,000th part? 3. In ordinary condensors, what would be about the average increase in the bulk of this air, through being heated by the steam? 4. Would the boiler, with steam up to 15lb. pressure be liable to burst, seeing there is 15lb. of air on outside; or is the steam indicated in excess of the atmosphere? Some common sense answers, without going into algebra, &c., would oblige an—ENGLISH MECHANIC.

[12882.]—**Vision.**—When I place a card between the accompanying figures, they do not at first unite so as to give a perspective view, but seem to move towards each



other till the proper effect is produced. What is the cause of the apparent motion of the figures towards each other?—PAUL GREGOR.

[12883.]—**Foul Air.**—Has an instrument, thermometer, indicator, or register of some sort ever been made to find out the state or quality of gases contaminating the atmosphere of a room? I mean gases besides the atmospheric air.—E. C.

[12884.]—**Evening Classes at University and King's Colleges.**—Will some brother reader inform me from his own experience or knowledge, whether the evening classes at King's College or those at University College are likely most to suit the purpose of an undergraduate reading for the degree of B. Sc. at the London University, with his reasons for such selection? Would the evening classes at either college be sufficient for this purpose, if supplemented by private study? I should also be glad to know what would be the advantage of entering as a matriculated, rather than as an occasional, student.—CERVUS.

[12885.]—**Seaside Telescope.**—I live by the seaside, and want a telescope for the hand. Up to what size of object-glass might I go, and should there be more than one draw? Is it not a fact that the more draws to a telescope the less perfect the instrument acts?—NOSILLOC.

[12886.]—**Smoky Boiler Furnace.**—I have a 2-horse vertical boiler with 10 tubes 2in. diameter, and find great difficulty in keeping steam up; the fire burns dead, apparently without draught, and fills the room with smoke. A 6in. elbow connects the boiler with chimney (which seems to have a good draught) but one day's use clogs boiler tubes nearly up with soot. Is it possible to produce a better draught without interfering with chimney, by means of a fan or some other appliance?—SMOKED OUT.

[12887.]—**Drum for Wire Rope.**—Will some one kindly tell me of a simple and accurate way to find the length of wire rope a drum will hold, single coil; a drum (say) 3ft. diameter, 5ft. between flanges, rope 1in. diameter?—TANTALUS.

[12888.]—**Screw Cutting.**—Would "Apprentice Turner" (let. 4762, p. 589) or any other reader kindly inform me the best way of compounding wheels for screw cutting—*i. e.*, to cut threads with over two wheels with leading screws from ⅝ pitch to 2, 4, 6, and 6½ threads per inch? I have Elliott and Greenwood's works, but I desire a more abridged method.—HIGH.

[12889.]—**Tempering Drills.**—I am a lead miner, and have hitherto sharpened my own tools with success. We have now come to a rock, composed, out of 100 parts, of 52½ per cent. of carbonate of lime, 41 per cent. of silica (or flint), 4½ per cent. of oxide of iron, and the remainder sulphate of iron and magnesia. We use the best cast steel drills, but I cannot temper a drill that will stand this stone. Can any reader help me out of this difficulty? Will any chemical added to the water effect my object, and what?—LEAD MINER.

[12890.]—**Faulty Negative Bath.**—Will some of our photographic readers kindly tell me how to rectify a negative bath (about a pint) which will not give enough intensity in the whites? I have just been copying a carte-de-visite portrait, and when I print from it I find the face is not dense enough, although the plate is fully intensified in other parts.—HYPO.

[12891.]—**Wheels for Lathe.**—Will some kind pattern-maker give instructions for marking and cutting the teeth in bevel and other cog-wheels? I have turned the patterns in the lathe.—A TURNER.

[12892.]—**Clutch.**—I should feel obliged if "Jack of All Trades," or some other correspondent, would give a description of the best form of clutch for expeditiously throwing drum barrel in and out of gear without stopping engine. Any information on the above subject would greatly oblige.—CUMRO BACH.

[12893.]—**Charcoal as a Fertiliser.**—I have heard it said that dressings of charcoal are very valuable to vegetables and flowers; will some reader who thoroughly understands the nature of charcoal tell me what kind of vegetables it is suitable for, and what kinds of flowers, as well as fruits, are benefited by it, and how it ought to be used, and what quantity?—WANTS TO KNOW.

[12894.]—**Bees.**—Can any correspondent inform me if our English bees have been introduced into New Zealand and Australia?—JOHN WALTON.

[12895.]—**British Museum.**—Can any one give the dimensions of the great reading-room of the museum, and the weight of iron used in constructing ribs, girders, &c.—JOHN WALTON.

[12896.]—**Electro-Metallurgy.**—Mr. Sprague states (No. 381, p. 423), writing about a single acid battery, "the silver is platinised after the cell is completed." Will he kindly explain how? and if it will not alter the action by putting in the platinising solution?—R. W. P.

[12897]—**Cleaning Stone Carving.**—I have a stone (carved) vase made of rather soft stone, which has got dirty. Will some one favour me with a recipe for cleaning it, as I cannot get into the recesses very well with a brush?—R. W. P.

[12898.]—**Light Wheels.**—I am about making a pair of light wheels, and would like to know how to get the bevel of the shoulders of the spokes where they fit against the nave, without first planing them up square, as I have never seen wheelwrights plane them. I should also like a description of the simplest form of chuck used for turning the spokes of wheels. Is there any kind of wooden chuck easy to make that would answer the purpose?—A NOVICE.

[12899.]—**Keeping Flowers in the Winter.**—Will some of your gardening correspondents be kind enough to tell me how to keep geraniums, fuchsias, verbenas, calceolarias, and such flowers in the winter? I have no frames or conservatory. Would it be sufficient to hang them in a dry room?—C. N. W.

[12900.]—**Acme Skates.**—I have heard such different opinions expressed about those skates that I should be glad if some one who has had experience in them would tell me what they think. Are they liable to tear off the heel of the boots, as I have heard they do; and are they good to learn figure-skating upon?—C. N. W.

[12901.]—**Split in Thumb Nail.**—Can any of the readers of the ENGLISH MECHANIC recommend a cure for a short split in the thumb nail. I have tried a permanent plaister; but this seemed to dry the nail, and make matters worse. The ailment is of a year's standing.—M. A.

[12902.]—**Whitworth Scholarships, &c.**—Can any reader give me the number of marks obtained by the successful candidates for the Whitworth Scholarships and Royal Exhibitions, 1871 and 1872.—S. W. HAYES.

[12903.]—**Dulcimer.**—Will some one tell me how to make a dulcimer?—C. M. B.

[12904.]—**Fixing Needle in Telegraph Coil.**—Can any kind reader inform me how I could fix a magnetic-needle in a telegraph coil so as that it would not oscillate after current being stopped?—C. M. B.

[12905.]—**Coil.**—I have made a coil according to the instructions given by "Glauphus" on p. 92 of Vol. XIII., but I fail to get the slightest current whatever. I made it as follows:—First, I made reel or bobbin 6in. overall, 3½ disc; and secondly, I wound on for the primary three layers of No. 16 cotton-covered wire; third, for secondary I wound on half a pound of 32 cotton-covered wire. Insulated secondary from primary with thick note paper. I soldered all the terminals with common solder and zinc dissolved in spirits of salts. I used a small Smee's cell, and tried a quart Bunsen cell, but to no use. I soldered one part of contact breaker to one end of primary and other end to handle of battery. I soldered one end of secondary to other part of contact breaker. If "Glauphus" will kindly come to my assistance I shall feel very much obliged to him.—D. STRATHERN.

[12906.]—**American Vermilion.**—What are the details of the process for manufacturing American vermilion—a pigment whose name sufficiently describes its colour; but which, on being ground, changes to orange? From examination I believe it to be a dichromate of lead; but it must, from the low price at which it is sold, and the circumstance that grinding would destroy the colour, be prepared otherwise than by projecting chromate of lead into melted nitre. This process, moreover, seems with commercial chrome yellow to yield an orange yellow, perhaps through some fault in manipulation.—CANADIAN.

[12907.]—**Painters' Colours.**—What is the best available work on the manufacture of painters' colours? Has the promised volume of Richardson and Watts' "Technology Relative to Pigments" yet appeared, and if so, is it procurable separately.—CANADIAN, S. Catherine's, Ontario.

[12908.]—**Brass Moulding.**—Will "Jack of All Trades," or some other practical reader, tell me how to make sand strip off a brass casting, one that has a deal of travel?—MOULDER.

[12909.]—**Economy of Coal.**—I should be obliged by replies to the subjoined queries. 1. The greatest weight of water evaporated by burning one pound of coal: state atmospheric pressure, and the kind of coal employed. 2. If when coal is burned in a furnace into which it is carried by a current of air in the form of dust, more heat is developed than when introduced by ordinary mechanical feeding or by a competent stoker. 3. What is the smallest recorded consumption of coal per hour for indicated horse-power? State kind of coal used; how supplied to furnace; steam pressure in boiler; ditto working pressure at commencement of stroke, amount of expansion, and vacuum. I lately saw a statement in the *Times* that a tug-boat working at 800lb. pressure consumed rather less than 2lb. per horse-power per hour. In Government steamers the average consumption was stated to be more than double, but Sir Spencer Robinson says the *Achilles* on one occasion only required 1·400lb. per horse-power per hour. See *Naval Science*. In a later statement the *Times*, it was asserted equally economical results to those in the lung were obtained at a pressure not exceeding four atmospheres.—THE HARMONIOUS BLACKSMITH.

[12910.]—**Welding Angle Iron.**—Could any of the numerous readers of the ENGLISH MECHANIC give me a few hints as to the best way to weld angle iron, 3in. × 3in. × ⅜in. turned to a hoop 4ft. diameter for end of boiler?—N. B.

[12911.]—**Variegated Maple.**—Will some reader oblige by informing me whether this shrub is grafted or budded, and on what description of stock, together with the time of year when the grafting or budding should be done?—S. E. C.

[12912.]—**Tooth Paste.**—There is one paste which passes under several names, one of which is cherry tooth-paste; the colour is red and the flavour that of cloves. Recipe will oblige—S. E. C.

[12913.]—**Cooking for Bachelors.**—Should I be asking too much if I appeal to some of "our" fair readers for assistance in this matter? There must be many of your readers who, like myself, are often at a loss to know what they can have for dinner by way of change, and for whom the cookery books do not condescend to give recipes. These books are written for families, and not for those in a state of single blessedness. I am obliged to gather hints on the subject from friends, but even then the number of dishes is not very varied. Will some one add to the number?—BACHELOR.

[12914.]—**Eminent Barbers.**—Will some kind correspondent give me some names of eminent men who were barbers in their earlier days?—RAZOR.

[12915.]—**Harmonium.**—I wish to build one with eight rows of reeds. I have had no difficulty in making the bellows, the size of which is 34in. × 17½in., and the fall 11in. The feeders are 19in. × 17½in. each. Is the bellows large enough? What kind of springs must I use for the inside of feeders? How must the pan or soundboard be arranged? I wish to use four pallets—one pallet to cover two sets of channels. How are the channels cut? are they cut with the grain or across? Instructions how to make the pan would be thankfully received. Also how to arrange the pallet bars, so that each bar shall be under the centre of key; the distance between each bar, &c. I should also like to know how the percussion system is applied to the harmonium, and what is its effect? I wish to have a small wheel on the end of the feeder levers. Can I do this, and would the friction be more or less than by the usual way of blowing?—IGNORAMUS.

[12916.]—**Grinding Edges of Watch-Glasses.**—Will some friend kindly tell me the best method of grinding down the edges of watch-glasses?—F. E.

[12917.]—**Coloured Tiles.**—Will any reader kindly inform me through your columns how red clay tiles are blacked in imitation of Staffordshire tiles, and, if by a composition, how to make and apply it?—K.

[12918.]—**Water Power.**—What is the most economical working apparatus for utilising a small stream of water, the fall not above 4ft.?—L. W. D.

[12919.]—**Pianoforte Hammers.**—I have lately covered the hammers of a "cottage" with taper felt (the old felt being entirely worn through) but I find the tone excessively weak since it was done. How is this? The felt was good and hard, and I compressed it as much as possible in putting it on. I found in stripping off the old felt, that just where the hammer strikes the string the felt came off easier, and of course I looked for the cause, and I found (or fancied so) that there was no glue applied just in that place—*i. e.*, the front of the hammer. Was I right or not, and has this anything to do with the weakness of tone? Can our practical friend "The Harmonious Blacksmith" throw a few sparks of light on the subject?—IGNORAMUS.

[12920.]—**Barlow Lens.**—Will "F.R.A.S." be kind enough to give the best distance for placing the Barlow lens from the eyepiece, in a 5ft. refractor, 3¼in. aperture? Length of tube carrying eyepiece, 4in.—J.

[12921.]—**Enormous Shell.**—I have been informed that there is a monster shell at the International Exhibition, weighing five tons. If there be such an enormous missile, I should feel obliged for dimensions and weight of shell and gun.—LOGAN.

[12922.]—**Sail for Canoe.**—I have a canoe for which I want to make a sprit sail. Will some brother subscriber give me instructions as to what size sail she will carry? The canoe is 10ft. 6in. long, beam 27in., weight between 40lb. and 50lb.—ROB ROY.

[12923.]—**Arithmetical.**—Can any one suggest any method shorter than that of indeterminate equations for solving the following problem? What number being divided by 47,474 will leave a remainder 4,747, being divided by 4,747 will leave a remainder of 474, being divided by 474 will leave a remainder of 47, being divided by 47 will leave a remainder 4?—H. H.

[12924.]—**Buying a Telescope.**—Will some one advise a novice how to spend five or six pounds in buying a telescope? Would a refractor or a reflector be best? If I could make the tube myself, and spend the above sum in mounted object-glass and eyepieces, would there be anything gained worth the trouble.—ORIEL.

[12925.]—**An Experiment.**—Given. A compartment (airtight) with a capacity of 20 cubic feet. Suspended from the top of this compartment there hang two pieces of platinum sponge, each one being 2ft. square and 1in. in thickness. The point of suspension being in connection with wires to carry off the heat of the combination of HO_2 in the form of electricity. The compartment to be filled with the gases HO_2 to the pressure of the atmosphere (15lb.) How long would it take to make the gases combine by this means.—VULCANITE.

[12926.]—**Weather Glass.**—Will any of your readers inform me how the loss of mercury will affect the registering of a barometer the old clock-face style, and if it is possible to make correct deductions from it?—DEMOSTHENES.

[12927.]—**Comets.**—Has the comet that so much has been said about lately been seen; if so, how, when, and where? Is it possible for a comet to appear and disappear in two days; if so, how? Replies will oblige.—DEMOSTHENES.

[12928.]—**Test for Phosphorus.** — Would some chemical reader kindly give me a test for the presence of phosphorus?—Q. Q.

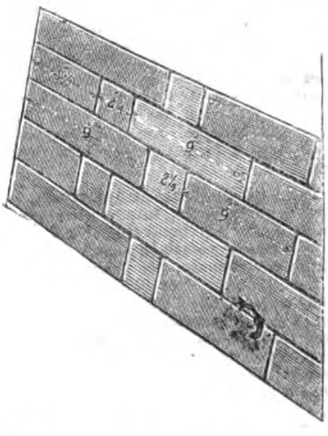
[12929.]—**Analysis.**—Would any of our chemical friends please state the *modus operandi* of detecting the presence of china clay, and also the quantitative analysis of the same in calicoes?—CALICO.

[12930.]—**Wheat Analysing.**—Can any of your readers give a simple plan of analysing, or ascertaining by other means, the percentage of starch contained in any given samples of wheat? Also, if there is any means of estimating the strength and purity of starch so obtained? Please be as plain as possible, as I am no adept at chemistry.—J. T. C.

[12931.]—**Brewing.**—Can any of your readers give a recipe for making drinkable good beer put into a musty barrel by mistake, and also how to more fully extract alcohol from malt? I cannot get the beer strong enough from mere malt and hops.—YOUNG BEGINNER.

[12932.]—**Strength of Hairspring.**—Will "West Cornwall" kindly inform me how the strength of a hairspring is determined upon by the size and weight of the balance? Also, how to tell the number of vibrations requisite per hour?—A YOUNG JOBBER.

[12933.] — **Skewbacks of Camber Arches.** — I should feel obliged if some of your readers would please to explain in your valuable paper the rule by which the skewbacks of camber arches are obtained. I find that many authors say that the skewbacks should



be inclined at an angle of 60°. If this is right it is not followed out in practice here, as I find that the inclination of the skewbacks of an arch over a 2ft. opening, is not the same as over a 7ft. opening. I have also seen an arch whose joints are tuck pointed, as per sketch. Is it right? If not, how should it be?—AN ANXIOUS BRICKLAYER.

[12934.]—**Organ.** — In planning a soundboard as directed by "J. D." (Vol. XIV., p. 483), he directs a certain number of the bass pipes to be placed at the treble end of the soundboard, and he directs separate slides for the stopped diapason—one for the bass and one for the treble—this, of course, taking up the space of two distinct rows of pipes; but this arrangement will admit of the bass or treble being shut off at pleasure. In the open diapason but one slide is used, therefore this row of pipes must be either wholly open or shut. Now, as the performer may wish to use the bass of this stop without the treble, how is the effect to be obtained? Would it be possible to divide the draw slide into three parts, the two ends working the bass, and connected by a tracker over the stock board, so as to act in unison, and the middle portion as a distinct treble stop, to be worked by a roller let down through the stockboard, having a small toothed brass pinion on its base, working in a toothed rack attached to the slide, the arm of the roller outside the stockboard being attached by a sticker or tracker to a square at the end of the board and continued on to the stop?—E. J. D.

[12935.]—**Water Power.**—I have a spring of water on the side of a sloping hill which will fill a 3in. pipe; after a course of near 200 yards, it has fallen vertically 125ft. Can any of your readers inform me what height is lost from friction in pipe, and what power could be got by turbine from this? A useful pond or head could be made.—JOHN.

[12936.]—**Hastings' Tricycle.**—In the ENGLISH MECHANIC for July 22, 1870, was described a tricycle by J. Hastings, possessing, in my judgment, considerable merit. If this should meet the eye of that gentleman, will he kindly say whether he is still of the same opinion about it, and whether he can recommend it as a vehicle easily driven, and satisfactory in respect of wear and tear?—J. C. H.

[12937.]—**Dumb-Bell Exercises.**—A better knowledge of the principles of dumb-bells, associated with a little understanding of the muscles of the human body, would, I think, add greatly to the zest of those who devote fifteen or twenty minutes of their mornings at home to the use of them. After a time they tire of the few too-evident exercises, occupying a brief page in the handbook to gymnastics, and long for some more substantial variations to bring out their other muscles. If some correspondent who has had experience would devote a paragraph—or the subject may be considered worthy of a chapter—treating of dumb-bell exercises, with a hint or two as to the muscles brought into play, I venture to say the subject would find interest with not a few, and probably benefit a great many. Let me caution him, however, that the class of which I speak is not composed of those crack gymnasts who despise the dumb-bells altogether, except when, may be, some showy and elegant, but useless, exercise questions their cleverness and sleight-of-hand. What we want are simple exercises calculated to bring out the different muscles of the chest and arms, to be regulated for the weight of the dumb-bells and the strength of the gymnast, simply by being repeated until the tiring point is arrived at, when a cessation ought to be made until the feeling of fatigue disperses itself. At least, this is my idea as regards the matter, and I call upon the more extended experience of others to present itself in the shape of an answer to this query.—INCHICORE.

[12938.]—**Dimensions of Mail Boats.**—To "Philanthropist."—I am very much obliged to "Philanthropist" for the information on the subject of the Irish mail boats, and should be very glad to have the "further information" which he offers (p. 623, reply 12599). Is the length, breadth, and depth of the vessel inside or outside measurement? Also, how many feet do the paddle-wheels dip into the water, and the number of float-boards, and their size on the wheels, and the consumption of coal per mile?—C. E. S.

[12939.]—**Bees and their Habits.**—Will some of our experienced bee-masters say if we are right in letting our bees enter the bottom of the hive? What are their objections to the entrance being near the top. As steam, hot air, &c., has a tendency to rise to the top of hive, would it not be more likely to flow off, carrying with it that damp which is fatal to bees, and also save the bees much labour in fanning the hot air down from the top? What are the habits of the Alps bees? Do they work up or down in their wild state? I have studied our forest bees, and find when they take possession of a tree, if there is the same room above as below the entrance, they in all cases go down. An answer to the above will much oblige.—MECHANICAL BEE-KEEPER.

[12940.]—**Concentrated Milk or Essence of Milk.**—Would any of your readers kindly inform me how to prepare the above.—ALECK.

[12941.]—**Pouncing Pattern on Printing Blocks.**—Many thanks to "Jack of All Trades" for answering my query (12842). As I work the block while damp the whiting rubs off. Will kind "Jack" tell me of some powder that will slightly stain a dark colour, and resist the damp on the block.—NEW SUBSCRIBER.

[12942.]—**Lightning.**—To "SIGMA."—I should like to know how electricians account for the fact of persons standing under trees being struck by lightning. It is well known that electricity will not leave a conductor to ignite gunpowder, even when the latter is close by; how, then, does it leave the tree to strike the person standing near its trunk? Surely, even supposing the sap of a tree to be a worse conductor than the fluids of the human body, the far greater sectional area of the tree than of the neck of the bystander ought to more than make up the difference in conductivity.—L. C. E.

[12943.]—**British Museum Library.**—I should be glad to know what course I must pursue to obtain a reader's ticket for the library of the British Museum, on what days and hours it can be used, and what privileges it will confer. Any further information on this subject will greatly oblige—CERVUS.

[12944.]—**New Watch-Works.**—A lady's gold watch has, for some time gone badly, and frequently stops. She shows it to a "watchmaker" in a country town, who reports that "the holes in the escapement are worn." He recommends her to purchase an English-made watch from him for sixteen guineas, or a Geneva one for eleven guineas, he agreeing to accept her old watch for £8 in part payment. It may, perhaps, be interesting to many readers of this journal if some instructed correspondent will say if this is the best resource. Would it not be better economy to send the watch to a London manufacturer of reputation to have the old escapement (and whatever else of the interior requires) replaced by new? Surely, the case, the gold dial-plate and hands, and the jewels being given, a watch can be completed for less than thirteen guineas, of first-rate workmanship. —HOROSCOPUS.

[12945.]—**Spectroscope Eyepiece for Microscope.**—A gentleman in Germany writes to me for information, having been informed that this is the latest thing out, that it will allow the minutest striæ of the solar spectrum to be examined, as well as the external and invisible rays both at the red and violet ends, and that by letting the latter pass through uranium glass they become visible. I shall be greatly indebted to any of your scientific readers who will say if this information is correct, and will explain how the spectroscope eyepiece can be so used, kindly adding any other useful information on the subject which may suggest itself.—KELBY.

[12946.]—**Original Gravities of Beers, &c.**—Can any of "our" chemical correspondents give me the true way to find the original gravities of beer, as I believe I must make some mistake somewhere, not being able to get within 1lb. gravity at any time. I try it by the distillation and also evaporation processes, which ought to prove each other, but they do not.—AROMA.

[12947.]—**Starch and New Collar.**—Why cannot our old collars be got up as new ones? What is used to obtain that smooth glossiness of new starched goods.—MUTUAL TOM.

[12948.]—**Colours of Birds.**—Can the colour of a bird be heightened through its stomach? For instance, will the new feathers of a canary be of a deeper colour if it is fed, during the moult, on saffron and marigold flowers?—TAI-KOONG-SOO.

[12949.]—**Cleaning Cricketing Boots.** — Could any brother reader inform me how to clean the brown leather on my cricket boots, as I have tried many plans this summer and have failed?—MIDDLE STUMP.

[12950.]—**Microscope.**—I have lately purchased a microscope, and can see nothing but transparencies through it. If I put a piece of paper or linen or any solid object under it, it shows all dark, instead of showing the surface of the object. Will any one enlighten me upon the subject, and how to see the surface of any solid object that is not transparent?—A CARPENTER.

[12951.]—**Dividing Wheel of Excentric Chuck.** —Will "J. K. P.," or some other correspondent, kindly give me a sketch or explanation as to how the dividing wheel of the excentric chuck is attached to the sliding-plate, so that it should move stiffly round; and also if the pulley and sliding-cone in the ornamental drilling instrument are let on square, or with a feather on the end of the spindle?—E. T. E.

[12952.]—**Preserving Salmon in Tins.**—Can any correspondent kindly inform me how this is done, also where any information can be obtained as regards the process?—SALMO.

[12953.]—**Chemistry of Tea and Concentrated Tea Fertiliser.**—I notice in the *Englishman* (an Indian newspaper) of the 18th July, 1872, an article by Dr. George King, on a tea fertiliser, prepared on a formula by Dr. Campbell Brown, an eminent English chemist, founded on a careful investigation and analysis of all parts of the tea plant. It further states that this chemist (Dr. Brown) has for some years been working at the chemistry of Indian tea. Would any kind correspondent render me information regarding the chemistry of Indian tea, and the component parts of this tea fertiliser by Dr. C. Brown, as also analysis of all parts of the tea plant, or if Dr. Brown has published any works or work on these, to me, important and useful subjects?—Melville Pike.

[12954.]—**Burner.**—Will "Tintub" kindly state to what use the "atmospheric burner" he has sketched (let. 4742, p. 567) could be applied? If we attempt to boil a kettle over it, shall we not be annoyed by the gassy fumes? Does "Tintub" mean us to apply it to the heating of bed-chambers, &c.? And can he (?) give an idea of the consumption of gas in this manner as compared with the ordinary manner?—H. O'B.

[12955.] — **Expansion Valve.** — Will some kind reader give us a description of a simple expansion valve for the steam-engine, to cut off at various parts of the stroke, worked by hand, or under the control of the governor?—Smalker.

CHESS.

All communications intended for this department to be addressed to J. W. Abbott, 88, Loughborough-road, Brixton, S.W.

The match between Steinitz and Zuckertort has terminated in favour of the former, who won seven games, losing one only, four being drawn.

ENIGMA IV.—By E. H. Courtenay, from the Dubuque *Chess Journal*.

White.

K on Q R sq; Rs on Q B sq and K Kt sq; Kts on Q Kt 2 and K B 5; B on Q B 7.

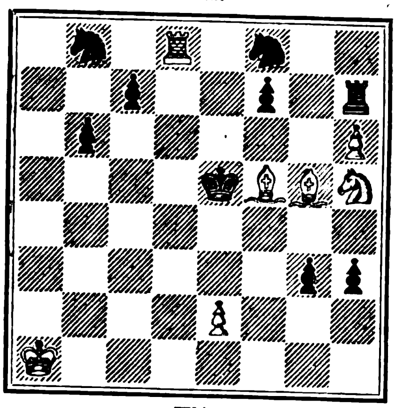
Black.

K on Q 7; Bs on Q B 7 and K 8; Ps on K 7; Q Kt 6 and K B 8.

White to play, and mate in *two* moves.

Problem XV.—By G. C. Heywood.

Black.



White.

White to play and mate in three moves.

Solution to Problem XIII.

White.	*Black.*
1. Q to K R sq. (ch).	1. Q to K 5.
2. B to Q R 6.	2. P takes B.
3. P takes P.	3. Anything.
4. P becomes a Q, mt.	

Solution to Enigma II.

White.	*Black.*
1. Kt takes P	1. Anything.
2. Kt B or P mates, acc.	

S. H. Thomas.—Kindly re-examine the problem in three moves, as it is wrong in the variation. The position in two moves is seemingly correct, and it shall shortly appear. The *Dundee Advertiser* publishes a draught column every week.

A. L.—Blank diagrams can be obtained through W. Morgan, Barbican. The other portion of your letter shall be attended to.

R. J. Pearce.—Your previous communication must have miscarried.

W. S. (Glasgow).—The mate is somewhat too obvious if you have copied the position correctly, as it can be done by (1) P takes P, discovering check, &c.

The following have sent correct solutions to Problem XIII.—H. Cherry; S. H. Thomas (Plymouth); W. Airey (Worsley); W. Nash (S. Neot's); A. W. Cooper; W. F. (Manchester); J. Beresford (Vauxhall); A. L. (Dulwich); R. J. Pearce; Argo (Yarmouth). All others are wrong.

Correct solutions to Enigma II. have been received from D. M. (Norwood); C. J. L. (Portsmouth); H. Cherry; J. C. U. (Leicester); R. Lines (Cinderford); W. F. (Manchester); A. W. Cooper; W. Airey; W. Nash; J. Bray (Langport); S. H. Thomas; R. J. Pearce; G & W. All others are wrong.

USEFUL AND SCIENTIFIC NOTES.

The Number of Eggs from a Hen.—A German naturalist answers the question how many eggs a hen can possibly lay as follows:—The ovary of a hen contains about six hundred embryo eggs, of which in the first year not more than twenty are matured; the second year produces one hundred and twenty; the third, one hundred and thirty-five; the fourth, one hundred and fourteen; and in the following four years the number decreases by twenty yearly. In the ninth year only ten eggs can be expected, and thus it appears that after the first four years hens cease to be profitable as layers.

Growth of Corals.—The *Honolulu Gazette* is responsible for the following:—An interesting fact has recently been observed respecting the growth of corals. Somewhat less than two years ago Captain McGregor, of the steamer *Kilauea*, moored a buoy in Kealakekua Bay. Last week he was ordered to hoist the anchor and examine the condition of the chain. The latter, which is a heavy two-inch cable, was found covered with corals and oyster shells, some of which are as large as a man's hand. The larger corals measure 4½in. in length, which represents their growth during the period of two years that the anchor and cable had been submerged. The specimen which we have seen shows the nature of its formation by the little coral insects more distinctly than any we have before examined. When taken out of the water, it had small crabs on it. A query arises whether these crabs live on the coral insects, or whether they simply seek the branches of the coral for protection. The popular supposition is that corals are of extremely slow growth. Here we have a formation equal to over 17ft. in a century.

Boring and Cutting Indiarubber.—To cut or bore indiarubber corks, says a correspondent of the *Chemical News*, dip the knife, or cork-borer, in a solution of caustic potash or soda. The strength is of very little consequence, but it should not be weaker than the ordinary reagent solution. Alcohol is generally recommended, and it works well until it evaporates, which is generally long before the cork is cut or bored through, and more has to be applied; water acts just as well as alcohol, and lasts longer. When, however, a tolerably sharp knife is moistened with soda-lye, it goes through indiarubber quite as easily as through common cork; and the same may be said of a cork-borer, of whatever size. I have frequently bored inch holes in large caoutchouc stoppers, perfectly smooth and cylindrical, by this method. In order to finish the hole without the usual contraction of its diameter, the stopper should be held firmly against a flat surface of common cork till the borer passes into the latter.

Odour of Flowers.—The delicate odour of pinks and other flowers may be obtained by a process devised by my son. He uses a glass funnel, with the narrow end drawn to a point. In this funnel he places lumps of ice, with salt, by which a very low temperature is produced. The funnel is supported on an ordinary retort stand, and placed near the flowering plants, when water and the ethereal odour of the blossom is deposited on the exterior of the glass funnel, and trickles down to the point, from which it drops at intervals into a glass vessel below. The scent thus obtained is very perfect and interesting, but is apt to become sour in a few days unless some pure alcohol is added. By this process many odours may be procured for comparison and study. To obtain the odour in perfection the blossom must be in its prime.—*Smee's "My Garden."*

Another Disabled Gun.—Whilst H.M.S. *Agincourt* was training her crew at target practice at sea, one of her six 12½-ton guns had its steel tube split through to the coils at the muzzle to a length of 24in. This gun had discharged seven empty shells at low elevations, and with sufficient intervals of time to keep the chamber cool, and prevent the too rapid consumption of the powder charges. None of the shells broke up. The supposition is that the front studs over-rode their grooves at the point where the increasing spiral brings them into bearing near the muzzle. This action would be facilitated by the compression of the walls of the shell due to the wedging of the rear studs over the lands. This makes the fifth heavy gun disabled within the last six months, and obliged to be returned to the Royal Arsenal for repair. The others are: two 12½-ton guns on board the *Bellerophon*, one 18-ton gun on board the *Hercules*, and one 18-ton gun at Shoeburyness.

ANSWERS TO CORRESPONDENTS.

*** *All communications should be addressed to the* Editor *of the* English Mechanic, 31, *Tavistock-street, Covent Garden, W.C.*

HINTS TO CORRESPONDENTS.

1. Write on one side of the paper only, and put drawings for illustration on separate pieces of paper. 2. Put titles to queries, and when answering queries put the numbers as well as the titles of the queries to which the replies refer. 3. No charge is made for inserting letters, queries, or replies. 4. Commercial letters, or queries, or replies, are not inserted. 5. No question asking for educational or scientific information is answered through the post. 6. Letters sent to correspondents, under cover to the Editor, are not forwarded; and the names of correspondents are not given to inquirers.

The following are the initials, &c., of letters to hand up to Tuesday morning, September 10, and unacknowledged elsewhere:—

W. Newman.—M. C. Henley.—Richard Thomas.— ... Burton.—F. R. A. S.—J. E. F. Wilson.—R. A. Pearce.— ... C. B.—J. K. P.—Hadrian Harris.—W. H. Plummer.— Wm. Airey.—J. Earl Clare.—John Tippen.—W... Roberts.—W. S. Hollingsworth.—Jas. Malkin.—Rev. L. Arthur.—W. E. Hincklin.—F. S. M. W.—J. ... Livins.—J. F. H.—J. H. Crellen.—H. B.—Major Oakes. —W. O'Neil.—Eastbourniensis.—W. H. H. C.— Memnon and Friends.—O. S. Round.—Alfred ... Wallace.—Barnes Richards.—Francis Weatherko...— J. C. Snell.—T. H. Bartlett.—J. W. J. H.—Wm. Macdowell.—John Razor.—Samuel Deards.—Ding-Dong. —A Constant Subscriber.—Sinbat.—R. J. P.—Y. A.— One who has Proved it.—W. H. Cash.—Argentum.— Johan.—Robert Ackland.—Felix Notro.—Candidate.— An Old Sufferer.—Seabird.—Another Constant Reader. —Samuel Neil.—Thos. Moody.—J. W. Worsey.—D. J. —M.—A. H.—W. W.—An Amateur.—H. M. A.—What you say about the time consumed between the receipt and the appearance of letters is quite correct, and will soon be rectified, or partially so, at all events.

Veritas.—The cost of inserting the letter as an advertisement would be 30s.

J. H.—Work out the sum for yourself, or get ... intelligent schoolboy to do it for you.

J. Pell (Birmingham).—Your advertisement is ... and your money is returned. See our "Answers to Correspondents," p. 575.

Peacock.—You had better consult the indices of published volumes, and seek out the information you require on the organ.

Lewis.—Put your query in more intelligible lang...

Zax.—We should be glad of the letter or letters on "Steam on the Road."

E. T. S.—The query on constipation has been ... answered, and may be allowed to drop.

A Constant Reader.—We know nothing about the post-card, and if we did we should not forward it.

R. Dixon.—It is quite possible, of course, for a private student to pass the preliminary medical examination, if possessed of sufficient ability. As to the subjects to be got up, why not apply to one of the medical schools where examinations are held.

David Grundy.—Do you want a book on engraving or wheelwrighting? We know of none on the latter subject.

V. C.—Try the "Vine Manual," *Journal of Hor...* office.

A Poor Boy.—No book specially devoted to the subject. Why not ask how to do what you want through our columns.

J. Stewart.—If the height of the siphon from the ... to the bend is more than 34ft. it will not act. What has drawing water from behind a hill more than ... high, or the depth of fall at delivery end, to do with the principle? The atmosphere will only balance a column of liquid equal to its own weight, theoretically 33ft. or 34ft. of water, but practically a siphon ought not to have a greater length of inlet leg than 32ft., on account of friction, and this length would act only at the places but slightly elevated above sea-level: not on top of the Himalayas. See reply 12696, last week.

[..]NSON.—Yes; there are professors who would, if they thought you a fit and proper person, give you instruction in mesmerism on the usual terms. We do not know the titles of books "leading to a practical acquaintance with this interesting science." Apply to Mr. Burns, of Southampton-row, W.C., or Mr. Truelove, of High Holborn, for catalogues.

C. E. S.—Please furnish the proffered information on "Block System of Railways," and, as you say, compressed as much as possible.

C. H. FISHER.—If you are too young to hold property in your own right you cannot take out a patent in your own name, as a patent is property.

A THINKER, A. T. B., J. D. H., C. Buddett and Co., and A Welshman, are informed that we do not answer queries asking where certain things are sold. See "Hints to Correspondents."

C. J. RECORDON.—Too speculative for us.

N. B., AND JAS. MCGRATH.—Consult medical men.

M. J. W.—It is merely the name given it.

J. D. H.—They are two distinct journals. Your second query is an advertisement.

C. F. H. H.—Your query is an advertisement. You can obtain hackles at most tackle makers.

G. S. W.—Why not answer "Emigrant," re sundials, through our columns?

J. W. PEARSON.—Don't alarm yourself, but consult a medical man. The symptoms you mention are *not* those of heart disease. You could not expect to obtain a satisfactory reply to such a query.

JOHN LEE.—Write to the publishers, Messrs. Churchill, New Burlington-street.

APPRENDRE.—Where do you find the question? Your solution is correct; the remainder is 22. 12 is probably a typographical error.

AFFLICTED SUBSCRIBER.—See pp. 593, 610, 619, Vol. XIV.

ZETA.—Your communication arrived toe late.

ASTRONOMICAL NOTES FOR SEPTEMBER.—ERRATA.—P. 605, column 2, lines 9 and 12, for ι^1 and ι^2 Aquarii read τ^1 and τ^2 Aquarii.

COMPARING ELECTROMOTIVE FORCES.—"Pi" writes:—"*Humanum est errare.* This truth and an illness from which I have even now scarcely recovered are my only excuses for the errors into which I have fallen in attempting to correct 'O.,' to whom I beg to apologise. His equations are perfectly accurate; a mistake in a sign in my last letter vitiates the whole argument therein proposed."

O.—See note from "Pi" above.

JOSEPH BAKER.—"F.R.A.S." distinctly refuses to give information by post. Please, therefore, ask him any admissible question through our columns.

H. S. A., E. W. H., A Paper Maker, Rip Van, and W. J. Richards.—Your queries are advertisements.

W. H. H. C., Memnon, and Friends.—What you say with regard to the mathematical column will be borne in mind.

H. T. T.—We believe there is no such office.

SUBAQUEOUS RAILWAY FOR CANALS.—Impracticable.

THE INVENTOR.

APPLICATIONS FOR LETTERS PATENT TO THE WEEK ENDING AUGUST 30, 1872.

2472 J. Brodie, Fifeshire, N.B., for improvements in the construction of fastenings for gates and doors, drawers, lids, and desks.

2473 R. Stone, Liverpool, for an improved concrete for surfacing or laying roadways, footways, and other similar large surfaces.

2474 T. Palmer, A. Pickup, and S. Carter, Oldham, for improvements in sewing machines.

2475 O. Ingham, Lidgate, Yorkshire, for improvements in pickers for looms for weaving.

2476 A. Deiss, Plaistow, Essex, for a new or improved process of percolation.

2477 W. Truswell and R. W. Holden, Sheffield, for an improved apparatus for heating air, and for supplying hot air to furnaces, cupolas, smiths' hearths, and other fires, to bakers' and other ovens, to kilns for drying and burning bricks, and for utilising the fire in open fire grates for making hot air and supplying it to rooms in private houses or public buildings.

2478 A. M. Clark, Chancery-lane, for improvements in cotton gins. A communication.

2479 P. Lanranson, Hatton-garden, London, for improvements in methods of manufacture, and combinations therewith, for producing book-binding clasps or mechanical bookbinders. A communication.

2480 J. H. Johnson, Lincoln's Inn-fields, for improvements in supplying hot blast to blast and other furnaces, and in the apparatus or means employed therefor. A communication.

2481 M. Gally, Rochester, New York, for automatically arranging or constructing forms for printing communications or other kinds of printed matter at hand or at a distance.

2482 J. Dodd, Oldham, for improvements in mules for spinning and doubling cotton and other fibrous materials.

2483 B. Hunt, Serle-street, Lincoln's Inn, for an improved physiological or "button" battery. A communication.

2484 W. Ambler, Bradford, for improvements in machinery for the manufacture of paper tubes.

2485 A. C. Bamlett, Thirsk, Yorkshire, for improvements in reaping and mowing machines.

2486 W. Chaine, Portrush, Ireland, for improvements in saddle bags for carrying water.

2487 W. Young, P. Brash, and A. Scott, Midlothian, N.B., for improvements in the destructive distillation of coal, shale, and other bituminous substances for the production of illuminating gas and of oils.

2488 G. Haseltine, Southampton-buildings, for improvements in treadle mechanism. A communication.

2489 H. J. Griswold, Southwark-street, Surrey, for improvements in knitting machinery.

2490 E Rostron, Waterfoot, Manchester, for improvements in machinery employed in the manufacture of felt.

2491 C. F. Sebille, Paris, for improvements in the composition known as "schisto-asphaltic and bituminous-beton," and novel applications thereof, together with improved machinery or apparatus in connection therewith.

2492 G. Haseltine, Southampton-buildings, for improvements in railway carriage springs. A communication.

2493 G. Haseltine, Southampton-buildings, for improvements in electrical apparatus to be worn upon the head for the alleviation and cure of nervous affections. A communication.

2494 T. A. Weston, Ridgewood, U.S., for improvements in friction clutches and the arrangement and mode of operating frictional surfaces for transmitting, regulating, and arresting motion in machinery.

2495 J. Winskill, Settle, Yorkshire, for a new or improved construction of lime kiln.

2496 M. H. Synge, Pall Mall, for improvements in deodorising apparatus.

2497 J. R. Wright and A. Alexander, Sheffield, for improvement in the treatment of iron and manufacture of steel.

2498 W. Brookes, Chancery-lane, for improvements in means for stopping the working of apparatus on the breaking or failure of thread in the roving, spinning, or twisting of wool, cotton, or other fibres. A communication.

2499 J. Thornton, Cleckheaton, Yorkshire, for improvements in utilising borings, turnings, filings, planings, and other particles of iron.

2500 M. Henry, Fleet-street, City, or improvements in the mode of and machinery or apparatus for preparing fibrous materials for being spun. A communication.

2501 J. Edwards, Cassland-crescent, South Hackney, for improvements in signal alarums for railway trains.

2502 C. O'L. L. Prendergast, Wokingham, Berkshire, for an improved means and apparatus whereby passengers in a railway train can communicate a signal to the guard and driver.

2503 J. Morgan, Dublin, for an inhaler for medical purposes.

2504 W. Morris, Deptford, for improvements in making connections with water mains under pressure.

2505 C. Blackmore, Guildford-street, Middlesex, for improvements in ornamenting surfaces.

2506 E. A. Cook, Midlothian, N.B., for improvements in treating animal charcoal.

2507 J. Clay, Yardley, Worcestershire, for improvements in saddles.

2508 P. Varnaison, Paris, for an improved system of apparatus to allow of producing rapidly the vacuum in the night-carts.

2509 T. Henderson, Liverpool, for an improved apparatus for supplying fuel to furnaces, and for removing clinkers from the same.

2510 W. Vincent, for improvements in apparatus for manufacturing gas.

2511 W. Carwood, Queen-street, Finsbury, for improvements in presses for letter-press printing.

2512 W. H. Harfield, Mansion House-buildings, City, for improvements in apparatus for multiplying power, applicable to windlasses, cranes, hoists, and other machines.

2513 R. Warry, Devonport, for improvements in the construction of portable cooking stoves.

2514 H. Alder, Edinburgh, for improvements in the construction of dry meters.

2515 R. Goodall, Armley, Leeds, for an improved means or method of and apparatus for clarifying impure or waste water from fulling mills, scouring mills or scouring processes, dye houses, sewage, and other impure waters.

2516 T. D. McFarlane, Glasgow, for improvements in loading grain into or discharging it from ships and other places, and in apparatus employed therefor.

2517 H. A. Bonneville, Piccadilly, for improvements in machines for cutting textile and other materials. A communication.

2518 W. Lockhead, Glasgow, for improvements in treating and applying asbestos or amianthus.

2519 J. G. Tongue, Southampton-buildings, for the application of platinised glass or "glace platinée" to various articles, such as needle and perfumery boxes or cases, and other useful or fancy articles. A communication.

2520 C. W. Stones, Manchester, and A. Lowcock, Salford, for improvements in the arrangement and construction of movable weirs and sluices.

2521 C. Bartholomew, Doncaster, for improvements in machinery for cutting coal.

2522 P. M. J. Chambiant, Paris, for improvements in sewing machines.

2523 J. Field, Oldbury, Worcestershire, for improvements in field and garden hose and other like implements.

2524 K. Hoskins, Birmingham, for a new mode of constructing and adapting the frames of bedsteads for the reception of tensional or other spring mattresses, as also in the means of applying such tensional or other spring mattresses to iron bedsteads.

2525 J. M. Plessner, Golden-square, Middlesex, for improvements in obtaining and applying motive power and in apparatus to be employed for the same.

2526 R. H. Radcliffe, Cheshire, for an improvement in the arrangement for the screw propeller in steam ships.

2527 C. Frickinger, Berlin, for improvements in the manufacture of malleable iron and in the furnaces employed therein

2528 J. F. Parker and A. Wade, Birmingham, for improvements in the manufacture from coal and petroleum of hydrocarbon gas, or gas for illuminating and heating.

2529 H. A. Dufrene, South-street, Finsbury, for an improved mode of preserving fruit. A communication.

2530 T. S. Harrison, Albemarle-street, Middlesex, for an improved attachment for sewing machines. A communication.

2531 T. S. Harrison, Albemarle street, Middlesex, for an improved attachment for sewing machines.

2532 T. S. Harrison, Albemarle-street, Middlesex, for an improved apparatus for oxidising metals. A communication.

2533 Sir A. Fairbairn, T. S. Kennedy, and J. W. Naylor, Leeds, for a machine to draw out and straighten the fibres of silk, flax, hemp, jute, or other fibrous substances.

2534 A. S. Ellefson, Norway, for improvements in apparatus for generating steam.

2535 E. H. Buch, Finsbury-square, City, for improvements in apparatus for cooking and for making coffee and other infusions.

2536 J. G. Tongue, Southampton-buildings, for improvements in closing and securing packing cases or boxes. A communication.

2537 G. Haseltine, Southampton-buildings, for an improved machine for making screw taps. A communication.

2538 H. Y. D. Scott, Ealing, for improvements in the treatment of sewage, and in the preparation of manures therefrom.

2539 G. F. Newton, Northampton, for an improved machine for burnishing, rolling, and setting leather.

2540 A. Henry, Edinburgh, for improvements in breech-loading fire-arms.

2541 J. S. Stevens, Princes-street, Leicester-square, for improvements in window-sash fasteners.

2542 W. W. Box, Crayford, Kent, for improvements in apparatus used in the manufacture of gas.

2543 J. Stone, Drayton, Somerset, for a new or improved apparatus for warming bed and other rooms, also applicable for warming or heating churches, conservatories, greenhouses, or other buildings or rooms requiring warming or heating.

2544 A. N. Dubosq, Bordeaux, for a new system of landau carriage.

2545 C. Morfit, Southampton-buildings, for improvements in vats or vessels for the various chemical and manufacturing operations which involve the use of acids.

2546 A. M. Clark, Chancery-lane, for improvements in fire-arms. A communication.

2547 H. Highton, M.A., Putney, for improvements in submarine and other cables for the conveyance of electricity.

2548 A. Bryce, Alloa, N.B., for improvements in branding stoves.

2549 W. Millen and J. Muir, Glasgow, for improvements in holding punches and drills in punching and drilling machines, and in the means employed therefor.

2550 C. H Hall, New York, U.S., for an improved steam and water gauge for use with steam boilers and analogous apparatus.

2551 H. Foster, Boxmoor, Hertford, for improvements in apparatus for condensing steam and other vapours, and for refrigerating fluids.

PATENTS SEALED.

1008 C. Stevenson, for improvements in apparatus employed in converting esparto, straw, wood, and other similar substances into pulp.

1162 H. Warry, for improvements in various beverages.

1566 P. Michaelis, for an improved means or apparatus for stoppering bottles.

1567 P. Michaelis, for an internal capsule for bottles.

1646 W. R. Lake, for improvements in railway sleepers or cross ties.

1712 J. Hough, for improvements in apparatus for coupling or connecting and disconnecting railway waggons.

1816 A. McGregor, for improvements in the construction of horse rakes.

1846 W. B. Burrow and J. S. Burrow, for an improved "bin" or receptacle for wine or other bottles.

1868 G. Maxwell, for improvements in the construction of machinery or apparatus used for making bricks and tiles.

1891 J. Thomas, for improvements in furnaces for generating gas and melting metals.

1941 J. K. Cazier, for an improvement in the application of safety valves to steam boilers.

1957 W. R. Lake, for improvements in fastenings for uniting and securing the parts of bedsteads and for other like purposes.

536 W. H. le Mesurier, for an improved mode of roofing buildings.

567 J. Rust, for an improved composition specially applicable for use for sanitary, pictorial, decorative, and building purposes.

673 R. Elsdon, for improvements in the conversion of cast iron into steel or wrought iron, and in the apparatus employed therein.

515 G. A. Williams, for improvements in the manufacture of outside sun blinds.

583 S. Yeadon, sen., for improvements in "healds" or "heddles" for weaving purposes, in the parts connected therewith, and in the means or apparatus employed in the manufacture of the parts of such "healds" or "heddles."

585 B. J. B. Mills, for improvements in the construction of railway rails or bars.

590 E. T. Hughes, for improvements in machines for sewing boots and shoes.

594 A. G. Wallis and W. Bradshaw, for improvements in the manufacture of cocoa fibre mats.

596 H. R. Minns, for improvements in metal doors.

597 T. Pepper, for an improved washing machine.

598 F. Ayrton and S. S. Brown, for improvements in looms for weaving.

613 W. Walker, for an improved packing for stuffing boxes.

614 O. G. Abbott, for improvements in school desks which are applicable to other purposes.

615 J. Reilly, for improved arrangements for communicating between the passengers, guards, and engine-drivers of railway trains.

636 W. Morgan, for improvements in baskets specially applicable to coaling ships and vessels.

684 W. Dalgliesh, for improvements in the manufacture of Scotch bonnets, and in the machinery or apparatus employed therefor.

685 G. D. Abel, for improvements in the manufacture of Bessemer steel and iron, and in the production of iron castings, and in apparatus therefor.

706 W. R. Lake, for an improved type-setting machine.

727 J. F. C. Farquhar, for improvements in lighthouse and other lamps.

776 J. Somerville, for improvements in gas retort lids and mouthpieces, and machinery for luting the same.

793 F. S. Thomas, for improvements in the materials for making roads, ways, and floors.

815 F. Johnson and W. Hatchman, for an improvement in the manufacture of fabrics for umbrellas.

891 T. Giles, for improvements in safety valves.

914 J. H. Johnson, for improvements in ice-cream freezers.

1048 W. Walton and J. T. Fallows, for improvements in and machinery for rolling wire for making wire cards, and for other purposes.

1086 W. H. Maw, for the construction of floating stations or decks for floating fire-engines.

1105 W. Walton, for improvements in the manufacture of wire cards.

1115 R. Stone, for an improved system of casting or moulding applicable to ceilings, internal and external walls, roads, navigable vessels, and other large surface structures.

1205 W. Ferry, for improvements in cistern filters.

1215 J. W. Gray, for a new or improved lithoidal composition to be used as a paint and for other purposes.

1226 J. K. Collett, for improvements in the method of packing and preserving butter, and in apparatus for that purpose.

1460 E. H. C. Monckton, for improvements in the construction and arrangement of furnaces suited for smelting and fusing every description of ores and metals and glass, for heating gas and other retorts, and for other useful purposes, and in the means and appliances necessary thereto.

1506 J. Jeyes, for an improved fuel.

1600 F. J. Cheesbrough, for improvements in machinery and apparatus to be used in the process of manufacturing oil from seeds.

1637 C. Moseley, for a new method and means for condensing the vapours of coal-tar naphtha.

1657 D. Nicoll, for improved preparations applicable to woven and other fabrics for the purpose of rendering the same uninflammable.

1660 C. Raymond, for improvements in sewing machines.

1679 C. W. Harrison and A. H. Harrison, for improvements in the manufacture of gas for lighting and heating purposes, and in the apparatus employed therein.

1892 G. A. Dorsett, for improvements in obtaining anthracene from heavy oils.

1895 J. F. Swinburn, for improvements in breech-loading small arms.

1919 C. W. Siemens, for improvements in the means of obtaining and applying magneto-electric currents and apparatus therefor.

1944 J. H. Johnson, for improvements in sifting or bolting machines.

1964 B. Russ, for improvements in the manufacture of gas, and in the treatment of the residues therefrom, in the means of purifying and rectifying the same; and in the combination or amalgamation of gases for the production of light and heat, and for other useful purposes, and in the machinery and apparatus to be employed therein.

1972 W. Walton, for improvements in window-sash fasteners, and in means of ventilation in connection with window sashes.

621 J. Thompson, for improvements in the lids or covers of vegetable dishes and other similar articles.

623 W. Roberts, for an improved machine for painting laths for venetian blinds and other purposes.

637 D. Hanna, for improvements in sewing machines.

638 J. Wilson and G. Landrum, for a new and improved method or means of finishing woollen cloth.

639 E. T. Hughes, for improved arrangements for rapidly and effectively destroying snow and ice in the streets, public places, courtyards, and other localities.

644 J. B. Saunders, for improvements in and connected with electrical instruments for signalling on railways.

645 W. Blackburn, for improvements in the construction of standards or supports for seats and desks or tables for school and other purposes.

656 J. P. R. Poch, for a new chemical compound for blasting purposes.

660 J. Tannett, J. Scott, jun., J. Craven, and S. Fox, for improvements in machinery for boring shaft couplings, and applicable for boring circular or other flanges.

692 B. Fitzpatrick, for improvements in apparatus for clipping horses and other animals.

755 S. Barton, for an improved rose and nozzle or jet to be used in connection with syringes and other apparatus for distributing water.

774 W. J. Lockyer, for improvements in the preparation of artificial manures.

813 S. Neville, for improvements in lears for annealing glass.

828 W. R. Lake, for improvements in printing telegraphs.

841 A. Pye-Smith and C. Ribbans, for improvements in non-conducting compositions for coating steam pipes and boilers, applicable also for preventing the passage of heat or cold to or from pipes, refrigerators, or other vessels.

890 R. M. Letchford and W. B. Nation, for improvements in the treatment of paraffin.

986 C. G. Hill, for improvements in machinery for goffering, fluting, and crimping fabrics.

1069 J. Worrall and J. Kershaw, for an improved apparatus for scouring pile fabrics.

1070 J. Worrall and J. Kershaw, for an improved mode of and apparatus for finishing cotton cords.

1117 G. Stavers, for improvements in apparatus for steering and manœuvring vessels.

1242 C. W. Vick and J. Cooke, for improved machinery for feeding, preparing, and carding engines.

1342 A. Clark, for improvements in corrugated metal revolving shutters.

1396 H. Turner, for improvements in the application of wire to building and other purposes.

1560 T. Cocks, for improved machinery or apparatus for planting potatoes.

1836 T. Lambert and E. J. White, for improvements in self-closing valves or cocks for drawing off water.

1851 V. van Baerle, for improvements in the manufacture of soap or compositions for washing purposes.

1883 J. Campbell, for improvements in the modes of decreasing the rolling of vessels.

1916 W. Macrone and W. McKenzie, for improvements in the production of stereotype plates and in apparatus employed therefor.

2017 W. Gorman, for improvements in manufacturing iron and steel and in apparatus connected therewith, part or parts of such improvements being applicable to various kinds of furnaces, and for the production of gases for heating and illuminating purposes, and for coking, carbonising, or calcining other substances.

2018 G. Westinghouse, jun., for improvements in brake apparatus for railway carriages.

2024 A. M. Clarke, for improvements in pads for stair and othe carpets.

651 L. Barnett, for improvements in reversible and seamless coats.

658 E. Powers, for improvements in the manufacture of iron steel, copper, and other metals.

664 E. M. Adams, for an improved galvanic apparatus to be used for curative purposes.

665 W. H. Carson and J. V. Toone, for an improved feed roller for chaff-cutting machines.

671 R. Blackburn, for improvements in apparatus and in means for treating sewage for agricultural purposes.

672 W. Exall, for improvements in tube expanders.

718 C. W. Lancaster, for improvements in shot, shell, and other similar missiles.

801 F. W. Gerhard and J. Light, jun., for improvements in the production of iron and steel.

1037 A. M. Clark, for improvements in the manufacture of illuminating gas and in apparatus for the same.

1077 J. H. Johnson, for improvements in rotatory steam-engines.

1345 J. H. Johnson, for improvements in carding engines.

1494 R. Porter and F. Porter, for improvements in distilling and in apparatus therefor.

1806 W. C. Sillar, R. G. Sillar, and C. Rawson, for improvements in treating animal matters in order to deoderise and decompose the same and to make a manure therefrom.

1889 W. R. Lake, for improved check tickets and methods of forming packages of the same, chiefly designdd for use on railways and steamboats.
