CYCLOPÆDIA

OF

ANATOMY AND PHYSIOLOGY.

EDITED BY

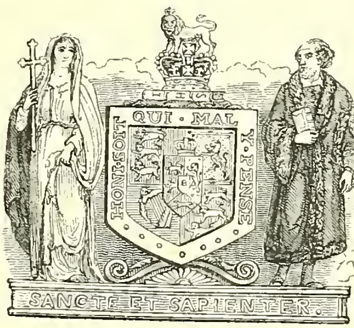
ROBERT B. TODD, M.D. F.R.S.

FELLOW OF THE ROYAL COLLEGE OF PHYSICIANS;

PHYSICIAN TO KING'S COLLEGE HOSPITAL; AND FORMERLY

PROFESSOR OF PHYSIOLOGY AND OF GENERAL AND MORBID ANATOMY IN KING'S COLLEGE,

LONDON, ETC. ETC.



VOL. I.

A—DEA

1835—1836

LONDON

LONGMAN, BROWN, GREEN, LONGMANS, & ROBERTS.

CONTENTS OF THE FIRST VOLUME.

PREFACE.

To collect a series of Essays on all the various subjects of Anatomy and Physiology, by the co-operation of several Authors, who, as far as possible, should be selected in consequence of their special attention to, or interest in, the subject-matter of the articles which each would undertake to furnish, was the object of the Editor in projecting the "Cyclopædia of Anatomy and Physiology."

The successful inauguration of a similar work on Practical Medicine, which had advanced some way prior to the commencement of this Cyclopædia, afforded great encouragement to the Publishers and to the Editor to prosecute their design.

The first part was published in 1835, twenty-four years ago. It was then calculated that twenty parts would complete the book, and that not many years would have been sufficient for that purpose.

A glance at the Table of classified Contents will show the multiplicity of topics on which it was proposed to treat: — Anatomy, both as it regards man and all the tribes of inferior creatures, — Anatomy descriptive, — Anatomy physiological or histological, — Comparative Anatomy, — Morbid Anatomy, general and special. To these were to be added: Physiology (human and comparative); some brief notice of Vegetable Physiology; the Anatomy and Physiology of the different classes of Animals, involving, in many instances, much reference to their Zoology; and lastly Animal Chemistry, including the physiology of the fluids and secretions.

Numerous as were the articles which, according to the first plan of the work, were to have been introduced, it was soon found indispensable not only to add others quite new, but also to enlarge considerably the space allotted to each of those which formed the original catalogue, and to multiply greatly the number of illustrations.

All this was rendered necessary by the rapid strides which our knowledge of many subjects in Anatomy and Physiology began to take at the time when the earlier parts of the Cyclopædia made their appearance. Perhaps there never was greater activity of research in any branch of science during a given period, than that under which the sciences of Anatomy and Physiology advanced during the last quarter of a century. Minute anatomy, which thirty years ago was crude and undigested, now takes very high rank among the various branches of Natural Knowledge. During these years every tissue has been scrutinised; many obscure points have been cleared up; much that was wholly unknown has been brought to light. The additions to our knowledge of Anatomy, although there is yet ample room for fresh discoveries, have given a totally new phase to Physiology. From being little more than a series of vague and ill-founded hypotheses, scarcely deserving even that name, it has become a well-arranged science, embracing a vast amount of clearly defined facts, which, at once, form a solid basis for a superstructure of sound theory, and throw much light upon the various processes of animal and vegetable life.

It was the constant aim of the Editor, where it was possible, to secure the assistance of Contributors who would be likely to make original investigations, and to employ new researches for furnishing the *matériel* of their articles. Whilst it is thankfully acknowledged, that in many instances the Editor's most sanguine hopes were fully attained, it is not less true that he was sometimes disappointed, and that much delay of publication and apparent breach of faith took place. A few completely failed to fulfil their engagements, without any assignable reason; others were unavoidably prevented from so doing. In several instances the articles were not completed at the stipulated time. For some of these the Editor was content to wait, notwithstanding that by so doing the immediate sale of the book was injured, and the Editor himself exposed (with apparent justice) to charges of violation of promises. But, in the particular cases referred to, the Editor knew that delay in the completion of the articles was caused by an earnest wish on the part of the Authors to do ample justice to their subjects, and a praiseworthy scrupulousness in recording facts which they had not verified by actual observation.

To this it must be added, that for a considerable period the continuance of the work was jeopardised, and its publication wholly suspended for two years, by the death, in rapid succession, of the leading partners of the publishing firm under whose auspices the work was conducted, prior to its passing into the hands of its present publishers, the Messrs. Longman.

Nor will the Editor attempt to shield himself from blame as regards the tardy completion of the Cyclopædia. He is quite ready to confess that, in other hands than his own, it would have been long since finished. He is conscious that he has been often dilatory, sometimes vacillating, occasionally appalled by the magnitude of the undertaking, and by the knowledge of the inadequacy of his powers to carry it on to a close. At the same time, in self-defence, he feels bound to plead that, soon after the publication of the first two or three parts of the work, certain onerous duties devolved upon him, which greatly curtailed the amount of leisure available for literary pursuits. In the first place, he was called upon, at short notice, to deliver a lengthened course of Lectures on Anatomy and Physiology of a kind quite new in this country, both as regards extent and nature, which demanded a large amount of study and of personal inquiry and investigation; soon afterwards was added the responsible office of a Hospital Physician and a Teacher of Clinical Medicine; these were, at no long interval, followed by professional engagements, which, although not more responsible, created more urgent and imperative claims upon his time and attention. With all these demands upon him, it will not excite surprise that literary work often became abandoned or postponed.

At length, "per varios casus et tot discrimina rerum," the period of completion has arrived. And the Editor, while he is impressed with a deep sense of gratitude that his own health and life have been spared till the completion of the book, acknowledges, with thankfulness and pride, the invaluable aid which he has obtained from all quarters. He looks back with much of the same feelings which fill the mind of an architect who has projected a large building requiring for its completion a long series of years. While the original design, as well in its defects as in its merits, is due to himself, he is conscious how little he has had to do in supplying the materials, and completing the details of the building. For these he has trusted, and not in vain, to a body of *collaborateurs*, among whom he is proud to reckon many of the first scientific men both in this country and in Europe. How efficiently this work has been done, it is not for the Editor to say, but he deems himself justified in affirming that, for years to come, this Cyclopædia will furnish a well-stocked field for reference to the student of Anatomy and Physiology.

It is remarkable how few of the members of this little phalanx of contributors have failed to see the completion of the work! Nevertheless, we have to deplore some serious losses; and the Editor trusts he may be pardoned for offering a passing tribute to the memory of some of the more distinguished among them.

Foremost among these, although but recently removed from amongst us, was the late Dr. Marshall Hall, who furnished articles on the (to him) favourite subjects, Hybernation, Irritability. Although a veteran in science, he had finished his career before he had reached the ordinary limits of human life. To large gifts of natural genius he added an indomitable industry and perseverance. His name must always occupy a prominent position in the annals of Physiology, by reason of the active and highly successful part which he took in advancing our knowledge of the Physiology of the Nervous System, and in promoting its application to the investigation of Pathology and the diagnosis and treatment of disease; and the extremely ingenious speculations and hypotheses which he, from time to time, suggested for the explanation of various natural and morbid phenomena. The manner in which his almost latest hours were employed in applying physiological knowledge to the treatment of asphyxia shows how little it could have been said of him,

"Superfluous lags the veteran on the stage."

Still more recently, another veteran, especially distinguished in anatomical science, has fallen while actually in the ranks. Professor Harrison, having been during the previous day engaged in the duties of his chair, rapidly succumbed, in the course of a night, under an apoplectic seizure. For forty years and upwards he maintained the highest reputation as a Teacher. At a time of life long subsequent to that at which most men seek repose from such labour, he was as fresh, clear, full, and impressive, in teaching anatomy, at once the most elementary and the most important of the studies accessory to medicine, as in his early days.

The celebrated discoverer of Endosmose, H. Dutrochet, lived to the ripe age of seventy-one. The article on that subject in this work was the contribution of his own pen. It contains a summary of his views up to the time of its publication. Dutrochet's discovery has the most interesting and important bearing upon the application of physical laws to the illustration of various processes of living organisms. It gave the clue to the elucidation of many obscure points in the physiology of animals and plants, and took a lead in directing the minds of Physiologists away from abstract and fruitless speculations concerning the nature of Life, into the true path of inquiry as to the dependence of vital phenomena on chemical and physical laws.

The value of this discovery is enhanced by the recent researches of Mr. Graham, which have developed the laws of Osmose (to use his more concise and comprehensive designation), and have shown the intimate connexion of osmotic with chemical action. Further experiments on the osmotic phenomena of living animals and plants, assisted by the additional light obtained from Mr. Graham's researches, can scarcely fail to lead to important, practical results, both in Physiology and Pathology.

The loss of Newport was a heavy blow to Physiology. A man of his skill as a dissector and observer of that large and most interesting tribe, the Insects, could ill be spared. The combination of such manual dexterity and of so much acuteness of observation as Newport displayed is rarely met with. His investigations embraced at once the most delicate anatomical analyses and the deepest questions of physiology. The article Insecta, contributed by him to this work, is perhaps the most comprehensive account extant of the anatomy and physiology of this class of invertebrate animals. Newport was cut down in the prime of life, when, after many struggles and difficulties his merits were becoming recognised, and the value of his researches appreciated. There can be no doubt, had health and life been given him, he would have largely extended our knowledge of this branch of Comparative Anatomy and Physiology.

Of not less promise, in a still wider field of research, was John Reid, who for a few years before his early removal under a painful and tedious disease, filled the chair of Medicine at the University of St. Andrew's, a position in which his great powers had but a limited scope. Reid was one of those men who are content to take nothing for granted which it was at all in their power to examine for themselves. His admirable investigation of the Anatomy and Physiology of the Eighth Pair of Nerves is a model of anatomical and physiological research, scarcely equalled and not surpassed by any similar essay of recent or remoter times. His articles, Heart and Respiration, in this Cyclopædia, bear ample testimony to his scientific character, and well sustain the high reputation he had acquired even at a very early age.

The late venerable Dr. Bostock, who died at an advanced age, belonged to a different school of Physiologists from those already referred to. No man was more remarkable for the patience and depth of his literary researches. Conscientious almost to a fault, he has left a scrupulously faithful record of all that was done in Physiology up to the time at which he wrote, affording to those who take an interest in that branch of inquiry an impartial historical review of the progress of science. From the great erudition aud sound judgment of this excellent man, the Editor derived many valuable hints in the first stages of the Cyclopædia, in the plan and early progress of which he was pleased to take a lively interest.

Born a British subject, the late W. F. Edwards (also a veteran in science although he had by no means attained a great age) had spent most of his life in France and followed his Physiological pursuits there. His principal researches were directed to the observation of the influence of various physical agents upon the phenomena of Life, and the investigation of the chemical changes which occur in some of the most important and recondite vital processes. Many of his Essays, which were at first published as detached Papers, were afterwards collected, and formed his well-known work on the "Influence of Physical Agents upon Life."* Dr. Edwards's researches, whilst they determined many new and highly interesting facts, were especially valuable as promoting more philosophical views of life than those which referred all vital phenomena to the influence of a hypothetical entity.

* Translated into English by Drs. Hodgkin and Fisher, an. 1832.

An important article on Animal Chemistry in this Cyclopædia (PROTEINE) was contributed by a young and rising chemist, JOHN E. BOWMAN, whose brief career sufficed to impress his friends with a strong sense of the serious loss which society and science experienced by his early removal. His acute and well-cultivated intellect would have done much for chemistry had his life been prolonged, or had he even enjoyed, during its short span, an ordinary amount of health. But his last few years were greatly marred in their usefulness by a singular chronic malady, which slowly undermined his vital powers, and greatly limited his ability for active exertion, whether bodily or mental. Nevertheless, he has left two works which, although of small size, are of considerable practical utility to the chemical student; the one devoted to practical chemistry, the other to chemistry in its application to practical medicine.

The Editor takes this opportunity of acknowledging his obligations to gentlemen who, at different periods, rendered him the most efficient assistance in superintending the passing of the work through the press, and in other matters connected with his province.

Dr. ROBERT WILLIS, formerly of London, now extensively engaged in medical practice at Barnes in Surrey, for many years took an active part in the superintendence of the printing of the work, and contributed largely to the Bibliography appended to most of the articles, as he was so well qualified to do by his extensive knowledge of books. Dr. Willis also contributed the article ANIMAL. Upon his retirement, the Editor derived similar valuable assistance from his friend and former pupil, Mr. S. ROOD PITTARD, who also contributed several articles. And, subsequently, Dr. HYDE SALTER, now well-known, and of deservedly high reputation as a Physiologist and Physician, kindly afforded his aid in the same way, as well as by his valuable contributions of the articles PANCREAS and TONGUE.

This seems the fitting place to state that it has been found necessary, in a few instances, to depart from the strict alphabetical arrangement, either by placing articles under names not commonly used, or by clubbing together two or more subjects, to which it would appear, at first, more natural to have devoted separate articles. The necessity for such modifications arose out of contingencies to which all works are liable, when they are published in Parts, and dependent for regularity of publication on the punctual contribution of the various articles. Where such punctuality could not be obtained, and where it was found absolutely necessary to curtail delay, the changes above alluded to were adopted as a matter of necessity rather than of choice. Thus, Ear is referred to HEARING, ORGAN OF; Kidney to REN. The union of certain articles together under one heading was sometimes found both convenient for treating the subjects, and œconomical of space. Thus, the Anatomy of the Brain was conveniently associated with that of the Spinal Cord, and will be found under NERVOUS CENTRES; that of the Intestinal Canal under STOMACH AND INTESTINAL CANAL (Dr. Brinton); and that of the Ovary in the elaborate article of Dr. Farre, UTERUS AND ITS APPENDAGES. SEROUS AND SYNOVIAL MEMBRANES have been treated of under one heading, from the close analogy of their structure; and Hairs, Nails, Skin, &c., are described under the general title TEGUMENTARY ORGANS.

It was found absolutely necessary, owing to difficulties which otherwise must have completely prevented the completion of the work, to place several articles in a supplementary volume, regardless of strict alphabetical arrangement. But it is hoped that for this, as well as the other departures from the strict Encyclopædic form, compensation will be found in the various Indices, and in the Table of Classified Contents.

26 Brook Street, Grosvenor Square, London,
Jan. 1859.

ANATOMY AND PHYSIOLOGY.

ABDOMEN, (in anatomy,) with which the terms *venter* and *alvus* are sometimes used synonymously. Gr. γαστηρ. Germ. *bauch*, *unterleib*, *hinterleib*. Ital. *ventre*, *pancia*, *abdomine:* the French anatomists use the word *abdomen* as we do, and also the term *ventre* as we do *belly;* also *bas-ventre*. It is so called, " quod *abdi* et tegi soleat, aut quod alimenta in eo *abdantur*, aut intestina ibi sint *abdita*."*

The term denotes a particular region and cavity in a large proportion of the animal series, being found in most of the classes from Mammalia down to Articulata. It is impossible to give such a definition of this region as will apply to all; it appears, however, to have one property sufficiently general, viz. that it contains in all these classes more or less of the digestive organs. Thus, to ascend from the Articulata:—

It is in the class Insecta of the Articulata that we find the most defined region bearing this name. This region is the most posterior of the three portions into which the body of an insect is divided, and is composed of a series of segments which unite to form a cavity enclosing the viscera subservient to nutrition, respiration, and reproduction; it does not contain any of the organs concerned in locomotion. It is composed of a series of simple hoops, united to each other by a ligamentous connexion, which allows the abdomen to be flexible or otherwise, according to the closeness of the union.† The abdomen is united by its anterior extremity to the thorax. (See INSECTA.) In the Arachnida there is also a similar division of the body, to which the name of abdomen has been applied, united in front with the cephalo-thorax, and separated from it by a deep groove, which leaves only a slender pedicle between them; like that of the Insecta it contains the principal viscera. (See ARACHNIDA.)

In all the divisions of the Vertebrata there is an abdomen. In fishes the abdomen is situated towards the posterior extremity of the body, and is separated from the heart in front by a strong membrane analogous to the diaphragm; it contains the digestive and generative organs. In reptiles the abdomen is that region which lies immediately anterior to the anus; in many classes it is not separated from the cavity containing the lungs, so that the lungs, heart, organs of digestion and generation are all contained in one great cavity; in the crocodile, however, a layer of muscular fibres, having the appearance of a diaphragm, covers the peritoneum, where it is connected with the liver, so that the lungs do not project into the abdomen. In birds, the abdomen extends from the posterior extremity of the sternum to the anus; it is, as in fishes, separated from the thorax by a membrane which, though not muscular, is analogous to the diaphragm, but is perforated so as to allow the air to pass into the abdominal cells. In Mammalia, the abdomen is placed between the pelvis and thorax, with the former of which it is continuous; but it is separated from the latter by the diaphragm; its principal contents consist of the digestive organs, and its size varies in reference to their respective degrees of development.

* Facciolati, in verb.

† See a very good engraving from Carus, of the segments of an insect, in Roget's Bridgewater Treatise, vol. i. p. 321.

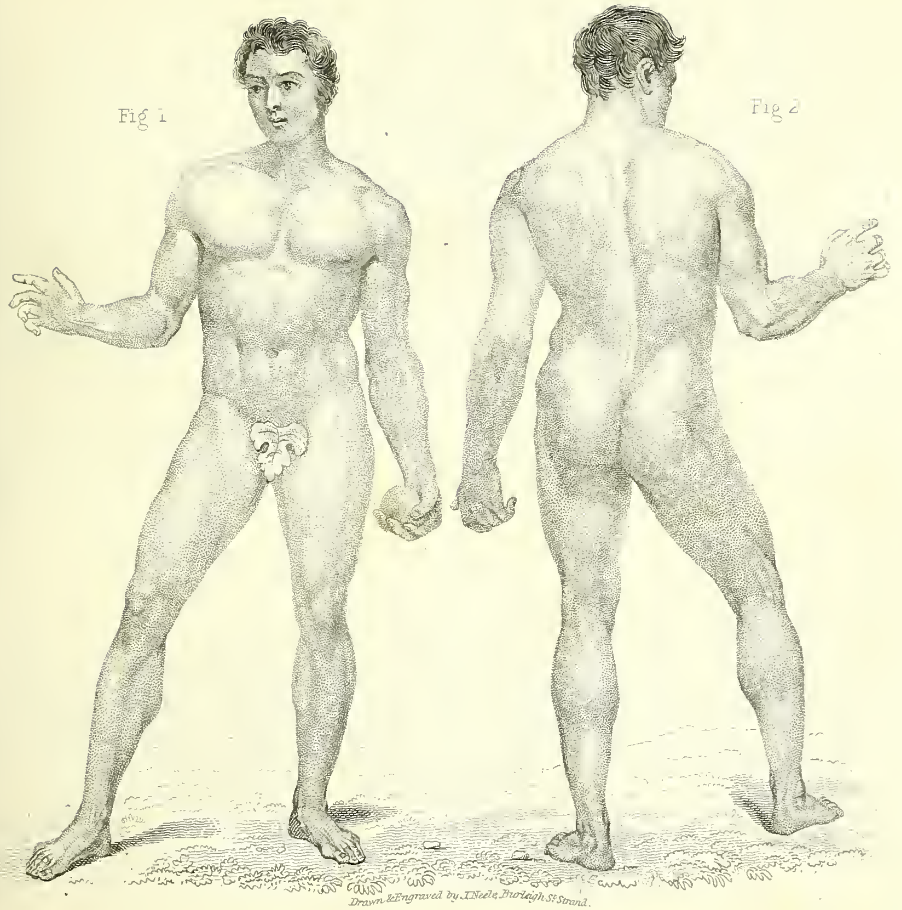
ABDOMEN (in human anatomy.) In examining the human skeleton, we notice that from the apex of the thorax to the inferior outlet of the pelvis, there exists one great oblong excavation. The two superior fifths of this cavity are separated from the remaining portion in the entire subject by a musculo-tendinous lamella, which, thrown into a vaulted form, constitutes the partition between the cavity of the thorax above and that of the abdomen below. This latter cavity communicates inferiorly with the space circumscribed by the ossa innominata, denominated the cavity of the pelvis; nor is there any natural line of demarcation between the two cavities. The communication between the two cavities is as free in the recent subject as it is in the skeleton, and under various conditions the contents of those cavities pass from the one to the other. A plane extended horizontally from the linea iliopectinea on one side to the corresponding line on the other would constitute an artificial floor to the cavity of the abdomen, properly so called, and a limit between it and the pelvis; and this artificial division of a cavity, naturally single, may be useful in describing the positions of viscera, but to understand the functions of the abdomen, it will be expedient to consider that cavity and the pelvis as one. Some anatomists object to the use of the term cavity as applied to the abdomen, because no cavity can be said to exist, except in the skeleton or in the eviscerated subject; neither can there properly be said to be a cavity of the thorax or of the cranium, inasmuch as that cavity is obliterated so long as the viscera are in a state of integrity. I apprehend that the objection is hypercritical, as it must be evident that the cavity does not become apparent till the viscera have been removed; nevertheless, it is perfectly correct to say that it contains the viscera, nor is it incorrect to make use of the expression "anatomy of the abdominal cavity," to imply the anatomy of its contents when in their natural position. Hence, then, we derive a natural subdivision, in treating the subject of this article, into two heads: 1. the anatomy of the walls of the abdomen; and, 2. the anatomy of the cavity of the abdomen.

I. *Of the walls of the abdomen.*—One of the most striking differences between the abdomen and the other great visceral cavities consists in the small proportion of bone that exists in its walls. The osseous boundaries of the abdomen may be thus enumerated: superiorly, towards the posterior and outer part, the false ribs; posteriorly, the lumbar region of the spine, which by its transverse processes affords strong points for the attachment of muscles, and by the bodies projects into the cavity, forming an imperfect septum, slightly convex on its anterior surface, and dividing the cavity into two symmetrical portions. Inferiorly, the alæ of the ilia afford lateral expansions, which support some of the contents of the abdomen, and the pelvic brim completed behind by the promontory of the sacrum, forms the opening by which the cavity of the true pelvis communicates with that of the abdomen. Between the inferior margin of the thorax and the superior margin of the false pelvis are stretched muscular lamellæ and tendinous aponeuroses, the *cingulum abdominis musculoso-aponeuroticum* of Albinus and Haller, which, with integument, cellular membrane, &c. form the anterior, lateral, and for the most part the posterior walls of the abdomen, and circumscribe that space to which we have already alluded under the name of the cavity of the abdomen.

The superior wall of the abdomen is the diaphragm, and the inferior wall of the abdomen, strictly so called, is formed by the ilia and their muscles, and is open in the centre at the superior outlet of the pelvis; but if the abdominal and pelvic cavities be considered as one, then those parts which fill up the inferior outlet of the latter must be considered as likewise constituting the inferior wall of the former.

In the male adult the abdomen presents an expanded convex surface anteriorly (the anterior wall or *proper abdominal region);* posteriorly a broad surface not so extensive, situated between the last ribs and the superior margin of the pelvis, and divided into two by the lumbar portion of the spine (the posterior wall, the loins, or *lumbar regions.)* The anterior and posterior walls are connected with each other on the sides by two narrow regions (the lateral walls or the flanks.)

The outline of the anterior wall or proper abdominal region constitutes an oval, whose long axis is vertical. The surface is generally more or less convex during life, proportionally with the degree of embonpoint of the individual, and also according to the condition of the diaphragm. After death, excepting in very fat subjects, or where the intestines or peritoneal cavity are much distended from any cause, this surface is in a variable degree collapsed, and more or less concave, but especially so in very thin and emaciated subjects. There is a constant adaptation in the condition of this surface to that of the abdominal viscera, so that the practitioner can in general argue pretty accurately, from the state of the abdominal surface, respecting that of the abdominal viscera, except in cases where every thing is masked by a superabundant deposition of adipose substance. So close is the apposition of the abdominal wall to the surfaces of the subjacent viscera, that in some cases of extreme emaciation the peristaltic movement of the intestinal canal is manifested by the successive elevation and depression of small portions of the walls corresponding to the dilated and contracted portions of intestine. This surface is divided into two equal and symmetrical portions by a groove which exists along the middle line, and which is chiefly apparent in the two superior thirds. This groove commences below the ensiform cartilage, where there is a slight depression, denominated the *scrobiculus cordis,* (creux de l'estomac.) In this line, about midway between the pubis and xiphoid cartilage, is the round depression called the *umbilicus* or navel. Just over the pubis there is a prominent surface in both sexes covered



with hair; in the female it is much more prominent than in the male, and is called the *mons Veneris*. In subjects where the muscular system is well developed, there exists on each side of this median groove an oblong convexity, extending from the anterior surface of the lower part of the chest to the pubis; these convexities indicate the situation of the *recti* muscles. In statues representing athletic men, the prominences occasioned by these muscles are generally very well shewn, and are divided by transverse superficial digressions into small quadrilateral portions, generally three in number. External to these prominences there is, in similar muscular subjects, a fissure extending from the border of the chest, in a slightly curved course with external convexity, to a point a little to the inner side of the anterior superior spine of the ilium; this fissure has internal to it the prominence from the recti muscles, and external that from the broad muscles of the abdomen. Gerdy calls it the lateral groove or furrow of the abdomen.* (See *fig.* 1.)

The posterior wall or the region of the loins, *(lumbar region,)* is in every way of less extent than the anterior. Its vertical height is equal to the distance between the last rib and the margin of the ilium. It is continuous on the sides with the flanks, and is divided along the middle line by a groove, corresponding to the lumbar spinous processes, into two symmetrical portions, each of which forms a large and prominent relief. Each relief corresponds to a great muscular mass, which almost wholly occupies this region, and its prominence is greatest when those muscles are in a state of contraction, as during the erect posture. Each relief is concave from above downwards, and in a degree directly proportionate to the contrac-

* Gerdy, Anatomie des Formes Extérieures, p.189. The above engraving is reduced from the folio plates which accompany this work.

tion of the muscles, insomuch that in some individuals the concavity is habitually very considerable, as in those who carry burdens on the head or in front of the body, in pregnant women, &c. (See *fig.* 2.)

The limit of this wall on each side is indicated by a groove or fissure which passes obliquely upwards and outwards towards the ribs, and corresponds to the outer margin of each relief, or that of the lumbar muscles; these lines also indicate the posterior limits of the lateral walls of the abdomen, or the flanks. Anteriorly the flank of each side is continuous with the anterior wall of the abdomen; above it is limited by the margin of the thorax, and below by the margin or crest of the ilium. It is concave on its surface from above downwards, (except in cases of great embonpoint, where the concavity is obliterated,) and convex from before backwards. Gerdy remarks that in subjects in which the muscles have a considerable development, a relief is formed just above the crista ilii by the broad muscles of the abdomen at their insertion into this osseous border. Upon antique statues this relief is in general made too prominent.

The anterior or proper abdominal region has been subdivided into smaller compartments, with a view to facilitating descriptions, pathological or otherwise. This subdivision is completely arbitrary, and therefore some differences will be found among the various anatomical authors as to the precise limits of each region. That which is here subjoined, however, appears to be pretty generally agreed upon in this country. Lines connecting particular points drawn upon the surface, mark out these subdivisions, and if planes be supposed to be carried from these lines horizontally backwards to the posterior wall, the cavity of the abdomen will thus be divided into segments, each of which has its particular portion of the abdominal viscera. It is an instructive exercise for the student to practise himself in examining the particular viscera which correspond to particular regions. We are thus enabled, as Blandin has remarked,* to resolve the problem, "a point of the surface of the abdomen being wounded deeply in a given direction, to determine what organs have been injured; and reciprocrally, an organ having been wounded in a particular part of the abdominal cavity by a sharp instrument, which entered in a given direction, to determine what part of the abdominal walls must necessarily have been injured."†

The limits of these several regions or compartments may be thus indicated:‡ let a line be drawn horizontally from the extremity of the last rib on one side to the same point on the other, and let another line parallel to the preceding be drawn between the two anterior superior spinous processes of the ilium: the abdominal surface is thus divided into three great regions, each of which is subdivided into three by means of a vertical line let fall on each side from the anterior extremity of the seventh or eighth rib to a point a little external to the spine of the pubis. Nine regions are thus marked out, the relations and boundaries of which may be described as follows.

* Anatomie Topographique, p. 423.

† The division of the surface of the abdomen into regions is as old as Aristotle.

‡ See an engraving exhibiting these subdivisions, in the article Abdomen of the Cyclopædia of Practical Medicine.

The superior region, or that above the first horizontal line, is the *Epigastrium*, which name it derives from its close relation to the stomach; (επι, upon, over; γαστηρ, the stomach.) The epigastrium is bounded superiorly and laterally by the margin of the thorax, and its inferior limit is indicated by the transverse line. The vertical lines subdivide it into two lateral regions, each of which is bounded immediately above by the lower margin of the thorax, beneath which these regions extend in a direction upwards and backwards: they are hence called hypochondria (υπο, under, χονδρος, cartilage). Between the hypochondria, is the proper *epigastric region*, which at its superior part and just below the xiphoid cartilage presents the depression already alluded to under the name of scrobiculus cordis (scrobiculus, the diminutive of *scrobs*, a depression).

Immediately below the epigastrium, and separated from it by the superior horizontal line, is the *umbilical* region, which has its name from the presence of the umbilicus in it. This region is limited above and below by the two horizontal lines, and is subdivided by the intersection of the two vertical lines into three regions: the lateral ones are the *lumbar* regions, so called from their correspondence with those portions of the posterior abdominal wall which bear the same name; and the middle one is the *proper umbilical* region.

Between the inferior horizontal line and the margin of the pelvis, is the *hypogastrium*, (υπο, beneath, γαστηρ, the stomach). This region is limited below in the centre by the pubis, and on each side it communicates with the upper part of the thigh. It is subdivided into the *iliac* regions on each side, and the proper hypogastric or *pubic* region in the centre. The two former constitute the upper or abdominal portion of the great region of the groin, which is completed inferiorly by the upper part of the anterior surface of the thigh. These regions afford peculiar interest to the surgical anatomist, in consequence of the occurrence in them of the most common forms of hernia.* (See Groin, Region of the.)

The structures which enter into the composition of the abdominal parietes, or their elements, (as the term has been lately applied,) are—1. the skin: 2. the subcutaneous tissue or superficial fascia: 3. muscles and their aponeurotic expansions: 4. a particular fibrous expansion, or fascia: 5. a thin and filamentous cellular tissue, which separates the fascia just named from the sixth element: 6. the peritoneum, which, however, is not to be found in the composition of all the walls of the abdomen.

* Velpeau applies the term *zone* to the primary regions included between the horizontal lines.—Anat. Chirurg. t. ii.

In and between these several structures ramify the various arteries, veins, lymphatics, and nerves, which constitute the vascular and nervous supply to the abdominal parietes.

1. The skin on the anterior and lateral parts of the abdomen is thin and smooth, and in some parts covered with hairs, as along the middle line, especially below the umbilicus and over the pubic region. Along the median line the cutaneous follicles are largely developed, and during pregnancy an increased secretion of pigmentum is said to take place, producing a brownish colour of the skin in these regions. In women who have borne children, the skin becomes wrinkled to a considerable degree, and the epidermis exhibits, as Winslow has remarked, a great number of lozenge-shaped spaces disposed in a reticular manner.*

In the epigastric region the skin is much more sensitive during life than in the other parts of the abdomen, and with some persons sympathizes with the stomach in a remarkable degree, so that pressure on it even in the healthy state produces a degree of pain or uneasiness in that organ, or even a tendency to nausea. In the umbilical region we observe a depression, the floor of which is more or less elevated in the centre. This depression is denominated the navel or *umbilicus*, (the diminutive of *umbo*, a nob or button.) It is produced by the firm adhesion of the skin to the subjacent structures, its true nature being that of a cicatrix, occupying the site of a former perforation through which the umbilical arteries and veins and the urachus passed in maintaining the circulation between the fœtus and placenta. In very fat persons, the depth of the depression is often very much increased by reason of the great thickness of the abdominal parietes, and in some instances its form assumes that of a slit, and sometimes, instead of a depression, there is a greater or less prominence of the integument.

In the lumbar region the skin is thicker and firmer than in the others; and we generally find it in a state of congestion after death, in consequence of the position of the body.

2. The subcutaneous cellular tissue on the anterior surface of the abdomen has obtained especial attention from anatomists, particularly that portion of it which is found in the hypogastric regions. It is denominated *the superficial fascia*,† and is merely an expanse of cellular tissue possessing the same general characters as that which is found in all other parts of the body; it is continued upwards over the thorax, laterally into the region of the back, inferiorly along the thighs, and into the scrotum. It varies in thickness according to the quantity of fat which is deposited in its cells;* in some instances it has been known to possess a thickness of three inches. Thin but muscular subjects afford the best examples from which to study the superfical fascia of the abdomen: in such subjects we find it in general of a much denser character than in others, very strong and elastic and easily divisible into laminæ, produced, no doubt, by the pressure which it experiences from the weight of the abdominal viscera, and the constant attrition occasioned by the action of the abdominal muscles. In the iliac region, immediately above Poupart's ligament, the density of this fascia is most conspicuous. Here some have regarded it as a fibro-cellular membrane; but the opaque bands which give it a fibrous appearance are merely the walls of the membranous cells rendered thicker and denser than they are in other parts. I cannot agree with Beclard† that it presents almost all the characters of an aponeurosis, inasmuch as it differs from an aponeurosis in wanting the shining and regular surface, and in possessing a degree of elasticity which never belongs to aponeurotic expansions. The elasticity of the superficial fascia is remarkable, and is by some compared to the elastic expansion over the abdomen of the larger quadrupeds;‡ the comparison, however, is inaccurate, inasmuch as they are two distinct tissues, the former being cellular, and the latter the aponeurosis of the oblique muscles, which in some degree partakes of the properties of the yellow elastic fibrous tissue *(tissu jaune)*.

Inferiorly the superficial fascia moves freely over Poupart's ligament, and is continued over the thigh (see GROIN, REGION OF THE). Along the middle line it is very adherent to the subjacent aponeurotic structure (the linea alba) as well as to the skin,—a fact which may be remarked of the subcutaneous cellular tissue in other parts of the body, and which was long ago noticed by Bordeu, when he observed that the cellular tissue is constricted *(etranglée)* in all its median portion, and that its cells *(ballons ou pouches)* are closed over the axis of the body. When this superficial fascia is dissected off, a very thin layer of cellular membrane, perfectly diaphanous, is found to adhere to the subjacent aponeurotic expansion. This will be found particularly adherent over Poupart's ligament, and is that which is referred to by some anatomists (as Manec, Cloquet, &c.,) as a deep *process* of the superficial fascia which adheres to Poupart's ligament, and so forms a superficial septum between the abdomen and thigh. To see this layer the superficial lamina should be raised by commencing the dissection of it

* Winslow's Anatomy, by Douglas, v. ii. p. 160.

† The application of the term *fascia* to the subcutaneous cellular investment in various parts of the body has occasioned no small degree of confusion among anatomists. A singular degree of confusion exists in Velpeau's description of this fascia: he observes in one place that the deep layers of the subcutaneous cellular tissue constitute the superficial fascia, and in the next page states that "the superficial fascia is nothing else than the cellular tissue condensed, whose laminæ strongly applied one against the other, are ultimately reduced to somewhat of the aponeurotic form." I shall adhere to this latter definition, and consider *superficial fascia* as synonymous with *subcutaneous cellular tissue*.—Velpeau Anat. Chirurg. vol. ii. p. 4 and 5.

* Cloquet says it is, as it were, decomposed by the deposition of fat.—Recherches Anat. sur les Hernies de l'Abdomen, p. 11.

† Dict. de Médecine, art. *abdomen*.

‡ *Vid. Blandin, Anat. Topog.*

below and carrying it upwards; the expansion will then appear to arise from Poupart's ligament, and spread over the subjacent aponeurosis. In some subjects it is so thin as to appear to be little more than the proper cellular covering of the muscle and its aponeurosis, but in others it assumes a considerable degree of density. It may be called the deep layer of the superficial fascia; it deserves attention from the fact that the femoral hernia, in its ascent on the abdomen, lies between it and the superficial layer. It is to this fascia that Scarpa must allude under the name of "aponeurotic web of the muscle of the fascia lata," and hence some have called it Scarpa's fascia.* The whole of the superficial fascia has been called Camper's fascia, because it was first fully described by that writer.†

On the posterior wall of the abdomen, in the lumbar regions, the cellular tissue is more abundant and more lax; here we frequently find it infiltrated with serous fluid, in consequence of the usual supine posture of the body after death. It is continuous above with the subcutaneous tissue in the dorsal region, and below with that in the glutæal regions. It, too, is firmly adherent along the middle line to the lumbar spine anteriorly, and to the skin posteriorly.

3. *Muscles and aponeuroses.*—The abdominal parietes owe their thickness chiefly to the muscular lamellæ and the aponeurotic expansions, which enter into their composition. In the anterior and lateral walls we find on each side five pairs of muscles, of which four are constantly present. These are, 1, M. obliquus externus; 2, obliquus internus; 3, transversalis; 4, rectus abdominis; 5, pyramidalis, which last is frequently absent.

1. *Obliquus externus. (Obliquus descendens; costo-abdominal; ilio-pubi-costo-abdominal.)*

When the superficial fascia covering the anterior and lateral surfaces of the abdomen has been dissected away, this muscle is brought into view. It consists of a flat muscular portion, situated superiorly and posteriorly, and of a tendinous or aponeurotic lamella anteriorly and inferiorly, but which is largest and strongest in the latter situation.

The muscular portion of the external oblique is attached by separate fasciculi to the external surfaces of the eight inferior ribs, from the fifth to the twelfth inclusive. These fasciculi indigitate at their attachment with similar ones, of the serratus magnus, from the fifth to the ninth inclusive, and of the latissimus dorsi from the tenth to the twelfth. From these points of attachment, described by most English anatomists as the origin of the muscle, the fibres pass obliquely downwards and forwards, with different degrees of obliquity, the middle fibres being the most oblique; the superior taking a direction nearly horizontally inwards, and the posterior ones passing nearly vertically downwards. The anterior and middle fibres are inserted into the outer convex border of the aponeurotic lamella of the muscle, but the posterior are inserted into the outer lip of the two anterior thirds of the crista of the ilium by short tendinous fibres. The fibres of this muscle vary considerably in length, those which are highest up being the shortest, the middle ones the longest, and next in length the posterior fibres. The aponeurotic lamella of the external oblique muscle is found on the anterior part of the abdomen, both superiorly and inferiorly. In the former situation the aponeurosis is extremely thin and weak; it is transparent, so that the upper extremity of the rectus muscle which it covers is visible through it. This, too, is the narrowest portion of the aponeurosis, which increases in breadth, strength, and thickness as it descends. The aponeurosis, like the muscular portion, consists of a series of fibres, for the most part inclined obliquely downwards and inwards, excepting the superior ones, whose direction is horizontal. At several places these fibres are separated from each other so as to allow the subjacent muscle to be seen through the interval. At various parts the tendon is perforated by vascular apertures, which are occasionally so enlarged as to admit little peritoneal prolongations to pass through them. Along the middle line, from the ensiform cartilage to the symphysis pubis, the aponeurosis forms an interlacement with its fellow of the opposite side, and this interlacement with that of the subjacent aponeuroses constitutes the tendinous line called *linea alba*, which, as Velpeau observes, may be regarded as the centre in which all the fibrous elements of the abdomen terminate. Just above the symphysis pubis, the decussating fibres are not intermixed in the same manner as in other parts of the linea alba: there the bundle of one side crosses anteriorly or posteriorly to that of the other, without any union of fibres, to be inserted into the pubis of the side opposite to that from which it came.

A little above and external to the pubis, a separation of the fibres of the tendon of the obliquus externus takes place, leaving an opening which is denominated *the external abdominal ring*, through which the rounded bundle composed of the spermatic vessels and duct *(the spermatic cord)* passes in the male, and the round ligament of the uterus in the female. The aponeurotic fibres which form the immediate boundaries of this opening are termed the pillars of the ring, of which one is superior, internal, and anterior, the other is inferior, external, and posterior, and passes behind the cord. External and inferior to this opening, we observe that the aponeurosis of the external oblique muscle is extended from the pubis to the anterior superior spine of the ilium. On the pubic side, the fibres, which are the same that form the inferior pillar of the ring, are inserted into the spine of the pubis, and being

* Vid. Scarpa on Hernia, by Wishart, p. 22; also Todd on Hernia, Dub. Hosp. Reports, vol. i. p. 246; and Flood's plates of Inguinal and Femoral Hernia.

‡ Camper, Icones Herniarum, p. 11.

reflected backwards, outwards, and a little upwards, they are likewise inserted into the linea ilio-pectinea, which commences at the spine of the pubis. The lower margin of the tendon is thus folded back a little as it arches over the excavation between the pubis and ilium, so as to present towards the abdomen a slight channel-like excavation, which affords origin to the muscular fibres of the internal oblique as well as to those of the transversalis, whilst it has the appearance of a rounded ligamentous cord towards the thigh. In this manner is formed *Poupart's ligament*, which, contrary to what its usual name denotes, is not a distinct ligamentous cord, but the inferior margin of the external oblique stretched from pubis to ilium, and folded a little upon itself. By its superior margin it is continuous with the fibres of the tendon of the external oblique, which fall obliquely upon it; by its inferior margin it is intimately connected with the fascia lata of the thigh; externally it is inserted into the anterior superior spine of the ilium; and by its pubic extremity it has three attachments, 1. to the body of the pubis; 2. to the spine of the same; and 3. to the linea ilio-pectinea, constituting what has been called *Gimbernat's ligament*, which has a sharp slightly crescentic margin directed backwards and outwards towards the femoral vessels.* (See Groin, Region of the.)

The external abdominal ring is a triangular opening, situated obliquely; the superior angle being directed upwards and outwards, and its base, represented by a line uniting the pubic insertions of the two pillars, resting upon the pubis. The superior angle is formed evidently by the separation of the fibres of the aponeurosis, the primitive direction of which is the same as that of a perpendicular from the apex to the base of the triangle, viz. downwards and inwards, (sacrad and pubad.) This separation, however, is strengthened, and the angle rounded by some tendinous fibres which intersect the oblique ones nearly at a right angle, arising as a cord of variable thickness from Poupart's ligament, and passing upwards and inwards over the apex of the ring, gradually separating into several tendinous fibres. These fibres are sometimes very strong, at other times very feeble and scarcely perceptible; but it rarely, if ever, happens that they are completely absent; they have been termed *intercolumnal bands*. I have seen them so strong that they could be distinctly dissected off the external oblique aponeurosis, like a separate tendinous expansion; but most frequently they are so united to the aponeurosis as to render it impossible to remove them without injury to it. These fibres are evidently intended, as Scarpa expresses it, "to fix the limits of the inguinal ring, and to oppose the further divergence of the tendinous pillars towards the side." They are equally met with, although not nearly so much developed, in women and children as in men; and Mr. Lawrence asserts that in old herniæ they are particularly strong. I cannot confirm this remark from my own observation, as in my dissections of old herniæ, I have not found them particularly developed; nor is it consistent with the general result of pressure from within on *tendinous* fibres to believe that such pressure would produce an increase of development in them.

The size of the external abdominal ring is greatest in the male subject, but here it varies considerably, sometimes closely embracing the cord as it passes through it, and at others appearing much too large for it. In the male the parts which pass through it are the spermatic cord, enveloped in its proper tunic, and in one of condensed cellular membrane prolonged from the fascia transversalis, a branch of the genito-crural nerve, the cremaster muscle, the cremasteric artery, and the spermaticus superficialis nerve. In the female, we find the round ligament of the uterus, covered and accompanied by similar parts, excepting the cremaster. From the margin of the external abdominal ring, a cellular expansion or fascia is carried over the cord or round ligament, and has been denominated *fascia spermatica*. This fascia consequently forms a covering of any hernia that may be protruded through the external ring; and, accordingly, in old herniæ we find it greatly thickened. Its formation is simply in accordance with what we find occurring in all parts of the body, viz. that when any part passes through an opening in a fibrous membrane, it carries with it a cellular expansion from the margin of that opening. This we observe in the passage of the vena cava through the diaphragm, of the urethra through the triangular ligament or deep perineal fascia. This view confirms the opinion of Sir A. Cooper, that this fascia is a production from the margin of the ring itself.

The external oblique muscle is covered in all its extent by the superficial fascia; its costal margin is related to the serratus magnus, and to the latissimus dorsi, with which muscle it is also in close relation by its posterior margin, being sometimes slightly overlapped by the anterior margin of the latissimus, but at others separated from that muscle by a triangular interval through which the fibres of the obliquus internus appear: inferiorly the fascia lata of the thigh is related to the margin of the external oblique muscle, both as it covers the glutæi, and as it lies in front of the thigh. Along the middle line the aponeuroses of opposite sides meet at the linea alba, and superiorly the muscular fibres are related to and sometimes connected by a fleshy slip with those of the pectoralis major, and the aponeurosis is continuous with that of the same muscle.* When the ex-

* The terms *crural arch*, and *ligament of Fallopius*, are also used synonymously with Poupart's ligament. Velpeau calls it *bandelette ilio-pubienne du grand oblique*.

* "By its position, the direction of its fibres, and the short distance to which its fleshy portion extends forwards, the external oblique corresponds so much to the external intercostals, that one is led to say that it represents them in the abdomen."—*Meckel*.

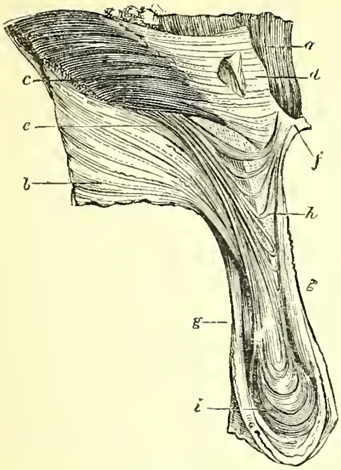
ternal oblique is removed from its osseous attachments, and raised inwards, it is found to cover the internal oblique, with part of the tendon of which it is ultimately united as the two tendons approach the linea alba.

2. *Obliquus internus (obliquus ascendens, ilio-abdominal, ilio-lumbo-costi-abdominal)* is smaller than the preceding muscle, which it resembles in shape and general characters. The direction of its fibres, however, is opposite, inasmuch as the fibres of the two muscles decussate with each other, thus adding considerably to the strength of the abdominal wall, and forming a great protection against visceral protrusions. The external attachments (or, as systematic writers call it, the origin of the muscle) is 1. by short fleshy fibres to the tendinous expansion covering the lumbar mass of muscles, called *fascia lumborum*, which is formed by the posterior lamina of the tendon of the transversalis abdominis: 2. to the two anterior thirds of the middle portion of the crista ilii, between the external oblique and the transversalis as far forwards as the anterior superior spine: 3. to the groove in the upper or abdominal surface of Poupart's ligament for about its external third. The superior fibres pass upwards and inwards, and are inserted by fleshy slips into the cartilages of the twelfth, eleventh, and tenth ribs, in the intervals between which they are either separated from the intercostal muscles by a fibrous intersection, or confounded with them, and by a tendinous aponeurosis into the cartilages of the ninth, eighth, and seventh ribs as well as into the xiphoid cartilage. Lower down, the fibres which arise from the crista ilii, as well as those from Poupart's ligament, pass inwards, the superior obliquely upwards and inwards, the inferior more horizontally, and the lowest fibres inclining a little downwards, and are all inserted, like those of the *obliquus externus* into the outer convex margin of an aponeurotic expansion, which goes to be inserted along the middle line. This tendon passes inwards for a short distance, nearly as far as the outer margin of the rectus muscle, as a single lamina. Along this margin, and as low down as the inferior fourth of the rectus muscle, the tendon divides into two laminæ, of which the anterior adheres to the posterior surface of the tendon of the external oblique, and the posterior to the subjacent tendon of the transversalis, both laminæ going to be inserted into the ensiform cartilage and linea alba, the one in front, the other behind, the rectus muscle. (See *fig.* 4, *a.*) For a distance, however, corresponding to the inferior fourth of the rectus muscle, the tendon of the obliquus internus remains undivided, and does not adhere to that of the obliquus externus. It, however, is united, although not inseparably, to the tendon of the transversalis, and both go in front of the rectus to be inserted into the linea alba and pubis: these tendons are here called by some *the conjoined tendons*. Along the line at which the tendon of the *obliquus internus* divides into two laminæ, the aponeurosis of the obliquus externus and that of the transversalis adhere to it more closely than they do externally to that line, and thus a thickened portion of the abdominal aponeurosis is formed, taking the course of the outer margin of the rectus muscle: this line is called the *linea semilunaris*, and is that in which the operation of *paracentesis abdominis* used formerly to be practised.

The inferior margin of the obliquus internus is deserving of particular attention. The inferior fibres attached to the external third of Poupart's ligament in the groove formed in it pass transversely inwards and parallel to the ligament, crossing over the spermatic cord, to be inserted into the pubis. Here the muscle is confounded with the inferior fibres of the subjacent one, the transversalis; so that it is not only difficult to say which muscle passes lowest down, but it is difficult, and often impossible, to separate the two muscles. Hence the lower margins of the fleshy fibres as well as of the aponeuroses of these two muscles are constantly spoken of conjointly; however, I have several times succeeded in separating them distinctly, and I am decidedly of opinion that the aponeurosis of the *obliquus* internus seldom or never descends so low down as that of the transversalis. The lowest of the fibres of the obliquus internus are sometimes observed to separate a little from the others, so as, instead of a directly transverse, to assume a course slightly curved with the concavity upwards and a little outwards, lying in front of the cord; in some cases fibres of this kind are observed to lie in front of the spermatic cord, and to descend much lower down, taking of course a much more curved direction, still attached on the outside to Poupart's ligament, and on the inside to the pubis, so that a series of curved fibres are thus found to adhere to the anterior surface of the cord and of the tunica vaginalis, exhibiting an equal number of reversed arches. But this disposition is rarely seen in its most highly developed state, excepting where some tumour has been connected with the cord or testicle, as hernia, hydrocele, &c.

This arched arrangement of muscular fibres in connection with the spermatic cord and tunica vaginalis testis constitutes *the Cremaster muscle* (*κρεμαω, suspendo*,) the great tenuity of which in the natural state of the parts has rendered it difficult to determine its precise attachments, and consequently has given rise to the great discrepancy which is observable between the descriptions of different writers. When this muscle is examined in a case of old hernia or hydrocele, it is found, as Scarpa originally described it, to consist of two bundles; the first, external to the cord which arises from Poupart's ligament along with the internal oblique, follows the course of the spermatic cord, which it accompanies through the external abdominal ring, sending at intervals fibres arching in front of the cord to join a similar bundle on the inner side, as may be seen in the accompanying engraving from a plate in Sir A. Cooper's work on the testis (*fig.* 3). Inferiorly, this bundle, a

Fig. 3.



c, the internal oblique; *e*, the descending fibres; *f*, point of insertion into the pubis; *h*, one of the reversed arches; *d*, conjoined tendons; *a*, rectus muscle.

good deal diminished in size, crosses over the inferior and anterior portion of the tunica vaginalis testis, and begins to ascend along the inner side of the testicle and cord, keeping more posteriorly: this constitutes the second bundle; it gradually increases in size as it ascends by receiving the transverse fibres from the bundle of the opposite side, and it is inserted, sometimes by a distinct tendon, into the pubis near its spine. In some cases I have totally failed, even after the most careful dissection, in detecting a continuity by *muscular* fibre between these two bundles, insomuch as to lead me to imagine that they may be connected by a very condensed cellular tissue or thin aponeurotic lamella after the manner of the digastric muscles. In general the external bundle is larger than the internal, but Cloquet has seen the reverse three times; and on referring to my notes, I find I have seen two instances in which the internal bundle exceeded the external in size.

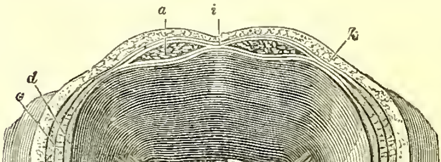
Many anatomists have noticed only the external bundle of the cremaster, and altogether overlooked its reversed arches, which is not to be wondered at when we remember that even where the lateral bundles are strong and well developed, the arched fibres are sometimes pale and thin. However, the description now given is pretty generally admitted as the true one, and is sanctioned by such observers as Scarpa, Cloquet, Cooper, Velpeau, and I may add that I have seen this arrangement in cases where both testicle and cord were healthy. It would appear that its formation is effected by the testicle in its descent, for before that takes place the muscle does not exist; at least such is the result of Cloquet's observations on a considerable number of fœtuses before, during, and after the descent of this organ. Before the descent the *gubernaculum testis* occupies the inguinal canal, and is covered by the fibres of the internal oblique, which adhere to it: when the gubernaculum is drawn down, these fibres descend with it, forming a series of reversed arches.

In some female subjects we see an arrangement of the inferior fibres of the internal oblique as they cross over the round ligament, which resemble a rudimentary state of the cremaster muscle.

A thin layer of cellular tissue, sometimes containing a small quantity of fat, is interposed between the anterior surface of the obliquus internus and the obliquus externus. At the inferior edge of the obliquus internus the spermatic cord is seen emerging from the abdomen and passing obliquely inwards and a little downwards to the external abdominal ring. Here it lies in a groove or channel, called *the inguinal canal,* which extends from the point at which the spermatic cord emerges from the abdomen, (the opening in the fascia transversalis called internal abdominal ring) to the external abdominal ring. This canal is bounded or covered anteriorly by the tendon of the obliquus externus; posteriorly by the fascia transversalis and some fibres of the tendon of the transversalis muscle towards the inner side; superiorly by the margin of the obliquus internus and transversalis muscles; and inferiorly by the groove of Poupart's ligament.* (A full description of this canal will be found in the article Groin, Region of the.)

3. *Transversalis (lumbo-abdominal, lumbo-ili-abdominal).* This muscle is immediately under cover of the obliquus internus; its name is derived from the transverse direction of its fibres. In its general character it resembles the obliqui, being like them a muscular lamella, inserted into a tendinous expansion, which again is inserted into the linea alba. Superiorly the fleshy fibres of this muscle are attached by distinct bundles to the internal surface of the cartilages of the ribs forming the lower margin of the thorax, where these bundles indigitate with those of the diaphragm: 2dly, in the interval between the last rib and the crista

Fig. 4.



* "The *obliquus internus* corresponds to the internal intercostals by the direction of its fibres, by its being situated under cover of the *obliquus externus*, and because its fleshy fibres extend much further forwards than those of the last-named muscle."—*Meckel.*

ilii, the fibres arise from a tendinous lamella, which itself is trifoliate in its origin. This tendon is found as an undivided lamella between the outer margin of the quadratus lamborum and the commencement of the fleshy fibres of the muscle, extending vertically from the last rib to the crista ilii. *(Fig. 4, l.)* The three laminæ of which this tendon is composed arise from different portions of the vertebræ in the lumbar region of the spine; the posterior, which is thick and strong, and is commonly called *fascia lumborum*, arises from the extremities of the spinous processes, and covers the lumbar mass of muscles. *(Fig. 4, g.)* The middle, which is weak, is attached to the apices of the transverse processes; it lies in front of the lumbar mass and behind the quadratus lumborum *(fig. 4, h)*; and the anterior arises from the pedicles which connect the transverse proeesses to the bodies of the vertebræ, and covers the quadratus lumborum muscle in front *(fig. 4, f)*. Inferiorly, the transversalis muscle attaches itself to the inner lip of the crista ilii for its three anterior fourths, and to the external third or half of Poupart's ligament, corresponding to the attachments of the obliquus internus. The fleshy fibres of the muscle pass from these several points of attachment transversely inwards, the middle being the longest, and the superior the shortest, and are inserted into the outer convex margin* of a tendinous aponeurosis, which extends to the linea alba. This aponeurosis is intimately connected with the posterior division of that of the obliquus internus for an extent corresponding to the three superior fourths of the rectus muscle, behind which both pass to be inserted into the ensiform cartilage and linea alba, *(fig. 4, a,)* forming the posterior wall of the sheath of the rectus. Inferiorly, as we have already remarked, these conjoined tendons go together in front of the rectus, and are inserted into the inferior fourth of the linea alba and into the pubis. At the inner extremity of the inguinal canal, it will be seen by carefully raising up the spermatic cord, that this union of the tendons of these two muscles ceases, and we can trace the fibres of the transversalis tendon passing down in a curved direction, more curved as they are more external, and insinuating themselves behind the cord to be inserted into Gimbernat's and Poupart's ligament for about its external third or fourth. This mode of insertion of the transversalis tendon was first described by Sir Astley Cooper,† and these fibres were by him called the *folded fibres* of the transversalis. They adhere to the subjacent fascia, (fascia transversalis,) and add to the strength of the inner portion of the posterior wall of the inguinal canal. They correspond, in a great measure, to the external abdominal ring, and may be counted as one of the obstacles provided against the direct descent of a hernia.

Such is unquestionably the usual mode of insertion of the tendon of the transversalis muscle; but Mr. Guthrie has lately called the attention of anatomists to a variety which it is important to know, although it cannot be of frequent occurrence. In this variety the spermatic cord appears to pass through a slit in the inferior margin of the transversalis muscle, so that a bundle of muscle passes behind as well as before the cord; the posterior one ending in tendinous fibres, which, like the folded fibres above described, are inserted into Poupart's ligament.* It is very generally believed that the inferior fibres of this muscle contribute, as well as those of the obliquus internus, to form the cremaster. The two muscles are so closely connected externally by their inferior margins, that it is natural to suppose that both do send fibres to the cremaster. Sir Astley Cooper expresses the relation of the cremaster to these two muscles in the clearest way, when he says that it arises from Poupart's ligament within the inguinal canal, and there *blends* with some of the fibres of both these muscles.†

A thin layer of cellular tissue covers the transversalis muscle, and separates it from the obliquus internus. At its superior margin it is intimately related to the diaphragm, and some of its fibres seem to be continuous with it: posteriorly, by the triple partition of its tendon, it ensheaths the lumbar muscles, and it lies upon the fascia transversalis, which, with a layer of cellular tissue, separates it from the peritoneum.‡

4. *Rectus abdominis (sterno-pubien).* After the superficial fascia has been removed so as to expose the aponeurosis of the external oblique, the recti muscles are seen on either side of the middle line covered by this aponeurosis, which it is necessary to slit up in order to expose the muscles. The rectus owes its name to the perpendicular course of its fibres, which pass from the pubis to the thorax, nearly parallel to the middle line. It is long and narrow; however, its breadth increases as it advances upwards, and as it increases in breadth it diminishes in thickness. At the pubis the muscle has its most fixed point of attachment, whence it is generally said to have its origin there: it arises by a short tendon from the symphysis of the pubis; this tendon is very narrow at its origin, but soon expands, and unites with the muscular fibres, which pass vertically upwards to the lower margin of the thorax, where the muscle is considerably increased in breadth, and divides into three portions; the first or internal one is inserted into the costoxiphoid ligament and cartilage of the seventh rib; the middle, larger than the preceding, into the cartilage of the sixth rib at its inferior edge and anterior surface;

* This margin forms the *linea semilunaris* of Spigelius.

† Cooper on the Testicle, p. 35.

* Guthrie on Inguinal and Femoral Hernia, pp. 11, 12, 13, 4to. Lond. 1833.

† Op. cit. p. 38.

‡ "The *transversalis* corresponds, by the direction of its fibres, to the '*triangularis sterni*;' also, by its situation, by the attachment of its external edge to the internal surface of the ribs, and by that of its internal edge to the sternum and linea alba."—*Meckel.*

and the external, the largest of the three, into the inferior edge of the cartilage of the fifth rib. This muscle is remarkable for its tendinous intersections, which cut the fibres at right angles, and are called *lineæ transversæ*;* they vary in number from three to five, and are always more numerous above than below the umbilicus. In general there is one on a level with the umbilicus; the superior one being about an inch below the superior attachment of the muscle, and a third midway between these two: when a fourth and a fifth exist, they are below the umbilicus. They adhere to the anterior wall of the sheath closely, and but very slightly or not at all to the posterior. Sometimes the intersection does not go completely through the thickness of the muscle so as to appear on its posterior surface, and thus the posterior fibres are longer than the anterior; but as Bichat remarks, it never happens that any of the muscular fibres pass from one extremity of the muscle to the other without uniting at least one of these intersections. Sometimes, too, the intersection does not go through the breadth of the muscle, and this is generally the case with that below the umbilicus. The effect of these intersections is to convert the muscle into so many distinct bellies, each of which has its proper action, and is, as Beclard asserts, provided with a separate nerve.†

The rectus muscle is enveloped in a fibrous sheath, the mode of formation of which the reader must have collected from the description of the oblique muscles. The anterior wall of this sheath is formed by the aponeurosis of the external oblique alone over the chest, and by the same aponeurosis and the anterior layer of that of the internal oblique, from the xiphoid cartilage to the inferior fourth of the muscle; (both which aponeuroses over the internal half of the muscle are so adherent to each other as to form but one lamina;) and in its inferior fourth by the conjoined aponeuroses of the two obliqui and transversalis.

The posterior wall of the sheath is deficient superiorly where the muscle covers the cartilages of the ribs with which it is in contact, and inferiorly for a space corresponding to the inferior fourth of the muscle. So much of it as exists is formed by the tendon of the transversalis and the posterior lamina of that of the internal oblique, so that the rectus appears to have passed at its inferior extremity through a transverse slit in these conjoined tendons, so as to get between them and the peritoneum.

The rectus muscle covers, at its superior extremity, the cartilages of the two last true ribs and a part of those of the two first false, and also the xiphoid appendix. The internal mammary and epigastric arteries are found behind it in the sheath.

Between the recti muscles is the fibrous cord called *linea alba*, produced by the interlacement of the aponeuroses of the opposite sides, noted in surgery as being in its inferior half the seat of the operations of paracentesis abdominis, paracentesis vesicæ supra pubem, the suprapubic lithotomy, and the Cæsarean operation. This cord extends from the xiphoid cartilage to the symphysis pubis, with the anterior ligament of which articulation it is identified. It does not present the same breadth in its whole course, being broader in the umbilical region than elsewhere. In this region we find in the linea alba the perforation which gave passage to the umbilical vessels in the fœtus and the urachus, and through which the fibrous remains of those vessels pass to be inserted into the skin, whereby is formed the cutaneous depression which marks the situation of this opening. In the adult the umbilicus may be considered as a point of considerable strength; in the estimation of some it is the strongest point in the abdominal parietes: in dissecting away the skin at this point, we find subjacent to it a very condensed cellular tissue, to which and to the skin the fibrous cords into which the umbilical vessels have degenerated adhere closely; these cords, too, adhere not only to the skin, but likewise to the margin of the fibrous ring through which they pass. "The umbilical opening, therefore," says Scarpa, "in the infant two months after birth, and still more in the adult, is not only like the other natural openings of the abdomen, strengthened internally by the application of the peritoneum and of the cellular substance, and on the outside by the common integuments, but it is likewise plugged up in the centre by the three umbilical ligaments and by the urachus; these ligaments form a triangle, the apex of which is fixed in the cicatrix of the integuments of the umbilicus, the base in the liver, in the two ilio-lumbar regions, and in the fundus of the urinary bladder; by this triangle is formed a strong and elastic bridle, capable of itself alone of opposing a powerful resistance to the viscera attempting to open a passage through the aponeurotic ring of the umbilicus, which apparatus does not exist at the inguinal ring or femoral arch."*

In the fœtus the ring of the umbilicus is proportionally larger than at any period after birth when the cicatrix is fully formed: it is, however, at the full term, or even at the seventh or eighth month, and in the healthy state of the parts, equally filled up by the umbilical vessels and urachus, and we would say is equally capable of resisting intestinal protusion as at any subsequent period. Hence it may be inferred that congenital umbilical ruptures are always of very early date, being attributable to the persistence of the opening at the umbilicus, and the continuance in it of the intestinal prolongation which exists there naturally at a very early period. It may likewise be inferred that the rupture in the adult can much more easily occur in the vicinity of, than through the umbilical ring; and experience confirms this deduction from the anatomy of the parts.

* Also called enervations.—*Winslow*. They are, says Meckel, incontestably incomplete repetitions of the ribs in the walls of the abdomen.

† Hence Meckel classes it among the polygastric muscles.

* Scarpa on Hernia, p. 373.

Above the umbilicus the linea alba is from two to four lines broad in the greater part of its extent; and below the umbilicus it gradually tapers down to the pubis, at the same time increasing in thickness.*

5. *Pyramidalis (pubio-sub-umbilical).* At the inferior extremity of the recti, and separating their origin, are two small muscles of a pyramidal form; their bases are inferior, and attached to the symphysis and body of the pubis, and uniting ligaments, and their apices superior and inserted into the linea alba by small tendons, from two to three inches above the symphysis pubis. Each muscle is enveloped in a distinct sheath, and lies a little more prominently than the origin of the rectus of the same side. These muscles are not unfrequently absent. Sometimes, on the contrary, there have been two on one side and one on the other, or even two on each side.†

The muscles which enter into the composition of the posterior wall of the abdomen are chiefly those which occupy the lumbar region of the back, filling up that empty space which in the skeleton is observed on each side of the spinal column between the crista ilii and the last rib. In dissecting from behind forwards in this region, having removed the skin and lax cellular tissue already described, we come upon the strong fibrous expansion, the *fascia lumborum.* This has extensive osseous attachments, and thus firmly binds down the subjacent muscles. When it is removed, the lumbar portions of the sacrolumbalis and longissimus dorsi, and a little of the spinalis dorsi, are brought into view, the two former of which are described by some as a single muscle—the sacrospinalis. The external of these muscles is the sacrolumbalis, and its outer margin may be said to constitute the limit of the posterior wall of the abdomen in that direction. In this situation the posterior and middle layers of the tendon of the transversalis separate from each other to ensheath these muscles, the posterior layer forming the fascia lumborum. We must refer to the article Back for a particular description of these muscles.

When the lumbar mass of muscles (as the three preceding have been called) has been removed, the next part brought into view is the anterior layer of their fibrous sheath formed by the middle lamina of the transversalis tendon, which is inserted into the apices of the transverse processes. This lamina is thin and semi-transparent, so that the fibres of the muscle which lies immediately before it, are seen through it. This muscle is the

Quadratus lumborum (ilio-costal, ilio-lumbi-costal). The term quadratus is applied to this muscle, more from its quadrilateral form than from any nearer resemblance to a square, inasmuch as all its sides are unequal. The most fixed attachment of this muscle is its inferior, where it is inserted by tendinous fibres into the iliolumbar ligament and into the inner lip of the crista ilii for about an inch to the outer side of the insertion of that ligament. From these points the fibres proceed vertically upwards, the external ones going to be inserted into the inferior margin of the last rib for nearly its entire length, and the internal fibres, those in particular which are attached to the ligament, terminating by four aponeurotic tongue-like bundles, which are inserted into the anterior surface of the transverse processes of the four superior lumbar vertebræ near their bases. The several bundles which end in these tongue-like processes vary in length; those which are external being the longest, as going to higher vertebræ. This muscle is covered on its anterior or abdominal surface by the anterior lamina of the tendon of the transversalis muscle, by which it is separated from the diaphragm as well as from the psoas magnus.* The last dorsal nerve and the first two branches of the lumbar plexus, pass between the quadratus and the aponeurotic lamina which covers it.

Psoas magnus, (ψοα, *lumbus*) *(prelombo, trochanterien, lumbaris.)* The greatest portion of this muscle belongs to the abdominal region; it lies along the side of, not only the lumbar but also of a small portion of the dorsal region of the spine, lodged in the angle between the transverse processes and bodies. It passes as high up as the twelfth dorsal vertebra, to the body of which as well as to those of the four succeeding lumbar vertebræ, and to their intervening fibro-cartilages, the muscle is attached: it likewise is attached to the bases of the corresponding transverse processes, so that the intervals between the portions that are attached to the bodies, and those to the transverse processes, correspond to the intervertebral foramina or points of exit of the lumbar nerves, the anterior branches of which plunge at once into the substance of the psoas muscle to form the lumbar plexus. The several bundles which thus take their origin from the vertebræ form a thick rounded muscle, which passes nearly vertically downwards, inclining a little outwards, over the brim of the true pelvis, so as often to appear to encroach upon the circumference of the upper outlet of that cavity. A little way above Poupart's ligament the muscular fibres are inserted around a strong thick tendon. This tendon, which had commenced high up by distinct portions in the interior of the muscle, passes under Poupart's ligament over the horizontal ramus of the pubis. It descends over the capsular ligament of the hip-

* "The linea alba performs the same office in the abdomen as the sternum does in the thorax, with this only difference, that it is not formed of bone. The anterior tendons of the broad muscles are attached to it, in the same way that the cartilages of the ribs are articulated with the sternum, and the difference of tissue which exists between it and the sternum is attributable to the general difference of structure between the abdominal and pectoral cavities, the latter being formed almost entirely of osseous parts, whilst the walls of the former are fleshy and tendinous."—*Meckel.*

† Meckel says that this muscle *rarely* presents anomalies; in this he must be mistaken, as its absence is certainly not a rare occurrence.

* See *fig.* 4, *f*; see also *fig.* 5, where on one side the muscle has been removed from between the laminæ of the transversalis tendon.

joint (from which as well as from the ramus of the pubis it is separated by a bursa) over the head and along the inner side of the neck of the femur, and is inserted into the posterior part of the trochanter minor at its base, being separated by a small bursa from the surface of that process. As the tendon is passing over the ramus of the pubis, it receives by its outer margin a series of fibres from the iliacus internus muscle. At its superior portion the psoas muscle is covered by a thin fibrous expansion, which is attached on the one hand to the apices of the transverse processes, and on the other to the bodies of the upper lumbar vertebræ; this expansion, the *arcus interior* of Senac and Haller,* also called *ligamentum arcuatum*, separates the psoas from the diaphragm. Below this the psoas muscle is covered with a lax, and in some degree fatty cellular tissue, which separates the muscle from the kidney externally, and from the peritoneum and ureter within, excepting where the psoas parvus covers it, and on the right side where the vena cava lies upon it. Along its internal margin are the lumbar portion of the sympathetic, the crura of the diaphragm, more especially on the left side, and on this side too the aorta approaches a little its internal margin. The common and external iliac arteries aud veins lie along the internal margin of the pelvic portion of the muscle, which is covered by the fascia iliaca. The several branches of the lumbar plexus issue from this muscle at its external margin, and the genito-crural nerve descends in front of it inferiorly. We refer to the article on the muscles of the thigh for a further account of this muscle, its relations in the upper part of the thigh, and its actions.

Psoas parvus, (prelombo-pubien). This muscle is similar to the psoas magnus in course and position. It is very much elongated, its fleshy portion being small and tapering. Superiorly it is attached to the body of the first lumbar vertebra, and to the intervertebral substance between it and the last dorsal, and sometimes to the body of the last dorsal vertebra. The fleshy belly soon ends in a flattened tendon, which descends obliquely downwards and outwards over the anterior surface of the *psoas magnus*, and at its inferior extremity expands considerably, and is inserted along the linea ilio-pectinea near the junction of the ilium and pubis. An expansion from the margins of this tendon becomes united on the outside to the fascia iliaca, and on the inside to the internal portion of the same fascia which covers the great psoas, and passes beneath the iliac vessels to become united at the brim of the pelvis to the pelvic fascia.

We must not omit to state that the crura of the diaphragm, as they descend over the bodies of the lumbar vertebræ, (see Diaphragm,) may be regarded as entering into the formation of the posterior wall of the abdomen. The inferior wall of the abdomen is not devoid of muscle, although those muscles can exercise very little, if any influence upon the contents of the cavity. The iliac fossa affords a large surface for the attachment of one of the principal muscles connecting the thigh with the trunk. This muscle is named

Iliacus internus, (iliaco-trochantcrien.) This muscle fills up the iliac fossa, to the whole of whose concavity as well as to its margin, and the two anterior spinous processes of the ilium and the interval between them, its fibres are attached. From these several points of origin the fibres converge to form a thick and broad belly, which passes over the upper part of the acetabulum and horizontal ramus of the pubis, filling up the external portion of the space between that bone and Poupart's ligament; and it is inserted, as we have already observed, into the outer margin of the tendon of the psoas magnus, which is for that reason generally described as the common tendon of the psoas and iliacus. The anterior surface of this muscle is traversed by two of the external branches of the lumbar plexus (inguino-cutaneous), and the anterior crural nerve passes between its internal margin and the psoas magnus.

The superior wall of the abdomen is entirely formed by the muscular vault of the diaphragm, which by its contraction and relaxation exercises a considerable influence on the abdominal contents, and causes very obvious changes in the form of the cavity. The concavity of this vault is towards the abdomen, and is greater on the right side than on the left, in consequence, as it is said, of the presence of the liver on that side. It is through the several openings in this wall that a communication is established between the thorax and abdomen. The largest of these openings are, that on the right side, which is completely tendinous, for the passage of the vena cava; the opening for the œsophagus; and that for the aorta; in addition to these there is a small one behind the centre of the xiphoid appendix formed by a divarication of the anterior fibres of the diaphragm, through which the cellular tissue of the anterior mediastinum communicates with the abdominal subserous tissue. There are, moreover, openings for the transmission of the splanchnic nerves, and the continued trunks of the sympathetics, as well as of branches of the phrenic arteries and nerves, and the abdominal branches of the internal mammary. The particular description of this muscle will be given under the article Diaphragm.

4. The next element which enters into the formation of the abdominal parietes is a fibrocellular expansion, which, varying in density in different situations, lines the whole internal surface of the muscular walls. It is strongest and exhibits most of the real fibrous character in the iliac region on the anterior wall, and over the iliac fossa in the inferior. In the former situation it has received the name of *fascia transversalis,* which was applied to it by Sir A. Cooper in consequence of its close connexion with the transversalis muscle: in the latter, it is called the *fascia iliaca,* from its connexion with the iliac fossa and muscle.

* Vid. Haller Icon. Septi Transversi. Op. Minora, tom. 1.

The fascia transversalis is best seen by removing the muscles which lie anterior to it: it is then distinctly observed to extend from the outer margin of the rectus muscle internally over the posterior surface of the anterior wall of the abdomen, and gradually to assume the character of a thin but condensed cellular lamella over the abdominal surface of the lateral wall: it may, however, be traced internally as far as the linea alba behind the rectus muscle, but here it is extremely thin, and has totally lost the fibrous character. Inferiorly this fascia adheres to Gimbernat's ligament and to the reflected margin of Poupart's, from which it is said, by some French anatomists, to originate. Along the line of Poupart's ligament and external to it along the crista ilii, this fascia is united with the *fascia iliaca*, the union being indicated by a white opaque line formed by a thickening of the membrane, taking the course of Poupart's ligament and the crista ilii, except where it is interrupted for the passage of vessels or other parts. Superiorly, the fascia transversalis also degenerates into a cellular lamella, which passes on the transversalis muscle to the diaphragm. It is for a short distance above Poupart's ligament that this fascia demands most attention; here it forms the posterior wall of the inguinal canal, and at a point a little external and superior to the middle of Poupart's ligament it presents an opening or separation of its fibres, through which the spermatic vessels and vas deferens united by lax cellular tissue pass into the inguinal canal, carrying around them a funnel-shaped membrane which seems to be a prolongation from or continuation of the margins of this opening, but which is in texture merely a condensed cellular layer. This prolonged membrane is the first covering which the spermatic cord receives upon its formation, which takes place as its several constituent parts meet at the opening or slit in the *fascia transversalis*; it immediately invests the cellular tissue connecting these parts, which is the *tunica vaginalis* of the cord; as it proceeds, the cremaster muscle adheres to it from the external oblique and transversalis muscles, and this again receives at its exit through the external abdominal ring another cellular expansion, to which we have already alluded.

The opening or slit in the fascia transversalis which we have just described is denominated by anatomists the *internal abdominal ring*, although, if we speak with reference to the middle line, it is external to the opening in the tendon of the obliquus externus, which is called the external ring. It would certainly be more consistent with the ordinary use of these adjectives in anatomy to reverse their application, or if the term anterior were applied to the external ring, and posterior to the internal, every purpose would be answered.

The direction of the internal abdominal ring is vertical and inclined very slightly outwards. When the fibrous character of the *fascia transversalis* is obvious, we can generally observe two very distinct portions of it, one on each side of the ring. The fibres of the external portion pass upwards and inwards; those of the internal portion, which are generally stronger and more developed than in the external, pass upwards and outwards so as to decussate with the external fibres at the upper extremity of the ring. The outer margin of this internal portion often presents towards the ring a lunated appearance, over which the vas deferens turns at a sharp angle; it can be best seen by examining the parts from behind after the peritoneum has been removed.* The fascia transversalis is continued upwards along the posterior and lateral surface of the abdominal muscles and over the diaphragm under the form of a fine lamina of very condensed cellular membrane, which adheres pretty closely to the muscles, but especially to the diaphragm, where it seems to be incorporated with the proper cellular covering of that muscle. We refer to the article GROIN, REGION OF THE, for further particulars respecting the fascia transversalis.

In the iliac fossa we find a very distinct fibrous expansion covering the whole abdominal surface of the iliacus internus muscle. This is the *fascia iliaca*. It is seen by raising the peritoneum and the subperitoneal cellular tissue from the fossa. Inferiorly this fascia is connected with the fascia transversalis along the line of Poupart's ligament, except where that connexion is interrupted by the passage of the vessels under the ligament. That space comprises the interval between the inner margin of the tendon of the Psoas and Gimbernat's ligament; and here the fascia lies close to the horizontal ramus of the pubis, and passes behind the vessels into the upper part of the thigh, where it adheres to the linea ilio-pectinea, and seems to become continuous with the fascia lata. Externally the fascia iliaca is continuous with the fascia transversalis along the crista ilii, where an opaque line indicates the union, and just internal to which it splits to ensheath the circumflexa ilii artery. On the inner side of the iliac fossa this fascia unites with the pelvic fascia along the brim of the pelvis, this union being likewise indicated by an opaque line similar to that already noticed along the crista ilii. To arrive at this point the fascia, in proceeding from without inwards, passes over the iliacus internus, then over the psoas magnus and parvus, upon which it is thinner than elsewhere; it then passes behind the iliac artery and vein, and arrives at the pelvic margin. Posteriorly this fascia is continuous with a thin and less fibrous expansion which covers the psoas and quadratus lumborum muscles, adheres to the ligamentum arcuatum, and is identified superiorly with the cellular expansion on the diaphragm, and externally with the fascia transversalis.

It has already been stated that the iliac fascia passes behind the iliac vessels. These vessels have also anterior to them a fibrous or cellulo-fibrous expansion, which is connected on the inner and outer side to the fascia iliaca. Some

* This lunated margin is very well delineated by Cloquet in the third figure of the first plate annexed to his work on Hernia, now translated by Mr. A. M. M'Whinnie.

consider this as merely a portion of the subperitoneal cellular tissue, but I cannot help regarding it as a process from the iliac fascia itself to envelope the vessels just as that fascia envelopes the circumflexa ilii artery between two lamina at its outer margin. I have never seen an instance in which this sheath was not perfectly distinct, in some cases it is of considerable strength, but in the majority weak and transparent. It was this sheath which impeded Mr. Abernethy in one of his earliest operations for applying a ligature to the external iliac artery.*

The connexion which the iliac fascia has with the fascia transversalis at the crural arch, and the relation both bear to the iliac vessels at their exit to become femoral, suggested to Mr. Colles a comparison which is constantly referred to by anatomists. "It may he said to resemble," he says, "a funnel, the wide part or mouth of which occupies the hollow of the ilium and lower part of the abdominal muscles, and the narrow part or pipe of which passes downwards on the thigh. The mouth of this funnel may be supposed to rise as high as the upper edge of the iliac muscle, and to be turned toward the cavity of the abdomen: the pipe joins the wide part where the external iliac vessels are passing under Poupart's ligament, and it is continued down on the thigh, so low as to reach the insertion of the saphena into the femoral vein."†

From the preceding sections it appears that a fibro-cellular expansion lines the whole internal surface of the abdominal parietes. It is so likewise with the pelvis, and also with the thorax. The cavity of the cranium, too, is lined with a fibrous membrane, although of a different nature, and doubtless performing a different office.

5. Between the internal fibrous expansion of the abdomen and the peritoneum is a cellular tissue, which presents different characters in each region; it is the subperitoneal cellular tissue. Along the anterior wall it is thin and fine, except inferiorly opposite the internal abdominal ring, where it becomes more abundant, as well as in the hypogastric region, immediately above the pubis. In the iliac fossa and lumbar region it is lax and abundant, especially in the latter, where there is also a considerable quantity of fat surrounding the kidney. In the iliac fossa this cellular tissue is stretched across the crural ring, and forms what Cloquet describes under the name of *septum crurale*. On the superior wall it is extremely fine, and in very small quantity. Immediately behind the sternum, and in the middle line, this cellular tissue communicates with that of the mediastinum through a separation of the anterior fibres of the diaphragm.

This subserous cellular tissue forms the primary covering of all herniæ, which push a peritoneal sac before them, and as being the fascia constituting the nearest investment of the sac, it is generally called the *fascia propria*.

* Abernethy's Surgical Works, vol. i. p. 225.

† Colles' Surgical Anatomy, pp. 68, 69.

Opposite the crural canal this cellular tissue is often so abundant, as, when condensed by the pressure of the hernial tumour, to form an expansion over the sac of considerable thickness. Sometimes it contains fat, and not unfrequently we find a large lymphatic ganglion in it, filling up the crural ring.

6. *Peritoneum.*—A considerable part of the abdominal surface of the walls of the abdomen is lined by a very fine transparent serous membrane—the peritoneum, which is likewise connected, to a greater or less extent, with every viscus within the cavity. In consequence of this double connexion, it happens that in various situations the peritoneum is reflected from the wall of the abdomen upon an adjacent viscus, and thus are produced various folds of this membrane, which demand the attention of the anatomist. These folds are rendered distinct when such a section of the anterior abdominal wall is made as without dividing them to allow of it being held apart from the viscera. I shall enumerate these folds in describing the relation of the peritoneum to the several walls. The anterior wall of the abdomen is entirely lined by peritoneum, and has in connexion with it four folds, all of which, as it were, radiate from the umbilicus. In the adult these folds are reflected round four ligamentous cords (three of which are the remains of bloodvessels in the fœtus), which meet at the umbilicus and diverge, one upwards, backwards, and to the right side *(the obliterated umbilical vein)*, two downwards and outwards towards Poupart's ligament on each side, so as to pass behind the inguinal canal, nearly midway between the two rings *(the obliterated umbilical arteries)*, and the fourth nearly vertically downwards along the middle line to be inserted into the apex of the bladder *(the urachus)*. The four folds are similar in direction to that of the fibrous cords contained within them: the fold which passes upwards towards the liver is falciform, the concavity being directed downwards and backwards. From its connexion with the convex surface of the liver it is also called the falciform ligament of the liver, and the fibrous cord contained in its inferior margiu, the ligamentum teres. The inferior and external folds pass each from the umbilicus, downwards and outwards to the iliac fossa, to a point a little on the inner side of the internal abdominal ring, where it disappears, being continued externally over the iliac fossa, and internally behind the rectus muscle. This fold, when stretched towards the umbilicus, evidently forms the partition between two pouches, *the external and internal inguinal pouches*, which correspond respectively to the internal and external abdominal rings, and indicate the situations at which make their escape those two forms of inguinal hernia, which, from their connexion with these pouches, are called by Hesselbach external and internal inguinal herniæ; the former being that by oblique descent, the latter that by direct descent.

The fourth or vertical fold indicates the reflection of the peritoneum from the anterior abdominal wall upon the superior fundus and posterior surface of the bladder: when that viscus is empty and contracted, this fold disappears totally; it is more apparent when the bladder is partially filled, and is still more distinct in the fœtus in consequence of the greater size of the urachus at that period. Just above the pubis the peritoneum is connected to the abdominal wall by a very lax cellular tissue; and accordingly when the bladder is much distended, the peritoneum is pushed upwards, and stripped off the abdominal wall to an extent proportioned to the degree of distension of the bladder, so that its anterior surface is then in immediate contact with the abdominal wall, and may be opened with impunity so far as the peritoneum is concerned.

The lateral walls of the abdomen are likewise completely lined by peritoneum, which extends backwards as far as the junction of these walls with the posterior, where it is reflected from them so as to involve the ascending colon on the right side and the descending on the left, and here it forms on each side the folds respectively termed right and left *mesocolon.* From the right lateral wall the peritoneum is continued upwards upon the diaphragm, and contributes to form the right lateral ligament of the liver; on the left side it is continued in a similar manner on the diaphragm, and in passing from the spleen to that muscle forms the fold called *splenico-phrenic.*

The concave surface of the diaphragm is in greatest part lined by peritoneum: the anterior half of the muscle is uninterruptedly covered by peritoneum, which adheres very closely to the central tendon, but is much more easily separated from the muscular portion. On the right side and in the middle, in front of the œsophageal opening, the peritoneum is reflected from the diaphragm to the liver, forming the right lateral, coronary, and left lateral ligaments of that organ. The posterior half of this surface is likewise covered by peritoneum, that membrane being deficient for a little way behind the opening for the vena cava and behind and on each side of the œsophageal and aortic openings: the crura of the diaphragm are covered chiefly on the outer side.

The peritoneum comes into immediate contact with the posterior abdominal wall only in a very small portion of its extent: in tracing it on the right side we find it covering the right colon, then passing inwards over the kidney and suprarenal capsule, the duodenum and vena cava, to the crus of the diaphragm above, and in the middle and below, where it also covers the vena cava, and the renal vessels, to form the right or superior lamina of the mesentery. On the left side it covers in a similar manner the left colon, the left kidney and capsule, and that portion of small intestine which projects just to the left of the superior mesenteric artery, which may be regarded as the commencement of the jejunum; below this it manifests its continuity with the layer of the opposite side by forming the left or inferior lamina of the mesentery. This lamina commences at the left side of the body of the second lumbar vertebra; as it descends, it gradually crosses more in front of the aorta, so as to terminate at the right sacro-iliac symphysis; the right lamina is situated quite on the right side of the spine.

In the iliac fossæ the peritoneum is in connexion with the *fascia iliaca,* except where it is separated by the cœcum on the right side (on which side it sometimes forms a fold termed *mesocæcum,*) and by the sigmoid flexure on the left. Internal to these portions of intestine on each side, the peritoneum covers the external iliac artery and vein, from which it is separated by a very loose and sometimes adipose cellular tissue, and by a process of the iliac fascia, to which allusion has already been made.

From the preceding description of the connection of the peritoneum with the parietes of the abdomen, it will appear how few are the situations at which the surgeon could cut through any portion of these walls without risk of wounding the serous membrane. Immediately above the pubis this may be done in consequence of the abundance of cellular membrane there which separates the serous membrane from the wall; but in the contracted state of the bladder the operator must proceed with the greatest caution: in the distended state of that viscus, however, the wall of the abdomen is deprived of its lining to an extent proportionate to the height to which the bladder ascends behind the recti muscles; and accordingly it is under such circumstances that the paracentesis vesicæ supra pubem, and the high operation for the stone may be performed with impunity to the serous membrane. At the posterior wall an instrument may be passed into any part of the posterior surface of the kidney without injury to the peritoneum; the pelvis of the kidney, or any part of the abdominal course of the ureter, may be opened too, or the vena cava; and by cutting into the bodies of the vertebræ, and the muscular portion of the posterior wall in the dead body, a view of all the parts which lie upon that wall may be obtained without at all injuring the peritoneum.*

Further details respecting the anatomy of the peritoneum will be found in the article under that head.

Vessels and nerves of the abdominal walls.— *a. The arteries.*—The most important arterial ramifications are found in the anterior wall. In the superficial fascia we find the *superficial epigastric* artery or tegumentary artery, which exists as a trunk in the iliac regions. This artery, arising from the femoral, pierces the fascia lata, and passes over Poupart's ligament upwards and inwards, crossing the anterior

* The reader may examine with advantage, Ludwig, Icones cavitatum thoracis et abdominis a tergo apertarum. Leipzig, 1789.

wall of the inguinal canal between the two rings; it is distributed in the integuments and fascia of the iliac and umbilical regions, and anastomoses with its fellow of the opposite side, and by deep branches which pierce the aponeuroses, with the deep epigastric artery. In the epigastrium and hypochondria the superficial fascia and integument are supplied by cutaneous branches from the internal mammary and the inferior intercostals. The deep-seated parts of this region are likewise supplied from the last-named arteries; the largest and most constant of which is the abdominal branch of the internal mammary, which in the sheath of the rectus supplies that muscle, and establishes an important communication with the epigastric: this anastomosis is said to have been known to Galen, who by it proposed to account for the sympathy which exists between the uterus and the breasts.* Another branch of the mammary supplies the muscles external to the rectus; it runs between the obliquus internus and transversalis, and is lost in anastomosing with the inferior intercostal, the lumbar, and the circumflexa ilii arteries.

Inferiorly, the abdominal wall is supplied by two considerable and very constant arteries, viz. the *epigastric*, which may be distinguished from the artery that supplies the integuments by the appellation *deep*, and the *circumflexa ilii*. The *epigastric artery* arises in general from the external iliac a little way above Poupart's ligament; it at first inclines downwards to that ligament, and then turns upwards, and directs itself forwards and inwards, crossing the iliac vein; it then runs along the posterior surface of the anterior wall of the abdomen, inclosed between the peritoneum and fascia transversalis, at first situated between the external and internal abdominal rings, and on arriving at the rectus muscle, the sheath of which it enters about two inches above the pubis, it gives off branches from either side to the abdominal muscles and peritoneum, and behind the linea alba, establishes a very free inosculation with its fellow of the opposite side. As it lies behind the inguinal canal, the epigastric artery is much nearer to the internal than to the external abdominal ring, being to the pubic side of the former; here the vas deferens, as it passes up from the pelvis to the inguinal canal, hooks over it, and receives one or two small branches from it. In passing to the rectus muscle, this artery lies internal to the linea semilunaris. It enters the sheath of the rectus, and then terminates by anastomosing with the internal mammary. The course of this artery demands particular attention from the surgical anatomist in reference to the operations for inguinal herniæ, and to that for paracentesis abdominis, when the abdomen is perforated in the linea semilunaris. The trunk of the artery is so distant from the linea alba in its whole course, that it is free from danger in any operation performed in that line, or in the internal half of the rectus muscle, and its security in such operations is increased under the altered state of parts consequent on pregnancy, ascites, or any abdominal tumour pressing similarly on the abdominal wall. In these cases the distance of the artery from the linea alba is increased by the flattening of the rectus muscle, which results from its compression. — (See Groin, Region of; Hernia; Iliac Artery.)

The *circumflexa ilii* artery comes likewise from the external iliac, near to the origin of the epigastric; it passes upwards and outwards towards the spine of the ilium, runs along the line of junction of the fascia iliaca with the fascia transversalis, covered by the fascia, and follows the circumference of the iliacus internus muscle to end in anastomosing with the iliolumbar artery. From that part of the artery which intervenes between its origin and the spine of the ilium, come the principal branches which it supplies to the abdominal muscles.

The lateral and posterior walls of the abdomen are supplied by the inferior intercostals, the lumbar, the iliolumbar, the circumflexa ilii arteries; the superior walls by the phrenic branches of the internal mammary and by those of the aorta. It is in cases where the aorta has been obliterated that we can see best the extent of arterial ramification on the abdomen, and can appreciate the benefit of these numerous anastomoses, and the connexion which they establish between the upper and lower portions of the aorta.*

b. The veins.—The veins of the abdominal parietes are much more numerous than the arteries; each artery has its accompanying vein or veins, but those which are especially deserving of attention are the tegumentary veins which accompany the superficial epigastric artery, and those which ramify along with the deep epigastric and mammary. The subcutaneous veins demand attention in consequence of the considerable size which they sometimes attain; this enlargement is commonly attendant on ascites and on pregnancy, and is occasionally, to a remarkable extent, a consequence of some irregularity, obstruction† or retardation of the circulation, in the deep-seated veins of the abdomen, more especially the inferior vena cava. The veins which accompany the superficial epigastric artery empty themselves by one or more trunks into the *vena saphena* at the upper part of the thigh.

Two veins generally accompany the deep epigastric artery, which empty themselves into the external iliac vein. These veins are equally subject to enlargement with the preceding, and from similar causes, and they are often found in a varicose condition in women who have borne many children.

Some curious anomalies have been observed in the venous circulation of the anterior abdominal wall, which, as being calculated to interfere with the operator, the practitioner would

* Dict. de Médecine, art. *Abdomen*.

* See the interesting case of obliterated aorta recorded by Messrs. Crampton and Goodissen. Dub. Hosp. Reports, vol. ii.

† As in the case of obliteration of the inferior vena cava from the pressure of an aneurismal tumour observed by Reynaud. Journal Hebdom. de Méd. vol. ii. p. 110.

do well to note. M. Meniere* has described a case in which a very large vein, arising from the external iliac, passed up along the linea alba to the umbilicus, was continued along the obliterated umbilical vein, and opened into the vena portæ. In another case, recorded by Manec, the vein originated in the same manner by two roots, reached the umbilicus, taking a course parallel to the umbilical artery, formed an arch outside the navel, and having re-entered the abdomen, opened into the vena portæ. In another instance which occurred to Cruveilhier the superficial veins in the hypogastric region were enormously enlarged, at the umbilicus they ended in a trunk as large as a finger, which communicated with the vena cava as it passed under the liver.† Berard proposes to explain, by the supposition of the existence of such anomalies as those above described, the occurrence of fatal hemorrhages from wounds inflicted at the umbilicus, which have been attributed to the persistence of the umbilical vein.‡

c. The lymphatics.—Those on the anterior wall communicate above with the axillary glands, and below with those of the groin: the deep-seated lymphatics of the posterior wall communicate with the glands which lie along the lateral and anterior surfaces of the lumbar spine.

d. The nerves.—The nerves of the abdominal parietes are derived from the inferior intercostals and from branches of the lumbar plexus. The seventh, eighth, ninth, tenth, eleventh, and twelfth intercostal nerves terminate in supplying the transverse and oblique muscles and the recti; the twelfth lies in front of the quadratus lumborum muscle, and gives several filaments to that muscle. The ilio-scrotal and inguino-cutaneous nerves are the branches of the lumbar plexus which mainly supply the inferior part of the oblique and transverse muscles. One branch of the genito-crural, which is found in the inguinal canal, also sends some twigs to these muscles.

The posterior wall is supplied by the subdivisions of the posterior branches of the lumbar nerves.

Physiological action of the abdominal parietes and muscles.—We have already alluded to the peculiarity which distinguishes the abdominal cavity when compared with the other great cavities, namely, that its walls are in greatest part composed of contractile tissue. At first view the muscular apparatus of the abdomen would appear to be a great constrictor muscle destined principally to exert its influence on the cavity and its contents; but when we take into account the attachments of those muscles to the ribs, the vertebræ, and the pelvis, it becomes evident that they must likewise be destined to act upon the thoracic and pelvic cavities, as well as upon the vertebral column. In the constitution of the abdominal parietes we observe, as Berard* remarks, the most happy adaptation of structure to uses. A completely osseous covering would have greatly interfered with the functions of the abdominal organs, which are liable to experience changes both extensive and often very rapid, either by reason of the introduction of alimentary matter, whether solids or fluids, or by the disengagement of gases within the digestive tube, or by the progressive development of the impregnated uterus. We may moreover add that an exact repetition of the structure of the walls of the thorax would not have been well adapted to the abdomen for the same reason, namely, the too great resistance which it would afford to compression from within, thereby interfering with the distensibility of the enclosed viscera. The resistance, too, which a wall so constituted would afford to impulses from *without* could not have been so easily adapted to the impetus of the forces likely to act upon them as a purely muscular wall whose contractions and the intensity of them are obedient to the will.

The consideration of the action and uses of the abdominal muscles naturally comes under two heads:—1. their action upon the abdominal cavity and its contents; 2. their influence on the trunk generally, or parts of it.

It is the muscles that enter into the composition of the anterior and lateral walls of the abdomen which act chiefly on the cavity and its contained viscera. The solidity of a considerable portion of the posterior wall, and the great strength of the lumbar muscles, give to that wall such a power of resistance as enables it to receive the compressed viscera without at all yielding. A reference simply to the attachments of the muscles of the anterior and lateral walls is sufficient to shew that these muscles when contracted must diminish the capacity of the abdomen, both in the lateral and antero-posterior directions; and as the posterior wall is but little influenced, the viscera will be pushed partly upwards against the diaphragm, and partly downwards into the cavity of the pelvis, where their further descent is opposed by the levator ani. Hence it appears that a degree of antagonism exists between the diaphragm and the abdominal muscles, as well as also between those muscles and the levator ani. It is extremely difficult to maintain the abdominal muscles and the diaphragm at the same moment in a state of contraction; in general they alternately yield the one to the other: and when it does happen that they are simultaneously contracted, the abdominal viscera must suffer an unusual degree of compression; and it is not improbable that vomiting is sometimes produced by such a cause, and defecation, no doubt, is likewise aided by it. The danger of the protrusion of some of the hollow viscera between the fibres

* Archives Gén. de Méd. t. x. p. 381. The vascular distribution which existed in this subject presents, as Meniere has remarked, a striking similarity to that which is naturally found in the Saurian, Ophidian, and Batrachian reptiles, viz. a division of the general venous system which communicates with the hepatic vena portæ.

‡ Dict. de Méd. art. *Abdomen*.

* Loc. cit.

of the muscles is provided against by the variation of direction in the fibres of the several layers; thus the fibres of the obliqui are in the directions of two intersecting diagonals, and those of the transversalis are different from both. By this arrangement a sort of network is formed, with meshes so small as to render a protrusion perfectly impossible in the healthy condition of the muscle. In the compression of the viscera the abdominal muscles are most completely congeneres, although the transversalis seems to be the best adapted to this action, and probably, for that reason, forms the layer which is placed nearest the peritoneum. The recti muscles are powerful auxiliaries in affording a fixed point of attachment in front for the aponeuroses of the broad muscles, and the pyramidales assist in a similar manner by rendering tense the linea alba. Is this constant action of the abdominal parietes on the viscera necessary or favourable to the due performance of the functions of those organs, or to the continuance of the abdominal circulation? There certainly does not appear to be any evidence for the *necessity* of them for this purpose: that they are favourable to it may be inferred from the fact that they do bear their present relation to them. We know from numerous experiments on animals, that both the transmission of the intestinal contents, and the abdominal circulation may go on when the abdominal muscles have been freely opened or removed. Hence we may answer this question with perfect justice in the words of Bichat: "The walls of the abdomen favour these functions by their motions; but these motions are by no means essential to them."

It is in consequence of the power which the abdominal muscles thus appear to exert in compressing the viscera, that some physiologists have attributed the act of vomiting to their action united with that of the diaphragm; and Magendie, reviving the opinions of Bayle, Chirac, and Shwartz,* went so far as to deny to the muscular coat of the stomach any participation in this act, and to ascribe it wholly to the influence of the abdominal muscles. But Beclard, to whom the question was referred by the Academy of Medicine of Paris, proved satisfactorily that the abdominal muscles are active in producing vomiting when the stomach is distended in a certain degree, and that the muscular coat of the stomach is also active in emptying the contents of that viscus. This conclusion Haller had arrived at long ago, and clearly expresses it in the following passage: "Evidentissimum ergo videtur, vomitus quidem causam esse in ventriculo eumque in contractionem niti propriis viribus atque aliquando vomitum perficere. Plerumque tamen irritationem in ventriculo natam et sensum summæ anxietatis, quæ vomitum præcedunt, facere ut ad levandam ægrimoniam vires diaphragmatis et musculorum abdominis excitatæ atque molestiam de homine amolituræ, vomitum perficiant. Unde neque a solâ voluntate in plerisque certe mortalibus vomitus cieri potest neque a solâ absque voluntate natura—Quare recte conjunctas vires ventriculi et organorum respirationis Cl. Viri fecerunt. Et videtur diaphragma et abdomen plus virium habere, quando ventriculus aut cibis repletus est, aut clausis ostiis distentus: tunc enim magis ad perpendiculum proximum ventriculum comprimunt et tota contingunt."*

If it be admitted that the abdominal muscles are active in producing vomiting, and in defecation and micturition, it will follow likewise that they must assist in parturition. While these pages were preparing for press, the following passage presented itself to me, in an able and interesting review of M. Velpeau's Treatise on Midwifery. It so fully illustrates the part which the abdominal muscles take in promoting parturition, that I venture to transcribe it, "It is certain," says the reviewer, "that a woman who 'bears down' as it is termed, with all her force, who makes the most of her pains, however feeble they may be, will thus accelerate her delivery; and that another may more or less delay delivery by voluntarily opposing muscular action as much as she can. For example;—a woman was admitted for delivery at M. Baudelocque's theatre; labour went on regularly, and the pupils assembled. The dilatation of the cervix now slackened, and no progress was made during the whole night. The *élèves* were fatigued and retired; the pains immediately returned, and dilatation again went on. The young men again entered; the phenomena of labour again ceased. Baudelocque, suspecting the cause, gave a hint to the students to retire, but to be at hand and enter upon a given signal. The patient now began to 'bear down,' and the head of the child was quickly at the vulva. The spectators were once more brought to the scene of action, and the labour was speedily terminated; for it had now advanced too far to be suspended by any voluntary effort or moral alarm of the woman."†

The fixedness of the inferior attachment of the abdominal muscles to the pelvis, and the mobility of the ribs, to which they are attached superiorly, evidently indicate that these muscles are destined to act upon the thoracic cavity. The transversalis does not, from the direction of its fibres, admit of this action to any extent; that office, therefore, devolves chiefly on the obliqui and recti. When these last-named muscles act together, they must compress the inferior opening of the thorax, draw its inferior margin downwards and backwards, and, by the compression thus exerted on the abdominal viscera, push them upwards against the diaphragm, which muscle is thus made to ascend into the thorax, and that cavity is thereby diminished in its vertical and antero-posterior diameters, and also, though not so obviously, in its transverse. Hence the lungs become so compressed as to be adapted to the altered capacity of the

* Vide Haller, Elementa Physiologiæ, t. vi. sect. iv. § xiv.

* Haller, ubi supra. See, also, Richerand, Physiologie par Berard, art. Digestion, § xxiv.

† Medical Quarterly Review for April, 1835. p.100.

thorax, and thus these muscles must be considered as very important agents in the act of expiration. It must be observed, however, that in order that they may act on the chest with their full force, it is necessary that that cavity should have been previously in a state of full dilatation, for under such circumstances the fibres of the obliqui and recti are considerably stretched and their levers elongated.* It is in the excited states of expiration, coughing, sneezing, &c., that this action of these muscles is most obvious.

But it is in the motions of the trunk that the abdominal muscles are called most into play. In all the inflexions of the trunk, whether the body be horizontal or erect, these muscles are main agents. When the body is recumbent on a horizontal plane, the recti are thrown into action when the individual attempts to raise up the thorax, the spine being thereby brought into the state of flexion. If the thorax be fixed, while the body is still supine, the action of the recti will draw the pelvis upwards and forwards, causing slight flexion of the spine, and slightly approximating the upper margin of the pelvis to the lower margin of the thorax. Although the recti muscles are the principal agents in thus flexing the spine, the *obliqui* co-operate with them very powerfully, and are especially useful in maintaining the due proportion between the middle and lateral regions of the abdomen. When the two obliqui of the same side act together, the direction of their force is, as with all oblique muscles whose fibres decussate, in the diagonal between their fibres; and, therefore, when the obliqui of opposite sides act in unison, they very powerfully aid the recti in flexion of the spine, approximating the thorax and pelvis anteriorly. When the obliqui of one side act, they produce a lateral inflexion of the trunk to that side,—the middle and opposite region of the abdomen being in this position rendered prominent by the viscera pushed over from the side of the contracted muscles. In what have been called the rotatory motions of the trunk, the obliqui muscles of the same side antagonize each other; thus in that movement by which the anterior surface of the trunk is made to look to the left side, the obliquus externus of the right side will co-operate with the obliquus internus of the left, but the obliquus internus of the right will antagonize the external muscle of the same side. "These muscles," *(obliqui externi et interni,)* says Dr. Barclay, "from occupying the whole of the lateral aspects extending between the ilia and ribs, and from acting at the greatest lateral distance from the centre of motion, must always be muscles principally concerned in producing inflexions dextrad and sinistrad on the lumbar vertebræ, principal directors in all the inflexions sternad and dorsad; and, from the assistance which they give to the recti, principal librators also of the trunk, whether we be sitting, standing, or walking."

The reciprocal action of the recti and obliqui on each other is one of the most beautiful parts of the mechanism of the abdominal muscles. This is mainly to be attributed to the close connection which subsists between these muscles in consequence of the formation of the sheaths of the recti by their aponeuroses, and the adhesion of the anterior wall of those sheaths to the tendinous intersections of the recti. When the recti contract, the antero-posterior diameter of the abdomen is diminished, and consequently the viscera are pushed towards the sides; when, on the other hand, the obliqui contract, they diminish the transverse diameter of the abdomen, and push the viscera forward in the middle line. In the one case, then, it will be evident that the obliqui act as moderators to the recti, and in the other the resistance of the recti moderates the action of obliqui,—the former muscles being, as Cruveilhier remarks, as it were, two active pillars compressing forcibly the viscera against the anterior surface of the spine. It is probably to enable the recti to act more completely as moderators upon the several segments of the obliqui that they are intersected by tendinous lines, with which the aponeuroses of those muscles are connected. Another use has been assigned to these intersections by Bertin, viz.,—to multiply the points of attachment of the obliqui muscles, and to associate them, in many actions, with the recti muscles. This is explained by a reference to the action of the recti in flexing the pelvis: were these muscles unconnected with the obliqui, they would act only on the pelvis, into which they are inserted; but in consequence of the insertion of the internal oblique into the intersections of the recti, and the attachment of that muscle also to the crista ilii, the force of contraction of the recti is communicated not only to the pubis, but also through the fibres of the obliquus internus to the rest of the pelvic margin.*

The action of the pyramidales seems to be chiefly on the linea alba, which they render tense; thus limiting the separation of the recti, and opposing the tendency to visceral protrusion. Fallopius supposed that they acted on the bladder, especially when it was in a distended state; and Parsons conjectured that they might depress the suspensory ligament of the bladder (the urachus), and thus facilitate the contraction of that organ.

The other muscles which are from situation abdominal muscles in consequence of their connexion with the posterior wall of the abdomen, are chiefly agents in the extension of the vertebral column: in their contracted state, however, they form a tense and resisting surface, against which the viscera are compressed by the contraction of the anterior muscles.

II. *Of the Abdominal Cavity.*—The annexed engraving (*fig.* 5.) exhibits a view of the abdominal cavity, the anterior and part of the lateral walls having been cut away and the viscera removed. The subject is so bent backwards as to render the bodies of the vertebræ very

(*Fig. 5.*)

prominent anteriorly, and the continuity of the abdominal and pelvic cavities is thus clearly shewn. It is useful to examine the relations of the axes of these two cavities; that of the pelvis passes forwards and upwards towards the umbilicus, while the axis of the abdomen passes from above downwards and forwards so as to terminate a little above the pubis, the two axes accordingly would intersect each other a little below the umbilicus at an obtuse angle. This angle may be obliterated by bringing the pelvis very much forward and producing a full flexion of the spine, and hence in all efforts for expulsion that attitude is almost instinctively assumed which shall identify the axes of the two cavities, and thus direct the efforts in the most favourable manner. The ordinary form of the cavity in the adult male is oval, but it presents some slight differences in the female and in the fœtus; and these differences are dependent on the great or incomplete development of the pelvis. In the female the abdomen is generally more capacious than in the male; and this greater size is more remarkable at the inferior part of it in the hypogastric region. In fact in the male it would seem that the great extremity of the oval is toward the thorax, and its smaller one towards the pelvis; but in the female it is just the reverse, the larger extremity being toward the pelvis. It should be observed, however, that the modern fashion of tightly compressing the lower part of the thorax has a material effect on the external characters of the female abdomeu, otherwise there is no reason that the superior part of it should be proportionally less than in the male. In the fœtus the abdomen is proportionally larger than at any other period of life: this is to be attributed to the imperfect development of the pelvis, and likewise to the great size which some of the abdominal viscera possess; and as some time must elapse before the pelvis reaches its full dimensions, or the viscera lose their superfluous parts, the abdomen continues of this large size for a long period after birth.

The subdivision of the abdomen into regions is especially useful in reference to the contents of the abdominal cavity, which it is highly desirable the student should examine, so as to be able to assign to each compartment its appropriate contents. The abdominal viscera may be subdivided into the membranous and the parenchymatous; the former being such as the stomach and intestinal canal, the latter, such as the liver, spleen, pancreas, &c. The viscera have likewise been distinguished in reference to their position with respect to the peritoneum, by the names *intra-peritoneal* and *extra-peritoneal;* but it is sufficient to know that no serous membrane contains any organ within it (*i. e.* within its sac) to see the error of such a distinction. But we cannot adopt a better division of the abdominal viscera than that which has reference to the functions of those organs, and which Beclard has adopted: viz. 1. the organs of digestion—the stomach, the intestinal canal, the liver and its appendages, the spleen, and the pancreas: 2. the urinary organs—the kidneys and the ureters, to which may be added from their close relation to the kidneys, the suprarenal capsules: 3. the organs of generation in the male—the vasa deferentia, and in the male fœtus at the sixth or seventh month of intra-uterine life, the testicles: none of the organs of generation can strictly be said to be abdominal organs in the female. In both male and female the other internal generative organs are *pelvic* viscera. If we add to the above enumeration of parts the abdominal portion of the aorta, its primary subdivision into the common iliacs; the anterior subdivision of these arteries under the name of external iliacs; the branches of the aorta which are distributed to the viscera as well as to the walls of the abdomen; the common and external iliac veins; the vena cava ascendens; the system of the vena portæ; the abdominal portion of the sympathetic system of nerves, both that which follows the arterial ramifications, and that which is the continuation of the chain of ganglia that lies along the spine, the termination of the par vagum; the mesenteric glands, and the lacteals; the lymphatics and their ganglia which lie along the spine; the origin of the thoracic duct, a portion of the course of that duct;—these will complete the list of parts contained in the abdominal cavity.

The full particulars of the relative positions of the contents of the abdomen, and the abnormal states of that cavity, both congenital and morbid, including also the abnormal states of its parietes, we prefer to bring together in a separate article under the head Cavity abdominal, to which we beg to refer the reader. The special anatomy, both natural and abnormal, of the several abdominal viscera is distributed among the articles Intestinal Canal, Kidney, Liver, Pancreas, Spleen, Suprarenal Capsule.

ABSORPTION in physiology (from *absorbeo*: Lat. *absorptio*, Fr. *absorption*, Ger. *die einsaugung*, Ital. *assorbimento*.) The term absorption is employed in physiology to designate a vital organic function, the primary or immediate object of which is to furnish the system with a due supply of matter for its growth and subsistence. It is proposed, in the following article, first, to give an account of the organs by which the function is performed; this will lead us, 2dly, to consider the question of venous absorption; in the third place, we shall inquire into the mode in which the absorbents act; and, lastly, we shall offer some remarks upon the specific uses of the different parts of the absorbent system, and upon the relation which it bears to the other vital functions.

§. 1. *Description of the Absorbent System.*—We propose, in the first instance, to restrict the term *absorbent system* to those organs, which are supposed to be exclusively appropriated to the function of absorption; these may be included under the two heads of vessels and glands, the vessels being again subdivided into the lacteals and the lymphatics.

Although the absorbents are distributed to almost every part of the body, and perform so important an office in the animal economy, they were among the organs which were the latest in being discovered by anatomists. There are, indeed, some passages in the writings of Galen,* which would lead us to suppose that certain parts of the absorbents had been seen by Erasistratus and Herophilus, as well as by himself; but it appears that they were, all of them, unacquainted with the relation which these vessels bore to the other organs, and were entirely ignorant of their office and destination. These scanty observations of the ancients seem to have been entirely neglected, or even forgotten, until the study of anatomy was revived, together with that of the other medical sciences, in the sixteenth century. In the course of the researches which were then made into the structure of the animal body, various parts of the absorbent system appear to have been brought into view, and are noticed, among other writers, by Fallopio,* who discovered the lymphatics, connected with some of the abdominal viscera, and by Eustachio,† who detected the thoracic duct. But although their descriptions, especially that of Eustachio, are sufficiently correct to enable us to identify them, as forming a part of the absorbent vessels, yet they were unacquainted with their specific nature and office, and with their relation to the sanguiferous system.

It is generally admitted that the merit of the discovery of the lacteals is due to Aselli; this discovery he made in the year 1622. While he was examining the abdominal viscera of a dog, he observed a series of vessels attached to the mesentery, which appeared to have no direct connexion with the arteries or veins, and which, from the circumstance of their containing a white opake fluid, he denominated Lacteals.‡

He regarded them as a distinct set of vessels, exercising a specific function, distinct from that of the sanguiferous system, and he ascertained that they took their origin from the surface of the intestines, and proceeded towards the more central parts of the body, but it was not until the year 1651, that their termination in the thoracic duct was discovered by Pecquet.§

The discovery of the other species of absorbent vessels, styled, from the appearance

‡ Dissertatio de Lactibus; first published in 1627. See Bartholin, de Lact. Thor., c. 4; Sheldon on the Absorbent Syst., p. 20, 1. Aselli's work is accompanied by plates of very rude execution, but sufficiently expressive of the object.

§ Exper. nova anat.; first published in 1651; Bartholin, c. 5. In 1652, Van Horne published the first plate of the thoracic duct. There is some reason to suppose that Vesling had an imperfect view of it previous to Pecquet; he published his Syntagma Anat. in 1647. In describing the pancreas he speaks of the venæ lacteæ, lately discovered by Aselli, which convey the chyle to the liver, and figures them in tab. 4. fig. 3.

of the fluid which they contain, the lymphatics, was posterior to that of the lacteals. The transparency of their contents rendered them less conspicuous and less easy of detection, so that, although certain parts of them appear to have been seen by Fallopio, and afterwards by Aselli and others, yet it was not until the year 1650, that they were distinctly recognized, and their connexions ascertained. The discovery of the lymphatic system was the subject of a warm controversy between Bartholin and Rudbek, on the merits of which we are, after so long an interval, scarcely able to decide. It appears, however, to have been the opinion of Haller, and the most distinguished anatomists of the last century, that the lymphatics were detected, in the first instance, by Rudbek; that Bartholin had some intimation of the discovery, that he then took up the subject, and pursued it much farther than it had been done by Rudbek.*

There is a third individual, on whose behalf a claim of priority has been made, which possesses at least considerable plausibility. We are informed by Glisson, that an English anatomist of the name of Joliffe distinctly recognized and exhibited the lymphatics of many of the abdominal viscera, previously to the alledged discovery of either Rudbek or Bartholin.† But even if we allow Joliffe the full merit both of discovering these vessels, and being aware of their specific nature, it does not appear that he published his discovery, so that it will scarcely affect the rival claims of the former anatomists. The discovery of the absorbent or conglobate glands, as they have been termed, was made, for the most part, at the same time with that of the vessels, as a necessary consequence of the intimate connexion which subsists between them.

After the existence of the lacteals had been clearly announced by Aselli, and of the lymphatics by Rudbek and Bartholin, the attention of anatomists was very generally directed to these organs, and discoveries were successively made, by various individuals, of the presence of the latter in almost every part of the body, and in connexion with almost every one of its organs. The labours of William and John Hunter, of Monro sec., and of Hewson, were among the most important in their results, while we are indebted to Cruikshank, and still more to Mascagni, for their minute descriptions and accurate representations of the absorbent system, in all its parts, and with its various relations and connexions.‡

‡ For the most original and correct description of the lacteals, the reader is referred to Haller, El. Phys. xxv. 1. 4..8; Mascagni, Vas. Lymph. Corp. Hist., p. 1. §. 7. art. 8. tab. 1. fig. 7; Sheldon, on the Absorb. Syst. ch. 2. pl. 3, 4, 5; Santorini, Tabulæ, No. 13. fig. 3; Magendie, Physiol. t. ii. p. 158..0. The translation of Mascagni's work, with copious notes by Bellini, may be advantageously consulted; it is not accompanied by plates. For the lymphatics we may refer to Haller, ii. 3. 2; Meckel, Diss. Epist. de Vasis Lymphaticis; Hewson, Enq., ch. 3. pl. 3, 6; Mascagni, ps. 1. sect. 7. tab. 4 et seq.; Cruikshank, on the Absorb., p. 148 et seq.; Sœmmering, Corp. Hum. Fabr. t. v. p. 388 et seq.; many of Mascagni's plates are transferred into Cloquet's valuable "Manuel." Art. "Inhalation," par Rullier, in Dict. des Sc. Méd. t. xxv. 3. Art. "Lymphatique," par Chaussier et Adelon, ibid, t. xxix. p. 249, 260; Meckel, Manuel, sect. 6. ch. 2; Quain's Elem. of Anat. p. 560..574. In Elliotson's Physiol. ch. 9. p. 140..2, we have a "short account of the first discovery of the absorbent system." Sœmmering's treatise, De Morbis Vasorum Absorb. contains a most ample and learned catalogue of the various works on absorption, from the earliest period to the date of its publication in 1795.

With respect to the minute anatomy of the lacteals, we are informed that they originate from certain small projecting bodies, termed villi, which are attached to the interior surface of the intestines, styled from this circumstance the villous coat. These villi are described as consisting of a number of capillary tubes, which terminate with open mouths, and that by the union of these tubes the branches of the lacteals are composed, which are sufficiently large to be visible to the eye. We must remark, however, that although these villi, as constituting the mouths of the lacteals, have been minutely described, and even figures given of the appearance which they exhibit in the microscope, yet that considerable doubt is still entertained of their existence, and that they are even entirely discredited by some anatomists of the first eminence.* Upon the whole we may conclude that the opinion, which has been generally adopted, respecting the capillary termination of the lacteals, is somewhat theoretical, rather derived from the supposed necessity of such a formation to carry on the functions of the vessels, than from any actual observations that have been made upon them.

When the lacteals have acquired sufficient magnitude to become visible to the eye, they are seen to proceed along the mesentery, the small vessels running together to form large branches, and these again forming others that are still larger, until the whole of them unite into a few main trunks, which terminate in the receptacle at the lower extremity of the thoracic duct. During their progress, the small vessels

* See Lieberkuhn, Diss. de Fabr. Vill. Intest. passim, cum tab. 1, 2; Hewson's Enq., c. 12, pt. 2; Cruikshank's letter to Clare, p. 32..4; Sheldon on the Absor. Sys., p. 32..8, tab. 1, 2; Hedwig, Disq. Ampull. In opposition to these and other authorities, on the affirmative side of the question, we have the strong negative evidence of Mascagni, whose plates do not sanction the description of Lieberkuhn, tab. 1. fig. 1. 3; and tab. 3. fig. 1, 2, 3, 5; and the decided opinion of Magendie, Journ. de Physiol. t. i. p. 3 et alibi. On this subject see the remarks of Haller, not. 9. ad §. 91. Boerhaave, Præl. et not. 4. ad §. 103. The observations of Du Vernoi, Mem. Petrop. t. i. p. 262 et seq., seem scarcely to have been confirmed.

frequently anastomose with each other, so as, in many instances, to form a complete network or plexus, in which respect their course differs from that of the veins, where the small branches unite to form the larger ones, without the lateral communications.

The lacteals are furnished with numerous valves, which are disposed in pairs, and have their convex surface turned towards the intestine,* so that, in the ordinary and healthy condition of the vessels, their contents are prevented from retrograding, and necessarily proceed from the small branches to the larger trunks. The coats of the lacteals are thin and transparent, and hence it is that these vessels, except when they are filled with chyle, are so difficult of detection. They seem, however, notwithstanding the apparent delicacy of their texture, to be possessed of considerable strength, and to bear being distended far beyond their ordinary dimensions without being ruptured. When they are completely filled with chyle, and still more, when they are forcibly distended by injections, the number of valves which they possess gives them a jointed or knotted appearance, and it seems to have been this circumstance, together with the white colour of their contents, which first attracted the notice of anatomists, and led to their discovery. With respect to their structure, besides the peritoneal covering which they possess in common with all the abdominal viscera, they seem to be composed of two distinct parts, an internal membrane, which by its duplicature forms the valves, and an external membrane, which constitutes the main substance of the vessel.

To these two obvious component parts many authors have added a muscular coat, and some anatomists of great respectability assert that they have actually detected transverse fibres, in which their contractile power is supposed to reside. Other anatomists, however, of equal authority, deny the existence of this muscular coat, and, it must be acknowledged, that the weight of the negative evidence seems to preponderate. But we may remark, on the other hand, that although these transverse fibres, constituting the muscular coat, in consequence of their transparency, or from some other cause, have hitherto eluded our observation, so that we have no positive proof of their existence, the lacteals certainly exhibit what appears to be very decided marks of contractility, and as they are not immediately connected with any organ equivalent to the heart, there seems to be no means, except their own contractility, by which their contents can be propelled.† See Chyliferous System; Lacteal.

* These were very minutely examined by Ruysch, Dilucid. Valvul., op. t. i. p. 1 . . 13; they are accurately described by Sheldon, p. 28.

† Mascagni, ps. i. sect. 4. p. 26, informs us that he could not detect the fibres; Cruikshank, on the contrary, conceives that he has seen them in the thoracic duct, p. 61 et alibi; and Sheldon speaks of the muscular coat as sufficiently obvious, p. 26. Meckel, Manuel, t. i. p. 185, does not admit their existence; and this is the case with Chaussier and Adelon, "Lymphatique," Dict. des Sc. Méd. t. xxix. p. 256. Breschet, art. "Lymphatique Systeme," Dict. de Méd. t. xiii. p. 389, considers it doubtful. Some curious observations were made by Desgenettes, on the action of the absorbents after the apparent death of the system, Journ. Méd. t. lxxxiv. p. 499 et seq. Similar observations were afterwards made by Valentin, t. lxxxvi. p. 231, et seq.; this action was not, however, supposed to depend on contractility. Wrisberg informs us that he has frequently seen spasmodic contractions in the large vessels and in the thoracic duct, Observ. Anat. Med. de Vas. Abs. Morb. in Comment. Soc. Reg. Gotting. v. ix. § 19. p. 149.

The anatomical structure of the lymphatics seems to be essentially similar to that of the lacteals; they are composed of a firm elastic membranous substance, capable of considerable distention without being ruptured, and furnished with numerous valves; like the lacteals they form very frequent anastomoses. We have the same evidence of their contractility as of that of the lacteals, although we are perhaps still less able to demonstrate the actual existence of their muscular fibres. We presume that they are likewise analogous to the lacteals in the nature of their office, and in their destination, although they differ from them with respect to their situation, or the parts of the body to which they are attached; the lacteals being confined to the membranes connected with the intestines, while the lymphatics are found in almost every part of the body, and connected with nearly all its various textures.* They differ also in the nature of the fluid which they contain, for while that of the lacteals, as has been stated above, is white and opaque, the fluid found in the lymphatics is transparent and colourless, so as to resemble water, from which they have derived their specific denomination.

It is very difficult, if not impossible, to trace the actual commencement of the lymphatics; but partly from anatomical researches, and partly from physiological considerations, we are led to conclude that they originate from the various surfaces of the body, of all descriptions, both internal and external. They resemble the lacteals, in passing from larger to smaller branches, which, after numerous anastomoses, unite in a few large trunks, the greatest part of which terminate in the thoracic duct. The great trunks of the lymphatics are, for the most part, arranged into two distinct series, one considerably more superficial than the other; it is observed that they generally follow the course of the great veins, but it may be doubted whether any direct communication

* For the extent of the lymphatic system, see Haller, El. Phys. ii. 3. 4, and the later account of M. Magendie, Physiol. t. ii. p. 174, and Jour. t. i. p. 3, who conceives that absorbent vessels have not been detected in the brain, the spine, and the organs of sense. Dr. Alison likewise conceives that they have not been detected in the cranium or nervous system, Outlines of Physiol. p. 76. Mascagni, however, appears to have detected a few small lymphatics in the brain, tab. 27. fig. 1. Monro secundus argues in favour of their existence, but it does not appear that he actually detected them in any part of the nervous system; on the Nervous System, ch. v. sect 1. and Three Treatises, ch. 4, 5.

exists between them during their course, and we are not aware of any physiological cause of this arrangement.

With respect to the mouths or origin of the lymphatics there is even more uncertainty than with respect to that of the lacteals; no anatomical investigation has hitherto been able to detect them, and although numerous facts of constant occurrence would seem to prove that their capillary extremities are distributed over all the surfaces of the body, it is from various pathological observations and from the analogy of the lacteals that we arrive at this conclusion.*

The thoracic duct is a vessel of considerable size, which is situated near the spine, and which extends from about the middle of the dorsal vertebræ to a short distance above the left subclavian vein; here it assumes an arched form, and is bent down until it enters the vessel near its junction with the jugular vein of the same side.† The duct, in its passage along the spine, is deflected in various ways, and proceeds in a somewhat irregular or tortuous course. For the most part it consists of a single trunk, but occasionally there are two trunks, either of the same or of different sizes, and we have not unfrequently partial appendages, which are added to the main trunk in different parts of its course.‡ Besides what is properly considered as the thoracic duct, in which all the lacteals and the greatest part of the lymphatics terminate, a portion of these latter, especially those which proceed from the upper part of the body and from the superior extremity of the right side, are generally collected into a separate trunk, named the great right lymphatic vessel, or right thoracic duct, which is connected with the right subclavian vein.§ These irregularities in the disposition and form of the thoracic duct may be considered as in no respect affecting its physiological uses, and to be no more than an anatomical variation of structure, probably depending upon some mechanical cause. It is, however, a circumstance of considerable importance in respect to the pathological conclusions that have been sometimes drawn from the obstructions of this organ, as well as from the experiments that have been performed upon it.* The structure and properties of the thoracic duct appear to be similar to those of the large trunks of the lacteals and lymphatics; its coats are comparatively thin and transparent, yet it is possessed of considerable strength, and is capable of being distended much beyond its ordinary bulk; it is furnished with numerous valves, and exhibits a great degree of contractility.

The lymphatic or conglobate glands† compose a very important part of the absorbent system, if we may judge from their number and their general diffusion over every part of the body. They are of various sizes, and are grouped together in various ways; occasionally they are single, but more frequently connected together in masses of considerable extent. They are found in almost every part of the body, always connected with the lacteals and lymphatics, and it is asserted that each one of these vessels, in some part of its course, passes through or is connected with one or more of these glands.‡ There are certain parts of the body in which they are more numerous, and are connected in larger masses; the lacteals are furnished with numerous glands in their passage along the mesentery, while the glands that belong to the lymphatics are found in the greatest number and largest masses in the groin, the axilla, and the neck. It is necessary to remark that this account of the distribution of the lymphatic glands applies only to the animals which belong to the class of the mammalia; in birds they are much more rare, and still more so in fish, while among the lower animals, where we have sufficient evidence of the existence of an absorbent system, the glands have not yet been satisfactorily demonstrated.§

With respect to the structure of these glands, as well as that of glands of other descriptions, a controversy has long existed among anatomists, whether they consist of a series of cells or follicles, as they have been termed, or whether they are composed simply of a congeries of vessels. The question may be regarded as still at issue; but it may be remarked that whereas the older anatomists generally leaned to the opinion of the follicular structure of the

* See Magendie, Physiol. t. ii. p. 175. Watson, however, conceived that he had detected their open mouths on the surface of the bladder, Phil. Trans. for 1769, pl. 16. Monro, in speaking of the lymphatics of fishes, remarks that there is "no doubt that they begin by open mouths," p. 30.

† For descriptions and plates of the thoracic duct the following works may be referred to; Haller, Prim. Lin. c. xxv. § 565; Op. Min. t. i. p. 586 et seq. tab. 11, 12; and El. Phys. xxv. 1. 10 . . 3: Albinus, Tab. Vas. Chylif.; Bolius and Saltzmann, in Haller, Disp. Anat. t. i.; Cheselden, Anat. pl. 26; Portal, Mém. Acad. pour 1770; Sabatier, ibid. pour 1786; Haase, De Vas. Cut. et Intest. Abs. tab. 2. and tab. 3. fig. 1; Mascagni, ps. i. sect. 7. art. 8. tab. 13, 15, 19; Sheldon, pl. 5; Cruikshank, p. 166 . . 176; Magendie, Physiol. t. ii. p. 160; Meckel, Manuel, § 1698.

‡ In Mascagni, tab. 15, we have an example of this irregularity.

§ This is said to have been discovered by Stenon in 1664; Meckel, Manuel, § 1703. See Haller, Prim. Lin. § 766 and Hewson's Enq. pt. 2. p. 61 . . 3, pl. 4. Cruikshank, p. 176, 7, conceives that Hewson was the first who described the lymphatics of the right side as being collected into one trunk. For the figure of this part, see Mascagni, tab. 19. nos. 185, 187.

* See on this subject Sir A. Cooper, in Med. Rec. and Res. p. 86 et seq., and Magendie, Journ. t. i. p. 21.

† Some of the late French physiologists prefer the term lymphatic ganglions, upon the principle that the term gland more properly belongs to an organ of secretion.

‡ Mascagni, ps. 1. sect. 4. p. 25: but this has been doubted by some anatomists; see Hewson, pt.2. p. 44, 5.

§ See Fleming's Zool. t. i. p. 338; Blumenbach's Comp. Anat. by Lawrence, ch. xiii. p. 256; Dict. des Sc. Méd. art. "Lymphatique," par Chaussier et Adelon, p. 249; Breschet, art. "Lymph. Syst.," Dict. de Méd. t. xiii. p. 397. Hewson informs us that birds have lymphatic glands in the glands,* the moderns have more frequently adopted the hypothesis of their vascular texture, so that we may consider this doctrine as supported by the most recent and elaborate researches.† See LYMPHATIC; GLAND.

§ 2. *The question of venous absorption considered.*—We have now been describing those organs, which are more specifically or appropriately termed the absorbent system, as being those parts the office of which is confined to this operation. But a very important and interesting question must now be discussed, whether the function of absorption is exclusively performed by the lacteals and the lymphatics.

The ancient anatomists and physiologists being unacquainted with the existence of the lacteals and the lymphatics, yet observing the evident effect of the operation of absorption, ascribed these effects to the action of the veins; and among the moderns, for some time after the discovery of what were more appropriately termed the absorbent vessels, it was still supposed that the veins co-operated with them, and in some cases were even the principal agents. This was the universal doctrine until the middle of the last century, and was one of the points which was decidedly maintained by Haller and his disciples.‡

The arguments by which the hypothesis of venous absorption was supported may be reduced to two classes, partly of a physiological and pathological, and partly of an anatomical nature; the first consisting of the results of experiments performed for the express purpose of investigating the subject, and of considerations derived from the morbid conditions of the system; the second depending more exclusively upon anatomical considerations. The experiments referred to consisted in passing injections from the veins to the absorbents, or the reverse, thus proving, as was supposed, that a direct connexion subsisted between these vessels. They were performed by the most skilful anatomists of the age, and were generally acquiesced in, without either the accuracy with which they were conducted, or that of the conclusions deduced from them, being ever called in question. Another class of experiments consisted in passing ligatures round the thoracic duct, so as to render it impervious to the passage of the chyle, when it was supposed that under these circumstances the nutrition of the animal was not interrupted,* and the same conclusion appeared to be substantiated by various cases of natural obstruction of the duct, or by certain malformations of the part, where it was either defective, or did not convey its contents, in the ordinary manner, into the veins. The other set of arguments, which are more purely anatomical, were derived from the supposed fact that various parts of the body, which were evidently subject to the operation of absorption, were without lymphatics, and that this was likewise the case with large classes of animals, the general structure of which, as far as regards their growth and nutrition, was analogous to that of the mammalia. Admitting these data, it seemed to be a necessary consequence that absorption must in these instances be performed by the veins, and hence it was inferred that in all classes of animals, and in all parts of the body, the veins co-operated with the lacteals and the lymphatics in the function of absorption.

The doctrine of venous absorption was first formally called in question, nearly at the same time,† by Wm. Hunter and by Monro secundus,‡ who, as it would appear, to a certain extent, entered upon the investigation independently of each other. The priority of discovery in this, as in so many points connected with anatomy, was for a long time the subject of warm controversy. We may remark concerning this question, that if the judgment of the present age should incline to ascribe to Hunter the original conception of the hypothesis, it is also disposed to allow to Monro the merit of establishing his opinion by a skilful and laborious process of experiment and observation.

The method which these illustrious rivals adopted was, first, to repeat the experiments of their predecessors, when, by noticing with scrupulous accuracy all the circumstances connected with them, they were able to demonstrate, or at least to render it highly probable, that in all those cases where injections had passed between the absorbents and the veins, either rupture or extravasation had taken place, and that, when this was carefully guarded

neck, but that they are not found connected with the absorbents of the abdomen, and that they are entirely wanting in fish and in the amphibia; Phil. Trans. for 1768, p. 217 et seq., and Enquiries, pt. ii. ch. 4, 5, 6. We have the same statement made by Monro, with respect to fish, p. 31. Antommarchi, on the contrary, asserts that birds, fish, reptiles, and amphibia have "pochissime glandule;" Prod. delle grande anat. di Mascagni, p. 8; but the statement is made in a general way, and without reference to any particular observations. It would appear that no specific apparatus for absorption has been discovered in any of the invertebrated animals.

* We have the authority of Nuck, in favour of the cellular structure, Adenologia, c. ii. p. 30 et seq., fig. 9 . . 12; also of Cruikshank, c. 14; and of Abernethy, Phil. Trans. for 1776, p. 27 et seq.

† See Hewson, v. iii. c. 2. pl. 2; Werner and Feller, Vas. Lact. and Lymph. Descript. tab. 2; their figures, however, appear to be exaggerated; Beclard, add. a Bichat, p. 231; Monro tert., Elem. v. i. p. 558. On the lymphatic glands generally see Haller, El. Phys. ii. 3. 16 . . 27; Boyer, Anat. t. iii. p. 243 . . 257; Mascagni, ps. i. sect. 5. p. 31; Rullier, ubi supra, p. 120 et seq.; Breschet, ubi supra, p. 394. For plates of the glands, see Mascagni, tab. 1. fig. 8 . . . 12, tab. 2. fig. 4 . . 8, tab. 4. fig. 2. tab. 8, 16, 26; Cruikshank, pl. 3; Sheldon, tab. 3, 5.

* Some experiments of this kind are referred to by M. Majendie, as having been performed by M. Dupuytren, Physiol. t. ii. p. 167. See also Richerand, Elémens de Physiologie par Berard.

† Medical Comment., passim; Cruikshank, Introd.; Walter, § 10 et seq.

‡ Dissert. de Sem. et Test. in Smellie, Thes. t. ii. and De Ven. Lymph. Valv.

against, the supposed connexion between the two sets of vessels could not be demonstrated.* In those experiments, where the thoracic duct had been artificially obstructed, or in the cases where the same thing had occurred as the result of disease or malformation, they were enabled to detect some supplementary vessels or some indirect channel, by means of which the chyle had been conveyed to the veins.

With respect to the parts of the body, or to the animals of an inferior order, which were supposed not to be furnished with absorbent vessels, by prosecuting their examination with more care they gradually detected the existence of these vessels in many cases where they had not been previously known to exist; and they were discovered in so many new situations that it became a fair inference that every part of the body, and every animal whose structure is generally analogous to that of the mammalia, is provided with an appropriate apparatus of absorption, although, from the texture or the peculiar nature of the vessels, it may be very difficult actually to demonstrate their existence. In this train of investigation the labours of William Hunter and Monro were ably seconded by various anatomists, both in this country and on the continent, among whom we may select the distinguished names of John Hunter, Hewson,† Cruikshank, and Mascagni.

* We must, however, bear in mind that we have the high authority of Meckel in favour of the communication between the lymphatics and the veins; "Sur Resorption," Nouv. Mém. Acad. Berl. ann. 1770, p. 19 et seq.

The researches of some of the most accurate among the anatomists of the present day seem also to show that occasional communications exist between some of the lymphatics and the contiguous veins; but this is a different kind of relation from that which was contemplated by the older anatomists between the sanguiferous and the absorbent systems. This point is fully discussed by Fohmann, in his late work, "Sur le commun. des vaiss. lymph. avec les veins," where we have an account of his own observations, as well as those of preceding anatomists; he conceives that the observations of Lippi, of which an account is given in his "Illustrazioni fisiol.", are not correct: see also the remarks of Antommarchi, Ann. Sc. Nat. t. xviii. p. 108, 9. The observations of Fohmann have been confirmed by Lauth, in his "Essai sur les Vaisseaux Lymph." We may here refer to the observations of Bleuland, which were made fifty years ago, on what he styles the arteriolæ lymphaticæ, by which a communication was supposed to be maintained between the sanguiferous and absorbent systems; see his "Experim. Anat." Panizza of Pavia also opposes the doctrine of Lippi; Osservazioni, c. 3 and 5. Mr. Abernethy, in examining the vascular system of the whale, discovered certain communications between the sanguiferous and the lymphatic vessels; but the nature of the connexion is perhaps a little doubtful; Phil. Trans. for 1796, p. 27 et seq. For further information on this subject, see a lecture on the lymphatic system lately published by Dr. Graves. Mr. Kiernan, in his elaborate researches into the anatomy of the liver, gives it as his opinion that the doctrine of Lippi has been "satisfactorily confuted" by Panizza; Ph. Tr. 1833, p. 729. See Elliotson's Physiol. p. 128, 9; s. 1. also a paper in Ann. Sc. Nat. t. 21. p. 252 et seq.

† Phil. Trans. for 1768 and 1769; in these volumes are contained his account of the lymphatics of birds and fishes.

The experiments of Hunter may deserve to be particularly noticed, because they consisted not merely in repeating and correcting those of preceding anatomists; but, in addition to these, he entered upon a series of original researches, which are highly characteristic of that ingenuity and acuteness for which he was so eminently distinguished. The experiments essentially consisted in filling portions of the small intestines with a fluid, the sensible properties of which might be easily recognized, and retaining it there so as to allow of its entering into the veins of the mesentery, were they capable of absorbing it; the result, however, is stated to have been that in no instance could the fluid be detected in these veins. These experiments appeared to have been so carefully conducted, and so frequently repeated, as to have impressed the minds of anatomists and physiologists with a conviction that the lacteals were the only vessels which are concerned in the absorption of the chyle; and although it was not possible to perform analogous experiments on the lymphatics, yet it seemed a natural inference, that we might extend to them the conclusion which had been established with respect to the lacteals.*

In proof of lymphatic absorption various facts were brought forward, which seemed clearly to show that when extraneous or noxious substances were introduced into the system, it was done by the medium of the lymphatic vessels rather than of the veins; and it was thence argued that, as these vessels perform the function of absorption under certain circumstances, and that we are not acquainted with any other office which they serve in the system, we may conclude that they are the sole agents in the action of absorption. Although the argument, as applied to the lymphatics, was far less direct and conclusive than to the lacteals, yet the analogy between the two organs appeared so strong, and so many concurring circumstances appeared to favour the doctrine, that it was very generally received, and may be considered as having been the established opinion at the conclusion of the last century.†

This unanimity of opinion was, however, of very short duration; for anatomists had scarcely ceased to contend for the honour of the discovery of the exclusive action of the lacteals and the lymphatics in the function of absorption, when the doctrine itself was impugned by physiologists of the first eminence, who supported their views by a powerful train of arguments, enforced by numerous experiments,

* Med. Comment. c. 5 p. 42..8; Cruikshank, c. 5. p. 21.

† See the judicious summary of opinions in Mascagni, ps. i. sect. 2, 3: and in Rullier, ubi supra, p. 136 et seq. The doctrine of venous absorption was, however, still maintained by many intelligent anatomists, especially by the high authority of Meckel, De Fin. Ven. et Vas. Lymph. 1772; and of Walter, Sur la Resorption, ubi supra. See particularly his general conclusion, § 92: he conceives that the veins are the only agents in the absorption which is carried on at the surface and from the cavities of the body.

and by various pathological considerations. Of these authors, one of the first, both in point of time and of ability, is M. Magendie, whose opinions on this subject, connected as as they are with some of those of his most distinguished countrymen, have been brought forward in a form which entitles them to the fullest and most respectful attention.

Of the two sets of observations by which Hunter and Monro attempted to establish their hypothesis respecting lymphatic absorption, those derived from the analogy of the lacteals may still be considered as maintaining their ground; while the conclusion which they deduced from their experiments has been called in question, partly because it was thought not to be the legitimate inference from the experiments, and partly in consequence of the experiments themselves having been conceived to be imperfect or incorrect. It is principally upon the latter ground that the force of the objections has been rested; and it has been, first, by repeating the experiments of Hunter, and afterwards by varying them in different ways, that their insuffficency has been attempted to be proved. It has been stated above that the main support of the doctrine of the exclusive action of the lacteals and the lymphatics was derived from those experiments of Hunter, in which it appeared that, when the circumstances were the most favourable for the reception of substances into the veins of the mesentery, they could not be proved to have entered these vessels; and hence it was concluded that the veins did not, under any circumstances, possess the power of absorption.

We are informed, however, by M. Magendie that experiments have been performed by himself and by M. Flandrin, which afforded directly contrary results, and that these experiments were so frequently repeated, and varied in such a manner, as to leave no doubt of their accuracy.* We have here the opposing testimony of individuals, both of them of the highest authority in science, and eminent for their skill in experimental research. From personal considerations it might be difficult, if not impossible, to decide between them; but when we take into account the circumstance that the experiments of MM. Magendie and Flandrin were executed subsequently to those of Hunter, and with the benefit of his experience and that of the improved state of the science during the last half century; when, moreover, we are informed that the experiments of the French physiologists were more numerous than those to which they were opposed, and that their results were uniform and unequivocal, we can scarcely refuse our assent to the conclusion, that the experiments of John Hunter do not afford a sufficient foundation for the doctrine of the non-absorption of the veins.

But the French physiologists have not satisfied themselves with repeating the experiments of Hunter; they have extended them in various ways, and have obtained results supposed to be still more decisive in favour of venous absorption. Among the most important, or at least the most curious of these, is an experiment which was performed by M. Magendie, in conjunction with M. Delille, and which was conceived by these physiologists to afford the most unequivocal proof of their hypothesis. It consisted in dividing all the parts of one of the posterior extremities of a living animal except the artery and the vein, and in applying to the foot a poisonous substance; when, in the short space of a few minutes, the effects of the poison on the functions of the animal were most distinctly apparent.* It was argued that in this case there was no mode of communication by which the poison could be conveyed from the extremity to the centre of the system except the vein, and that, therefore, the vein must have acted as the absorbing vessel. The experiment was rendered more striking, and, as was conceived, more conclusive, by dividing the bloodvessels themselves and introducing metallic tubes between the divided ends, through which alone the two currents of the arterial and venous blood respectively could pass in forming the communication between the extremity and the trunk of the animal, yet, under these apparently unfavourable circumstances, the deleterious effects were manifested on the system as in the former case.† Experiments of this description appear to have been sufficiently multiplied to establish the fact, that the poison in these cases passed along the vein, and was conveyed in the general mass of the blood.

The result of these experiments is no doubt very remarkable, and what would scarcely have been anticipated; yet we may remark, that there is one circumstance connected with them, which, in a great measure, invalidates the conclusion that has been supposed to follow so necessarily from them. It may be inferred from the expression made use of, that the poison employed, which was the extract of the upas tree, was inserted by a puncture or incision into the foot of the animal, and would, therefore, in the first instance, be mixed with the blood; so that the only deduction which we are warranted to draw from the experiment is, that the venous blood, being infected with the poison, had the power of communicating the infection to the system at large.‡ On this view of the subject we should not regard the above as a case of absorption, but merely as an instance of the power of extraneous substances, under certain circumstances, of uniting with the venous blood and retaining their specific properties.

In connexion with these experiments of M. Magendie and his associates, we have another series which were performed by MM. Tiedemann and Gmelin, and which bear directly upon the question of venous absorption. Their object was to ascertain whether there

was any direct communication between the organs of digestion and the bloodvessels except by means of the lacteals. For this purpose they mixed with the food of an animal various substances, which by their colour, odour, or other sensible and physical properties, might be easily detected in the fluids of the body. After some time the animal was examined, and the result was that unequivocal traces of the substances were not unfrequently detected in the venous blood and in the urine, while it was only in a very few instances that any indicatiou of them could be discovered in the chyle. The colouring matters employed were various vegetable substances, such as gamboge, madder, and rhubarb; the odorous substances were camphor, musk, assafœtida, &c.; while, in other cases, various saline bodies, such as muriate of barytes, acetate of lead and of mercury, and some of the prussiates, which might be easily detected by chemical tests, were mixed with the food. The colouring matters, for the most part, were carried out of the system without being received either into the veins or the lacteals; the odorous substances were generally detected in the venous blood and in the urine, but not in the chyle, while of the saline substances many were found in the blood and in the urine, and a very few only in the chyle.*

The conclusion, which we are disposed to regard as the fair inference, from the facts and arguments that have been adduced on the subject of venous absorption, is that, although there are strong analogies and various pathological considerations which would induce us to confine the function of absorption to the lacteals and the lymphatics, yet that the result of the experiments, although not uniform, is upon the whole in favour of venous absorption. It only remains for us to inquire how far the state and actions of the parts on which the experiments were made, were so far necessarily deranged by the process to which they were subjected as to render the results inapplicable to the natural condition of these organs. Now this certainly appears to be the case in the experiments of MM. Magendie and Delille, where the poisonous substance was introduced into the blood; and the same remark may probably be applied to a number of pathological occurrences that have been supposed to afford a proof of venous absorption, such, for example, as the case of ulcerated surfaces, where pus has been detected in the veins, and still more extraneous bodies, which may have been either accidentally or designedly inserted into the ulcerated part.† But it is not unreasonable to suppose that in these instances, in consequence of the erosion and partial destruction of the organs, the small branches of the veins will present an external orifice, through which the pus or other extraneous substance may be immediately received into the sanguiferous system, nearly upon the same principle as in the experiments related above.

The experiments of MM. Magendie and Flandrin, the results of which were so opposite to those of Hunter, do not indeed lie open to the same objection; but even here there is perhaps some ground for inquiry, before we implicitly adopt the conclusion that has been deduced from them. The experiment, as originally performed by Hunter, necessarily implies a degree of mechanical violence, which must produce a considerable derangement of the actions of the parts concerned. Acute inflammation of a peculiarly irritable and sensitive organ must have ensued, the vessels of all descriptions must have become much distended; rupture and extravasation may have been not an improbable consequence of this inflammation and distention, and, in short, a general derangement both of structure and functions may have occurred, which must prevent us from drawing any positive inference respecting their natural condition.

These observations will apply with much greater force to a subsequent variation of the experiment, which consisted in entirely detaching a portion of the intestine from the remainder of the tube, and filling this divided portion with the fluid, which, as in the former case, was detected in the vein of the mesentery. This arrangement was supposed to afford a still more decisive proof of venous absorption than the experiment in its original state, and if we consider the mechanical disposition of the organ only, we may admit that this would be the case. But it is obvious, on the other hand, that the vital actions of all the parts concerned must have been much more deranged, and that, on this account, we ought to be proportionally cautious in the application of such experiments to our physiological theories.

We would venture to suggest, that the remarkable discrepancy which exists between the experiments of Hunter and of the French physiologists may perhaps be reconciled, by having recourse to the supposition, that in the former case there was less violence used to the parts, and that they were left more in their natural condition; whereas M. Magendie, as we presume, from a desire to render the effect more certain or more decisive, either produced a greater degree of distention of the intestines, or, in some other way, caused a greater derangement of the parts, so as to produce a difference in the results. But this idea is offered merely as a conjecture, from which we do not venture to deduce any of our conclusions.

Upon the whole we feel disposed to regard the experiments of MM. Tiedemann and Gmelin, and those of an analogous kind, in which extraneous substances were found in the venous blood, and in some of the secretions, when they could not be detected in the chyle, as more directly

* Ed. Med. Journ. vol. xvii. p. 455 et seq. On the absorption of foreign bodies see the early experiments of Lister and Musgrave, Ph. Trans. for 1683 and 1701; also Lowthorp's Abrid. vol. iii. p. 101 . . 5, and La Motte's Abrid. par. 2. ch. iv. p. 75, 6; with Haller's sanction of their accuracy, El. Phys. xxiv. 2. 3; see also J. Hunter, in Med. Com. p. 44 et seq., and Cruickshank, ch. viii. On the other hand, the experiments of M. Magendie and his friends would lead us to form an opposite conclusion; Elem. t. ii. p. 168, 9. See Elliotson's Physiol. p. 126.

† See the experiments of Mr. Key, in Med. Chir. Trans. vol. xviii. p. 212, 13.

favouring the doctrine of venous absorption, because they are free from the objection which must always attach to those operations, where any considerable degree of mechanical violence has been employed. It may indeed be objected, that in these cases, the examination of the body did not take place at the proper point of time; that, in some instances, it was made at too early a period, before the extraneous body had time to enter the lacteals, and, in other cases, not until it had left them, and had been discharged from the thoracic duct into the veins. But this contingency must be regarded as rather a possible than a probable occurrence, and it is obvious that if any considerable number of experiments were performed, we can scarcely suppose it to exist.

The conclusion that we are disposed to draw from all the facts and arguments that have been brought forwards on the subject is in favour of the possibility of venous absorption, at least under peculiar circumstances; at the same time that there are strong anatomical considerations, which would induce us to suppose, that in the ordinary actions of the system, the function of absorption is confined to the lacteals and the lymphatics.*

§. 3. *Inquiry into the mode in which the absorbents act.*—In entering upon this inquiry there are two distinct subjects which present themselves for our consideration; we must first ascertain by what means the substances that are absorbed enter the mouths of the vessels, and, in the second place, after they have entered the mouths, how they are conveyed along the vessels themselves.

With regard to the first of these points we may remark, that while there is so much uncertainty respecting the anatomical and physiological structure of the mouths of the lacteals, and still more, while we are completely ignorant of that of the lymphatics, we cannot expect to arrive at any definite conclusion concerning the mode of their action. We may, however, venture to say, that there is strong reason to believe, that the absorbents terminate in very minute or capillary vessels, that have open mouths, and that these mouths are brought into contact or close approximation with the substances to be absorbed. Hence, by an analogy, which it must be acknowledged is somewhat vague, the action of these minute vessels has been referred to capillary attraction. But it may be doubted whether in this inference, as in so many other cases of physiology, we have not been misled by a mere nominal resemblance, and have applied the term capillary to the action of the lacteals, because it had been used to denote their dimensions. Perhaps, strictly speaking, there is scarcely a single circumstance, in which the action of the lacteals can be assimilated to that by which fluids are taken up by capillary tubes. The structure and consistence of the tube itself, the nature of the substance on which it is supposed to act, and their relative situation, are all of them more or less different from what occurs in the ordinary cases of capillary attraction. And if there is a difficulty with respect to the lacteals, where we have at least some indistinct evidence of the mechanical disposition of the parts, which may seem favourable to this hypothesis, in a much greater degree will it exist with respect to the lymphatics, where we have nothing to direct our opinion, except the analogy which may be presumed to exist between the two species of absorbent vessels.

In consequence of these difficulties, and of the supposed inadequacy of the mechanical theory, many physiologists have had recourse to a certain specific action of the vessels, and have conceived that the chyle was taken up by a power, which has been supposed to be analogous to an elective attraction between the vessel and the substance that is absorbed.* There are indeed many circumstances which would appear to indicate, that a certain kind of selection is exercised by the mouths of the vessels, for, as far as we are capable of judging, when substances possessed of the same consistence and physical properties are placed in contact with these mouths, some of them are received, while others are rejected. But we must remark, that the same objection may be urged against this as against the former explanation, that the term elective, which is borrowed from the chemical relation of bodies to each other, is perhaps as little applicable to the case under consideration as that of capillary, which refers more to their mechanical action.

Discarding therefore all these analogical illustrations, which are at least of doubtful application, we may remark, that the lacteals ought to be regarded, like every other part of the animal frame, as vital organs, possessed of appropriate and specific powers; that, in this instance, we are not able to refer to any general principle the train of events now under consideration, and that we must therefore be satisfied with simply stating the fact, that the lacteals have the power of taking up by their extremities certain substances, with which they are in close approximation; that, for the most part, the substances which they receive are the elements of the chyle, that they select these from the contents of the intestinal canal, and

* A summary of M. Magendie's experiments and deductions is contained in his Journ. t. i. p. 18 et seq. and his Elem. t. ii. 238 . . 243; on this subject see also Bichat, Anat. Gén. t. ii. 104, 5, with the remarks of Beclard, p. 130. We must not omit to notice the experiments of M. Ségalas, who by dividing the bloodvessels of a portion of the intestine, and leaving the lacteals, thus, as it were, reversing the experiments of M. Magendie, found that no absorption took place, and hence concludes that the lacteals do not possess this power; Magendie's Journal, t. ii. p. 117 et seq. So singular a conclusion must, we conceive, lead us to place but little confidence in the result of such complicated experiments. Franchini of Bologna thought that the lymphatics absorb "la sostanza assimilabile," but that the substances which do not directly contribute to nutrition are absorbed by the veins; Consider. Fisiol. sull' Assorb. p. 44.

* See Bichat, Anat. Gén. t. ii. p. 125; Dumas, Physiol. t. ii. p. 397, 8; Young's Med. Lit. p. 112; Bell's Anat. v. iv. p. 290. M. Magendie, however, is disposed to reject all these hypothetical explanations; Elem. t. ii. p. 162, 3, and Journ. t. i. p. 3. et alibi.

that, except under peculiar circumstances, they reject every other substance.*

When the elements of the chyle have been received into the lacteals, it appears to undergo a certain degree of elaboration, by which it is farther assimilated and perfected, an operation, the intimate nature of which we are unable to explain, but which, as well as its entrance into the mouths of the vessels, we correctly refer to their vital action. After the chyle has entered the lacteals, there is less difficulty in conceiving the subsequent steps of the process. We are at least able to generalize the operation, by referring it to contractility, the same power which originates motion in other parts of the system. It must, no doubt, be admitted, that the existence of the muscular fibres of the lacteals has not beeu satisfactorily demonstrated, and that, until this has been accomplished, our opinion can only be regarded as hypothetieal : but we have here the advantage of being able to assign a probable and sufficient cause of the effect, and are aware of the point towards which we must direct our future investigations.† Before we conclude this branch of the subject, we may remark concerning the contents of the lacteals, that, under ordinary circumstances, we have no decided proof of these vessels containing any substance except the elements of the chyle, and that, although in some of the experiments referred to above, extraneous bodies have been occasionally found in them in minute quantity, these cases must be regarded as exceptions to the general fact.

With respect to the ehyle itself, it has been a subject of examination by the chemists, whether its properties are always uniform in the same animal, or class of animals, under the various circumstances of age, constitution, and still more of diet, to which they are subject. But it may be necessary, before we enter upon this inquiry, to premise a few remarks upon the meaning of the terms chyme and chyle. By the older physiologists they were very generally employed as synonymous, and this is still the case with some of the modern writers, more especially on the continent.‡ A clear distinction between them has, however, been pointed out and recognized, and as there appears to be an essential difference between them, it is desirable that it should be generally adopted. The first of these substances is the immediate product of the action of the gastric juice on the aliment, as received into the proper digestive stomach, while the latter is the substance which is produced by a subsequent part of the process of digestion. The conversion of ehyme into chyle seems to commence shortly after it leaves the stomach, and while it still remains in the duodenum, is so far advanced as to be reduced into a condition proper for being received into the lacteals. There is, however, reason to believe that the completion of the process takes place in the lacteals themselves, and even that it is not until the chyle arrives at the thoracic duct, or at least at the great trunks of the lacteals, that it is fully elaborated. The nature of the change which the chyme experiences in the duodenum, and the agents by which this change is effected, what share the secretions of the part itself, the bile, or the pancreatic juice have in the operation, are questions that still remain in discussion, and which will be considered in the appropriate parts of this work.*

For the analysis of the chyle we are prineipally indebted to Vauquelin, Marcet, and to Dr. Prout. Vauquelin employed the chyle of the horse, as taken from the large trunks of the lacteals and from the thoracic duct.† The experiments of Marcet were principally directed to the inquiry, how far the chyle of the same kind of animal was affected by differences in the diet, according as it consisted principally of animal or vegetable substances.‡ Dr. Prout's experiments on the chyle extended both to its general properties, and to the differences produced by different kinds of diet, while, in addition to these points, he entered into a very interesting examination of the successive changes which it experiences, from its first entrance into the lacteals until its final deposition in the thoracic duct.§ The result of these experiments, as far as our present inquiry is concerned, tends to shew that the vegetable chyle differs somewhat, in its physical and ehemical properties, from that of animal origin, and that the chyle, when it first enters the lacteals, is in a less perfect state, while it becomes more assimilated to the blood in proportion as it advances towards the thoracic duct.

With respect to the means by which the animalization of the chyle is perfected after it enters the vessels, we have no certain information, and we have scarcely any analogy which may assist in guiding our opinion. What is termed by modern physiologists the action of the vessels, by which so many operations of the animal economy are supposed to be effeeted, we may regard rather as an expression which serves as a convenient veil for our ignorance, than as throwing any light upon the process. We have no evidence that any addition is made to the chyle while in the lacteals ; and indeed we can scarcely suppose it possible that this is the case, so that the only conceivable effect of this action is reduced to the motion which is imparted to the chyle by the alternate contraction and relaxation of the vessels, in conse-

* See the remarks of MM. Chaussier and Adelon, ubi supra, p. 272 et seq. ; also Adelon, Physiol. t. iii. p. 85 et seq. ; and Alison's Outlines, p. 79.

† This is essentially the doctrine of Haller, Prim. Lin. c. xxv. §. 568. Sheldon, p. 28, and Cruikshank, c. 12, are advocates for this doctrine ; but it is opposed by the high authority of Mascagni, ps. i. sect. 4. p. 27, 8.

‡ This appears to be the case with M. Rullier, art. "Chyme," in Dict. de Méd. t. v. p. 241 . . 4 ; M. Adelon, however, clearly marks the distinction, Physiol. t. iii. p. 25, et alibi.

* See the remarks of Adelon, art. "Chylifères," Dict. de Méd. t. v.

† Ann. Chim. t. lxxxi. p. 113 et seq. ; Ann. Phil. v. ii. p. 220 et seq.

§ Ann. Phil. v. xiii. p. 22 . . 5.

quence of which the constituents may be more completely mixed together, and to a certain degree of pressure and temperature to which it is exposed, which may modify any spontaneous change that might otherwise take place in the arrangement of its elements. But to whatever cause it may be referred, we must consider the chemical and physical change in the nature of the chyle as one effect produced by the lacteals, as well as the progressive motion which is imparted to their contents.

In the present state of our knowledge on the subject, it remains for us to consider whether we have any independent evidence of the existence of the muscular fibres of the absorbent vessels, whether, if their existence be proved, and their contractility thus established, it would be necessary for us to search out for other causes of the effects, and lastly, to what other principle the acknowledged effects might be attributed, should it appear, upon full consideration, that the assigned cause is insufficient or inadequate.

The above considerations lead us to give an account of the hypothesis of the action of the absorbents, which has been proposed by M. Magendie. He had ascertained, by a previous train of experiments, that according to the condition of the system as to depletion or plethora, the process of absorption was respectively accelerated or retarded. Hence he draws the conclusion, which, however, we conceive not to be a necessary consequence of the premises, that the function depends on a mere mechanical principle, independent of any vital action. The mechanical principle to which he has recourse, and which he thinks can alone account for the effect, is that of capillary attraction; but this he conceives not to take place from the open mouths of the vessels, according to the ordinary conception of the subject, but that the fluid is imbibed by the substance of the vessel itself, and is, as it were, filtered through its pores.* He explains its further progress by supposing, that when it has entered these pores, it is carried forwards by the current of the fluid previously in the vessel.

To prove his idea of the permeability of the parietes of the vessels, he instituted a series of experiments on the veins of an animal shortly after death, when he found that they were capable of imbibing and transmitting certain fluids with which they were placed in contact. Still farther to substantiate the hypothesis, M. Magendie repeated a set of analogous experiments on the vessels of a living animal. They consisted essentially in detaching a portion of one of the great veins, and applying to its surface the solution of some narcotic or poisonous substance, the effects of which were, in a short time, manifested in the system at large.*

This doctrine of imbibition and transudation has been embraced by M. Fodéra, who has endeavoured to confirm the opinion of M. Magendie by additional experiments, which he conceives tend directly to prove that the vessels of the living body possess this power of imbibition. The method which he adopted to prove this point, in the most unequivocal manner, was to inject into two separate cavities of the body two fluids, which by their union produce a compound, the presence of which may be easily detected, and which could be formed by no other means except by this union. For example, into the cavities of the pleura and the peritoneum were respectively injected the solutions of the ferro-prussiate of potash and of the sulphate of iron, when it was found, after a certain length of time, that various membranes and glands, connected with the thorax and the abdomen, were tinged with a blue colour.

M. Magendie afterwards performed an experiment, which seemed more directly to bear upon the question, where a solution of the ferro-prussiate was retained in a portion of the intestine, at the same time that its external surface was placed in contact with a solution of the sulphate of iron: the part was then exposed to the galvanic influence, the result of which was that a blue tinge was communicated to the sulphate. We are further informed, that according to the direction of the galvanic current, the blue colour was produced either in the sulphate or in the ferro-prussiate. From these experiments M. Fodéra draws the conclusion, that the processes of absorption and of exhalation may be referred to the mechanical operations of imbibition and transudation, which take place through the pores or capillary openings of the various textures of the body.†

On these experiments, and the conclusion deduced from them, we shall remark, that the facts appear to prove that membranes, perhaps during life, and certainly after death, before any visible decomposition has taken place, are capable of transmitting fluids through their texture; but we conceive that the analogy between this case and that of the entrance of chyle into the lacteals is so incomplete, that we can draw no inference from the one of these events which can be fairly applied to the other. Both the mechanical and the physiological properties of membranes and vessels differ much from each other, while the nature of the fluids employed in

* Journ. t. i. p. 6 et seq. and Dict. de Méd. et Chir. Prat. "Absorption," t. i. p. 91 et seq. The doctrine of transudation was maintained by many of the older physiologists; see Kauw Boerhaave, de Persp.; also Haller, El. Phys. ii. 2. 23; more lately it was supported by W. Hunter, Med. Com. ch. 5; by Walter, ubi supra, § 28 . . 35; and by Mascagni, ps. 1. sect. i. and is zealously maintained by his commentator Bellini, t. i. not. 4. p. 33 . . 6. The "pénétrabilité" of the cellular texture was one of the fundamental doctrines of Bordeu, Recherches sur le Tissue muqueux, § 72.

* Journ. t. i. p. 9, 10.

† "Recherches sur l'Absorption et l'Exhalation," and Magendie's Journ. t. iii. p. 35 et seq.; see, also Med. Repos. v. xix. p. 419, et Med. Journ. v. xix, p. 488, 9. On this subject see the remarks of Tiedemann, Traité de Physiol. par Jourdan, § 168. p. 242. Mr. Mayo remarks, that the principle of imbibition and transudation affords a more easy explanation of the experiments of MM. Magendie and Ségalas, than that of venous absorption; Physiol. (3rd ed.) p. 97 et seq. See the remarks and objections of Sir D. Barry, Exper. Researches, p. 80 . . 2 et alibi; also Elliotson's Physiol. p. 133.

the experiments is totally different from any thing to which the parts are exposed under ordinary circumstances. It may be further remarked, that if the texture of the vessels is so permeable to fluids of all kinds and in all directions, it is difficult to conceive of any cause which can retain them there when they have entered, and which should prevent their escaping through the same pores when any pressure is made on the contents of the vessels by its contractile power or by any extraneous force.

And it may be further remarked concerning these experiments, without impugning the accuracy or the dexterity of the operator, that they imply a degree of minuteness in the execution, and of attention to a variety of concurrent circumstances, and are altogether of so extremely delicate a nature, as to render it undesirable that any physiological conclusion should be founded on them. If a single bloodvessel be divided, however minute, and its extremity be exposed, or even if a single cell of the membranous texture be laid open, so as to admit of the introduction of the fluid, the essence of the experiment is destroyed, and its results must become equivocal.

Another hypothesis respecting the nature of absorption has been lately brought forward by Sir D. Barry, according to which it immediately depends on atmospheric pressure, either exercised directly on the surface of the body, or acting indirectly on the absorbents through the medium of the great internal cavities. The experiments on which the hypothesis rests consisted in introducing a portion of some poisonous substance into a wound, and forming a vacuum over it by means of a cupping-glass; when, by contrasting the effect of the poison in this case with that which ensues from the same application where the cupping-glass was not employed, he concludes that the process of absorption was suspended by removing the atmospheric pressure, and he hence infers that this pressure is the cause of absorption.*

The results of these experiments, in a practical point of view, are of great interest, but with respect to the physiological conclusion that has been drawn from them, there are various circumstances to be taken into account, which appear not to have been duly attended to.

In the first place, a similar kind of objection occurs in this case as in the experiments of MM. Magendie and Delille related above, that the poison was introduced into a wounded part, and would therefore be immediately mixed with the blood and carried into the general circulation. The effect of a vacuum formed over the divided extremity of a vessel, must be to retard the progress of its contents, whatever be its description, or in whatever cause it originates. This effect is therefore not specifically applicable to absorption, even in the natural state of the parts; and when we consider that in this case there was an artificial opening made into the vessel, we may venture to affirm that the conclusion which was drawn from it is in no respect the necessary inference from the facts.

* Barry's Exper. Researches, pt. 2 "On Absorption;" Alison's Outlines, p. 85; Bostock's Physiol. v. ii. p. 593 et seq.

And besides this general objection, it may be fairly questioned how far the removal of pressure from the surface of the body could act in retarding the progress of a fluid along a vessel which has no external opening, and which is provided with valves, such as is strictly the case with the lacteals, and may be almost said to be so with the lymphatics. And with respect to the lacteals, it appears a very obvious objection to the hypothesis, that they are altogether defended from the effects of atmospheric pressure, either as applied directly, or as indirectly acting on them through the medium of any of the internal cavities. Besides, we have sufficient proof of the spontaneous and independent action of these vessels, whatever may be our opinion respecting the existence of their muscular coat, and to whatever principle we may refer this action, and we have thus an actual cause for the propulsion of their contents, although it is impossible to estimate its actual amount, it would appear unnecessary to search for any farther agent, unless we have good ground for concluding that the existing cause is inadequate to produce the effect required.

Cutaneous absorption.—There is a branch of the subject to which we must now direct our inquiry, the existence and extent of what has been termed cutaneous absorption. When we trace the progress of the lymphatic vessels from their great central trunks, and follow them through all their minute ramifications, we find that many of them appear to have their origin from the surface of the body,* and hence we are led to suppose that the function of absorption is exercised, to a certain extent, by the cutis, or the parts immediately connected with it. That this is the case is proved by various pathological facts; we have daily opportunities of observing, that various medicinal substances, by mere application to the surface, and still more when aided by friction, produce the same effect upon the system as if they had been received, in the ordinary way, through the medium of the stomach. By this means mercury manifests its specific action on the salivary glands, the salts of lead destroy the contractility of the muscular fibre, while opium, tobacco, and other narcotics produce their peculiar effects on the nervous system.

But, besides this kind of absorption, which is brought about by the substances being, as it were, mechanically forced into the pores of the skin, and thus applied to the mouths of the lymphatics, it was an opinion very generally embraced by the older physiologists, and still retained by many of our contemporaries, that the lymphatics, which are distributed over the surface, possess the power of imbibing water, when simply applied to it by the immersion of the body, or even when it is exposed to

* See Haase, De Vas. Cut. et Intest. Absorb., tab. fig. 2; also, Mascagni, tab. 2. fig. 9..28, tab. 3.

aqueous vapour diffused through the atmosphere. This supposed power of cutaneous absorption was called in to account for various physiological or pathological facts, for which it appeared to afford a plausible explanation, while, on the other hand, the easy mode in which it appeared to account for these facts was made use of as the great argument to prove its existence. The statical experiments of Sanctorius, which have, since his time, been so much multiplied and extended, were supposed to prove unequivocally that the body is capable of gaining weight independently of any substance received into the stomach, and to account for this addition, recourse was always had to the cutaneous absorption. Of late, indeed, it has been discovered, that a part of the effect ascribed by Sanctorius to the action of the skin is in reality due to the lungs, but still, after making the necessary deduction for the operation of the latter organ, there remained a certain increase of weight, which it was supposed could only be accounted for by admitting the existence of the cutaneous absorption.*

The doctrine of cutaneous absorption has, however, been altogether called in question by Seguin, who performed a series of experiments, which consisted in immersing a part of the body in a saline solution, for example, that of corrosive sublimate, the effects of which on the system at large would be easily recognized, if any part had been absorbed. The result was, that when the cuticle was entire, no effect that could be attributed to absorption took place, and the conclusion seemed not unnatural, that under ordinary circumstances it did not exist.† Currie was led to form the same conclusion by accurately weighing the body before and after immersion in the warm bath, under circumstances which were conceived to be favourable to the process,‡ and as the results of his experiments coincided with those of Seguin and others, the doctrine of cutaneous absorption, except under the particular circumstances mentioned above, was very generally abandoned. Experiments have been adduced to prove, that even under these particular circumstances, when substances are applied by friction to the surface, they do not enter into the mouths of the vessels, but being volatilized by the heat of the body, that the vapour thus produced is inhaled by the lungs;§ an opinion which one might be inclined to think was almost too extravagant to be seriously maintained.

The subject of cutaneous absorption has been lately investigated by Dr. Edwards, with that skill and address which he has applied to so many departments of physiology. By a number of experiments, which were performed on cold-blooded animals, where it was more easy to observe the effects, he found that absorption was carried on, to a considerable extent, when the animal, or a part of it was immersed in water. The conclusion which the experiments seemed to warrant was, that transudation and absorption are, at all times, going forwards at the surface, but that the operations proceed at different rates, according to the circumstances in which the animal is placed, and that the body gains or loses weight, in proportion to the excess of one of them above the other. The analogy of the cold-blooded animals he applies to those with warm blood, and he supposes that they are subject to the same double action, a conclusion which appears to be confirmed by some experiments that were performed on guinea-pigs immersed in moist air, when an increase of weight was found to have taken place, which, after taking every circumstance into consideration, seemed necessarily to depend on absorption.* With respect to the experiments of Seguin, Dr. Edwards is not disposed to call their accuracy in question, but he points out various circumstances connected with them, which he conceives would tend to increase the transudation, and to diminish, or even entirely to suspend the absorption.† The experiments of Dr. Edwards, considered in all their relations, are generally conceived to decide the question respecting the existence of cutaneous absorption, under the ordinary circumstances, and in the natural conditions of the system.

§. 4. *Of the specific uses of the different parts of the absorbent system, and of the relation which that system bears to the other vital functions.*—Whatever opinion we may form on the controverted question respecting venous absorption, and in whatever manner we may explain the action of the lacteals and the lymphatics, there can be no doubt that their specific use is to absorb certain substances which are presented to their extremities.‡ There is, however, so well marked a distinction between the situation and the anatomical relations of these two kinds of vessels, as well as between the substances that are found to be contained

* De l'Influence des Agens, &c. ch. xii. p. 345 et seq.

† De l'Influence, &c. ch. xiii. p. 556 et seq. See on this subject, Magendie, Physiol. t. ii. p. 189 . . 196, and Dict. de Méd. et Chir. Prat. "Absorption;" where he endeavours to prove, that it is the veins and not the lymphatics which are the agents in cutaneous absorption. See also the remarks of M. Rullier, ch. ii.; and of M. Adelon, Physiol. t. iii. p. 10 et seq.; also art. "Absorption," Dict. de Méd. t. i. p. 124 et seq. M. Chaussier found that sulphuretted hydrogen gas, when applied to the surface of the body, manifested its deleterious effects on the system, Bibl. Méd. t. i. We have already had occasion to notice the opinion of Walter on this subject, p. 25, which is similar to that of M. Magendie. M. Buisson attempts to establish a distinction between the absorption which is carried on by the membranes and by the cellular texture, De la Divis. des Physiol. Phenom. p. 251 et seq.

‡ M. Magendie indeed doubts this position so far as the lymphatics are concerned; Journ. Physiol. t. i. p. 18 et seq. and Physiol. t. ii. p. 238 . . 243.

in them, that we are naturally led to conclude, that they are destined for different uses, and serve different purposes in the animal economy. With regard to the lacteals, their use seems to be clearly marked by their connexion with the digestive organs, and by their contents, as constituting the channel by which the chyle is conveyed from the intestines to the thoracic duct, and ultimately to the bloodvessels. We cannot doubt that their primary function is to supply the body with the elements which compose the blood, and thus become the immediate agents in its nutrition. Although, from the experiments which have been related above, it will appear that, on certain occasions, the lacteals are not incapable of receiving extraneous bodies, yet we may conclude, that this is the case only under extraordinary circumstances, or in an unnatural state of the parts.

With respect to the lymphatics, their specific use is less obvious. As their contents are ultimately mixed with those of the lacteals, we may suppose that they contribute indirectly to the nutrition of the body; but this would appear not to be their primary, or even their principal destination. Still we can scarcely refuse our assent to the position, that absorption is the specific function of the lymphatics; and this will be equally the case, although we may suppose that the veins cooperate with them in this action.

We are indebted to the genius of John Hunter for a consistent or plausible theory of the use of the lymphatics, which, with certain modifications, is generally admitted to be correct. Conceiving that the appropriate and specific action of the lacteals is to nourish the body, and to support the system by the addition of new matter, that of the lymphatics is to mould and fashion the body, to admit of the growth and extension of the whole, while each individual part retains its proper form and position. When we consider in what manner an organized part increases in its dimensions, we immediately perceive that it is not by mere accretion, nor by simple distention; it is, on the contrary, by an addition to every individual portion, while they retain the same relation to each other and to the whole. If we take the case of a muscle, we find that each particular fibre must be increased in length, so that the distance may be augmented between the tendinous extremities, while probably the number of fibres that are contained in the membranous covering is also increased; the whole organ consequently becomes larger in every one of its individual parts, while they each retain their former proportions and connexions.*

We may apply the same train of reasoning to the bones, which offer a still more remarkable example of this change of form, inasmuch as the firmness of their texture must render it less easy to conceive of any alteration in their dimensions and in the disposition of their component parts. Here it is still more obvious than in the case of the muscle, that the change cannot be effected either by accretion or by distention, but that a completely new disposition of the integrant parts must have taken place. The only means, however, by which this can be accomplished is by the former particles of the body being gradually removed, and new ones deposited to supply their place; the process being so gradual, that, although the deposition of the new particle is not precisely in the same situation with the former, yet that of each particle is so nearly so as to cause no obstruction or interruption to the action of the organ. Now it is evident that this removal of the old matter can be effected by no process but by absorption, and we may therefore conclude that the lymphatics, either alone or in conjunction with the veins, are the agents destined to perform this office.

With respect to the actual nature of the contents of the lymphatics there appears to be some uncertainty. We have the analysis of the fluid taken from the vessels of a dog by M. Chevreul,* from which it would appear that the lymph contains nearly the same ingredients with the blood, but diluted with a much larger proportion of water. We must, however, suppose that the fluid contained in the lymphatics will vary very considerably in its composition, according to the part of the body from which it is taken, or the condition of the same part at different times; yet we are scarcely able to detect an actual state of things which altogether corresponds with what we might have been led to expect would have been the case.† It may indeed be presumed that in the ordinary condition of the system, the process by which the parts of the body are absorbed is so very gradual, that the change in the chemical constitution of the lymphatic fluid is as inconspicuous as the change in the organs from which it is absorbed, and that it is only in morbid cases, where there is some extraordinary quantity of matter to be removed, that we should expect to be able to detect it in the lymph. And this, to a certain extent, agrees with the fact; for when the absorbents are called into action to remove collections of pus, or when they become the vehicles of any poisonous or morbid body, the substance in question has been occasionally found in them.

The doctrine of the removal or absorption of all the parts of the body is rendered evident by a variety of cases, in which any particular organ or texture is broken down or removed, merely by cutting off the supply of fresh matter. It is upon this principle that we explain the

* See Winterbottom, de Vas. Absorb. in Smellie's Thes. Med. t. iv.; also Cruikshank, p. 108, 9. For the more recent views of physiologists on the subject the reader is referred to Adelon, art. "Absorption," Dict. des Scien. Méd. t. i.

* Magendie, Elem. t. ii. p. 171, 2.

† Magendie, Elem. t. ii. p. 196, 7, et alibi. Mascagni, however, states that the lymph varies according to the parts to which it is contiguous, ps. 1. §. 4.; see also Blumenbach, §. 438.

removal of a part by pressure. If a muscle, or even a solid bone be exposed to constant pressure, by which its nutritive arteries are obstructed, it will be gradually diminished in bulk, and at length completely abstracted. And this is frequently effected by the action of a body much softer than the substance which is removed, as, for instance, we observe a bone to be absorbed by the pulsation of a blood-vessel, or the growth of a fleshy tumour.*

But although we may venture to affirm that this moulding of the body, or rather of its individual parts, is effected by the lymphatics, either alone or in conjunction with the veins, there is considerable difficulty in forming a distinct conception of the mode in which they operate. The operation cannot, strictly speaking, be mechanical, nor have we any evidence of the existence of a chemical solvent, by which the parts may be reduced to a liquid state, so as to fit them for entering into the mouths of the vessels. We may conceive of the source of supply being cut off by pressure or in other ways, but still we are at a loss to account for the mode in which the solids are either dissolved or broken down, so as to adapt them to the process of absorption. There is, however, one principal or general fact in the animal economy, which will probably somewhat assist us in our inquiry, viz. that it appears to be essential to the well-being, or even to the existence of the corporeal frame, that all the materials of which it is composed should undergo a constant change. It appears that these materials, after a certain length of time, experience some alteration in their nature, by which they are rendered unfit for the further performance of their functions as constituents of the living body. They are therefore removed and are replaced by fresh matter, this interchange being brought about in the gradual manner which was described above. Now this process implies a constant decomposition of the parts of the body, and as this decomposition is effected particle by particle, it may not be unreasonable to conjecture, that each particle, when it ceases to form an integral part of an organ, is left in a state proper for being taken up by the absorbents. But independent of any hypothetical views of this description, we may assume it as a probable conclusion, that the configuration and moulding of the body is the specific and appropriate office of the lymphatics, while its nutrition is effected more immediately by the lacteals.

With respect to the lymphatic glands we have seen above that their structure is involved in considerable obscurity, and we may remark, that their use is at least equally obscure. Among other opinions that have been entertained on the subject, some physiologists have supposed that the glands are proper secreting organs, which are destined for the purpose of preparing a peculiar substance that is mixed with the chyle and the lymph, or that they merely serve the mechanical purpose of mixing together more completely the constituents of the fluid that is contained in the vessels, and thus produce some change in its nature or consistence.* There do not appear to be any arguments, either anatomical or physiological, by which this point can be decided; but we may remark, that while the number and mode of distribution of these glands in the mammalia would seem to point them out as performing some important office in the animal economy, their rarity in birds and fishes proves that they are not essential to the existence of most of the functions of animal life, nor have we any mode of explaining the cause why they should be more necessary to the mammalia than to the other classes, which in many of their functions so nearly resemble them.

It only remains for us to offer a few remarks on the connexion between the function of absorption, and the other vital actions of the system, especially with the two leading principles of contractility and sensibility. We have already had occasion to remark on the connexion of absorption with muscular contractility, and although it may be difficult, or even impossible, to demonstrate the muscular fibres, or to exhibit any apparatus of this description, by which the action of the vessels can be accounted for, still we have strong reason for supposing that the absorbents possess this power, and that it is the main cause by which their contents are propelled.

With respect to the relation which subsists between the nervous and the absorbent systems, we are induced to suppose, both from anatomical and from physiological considerations, that it is merely of an indirect nature. From the researches of the anatomists, we learn that there are few nerves sent to the absorbent vessels or glands, and that even these seem rather to pass by them, in order to be transmitted to some other organs, than to be ultimately destined for the use of the absorbent system. The action of the mouths of the lacteals, or the power by which they are enabled to take up the substances that are afterwards transmitted along them, is involved in much obscurity, as is likewise the case with the power which these vessels seem to possess of changing the nature of their contents. Both of these have been referred to the nervous influence, but this has been done in that loose and general way, which

* For the absorption of the solids, see Monro on the Brain, c. 5; also Blumenbach, §. 436; and Bell's Anat. vol. iv. p. 311, 2. Ribes, who is a zealous defender of the doctrine of venous absorption, remarks that the absorption of the bones must be effected by the veins, because they are not furnished with lymphatics; Mém. Soc. d'Emulation, t. viii. p. 621.

* On this subject we may refer to Haller, El. Phys. ii. 3. 25; Blumenbach, Inst. Phys. §. 425, 442; Richerand, Elem. p. 153; Mascagni, ps. i. sect. 5. p. 33; Magendie, Elem. t. ii. p. 166, 201; Chaussier et Adelon, ubi supra, p. 278. Rullier, art. "Inhalation," in Dict. Sc. Méd.; Meckel, Manuel, sect. 6. ch. i.; Adelon, art. "Lymphatique (Physiologie)," Dict. de Méd. t. xiii, also art. "Chylifères," ibid. t. v. p. 239; Desgenettes, Journ. Méd. t. xc. p. 322, et seq.

is too frequently met with in the reasoning of physiologists. We do not perceive, in either case, how it can be referred to this power, nor how it can be employed in any way to explain or elucidate the effects that are produced.*

It is admitted that the chyle is elaborated during its passage along the lacteals, and becomes more nearly assimilated, both in its physical and chemical properties, to the blood. Still, however, its complete sanguification does not take place until it leaves the lacteals, and it becomes a very interesting subject of inquiry, by what means this is effected; in what degree the function of respiration contributes to it, whether the abstraction of carbone and the introduction of oxygene, which is supposed to be effected by the passage of the blood through the lungs, is the immediate cause of the conversion of chyle into blood; whether it be brought about more gradually, by the removal of the various secretions and excretions, or whether there be any particular organ, which may more especially produce the change in question. These are all of them points of high interest, but as they are concerned in an indirect manner only with the subject of this article, and as they will be considered in the appropriate parts of this work, we shall not pursue the inquiry any further.

ACALEPHÆ (from ακαληφη, a nettle); syn. *urticæ marinæ*. Fr. *Acalèphes*; Germ. *Acalephen*; the name of a class of invertebrate animals. They are all inhabitants of the sea, and are such as are commonly known by the names of sea-jelly, sea-nettle, Portuguese man-of-war, &c. It is from the property, which many of these animals possess, of irritating the surface of our skin so as to produce nearly the same effect as that resulting from the sting of a common nettle, that the class derives its name.

Aristotle used the word ακαληφη to designate some of these animals; but it was by Cuvier that the class was formed, and the term acalephæ applied to it. As this class now stands in the last edition of the *Règne Animal*, (t. iii. p. 274,) it is formed chiefly by the animals constituting the Linnæan genus *Medusa* and *les acalèphes hydrostatiques* of Cuvier.

On many accounts the acalephæ are objects of extreme interest to the anatomist and physiologist. They have occupied the attention of the most learned naturalists of every age, from the time of Pliny until the present day; their numbers are, perhaps, greater than those of any other class of marine animals: they exist in all seas; and yet we remain very ignorant with regard to several points in their structure and history. The peculiar nature of their tissues, the singular arrangements of their organs, the anomalies in their functions, present as many objects of interesting inquiry to the physiologist, as the wonderful variety and striking elegance of their forms, and their splendid colouring present to the admiration of the naturalist. Peron,* in his animated description of the *Medusæ*, observes, "Among the animals of this family we find the most important functions of life performed in bodies which offer to the eye little more than a mass of jelly. They grow frequently to a large size, so as to measure several feet in diameter; and yet we cannot always determine what are their organs of nutrition. They move with rapidity, and continue their motions for a long time; and yet we cannot always satisfactorily demonstrate their muscular system. Their secretions are frequently very abundant, and yet the secreting organs remain to be discovered. They seem to be too weak to seize any vigorous animal, and yet fishes are sometimes their prey. Their delicate stomachs appear to be wholly incapable of acting upon such food, and yet it is digested within a very short time. Most of them shine at night with great brilliancy, and yet we know little or nothing of the nature of the agent which produces so remarkable an effect, or of the organs by which it is elaborated. And, lastly, many of them sting the hand which touches them; but how, or by what means, they do so still remains a mystery." It is, therefore, but a very imperfect account of the anatomy and physiology of this class that can be at present given.

The following are the names and characters of the groups into which the acalephæ have been divided by M. De Blainville,† whose arrangement is nearly the same as that adopted by Eschscholtz.‡

I. Physograda. Body regular, symmetrical, bilateral, fleshy, contractile, often very long, provided with an aeriferous sac. Branchiæ in the form of long cirri, very contractile.

1. Organ of natation simple and lamellated. *Gen.* Physalus. (*Physalia*, Lam.)

2. Locomotive organs complex and vesicular. *Gen.* Physsophora. Diphysa. Rhizophysa.

3. Locomotive organs in the form of smooth scales, disposed in transverse series. *Gen.* Stephanomia. Agalma. Protomedea. Rhodophysa.

II. Diphyda. Body bilateral and symmetrical, composed of a visceral mass of small size and of two swimming organs, hollow, contractile, somewhat cartilaginous, and placed one before the other, the anterior one being in more direct connexion with the central visceral mass, which it seems to surround; the other posterior, and very slightly adherent. Mouth at the extremity of a stomach more or less extensile. Anus unknown. A long filamentary organ, ovigerous, rises from the root of the central mass, and is prolonged more or less posteriorly.

Gen. Cucubalus. Cucullus. Cymba. Cuboides. Enneagona. Amphiroa. Calpe. Abyla. Diphyes. Ersaea. Eudoxia. Pyramis. Praia. Tetragona. Sulculeolaria. Galeolaria. Rosacea. Noctiluca. Doliolum.

III. Ciliograda. (*Ctenophoræ*, Esch.) Body gelatinous, free, varying in form, marked on the surface with narrow *ambulacra* formed by rows of vibratile *cilia*. Intestinal canal complete, with two orifices.*

Gen. Beroë. Eucharis. Mnenia. Calymma. Axiotoma. Callianira. Pandora. Medea. Alcynoë. Cestum. Cydippe. Idya.

IV. Pulmograda. (*Discophoræ*, Esch.) Body entirely gelatinous, circular, without any solid part internally, margin provided with cirri of various forms, or with foliaceous appendages pendent from the inferior surface.

1. Simple: without true tentacula, peduncles or arms.

Gen. Eudora. Ephyra. Phorcynia. Eulymene. Carybdea. Euryale.

2. Tentaculated: the circumference of the body, and sometimes the mouth, surrounded by tentacula.

Gen. Berenice. Equorea. Foveolia. Pegasia. Cunina. Ægina. Eurybdia. Thaumantias. Obelia. Linuche. Eirene.

3. Subproboscic: gastric cavity prolonged into a short peduncle, at the extremity of which is the mouth, surrounded by four brachial appendages.

Gen. Oceania. Aglaura. Melicerta. Saphenia. Tima.

4. Proboscic: the lower and central part of the body prolonged into a proboscis-like appendage, either simple or provided with arms.

Gen. Orythia. Geryonia. Dianœa. Favonia. Cytæis.

5. Brachigerous: lower surface furnished with more or less numerous appendages, brachial, ramified.

Gen. Ocyroë. Cassiopea. Medusa (Aurelia of Peron). Callirhoë. Melitea. Evagora. Cephea. Rhizostoma. Chrysaora. Cyanea. Pelagia. Sthenonia.

V. Cirrigrada. (*Velellidæ*, Esch.)

* Peron. Ann. du Mus. xiv. 220.

† Dict. des Sc. Nat. "Zoophytes." 1830.

‡ System der Acalephen. Berlin, 1829. The most complete treatise on the anatomy and history of the acalepha hitherto published. Its learned author enjoyed excellent opportunities of studying these animals in the course of the two voyages round the world undertaken by Kotzebue, of whose expeditions he was naturalist.

* M. De Blainville regards the animals included in this and the two preceding sections as being more allied in structure to the Mollusca, (his *Malacozoaires*,) than to the Radiata, with which they are arranged by most zoologists. Accordingly he separates them from the two succeeding sections, which are truly radiate animals, and of which he forms a class in his great division *Actinozoaires*, under the name of *Arachnoderma*.

Body oval or circular, gelatinous, supported by an internal, solid, subcartilaginous body, and provided with very extensile tentacule-like cirri pendent from the whole of the lower surface.

Gen. Velella. Porpita. Rataria.*

Of the genera above enumerated, Eschscholtz has described about two hundred species. Messrs. Quoy and Gaimard have made us acquainted with several others; but of all these a comparatively small number only have been described in detail: so that, although in the account which we are now to give of the anatomy and physiology of the acalephæ, we shall, for the sake of brevity, make use of the sectional designations, it must be understood that the descriptions apply only to a few species, and that, with regard to the others grouped along with these, we can only say it is *probable* that they are similarly constructed.

I. *Locomotion.* The principal organ of locomotion in the physograda is the air-filled vesicle or bladder, which exists, of various sizes, in all the species. In *physalus*, (*Fig.* 6.) it is a large organ, forming a great portion of the general mass of the animal. It is placed superiorly, and, for the most part, rises above the surface of the water. It has an elongated form; the longest diameter being the horizontal. It is somewhat pointed at one end, at the other truncated; and at either there is a small opening, the place of which is marked by a superficial dimple, surrounded by delicate muscular fibres, acting as sphincters. When

(*Fig.* 6.)

Physalus Utriculus, (Esch.)

the bladder is squeezed by the hand, so as to force the contained air towards one of these openings, the air makes its escape through it; but whenever the pressure is taken off, the opening again closes. M. De Blainville states that he has satisfied himself that this air-bladder is really a dilatation of the intestinal canal; and that he regards the two openings mentioned above as the mouth and the anus. We are ignorant of the data upon which M. De Blainville grounds his conclusion. It does not appear that any observer has found alimentary matter lodged within the air-sac. But whether or not it be an organ of digestion, it is certainly an organ of locomotion, although only a passive one; for it is by its contained air that the animal floats on the surface of the water, so as to expose a large superficies of its crest and bladder to the wind, by which it is driven to and fro frequently with great velocity. The walls of this sac are muscular, so that by their contraction its cavity can be considerably diminished. And thus, partly by the escape of air forced out through the openings, and partly by the compression of what remains, the specific gravity is so much altered as to admit of the

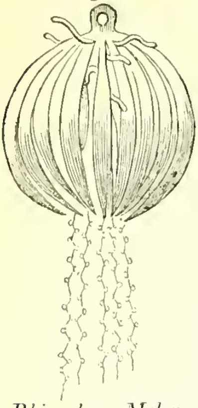
* The following neat but artificial arrangement of *acalephæ* forms the subject of a communication lately made to the Zoological Society by M. Lesson, foreign member of that body: we are indebted for it to our friend Mr. Owen.

- I. Without a central solid axis.
  - A. Body simple, entire.
    - 1. Symmetrical, terminated at each pole by an opening . . . . 1 *Beroidæ.*
    - 2. Non-symmetrical, the upper pole disciform or umbelliform, imperforate . . . . 2 *Medusæ.*
  - B. Body multiple or aggregated.
    - *a.* Homogeneous.
      - 3. Composed of two pieces adhering together, and capable of separation . 3 *Diphydes.*
      - 4. Composed of numerous pieces aggregated together . . . . . . 4 *Polytoma.*
    - *b.* Heterogeneous.
      - 5. Animal furnished with appendages of different kinds.
        - * Vesicle small, regular, placed at the summit of a kind of stalk furnished with lateral ampullæ, and terminal suckers . . . . . 5 *Physsophoræ.*
        - ** Vesicle large, irregular, without stalk or ampullæ, but having terminal suckers and cirriferous processes . . 6 *Physaliæ.*
- II. With a central cartilaginous axis.
  - 6. Body simple, with suckers and lateral *tentacula.*
    - *a.* Body irregularly oblong, with a vertical lamina on its upper surface . 7 *Velellæ.*
    - *b.* Body discoid, flat above. 8 *Porpitæ.*

R. B. T.

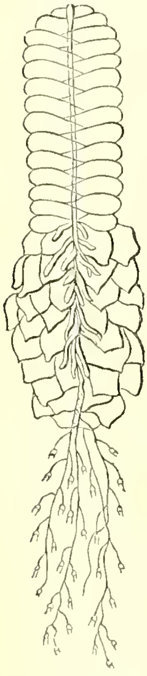
animal's sinking into the deep when danger threatens. In the other physograda, the air-vesicle is so small in proportion to the general mass of the animal that it is not sufficient to raise it above the surface of the water. It is generally an ovate sac, with an opening at its upper end, closed by a sphincter muscle. It is probable that its walls are muscular, and that by pressing out a portion of the contained air, and by secreting more, alternately the animal can sink and rise at pleasure. The nature of the air contained in these vesicles has not yet been ascertained. In *rhizophysa* (*Fig.* 7.) there are, pendent from one part of the body, certain peculiar organs, arranged very regularly in pairs, of a muscular structure, hollow, and furnished each with a round orifice. They differ from the tentacula in structure, and are, probably, organs of natation. Similar tubes, but only two in number, exist in *diphysa*; and, anterior to them, in the same animal, there is a two-lobed organ, the use of which is doubtful. In *agalma*, (*fig.* 8.) and some of the genera allied to it, there are certain cartilaginous plates disposed in an imbricated manner along the sides of the body. These, Eschscholtz regards as locomotive organs. The muscles by which they are set in motion must be extremely delicate, as a slight touch is sufficient to separate the plates from one another.

Fig. 7.



Rhizophysa Melon.

Fig. 8.

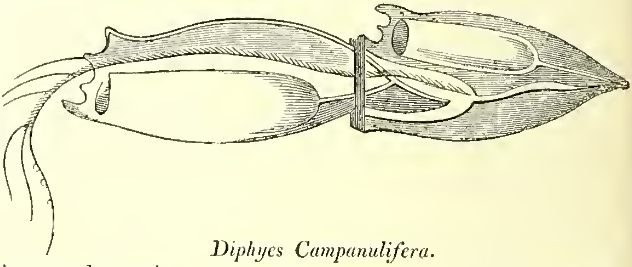


Agalma okenii.

The chief bulk of the singularly formed diphyda is made up of the swimming organs, which are two subcartilaginous bodies, polygonal, generally pointed anteriorly, truncated posteriorly, placed one behind the other, and one a little within the other; the posterior portion being lodged in a little excavation which exists in the anterior. These two parts differ somewhat from one another in form, but both are hollow, and have large openings. Their attachment is so slight as to admit of their being separated by agitation of the water. It is at the bottom of the anterior cavity that the essential parts of the animal are placed. Locomotion is effected by means of the impulse of a current which is kept up by the successive contractions and dilatations of the organs above described. The contractions of the two bodies are not synchronous; but they succeed one another within a short time, so that a steady progression is maintained; and in some species it is very rapid.

In the ciliograda, the locomotive organs are large cilia, disposed in longitudinal bands on the surface of the body. These bands are generally eight in number; but in some species, (e. g. *axiotoma Gaedii*, Esch,) there are only four. The arches supporting the cilia are of firmer texture, and are less transparent than the rest of the body. In many species they extend from one end of the body to the other; in some only along a part of the circumference. The structure of the cilia themselves has lately

Fig. 9.



Diphyes Campanulifera.

been examined by Dr. Grant,* with his usual care, in the *Beroë pileus*;† and he has found that they are fin-like processes, and that each is composed of several short, transparent, somewhat curved filaments, placed parallel to each other in a single row, and connected together by the skin of the animal, like the rays supporting the fin of a fish. The rays in the middle of the cilium are a little longer than those at the sides. All the rays appear as transparent tubes under high magnifying powers. They are so curved that their extremities are directed backwards towards the closed extremity of the animal. There are about forty cilia attached to each arch in this species, which is nearly an inch in length. The cilia are so large as to be visible to the naked eye. Most of the ciliograda have their cilia quite exposed; but *Pandora* is provided with moveable folds of the skin along the cilia-bearing arches, which can be brought over the cilia, in whole or in part, at the animal's pleasure, so as to cover them more or less completely. These cilia are moved nearly in the same manner as the pectoral fins of fishes. But their motion is so rapid, when the animal is vigorous, that the eye cannot follow it. The existence of motion is pointed out, however, by lines of beautiful iridiscent colours playing along the arches, and

* Trans. Zool. Soc. of London, i. 10.

† Pleurobrachia pileus. Fleming. Brit. Anim. 504. Cydippe p. Esch.

by the currents which are generated in the circumambient fluid. The animal has the power of arresting completely the motion of one, two, or more rows of cilia, while the others are moving. When all are set in motion together, the animal moves onwards with the inferior or oral surface (inferior in a state of rest) directed forwards. When the motion of some is arrested, the whole body acquires a rotatory motion, and advances in a curvilinear path. The animal has also the power of changing the direction of the currents caused by its cilia, so that it can ascend or descend in the water at pleasure. It can also increase and diminish at will the velocity of the motions of the cilia. Those animals which have the largest cilia, (e. g. *Medea*,) swim with the greatest rapidity. The cilia continue to move for some time after having been separated from the body, in connexion with part of their arches. Immediately beneath the arches there are vessels conveying a fluid, which is in motion during the vibrations of the cilia. Whether these vessels are destined only for the conveyance of the circulating fluid to the cilia, (which in all probability act as organs of respiration as well as of locomotion,) or carry a stimulus fitted to excite their vibrations, is not yet determined. Eschscholtz compares these vessels to those which Tiedemann has described as connected with the feet in the echinodermata. And Dr. Grant is of opinion, with MM. Audouin and Milne Edwards, that it is not improbable that the motions of the cilia are somehow dependent on the movements of the fluids contained in the above-mentioned vessels, seeing that in the *actiniæ* the tentacula are projected by water being forced from below into them. In the other classes of the acalephæ also the same kind of structure prevails. Such of the pulmograda as have cilia around their margins have also circular vessels running along their bases; and almost all projectile and extensile tentacules and filaments are provided with sacs and canals, containing fluids, at their roots.

In addition to their cilia, several of the ciliograde acalephæ have other organs of locomotion in the form of long filamentary arms or tentacules, with which they can poise themselves in the water without moving their cilia. In *Cydippe** these are two in number. They are lodged in two tubes placed alongside of the stomach, from which they issue near the mouth. They can be extended to four times the length of the animal. They terminate in very fine points, and along their whole course present minute filaments placed at equal distances, which are coiled up spirally, close to the tentacules, when these are about to be withdrawn into their sheaths. The tentacules are also coiled up in a spiral form when completely contracted. They are sometimes suddenly sent forth from their tubes to their full length by one impulse, and then their lateral filaments are gradually uncoiled; a process this of no less interest on account of the gracefulness of the motion than on account of the peculiar mechanism which it indicates.

* Grant. Trans. Zool. Soc. i. 10.

The principal organ of motion in the pulmograda is the large campanulate, or mushroom-shaped, disc, of gelatinous consistence, which constitutes the great mass of the animal. In this, for the most part, no muscular fibres can be seen, and yet the animals move about with some quickness. They have the power of contracting and dilating their discs at pleasure, in whole or in part. By alternately contracting and dilating their inferior surface, they strike the water in such a manner and with such force as to raise themselves; when they discontinue this motion, they again sink, being of greater specific gravity than the sea-water. They move onwards horizontally, by acting only with one side of the margin of their disc. Lamarck was of opinion that these isochronous movements of the disc, by means of which the pulmograda seem to swim, were fitted merely to facilitate the internal vital processes, and not to move the animals through the water; and he regarded them as dependent entirely on the influence of imponderable agents existing in the circumambient fluid, and alternately entering into, and flowing from, the general mass of the animal. He compared the motions with those of the fluid in Franklin's thermoscope, when held in the hand.* In the course of the ordinary progression of the large *Medusa aurita* of our seas, the contractions of the disc take place from twelve to fifteen times in a minute. The convex surface of the disc always advances foremost.

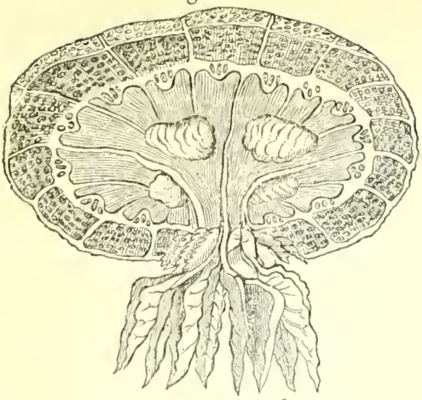
No fibrous structure has hitherto been discovered in the general mass of the disc. Internally, it is cellular, uniform, and very soft. The quantity of solid matter in the disc, and, indeed, in the whole body, is very small. Some *medusæ*, which, when recently taken out of the water, weighed fifty ounces, on being dried, left remains weighing scarcely more than five or six grains. "It is therefore evident, that the sea-water, penetrating the organic texture, constitutes the greater part of the volume of these animals."† But in some species there exists a fine muscular membrane, stretched over a certain extent of the lower surface just within its outer margin. Under a lens, this has the appearance of being composed of numerous fleshy fibres, forming little bundles, arranged in a radiate manner as regards the axis of the animal, and closely adherent to the gelatinous tissue of the disc. When portions of the disc are cut off from living *medusæ*, without any part of this muscular membrane being attached to them, they remain motionless; but when their connexion with the membrane is preserved, even small portions continue their motions of contraction and dilatation for a considerable time.

The tentacula of the pulmograda (which are always pendent from the inferior surface) may be regarded as supplementary organs of locomotion, although they are, in all probability, subservient chiefly to the nutritive function. They are all simple, not branched, generally

* Anim. sans Vert. ii. 454.

† Spallanzani, Travels in the Two Sicilies, iv 218.

Fig. 10.

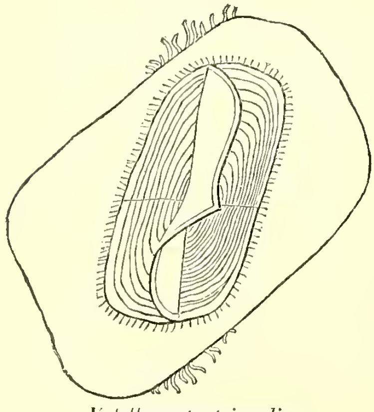


Rhizostoma cærulea.

hollow; and, when connected with the appendages of the digestive cavities, or when they have a vesicle at their base, very extensile. Several genera have suckers at the extremities, and along the sides, of their tentacula, by means of which the passing prey is seized. The tentacula which are extensile seem to be projected by the forcing of water into their internal cavity, by the contractions of the vesicles at their base. The extent to which the filamentary organ is thus lengthened, in some species, is very extraordinary.* It seems to be shortened again by means of the contractions of circular muscles, which force back the water into the vesicle, and of longitudinal muscles which draw it in. Peron thought that some of the pulmograda were furnished with internal air-bladders; but Eschscholtz, on directing his attention to this point, satisfied himself that what Peron had taken for air-bladders were merely appendages of the gastric cavities, into which air had accidentally been introduced during the removal of the animals from their native element.

In the cirrigrada, locomotion is effected

Fig. 11.

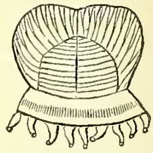


Velella septentrionalis.

* In the tentacula of some of the physograda, also, a similar extensibility exists. The lower surface of *physalus*, for instance, which itself seldom exceeds six inches in length, is provided with tentacula sixteen and even eighteen feet long.

partly by the movements of the tentacules which hang down from the inferior surface; but chiefly, perhaps, by the action of the wind on the raised crest, with which most of these animals are provided. Immediately around the mouth are placed numerous small tubular suckers, similar to the feet of many echinodermata. Exterior to these there are longer tentacula, for the most part in a single row, and simple; sometimes branched. Neither of these two kinds of organs is very extensile. The disc from which the tentacules hang, and the crest, are supported internally by a calcareous plate, which is the only organ of the kind in the whole class of acalephæ. It somewhat resembles in structure the calcareous axis of *retepora*, being cellular and porous. Its numerous cells are filled with air, which renders the whole animal so buoyant that it floats on the surface of the water, and is wafted along by the winds. In *velella* (*Fig.* 11.) there are two plates, one placed horizontally, the other perpendicularly upon the upper surface of the former. They are marked with lines of growth, enlarging from within outwards, like the extravascular shells of the mollusca. The perpendicular plate in velella supports the crest, which stands upright, and exposes a large surface to the wind. *Rataria* (*Fig.* 12.) has its crest provided with strong muscular bands running perpendicularly. It lies on the surface of the water, with the crest stretched out, so that its whole side touches the water. When it is alarmed, the crest is suddenly contracted, and the centre of gravity is so altered in consequence, that the position of the body is almost reversed. When the crest is again raised, the body immediately resumes its former position.

Fig. 12.



Rataria cordata.

Porpita has a simple plate supporting its disc, without any crest, and long tentacula, which are so delicate as scarcely to bear the slightest touch when the animal is taken out of the water. When the position of the animal is altered by the hand, so as to make the surface covered with suckers the upper one, all the tentacula of one half of the body turn round to the dorsal surface, and all those of the other half stretch over their own surface, and thus the animal very soon regains its old position.

II. *Motility and Sensation.* — Almost all observers have failed to discover anything resembling a nervous system in the Acalephæ. Even Eschscholtz,* who devoted so much attention to their anatomy, could not see nerves in the largest that he examined. But in *Cydippe*, according to Dr. Grant,† there is a structure which can be regarded only as belonging to the nervous system. It consists of a double transverse filament of a milky white colour, running round the body, near its surface, at a short distance above the mouth. The two cords of which this filament is composed unite in the middle of each of the spaces between

* System, p. 19.

† Trans. Zool. Soc. of Lond. i. 10.

the ciliated arches to form eight ganglia, from each of which two nerves go to the adjoining bands, and one, larger than the others, runs upwards in the middle of the transparent space between the bands, and can be traced to beyond the middle of the body. In the course of these last-mentioned nerves, two or three smaller ganglia are visible, from which filaments pass inwards to the viscera. Dr. Grant likens these nerves and filaments to the abdominal nerves of *pectinaria* and other transparent animals.

The circular fibres forming the sphincters of the orifices of the air-bladder in *physalus* have been mistaken for nerves.*

There is no evidence that the acalephæ possess any other sense than that of touch. But, although they cannot be said to have the sense of sight, they are evidently affected by light. At least some of the smaller tribes shun a bright light, and sink into the deep to escape from it.

In most of the tribes of acalephæ, the sense of touch seems to have its seat chiefly in the tentacula and cirri, with which almost all are provided. The degree of sensitiveness with which these are endowed varies much. In some, the slightest touch, even agitation of the water, is sufficient to excite them to contraction. These organs of touch, as has been already mentioned, are subservient chiefly to the nutritive functions. Other parts of the bodies of most acalephæ also manifest, by their contractions, a certain degree of sensitiveness. Several of the ciliograda alter the shape of their general mass when touched. In physalus the crest appears to be more sensitive than any other part. Many species, particularly of the pulmograda, give no signs of their feeling even the deepest and most extensive wounds of their discs. But it was observed by Spallanzani, that, by friction, and by punctures of the muscular membrane of the disc, the movements of contraction and dilatation could be excited in medusæ, which, having been kept in a dry place during twenty-four hours, had discontinued their ordinary motions, and had lost nearly two-thirds of their bulk by the running out of their contained fluids.†

* Isis. Nov. 1819.

† Professor Ehrenberg has very recently attempted to shew that *medusa aurita* is possessed of eyes, in the form of minute red points, which are seen on the surface of the eight brown-coloured masses set round the circumference of the disc. These masses, according to his observations, consist each of a yellowish, oval, or cylindrical little body, which is attached to a small and delicate pedicle. This short pedicle arises from a vesicle, in which there is placed a glandular body, unattached, presenting a yellow colour when viewed with transmitted light, a white colour under reflected light. It is upon the dorsal aspect of the yellow head, which surmounts the pedicle, that the well defined red point is seen, which Ehrenberg considers as an eye. He compares the eyes of *medusa* to those of some *rotifera* and *entomostraca*. The glandular body situated at the base of the pedicle, he regards as an optic ganglion, which, he seems to have satisfied himself, is connected with two filaments that decussate one another at about the middle of their course. These he describes as forming part of a nervous circle placed, throughout the greater part of its course, immediately along the bases of the row of tentacules that surround the disc, so as to form, as it were, the outer wall of the circular vessel, or appendage of the intestinal cavity, which runs round the margin of the disc. The same observer describes another nervous circle, composed of four ganglion-like masses, disposed around the mouth, each being in connexion with a corresponding group of tentacules. (Ehrenberg, in Müller's Archiv für Anat. Physiol., &c. 1834. p. 562.)

III. *Digestion.*—The structure and action of the organs concerned in the function of digestion in the acalephæ are still involved in much obscurity. Even in the large and frequently examined physalus, it is difficult to ascertain the functions of the various parts in a satisfactory manner; and, accordingly, there exists so much difference of opinion amongst anatomists with regard to them, that some will not even admit that it has a mouth, while others assign to it both a mouth and an anus, as well as cœcal prolongations of the stomach. Eschscholtz concluded, from his numerous observations on the living animals, that, in all the physograda, the digestive organs consist merely of absorbing tubes or suckers, all of which are simple, and pendent from the inferior surface. He seemed to think that the action of these filamentary organs was analogous to that of the roots of plants;—that they were endowed with an endosmosic power, which enabled them to imbibe nutritious matter from the water. However this may be with regard to the simple filaments, or cirri, it appears probable that the *suckers* are provided with orifices at their extremities, through which proper alimentary matter passes into the interior; for several observers agree in stating, that both the physograda, and the diphyda apply their suckers to the bodies of other animals, and remain adherent to them for some time, during which they seem to take up some nourishing matter. *Eudoxia* has only one sucker. Messrs. Quoy and Gaimard have described in detail the singular filamentary organ which bears these suckers in *diphyes*. Generally it is seen, at first, only as a shapeless opaque mass, of a reddish colour, lying contracted within the swimming cavity. But, gradually, it is extended, and then there are perceptible, along the whole of one side of a fine transparent tube, numerous suckers, of a lengthened form; each is covered by a very delicate bell-shaped case, and has its base surrounded by groups of minute vesicles, which are, probably, the ovaries. From the base there arises also a little tentacule or filament, susceptible of very great elongation, and which sends off many secondary filaments.*

The digestive organs of the ciliograda are less dubious. In these we find uniformly a straight alimentary canal with two orifices, the mouth inferior, the anus superior, in the ordinary position of the animal. In some species there are lips formed by short and broad folds of the integument, four in number, and very sensitive. In cydippe, Dr. Grant found these lips capable of rapid extension and retraction.

* Ann. des Sc. Nat. x. 8.

The mouth is large, the œsophagus straight and wide; the stomach is, for the most part, of an ovate form, the intestine passes in a straight line, and with a uniform diameter, to its extremity. The anus has a prominent circular margin in cydippe. No absorbent vessels can be seen arising from the gastric cavity. In many species, the alimentary canal is so large as to occupy the greater part of the interior of the body. When there is no food within it, it remains open at both extremities, and, as the animal swims generally with its mouth foremost, there is a current of water continually passing through it. Eschscholtz observed, that when suitable aliment was carried by this current against the walls of the stomach, the orifices were immediately contracted, and the digestive process begun. Minute crustacea, salpæ, &c., have been found in the stomachs of ciliograda. The diligent observer just mentioned seemed to regard the canal leading from the stomach to the dorsal surface, (which we have called the intestine,) as forming no part of the digestive organs. He termed it " the water-canal," and considered it as connected merely with the peculiar mode of locomotion, inasmuch as he observed it so patent while the animal was swimming and not digesting as to admit of a free passage for the water; which, otherwise, in entering the open mouth, would have much impeded progressive motion.

It was generally believed, until within a very recent period, that some of the pulmograda were destitute of stomachs. Hence the term of *agastric medusæ* which was applied to them by Peron. The researches of Dr. Milne Edwards, however, have rendered it probable that this supposition was erroneous, and founded on inaccurate observations. We have now reason to believe that all the pulmograda have gastric cavities; but all have not true mouths. There are some in which the only communication between the stomach and the outer surface is through numerous ramified canals in the pendent arms, which open externally by extremely minute orifices, barely sufficient, even in large species, to admit the smaller entomostraca. Such a structure exists in *rhizostoma*. By injecting milk into its gastric cavity, the canals in its arms, and their oscules can be rendered visible; and it is then discovered that from the minute oscules, which are situated in indentations along the margins of the arms, small vessels proceed inwards, and, uniting in twos and threes together, open into one large canal which runs through the middle of each arm. These arms are large, fleshy, foliated organs, eight in number; each of which has a triangular shape. The eight canals above mentioned unite two and two, so as to form four great trunks, which open into a large central cavity,—the only one in the body. This cavity is situated at the base of the central process pendent from the lower surface of the disc. The base, in rising upwards, enlarges into four fleshy columns, which lose themselves in the disc. It is between these four fleshy columns that the cavity of the stomach is placed. The intervals between the columns would form so many openings into this cavity were they not closed by a fine and plaited membrane, which bulges outwards when the stomach is filled. From the circumference of the stomach, at equal distances, sixteen vessels arise, and run directly towards the margin of the disc. These vessels may be regarded as arteries, and will be hereafter described along with other structures more nearly resembling the parts of a circulating system. But Cuvier* was disposed to consider them as cœca; although he admitted that he could discover no other vessels fitted to discharge the functions of arteries. He remarked that if we regard them as arteries, we must look upon the little vessels which lead from the appendages or arms to the central cavity, as veins, or as lymphatics; and then we might say that the sea is as a stomach to the *rhizostoma*, in the same way as the earth acts as a stomach for plants. But, at all events, Cuvier was convinced by his dissections that alimentary matter enters the body through the marginal oscules of the arms, and that it is accumulated in the internal cavity before passing into the radiating vessels. By experiments on the living animal, Dr. Milne Edwards has recently proved† that the circumambient fluid and its contents of minute size do really enter the body of the *rhizostoma* through the margins of the arms. He placed a living rhizostoma in sea-water, artificially coloured red. The animal did not appear to suffer from the presence of the colouring matter. Within a very short time, the puckered membrane which borders the arms was distinctly tinged red, and, gradually, the colour ascended, until the whole body assumed the same tint. Dr. Edwards does not state, however, whether he traced the progress of the coloured fluid through the brachial canals and the vascular system. On placing the same individual again in pure sea-water, the colouring matter which had been absorbed disappeared gradually, and it seemed to Dr. E. that it was thrown out chiefly from the brachial fringes, but partly also from the margin of the disc, and from the capillary orifices situated at the extremities of the arms. Dr. Edwards satisfied himself that it is impossible for animals larger than small animalcules to enter the central cavity of the rhizostoma. But most of the pulmograda have large central mouths, either simple and sessile, or placed at the extremity of a projection from the lower surface of the disc. In some, the mouth is more or less patent, but capable of being closed by the approximation of the base of the arms. In others it is surrounded by a ring of considerable density, in which muscular fibres can be distinctly seen. In *medusa aurita*, there are, just within the cavity of the mouth, four openings, which lead, by as many short but wide canals, into four spherical sacs of considerable size. These are completely separated from one another by membranous partitions. That they are stomachs is proved by the circum-

* Journ. de Phys. xlix. 438

† Ann. des Sc. Nat. xxviii. 249.

stance of fishes being found in them.* From each sac, four vessels arise, which run outwards to the circumference of the animal. Other species (e. g. *medusa capillata*) have the four gastric sacs in free communication with one another; and, frequently, (e. g. in *pelagia*, *chrysaora*, and *ægina*,) in connexion with these, there are four other sacs, lined with a more dense membrane than the former. These gastric appendages have the form of simple canals in *equorea* and *tima*; and of branched vessels in *medusa* and *sthenonia*.

They were chiefly such pulmograda as have their disc bell-shaped that were formerly supposed to be *agastric*. It was imagined that alimentary matter being received within the campanulate depression, its orifice was contracted, and nourishment taken up by imbibition through the walls of the disc. But an attentive examination of *Carybdea marsupialis*, (Peron,) one of the animals which was believed to be agastric, has satisfied Dr. Milne Edwards that a mouth and an internal cavity connected with it do really exist. The great transparency of this animal renders the discovery of its internal structure a matter of considerable difficulty, excepting when coloured injections are used. Dr. Edwards found within the funnel-shaped cavity of Carybdea, and, as it were, pendent from its roof, a projection of very delicate tissues, evidently forming tentacula surrounding a central mouth, and a stomach, from which proceed four long canals leading to the tapering filaments which hang down from the margin of the body of the animal. These canals, Dr. Edwards believes to be analogous to the radiating vessels of rhizostoma. There exists just at the commencement of each canal, and opening into it, a group of minute cylindrical sacs, which may be regarded as biliary organs.† But in most of the pulmograda these organs are situated on the margin of the disc. Generally, they present the appearance of glands, being distinctly granular in their structure. They are opaque, have a lengthened form, and are lodged in little depressions, and surrounded by cup-shaped folds of the external integument. They are connected with the gastric appendages by small tubes.‡

In *Aurelia phosphorea*, (Lam.) (*Pelagia*, Esch.) which formed the principal subject of Spallanzani's observations on the acalephæ, there are four groups of membranous tubes, convoluted, and resembling in structure the intestines of vertebrate animals. Although he did not trace their connexions, Spallanzani appears to have regarded them as truly parts of the alimentary canal. He observed that they exhibit a peristaltic motion, both in the water and in air, which can be increased by the application of stimuli.§

The food of the pulmograda consists of various marine animals—small fishes, mollusks, crabs, and worms. Even large fishes are sometimes found entangled amongst the arms and tentacules. They are probably killed by the peculiar excretion which covers the surface of these organs, and which produces a stinging effect on man. The long filamentary appendages which hang from the margins of the disc in Carybdea and others, are covered with a glutinous matter to which passing objects adhere; the animal has the power of stretching them out and withdrawing them at pleasure, and of so folding them inwards as to carry to the mouth whatever may be attached to their sides. It would appear that some species are endowed with the power of discriminating the food most suitable to their own nature. Gaede remarks that he has never found fishes in the stomach of *medusa capillata*, but often worms; while in that of *medusa aurita* there are frequently fishes, rarely worms. In none of the pulmograda have either masticatory or salivary organs been discovered.

The cirrigrada have, in the middle of their lower surface, a large flask-shaped stomach, the mouth of which is formed like a sucker. There appears to be a communication between this organ and the numerous tentacula which surround the mouth, through minute canals. The food consists of small animals, such as entomostracous crustacea; the undigested remains of which are again ejected through the mouth.

IV. *Circulation.*—No distinct circulating system has hitherto been discovered in the acalephæ. But perhaps the peculiar apparatus of radiating vessels connected with the gastric cavities in the pulmograda, and the aquiferous canals of the ciliograda, which seem to perform nearly the same functions as the vascular system of higher animals, may be conveniently and properly considered under this head.

In the physograda, Eschscholtz saw what he considered as the rudiments of a circulation; namely, distinct vessels arising from the roots of the tentacula, and ramifying on the internal surface of the air-bladders; but it does not appear that he traced these further, or that he saw the movements of a fluid within them.

The vessels in the ciliograda, within which a fluid is seen to move, are situated chiefly beneath the cilia-bearing arches. This fluid is supposed by most modern anatomists to be merely water; but by some it is regarded as a peculiar fluid, the product of the animal's digestive powers. If it be water only, the canals in which it moves must be considered as being analogous to those of the aquiferous system of other classes of invertebrate animals, which has been so fully illustrated by the researches of Delle Chiaje,* and which is presumed to be subservient to the respiratory function. The vessels in question arise in *Beröe* from a vascular circle which surrounds the intestine near the anus. They are eight in number, and one runs beneath each cilia-bearing arch, from one extremity of the body to

* Mem. sur la Storia e notomia degli animali senza Vertebre, 4to. Napoli, 1823-25.

the other. They then terminate in another annular vessel, which surrounds the mouth. In their course they give off numerous branches. From the oral circle of vascular structure arise two large vessels, which run along the walls of the gastric cavity, and appear to unite with the other circle at the anal extremity. These last Eschscholtz regarded as veins, and the eight external vessels as arteries. He supposed that the veins, passing along the walls of the stomach, absorbed the nutriment, and then carried the circulating fluid to the cilia for aëration. In the course of his observations on the *Beröe ovatus*, Dr. Fleming* distinctly saw a fluid moving " backwards and forwards" in the external vessels; and he states that " while the animal was active, there were numerous small spaces in the different vessels where the contained fluid circulated in eddies." Dr. Fleming failed to detect any structure in the vessels which could produce these partial motions. In *cestum naiadis*, Eschscholtz thought that he saw the system of vessels more distinctly than in any other of the acalephæ. He thus described it: " From the base of each of the two tentacules, a vessel takes its rise, and goes towards the bottom of the stomach. Here the two vessels unite, and form a little vascular circle around the water-canal (intestine). From the upper margin of this circle, four straight vessels arise, which go towards the two rows of cilia-bearing organs placed on the dorsal surface. Under these they run, two in one direction, and two in the other. At either extremity of the body, these unite with certain vessels running superficially along the sides, and which complete the circulation by entering the first set of vessels just before they begin to run beneath the ciliated organs. All these vessels are simple canals, of the same diameter throughout, without any visible branches. They contain a colourless watery fluid, in which minute yellowish globules are seen to move. In the vessels which arise from the bases of the tentacules, the globules mount upwards; they assume a rotatory motion in the vascular circle; and, in the four dorsal vessels, they seem to move, some in one direction, others in the other. It is probable that what appears to the eye as one vessel, is, in reality, composed of two vessels, running parallel and close together."†

Seeing that the radiating vessels which arise from the gastric cavities of the pulmograda seem to carry out the nourishing material to all parts of the body, and that they are, in some species at least, connected with other vessels which form a complete circle, we are disposed to class them under this head along with the vascular structures already described. The exact analogies of their functions, however, have not yet, we conceive, been distinctly made out.

From the stomach of rhizostoma, formerly described, sixteen vessels arise, and pursue a straight course outwards to the margin of the disc, near which they all enter, at equal distances, a circular vessel, which passes completely round the circumference of the animal. Four of the radiating vessels correspond with the four fleshy pillars of the process supporting the arms, and there exists on the internal surface of each of these pillars, a groove, which establishes a direct communication between the corresponding vessel, and one of the large vessels of the central process. The other twelve are distributed by threes in the intervals between the first four, and arise from those parts of the stomach which are closed by the plaited membranes. The space intervening between the circular vessel and the margin of the disc is occupied by an innumerable multitude of little vessels which form a net-work like the finest lace.* In medusa aurita, there are also sixteen radiating vessels, four of which arise from each of the four sacs, into which the gastric cavity in this species is divided. Two of the four vessels in each group are simple, the other two are several times bifurcated; both the simple main trunks and all the branches so formed, enter a circular vessel surrounding the disc, which seems to be connected also with the tubular cavities of the numerous cilia which surround the margin like a fringe, and which are capable of elongation and contraction.† Carus remarks with regard to the circular vessel, that " it may be considered as an extremely simple rudiment of the great circulation of superior animals, in case we view the radiating as chyliferous vessels."‡

V. *Respiration.*—It is probable that the air-bladders of the physograda, the swimming organs of the diphyda, and the cilia of the ciliograda are all subservient, in a greater or less degree, to the respiratory function, as well as to locomotion. The vessels in the last mentioned class, which have been described above as appertaining to the circulating system, are regarded by some as respiratory organs; and by Lamarck were compared to the tracheæ of insects. They have been called *aquiferous tracheæ*. Those who consider them in this light believe that they are open at two points, so as to admit the circumambient fluid to pass freely through them. The most recent and accurate observations, however, leave it doubtful whether this really takes place in the ciliograde acalephæ.

With regard to the pulmograda, several parts and organs have been pointed out by different observers as being, in all probability, the seats of the respiratory function. Cuvier thought that the delicate plaited membranes which exist between the fleshy pillars of the central process in *rhizostoma*, and which form in part the walls of the stomach, might be regarded as the organs of respirarion. Eisenhardt supposed that he saw them in certain tentaculated processes attached to the membranous partitions which divide the gastric sacs of some species from one another; while Gaede looked upon the four small sacs which overlie the

‡ Carus, Comp. Anat. (by Gore,) ii. 266.

gastric cavities in *medusa aurita* as subservient to the same function. These sacs communicate directly with the gastric cavities by means of openings in the membranous partitions which separate them. The partitions bear on their inferior surfaces, plaited membranes, which, under the microscope, present the appearance of being studded with vesicles containing a little watery fluid. A row of filamentary organs is also attached to these membranes, which move like external cilia, even for some time after they have been removed from the body of the animal.

VI. *Secretion.*—The existence of this function in the acalephæ is made known to us by the emission from their bodies, under certain circumstances, of a glairy mucus; by the stinging effect which some unknown product of their organization has upon our skin; and by the remarkable phenomenon of luminousness, which a large number of them present. The organs by which the mucus is secreted have not been satisfactorily observed. Dr. Milne Edwards saw reason to conclude with regard to the rhizostoma, that a large quantity of this fluid is secreted by a glandular structure situated along the margins of the arms. The stinging property possessed by several animals of this class has been the subject of inquiry since the time of Aristotle, but to this day we remain in doubt with regard to the nature and mode of production of the agent which causes this effect. Some men seem to be insensible to the irritation generally produced by the contact of living acalephæ. But, for the most part, a slight touch of any part of their surface, and chiefly of the pendent tentacula, is followed within a few minutes, at most, by a burning pain, redness, swelling, and sometimes even a vesication, of all that portion of the skin which touched the animal. Sloane said of the physalus, ("what the seamen call caravels, or Portuguese men-of-war,") "They burn violently—they do suck themselves so close to the skin that they raise blisters, and cause sometimes St. Antony's fire."* Even on our own coasts, severe cases of inflammation of the skin are occasionally seen, which have been produced by the irritation received during bathing from some of the larger pulmograda. In physalus, the stinging property seems to reside chiefly in the fluid with which the tentacula are filled. It continues to act powerfully even after the organs containing it have been detached from the body. And not only so, but it is said by some observers that its peculiar properties are so permanent, that vessels in which the animals have been placed must be washed several times in water, and carefully scoured before they can be used without inconvenience. On one occasion it was found that linen, which had been merely rinsed in soap and water, had this quality of irritation fifteen days after it had been used in making observations on the physalus.* None of the cirrigrada hitherto examined possess the stinging property.

The organs by which the luminous matter is elaborated are unknown. In some species, it is evidently mixed with the mucous fluid, which is so abundantly poured out from the margins of the arms and the disc. It has been frequently observed that the ciliograda are luminous chiefly along their rows of cilia, and that these continue to emit light for some time after their removal from the body. Perhaps the greater number of the acalephæ are luminous. According to Dr. M'Culloch, all inhabiting the British seas are so; and indeed it is chiefly to the emission of light by animals of this class that the beautiful phenomenon of the luminousness of the sea is owing in all situations. Spallanzani, however, whose observations and experiments on this subject were as extensive as they were careful and ingenious, came to the conclusion that "the medusæ which are possessed of luminous properties are extremely few compared with those which are destitute of it." The same philosopher remarked, with regard to some of the pulmograda, that they emit light more strongly during the contractions of their disc than at other times; that the intensity of their light increases when they are pressed in any way; that the luminousness resides chiefly in a peculiar fluid secreted by glands situated around the margins of the disc, along the edges of the tentacula, and in the fringed partitions of the gastric cavities; that this fluid being mixed with other fluids, as with fresh and salt water, and especially cow's milk, imparts its luminousness to them; that when spread over solid bodies it continues to shine for several minutes; and that in it there generally exists that irritating substance which produces the stinging effect. Spallanzani applied some of this fluid on two occasions to the tip of his tongue. It excited a burning sensation, which lasted more than a day. A similar feeling, but much more painful, followed the accidental application of a single drop of the same fluid to the conjunctiva.† In most of the acalephæ, the external covering is very fine, smooth, and delicate; but sometimes it is granular, or even warty. It does not appear that these differences in its structure have been observed by any naturalist to be connected with corresponding differences in the power of emitting light. (See LUMINOUSNESS, ANIMAL.)

VII. *Generation.*—The organs of this function cannot always be satisfactorily ascertained. This may, in a great measure, be owing to their minuteness and transparency when not in action. Ovaria and oviducts, however, are distinctly seen in several species; but no other organs connected with the generative function have hitherto been discovered. According to Eschscholtz, the ovaria in the physograda consist of several groups of vesicles and filaments,

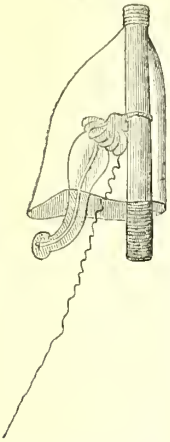
* Nat. Hist. of Jamaica, ii. p. 273. Sloane recommends acajou oil as "*the* remedy for the stinging of this nettle." Mr. Bennett has lately found (Lond. Med. Gaz. xiv. 908.) that the application of vinegar to the irritated surface in some degree alleviates the pain.

* Journ. Roy. Inst. 1831, p. 205.

† Travels in the two Sicilies, iv. 250.

loosely attached to the lower surface of the air-bladder. In the diphyda, they are in the form of numerous vesicles, having thick tunics filled with an opaque white fluid, and situated within one of their swimming organs. Such parts were seen by Eschscholtz only in some individuals, and on this account he was disposed to regard them as ovaries. But Messrs. Quoy and Gaimard seem to consider it more probable that the minute botryoidal bunches of vesicles, which surround the base of each sucker on the lengthened filaments, (before alluded to as being subservient both to nutrition and to locomotion,) are the ovaries.*

Fig. 13.



A portion of the ovigerous filament of Diphyes much magnified.

It does not appear that either Eschscholtz or Messrs. Quoy and Gaimard saw the ova.

In the ciliograda, the ovaries are more obvious. They consist of two or four vesicular organs, each placed between two of the cilia-bearing arches. In cydippe, they are of a red colour, and nearly cylindrical shape. The ova are spherical.

The parts in the pulmograda corresponding to the organs just referred to, are eight round bodies, of small size, situated near the margin of the disc, each formed of a vesicle, containing, at its free extremity, many minute hexagonal corpuscules; there is attached to each vesicle a digitated appendix, which seems to be hollow, and to communicate with the circular vessel. These organs were seen by Gaede and by Müller in *medusa capillata*, and *M. aurita*, and by Eschscholtz in some species of *cyanea*, *sthenonia*, *pelagia*, and *chrysaora*; Dr. M. Edwards has observed them also, at certain seasons, in *rhizostoma*; and in *carybdea marsupialis*, he found, midway between each pair of pendent filaments, and immediately above a little notch in the margin, four spots of a deep brown colour, each of which appeared, under the microscope, to be formed partly by a minute spherical body, having a granular aspect, as if it were filled with eggs, and partly by a little sac, with puckered sides, which is imbedded in the gelatinous substance of the body. These he regards as the ovaries.† But, notwithstanding their having found granular bodies like ova in the organs above described, neither Gaede nor Müller considered them as ovaries. Müller regarded the granules as excrementitious matters; and Gaede thought that he saw the ovaries in the plaited membranes of the gastric cavities; whence he observed the ova descend into certain minute vesicles imbedded in the margins of the arms. He remarked that, in *medusa aurita*, when the cells in the arms were filled with eggs, the plaited membranes had none; and, on the other hand, when there were no eggs in the arms, the plaited membranes were studded with them. Cuvier was also of opinion that the ova are formed in the plaited membranes above mentioned, and that they are matured in the margins of the arms.*

No observations, so far as we know, have hitherto been made on the development of the ova; but Dr. Grant has recently stated that the ova of *equorea* are furnished with cilia, and have locomotive powers, like the ova of the *porifera* and *polypifera*.† The colours of the acalephæ often depend on the tints of their ova: these are generally red, but sometimes brown, yellow, or purple.

VIII. *Geographical distribution.*—We conceive that a brief notice of this part of their natural history may, in some measure, illustrate the physiology of the acalephæ. They are met with in all seas; but certain families exist more abundantly in some localities than in others. The ciliograda and pulmograda, for instance, are inhabitants chiefly of the colder regions, while the physograda are seldom found beyond the limits of the tropical zone. Some float in bays, and near land, but the greater number in the high seas. *Medusæ* and *cyaneæ* are met with only in the cold and temperate zones of the northern hemisphere. *Cydippe* lives in the North Arctic Ocean, as well as in the Pacific, under the equator. One species of *cestum* inhabits the Mediterranean,—another the South Sea. It frequently happens that enormous numbers of one species are met with closely grouped together, so as somewhat to impede a ship's progress for two or three successive days; after which, not a single individual of the same species is seen. In the European seas, it is chiefly in summer and autumn that the acalephæ swim on the surface. In winter, they probably sink to the bottom.

ACIDS, ANIMAL. Several acids are found in animal products, some of which are peculiar to organized bodies, and others common to them and to the other kingdoms in nature. The former are characterized by their analogy to other organic compounds, and are ternary or quaternary combinations of carbon, hydrogen, oxygen, and nitrogen. The latter are for the most part binary compounds, such as the phosphoric, carbonic, muriatic, sulphuric, and fluoric acids.

With the exception of lactic acid, the existence of which as a distinct definite compound is doubtful, there is only one acid which can strictly be called peculiar to animals, namely, the *uric acid*. The oxalic, benzoic, and acetic acids are common to animals and vegetables.

The other animal acids are not found ready formed, but are artificially produced by various chemical processes in which animal matters are concerned. Such are the various acids from fat and oil, the animal pyroacids, the purpuric acid,* and a few others. There are also certain acids almost peculiar to individual animals, such as the formic,† the allantoic or amniotic,‡ the bombic, &c.,§ and one or two which are the products of disease.

Under the articles FAT, URINE, MILK, and BONE, will be found the details respecting the principal animal acids.

(W. T. Brande.)

ACRITA (α, priv. κρινω, *discerno*,) a primary division of the animal kingdom founded by Virey, and so called by Macleay,|| composed of the lowest classes of the radiate animals of Cuvier, and characterised by an *indistinct*, diffused, or molecular condition of the nervous system.

The necessity for a dismemberment of the Radiata of Cuvier, which Rudolphi¶ justly calls a chaotic group, has been felt, and directly or indirectly expressed, by most naturalists and comparative anatomists.** It is impossible, indeed, to predicate a community of structure in either the locomotive, excretive, digestive, sensitive, or generative systems, with respect to this division, as it now stands in the "Règne Animal."

As in the animal organization the nervous system is that which is subject to the fewest varieties, and as its relative perfection is the surest indication of the relative perfection of the entire animal, the modifications of this system necessarily indicate the highest or primary divisions of the animal kingdom, and form their distinguishing characters.

Taking, then, the nervous system as a guide, the radiata of Cuvier will be found to resolve themselves into two natural groups, of which the first, composed of the *Polygastric Infusoria* of Ehrenberg, the *Polypi* of Cuvier, the *Entozoa parenchymatosa*, Cuv. or *Sterelmintha*, and the *Acalephæ*, differs in the absence or obscure traces of nervous filaments from the second division, including the *Echinoderma*, the *Entozoa cavitaria* or *Cœlelmintha*, the *epizoa*, and the *Rotifera*, Ehr., in which nervous filaments are always distinctly traceable, either radiating from an oral ring, or distributed, in a parallel longitudinal direction, according to the form of the body.

These different conditions of the nervous system are accompanied with corresponding modifications of the muscular, digestive, and vascular systems, and a negative character, applicable to the higher division of Cuvier's Radiata, may be derived from the generative system.

With respect to the muscular system, we find that although all the Acrita possess the locomotive faculty at some period of their existence, and many never become fixed, yet that distinct muscular fasciculi are not necessarily developed. In the fresh-water polype, for example, the whole of the homogeneous parenchyma of which it consists is equally contractile; and even in the medusa, which ranks among the highest of the Acrita, no distinct muscular organs for effecting the contractions of the gelatinous disc have yet been detected. In the higher division of radiata, on the other hand, which from the filamentous condition of the nervous system may be termed *Nematoneura*, the muscular system is always distinctly eliminated.

The difference in the condition of the digestive system between the Acrite and Nematoneurous classes is still more striking: in the former the alimentary canal is excavated in the parenchyma of the body, and is devoid of distinct parietes: in the Nematoneura it is provided with a proper muscular tunic, and floats in an abdominal cavity.

A corresponding difference is presented by these two divisions of the invertebrate animals, in the condition of the vascular system. Where traces of sanguiferous organs are met with in the Acrita, they are equally with the digestive organ devoid of proper parietes, but consist of reticulate canals in the substance of the body, generally situated near the surface, and in which a *cyclosis* of the nutrient fluids is observed analogous to that of plants, but not a true circulation. This structure obtains in the Acrita as low down in the scale as the polygastrica, in which class Ehrenberg has determined the existence of a superficial network of vessels containing an opaline fluid. In those

|| Horæ Entomologicæ, vol. i. pt. ii. p. 202.

¶ Synopsis Entozoorum, p. 572.

** Lamarck observes, "Les *animaux apathiques* (as he terms the *Acrita*) furent très-improprement appelés *zoophytes*: ils ne tiennent rien de la nature végétale, et tous généralemeut sont complétement des animaux. La dénomination *d'animaux rayonnés* ne leur convient pas plus que la précédente; car elle ne peut s'appliquer; qu'à une partie d'entr'eux; et il s'en trouve beaucoup parmi eux qui n'ont absolument rien de la forme rayonnante." Anim. sans Vertèbres i. p. 390.

genera of sterelmintha or parenchymatous intestinal worms which manifest traces of the circulating system, the fluids undulate in canals of a similar structure, as is displayed in the planariæ, and parasitic trematoda, and also in the echinorhynchi, in some species of which genus the cutaneous canals form a rich network.* In the acalephæ the condition of the vascular system is equally simple with that of the lowest Acrita, as is exemplified in the marginal reticulate canals in the disk of the rhizostoma. In the Nematoneura, on the contrary, those classes which manifest a circulating system distinct from the digestive tube, as the echinoderma and rotifera, possess vessels with proper parietes, distinguishable into arteries and veins.

No Nematoneurous class presents an example of generation by spontaneous fision or gemmation, but these modes of reproduction are common in the Acrite division.

The planariæ among the sterelmintha are capable of indefinite multiplication by simple division; and the medusæ are stated to produce, not ova, but ciliated locomotive gemmules or internal buds. The various examples of these plant-like modes of generation which the polypi and polygastrica present are familiar to most persons, and will be especially treated of under their respective articles.

The fissiparous and gemmiparous modes of reproduction are not, however, the exclusive modes by which the Acrite classes are perpetuated. Most of the sterelmintha are propagated by means of ova: in the *cystica* and *cestoidea*, the generative organs consist of ovaries alone, or are cryptandrous; in the trematoda, a fecundating gland is superadded to the ovary; while in the acanthocephala the sexes are separate, so that thus early in the animal kingdom, we find typified all the different modes of generation by which the race is continued in the higher classes of animals.

The different conditions of the important organic systems which are thus seen to obtain in the great group of animals called Radiata and Zoophyta fully justify a partition of the group corresponding with those differences. For the lower organized division we retain the name proposed by Macleay, but extend its application to the acalephæ; and thus constituted it may be characterized as follows.

Sub-kingdom Acrita.—*Gelatinous polymorphous animals, without distinct nervous fibre, or visceral cavities.*

Alimentary canal excavated in the parenchyma of the body, generally without an anus.

Sanguiferous system composed of reticulate canals without proper tunics.

Generation in most fissiparous or gemmiparous; in some oviparous.†

The Acrita have been termed *Protozoa*, as being on the first step of animal organization. They are analogous to the ova or germs of the higher classes, and have, therefore, been termed by Carus *Oozoa*; and as the changes of the embryo succeed each other with a rapidity proportionate to the proximity of the ovum to the commencement of its development, so also we find that in each class of Acrita there are genera which advance into close approximation with some one or other of the classes belonging to the higher divisions of the animal kingdom. It results, therefore, from this tendency to ascend in the scale of organization that there is greater difficulty in assigning constant or general organic characters to the Acrita than to any of the higher divisions of animals. Even in the nervous system, we find as we are led step by step from the hydra to the actinia in the class Polypi, that the nervous globules begin to manifest the filamentary arrangement about the oral orifice in the last named genus. That, again, in tracing the successive complication of the sterelmintha from the hydatid to the echinorhynchus we also come to perceive traces of longitudinal nervous filaments in the latter highly organized genus of parenchymatous worms. In the acalephæ the examples of the aggregate form of the nervous system would seem to be more numerous and distinct. Ehrenberg has detected what he considers as a nervous system in a gelatinous medusa; and Dr. Grant has recently described a nervous collar giving off simple filaments in the more highly organized beroë, which, in its distinct intestine and anal outlet, recedes too far from the medusidæ to be placed in a natural arrangement in the same class. Many of the polygastrica are endowed with simple visual organs or ocelli, in the form of red or yellow spots; similar organs of a dark colour are exhibited by the planariæ, and Nordmann also describes them in some internal parasitic trematoda. Ehrenberg has recently discovered coloured ocelli in a medusa, and he ascribes a sense of taste to the polygastrica.

The indications, however, of the special senses in the Acrita are feeble and obscure, and in the least doubtful instances the organs are evidently of the simplest and most elementary nature.

For the most part all the different systems seem blended together, and the homogeneous granular parenchyma possesses many functions in common.

Where a distinct organ is eliminated it is often repeated indefinitely in the same individual. Thus in the polypi the nutritious tubes of one individual are generally supplied by numerous mouths, and it has, consequently, the semblance

* Rudolphi terms one species *echinorhynchus vasculosus*, from this circumstance.—Synopsis Entozoorum, p. 581.

† The definition of the Acrita given by Macleay is confessedly a negative one as referred to animals; it is as follows:

"Animalia gelatinosa polymorpha, interaneis nullis medullaque indistincta.

"Os interdum indistinctum, sed nutritio absorptione externa vel interna semper sistit. Anus nullus.

"Reproductio fissipara vel gemmipara, gemmis modo exteris, modo internis, interdum acervatis.

"Pleraque ex individuis pluribus semper cohærentibus animalia composita sistunt."—Horæ Entomologicæ, ii. p. 224. *See also* Lamarck, Anim. sans Vertèbres, ii. p. 2.

of a composite animal; the polygastrica derive their name from an analogous multiplication of the digestive organ itself. Among the sterelmintha we find instances where the generative system is the subject of a similar repetition, each joint of the tæniæ being the seat of a separate ovary, though all are nourished by continuations of one simple system of nutritious tubes. The calcareous and siliceous sponges, again, which, in eliminating the first sketch of an internal earthy skeleton, seem to lose the few characteristics of animal life which they before possessed, are limited to the repetition of a simple spiculum.

The formative energies of the Acrita being thus expended on a few simple operations, and not concentrated on the perfect development of any single organ, it is not surprising that the different classes should exhibit the greatest diversity of external figure.* But it has been well observed that Nature, so far from forgetting order, has, at the commencement of her work, in these imperfect animals given us a sketch of the different forms which she intended afterwards to adopt for the whole animal kingdom. Thus in the soft, sluggish sterelmintha we have the outline of the mollusca; in the fleshy living mass which surrounds the earthy hollow axis of the polypi natantes, she has sketched a vertebrated animal; and in the crustaceous covering of the living mass, and the structure more or less articulated of the polypi vaginati we trace the form of the annulose or articulate classes.

(Richard Owen.)

ADHESION, (from *ad-hærere*, Lat. *adhesio*, Fr. *adherence*, Germ. *wiederanheilung*, Ital. *adesione*,) that process, by the occurrence of which, when two living surfaces, naturally or artificially separated the one from the other, are brought into mediate or immediate contact, and inflammation is developed, those surfaces may become adherent the one to the other.

This adhesion may be effected either by the intervention of a stratum of exhaled fibrino-albuminous matter, inorganic in the first instance, but at a subsequent period acquiring organization, and becoming a perfect and permanent cellular bond of union; or it may not occur until after suppuration has been established and granulating surfaces are presented; these surfaces enter into adhesion, and in this case the bond of union is not so decidedly cellular in character as in the former; it is more or less dense and fibro-cellular.

In either case, the medium of union presents peculiar modifications dependent upon the tissue on which it is developed. This circumstance, and especially the deposition of osseous matter, where bony union is required, was one of the strongest arguments used for the purpose of establishing the existence of the presiding intelligent principle of Stahl.

If the first process, that in which the fibrino-albuminous exhalation obtains, be interfered with, that is, if a more intense degree of inflammation be developed, such exhalation can no longer occur, but the second state, that in which a purulent exhalation shall be the product, may be induced.

It is upon this principle, viz. that a certain quantity of inflammation shall predispose to the first species of union, which is termed union by the first intention; and that a greater quantity may produce a purulent exhalation, and therefore be opposed to such union, that is founded the following precept. "When it is deemed prudent to prevent union by the *first intention*, we have merely to introduce between the surfaces, and retain there from eighteen to twenty-four hours a piece of lint, by which a sufficient degree of inflammation will, usually, be excited to ensure a suppurating surface."

From the time when the phenomena of inflammation were first carefully studied, until very recently, it has been commonly, if not universally maintained, that adhesion could never be accomplished in the absence of inflammation.

In the present day, Breschet* and some others have endeavoured to establish that adhesion does not, necessarily, imply the pre-existence or co-existence of inflammation; and as it appears to me upon very insufficient evidence. They say that adhesion may result from a "*primitive disposition of the organization*," and as evidence of the existence of this *disposition*, they refer to certain congenital affections, occlusion of the eyelids, and of the lachrymal canal, imperforations of the mouth, the anus, and so on. Why they should assume that phenomena, the mechanism of which appears identical, should be effected by a totally different agency in intra and in extra-uterine life, it is not easy to understand, and I believe such is not the fact.

We may have certain of these occlusions, accomplished in extra-uterine life, but never without the intervention of inflammation; and what possible reason have we for supposing that if these occlusions do commonly, nay always, occur in consequence of the development of inflammatory action, that this agency shall be wanting during uterine life? None, I apprehend, beyond simple assumption.

Imperforation of the eyelids and occlusion of the lachrymal canal differ from imperforation of the mouth and of the anus, in that the former result, not from the presence of an anomalous membrane, but only from the union of existing membranes, which are normally separated the one from the other. In the greater number of cases the eyelids are simply adherent, either at one or many points, or along the whole length of their border, and I would say are always so in consequence of inflammation.

The other imperforations to which allusion has been made, are dissimilar to those of the eyelids. Imperforation of canals opening upon the surface of the body is a case in which, almost always, there has been an arrest of development; all the canals which in the adult are lined by a mucous membrane, continuous with the skin at their orifice, are naturally, at

* Macleay, ibid, p. 123.

* Dict. de Méd. art. Adhérence.

a certain epoch of embryo life, imperforate. These organic states, which nosologists have so often considered as diseases, are, therefore, simply primitive conditions preserved by anomaly, and become permanent instead of transient.* It may, therefore, be inferred that the greater number of cases adduced as evidence of adhesion in intra-uterine life are not in point, and if they were it may still be asserted, and the assertion be borne out by analogy, that they had not occurred in the absence of inflammation.

John Hunter seems to have had the idea that adhesion may occur in the absence of inflammation in certain cases, namely, in those where blood has been effused, that this blood may become organized and form a bond of union. He says, " It does not seem necessary that *both* surfaces, which are to be united, should be in a state of inflammation for the purpose of effecting an union ; it appears *only necessary that one* should be in such a state, which is to furnish the materials, viz. to throw out the coagulating lymph, and the opposite uninflamed surface accepts simply of the union ; nor is it even necessary that *either* surface should be in a state of inflammation to admit of union: we often find adhesions of parts which can *hardly* be called inflamed."†

I believe that no solution of continuity can be obliterated in the absence of inflammation, the injury which has occasioned the solution of continuity, and the effusion of blood, being sufficient to excite inflammation. The only circumstance under which it seems to me to be possible that union could be produced in the absence of inflammation, is one which can only rarely occur; and even then, although the possibility of the occurrence can hardly be denied, its reality may be reasonably questioned. If a portion of blood, for instance, be effused into a serous cavity, its colouring matter is, after a time, removed, and a fibrino-albuminous coagulum remains. This coagulum coming in contact with a previously uninflamed serous membrane, may become united to this membrane: and it is believed by some pathologists that this union occurs without the supervention of inflammation. Another situation where it is believed by certain pathologists that union is produced by similar means, is in a portion of artery included between two ligatures, the blood which has been included between the two points undergoing a similar change to that which I have already described, and adhesion of the clot to the internal tunic of the artery being effected in the absence of inflammation.

Such cases may carry conviction to the mind of a superficial observer, but a more careful investigation will lead to an opposite conclusion. My own observations induce me to think, that of all the causes by which adhesive inflammation of serous membranes may be produced, the most remarkable perhaps is an extravasation of blood into their cavities, which appears to excite just the precise quantity of inflammation necessary for the production of adhesion. If we examine the point at which such coagula are maintained in contact with serous membranes, before perfect union is established, we shall find between the coagulum and the membranes a stratum of exhaled matter, the existence of which would lead to the conclusion that the clot has excited in the membrane as much inflammation as is necessary for the production of such exhalation.

In solutions of continuity where blood has been effused between the edges, it was maintained by John Hunter* that this blood was the provisional bond of union ; this, I apprehend, is not the case. Whether protected from the atmospheric air, which appears to exercise a very decided influence in decomposing it, as in some fractures, or directly exposed to it, as in ordinary solutions of continuity, this coagulum never, during the early periods, adheres with sufficient firmness to attach to each other the borders of a wound If, however, any portion of the coagulum remain after a fibrino-albuminous exhalation has been formed upon the divided surfaces, it may become in this way organised, and permanently adherent.

After the preceding remarks, it will therefore be held in this article that whenever an adhesion has been effected between two surfaces, naturally or artificially separated, that that adhesion must have taken place through the intervention of inflammation ; that inflammation arrived at a certain height will be accompanied by a fibrino-albuminous exhalation;—that if the inflammation be carried beyond that point, a purulent secretion may be established, and when this is developed, union, by what is termed the first intention, cannot occur ; granulations are then developed, and union by what is termed the second intention, may follow. The process by which each kind of union is effected I shall now proceed to describe in detail.

In all cases, whether two naturally separate tissues are to be united, or whether a solution of continuity is to be repaired, there appears to be a certain uniformity in the means by which the union is accomplished. Inflammation is developed, and a material susceptible of organization is exhaled, which becomes the connecting medium. This matter in its greatest state of simplicity is exuded under the form of *lymph*, upon the surface of the parts to be united ; it is coagulated, and transformed into a soft pulp ; it gradually increases in density, acquires a reticular or porous aspect, a first rudiment of organization, and as a second degree exhibits in its substance red spots, then striæ, which have the appearance of vascular ramifications, and at last bloodvessels.

It is hardly possible to collect this lymph in a state of purity except in the canal of an artery where it has been exhaled between two ligatures. It is then presented under the form of a whitish matter, of a soft and fibrinous consistence, which

* Isid. Geoff. St. Hilaire, Hist. des Anomalies de l'Organization, t. i. p. 532.

† On the Blood and Inflam. Ed. 1828, p. 319.

* Loc. cit. p. 253.

is rendered particularly evident when the lymph is submitted to the action of boiling water; it dissolves almost completely in a warm solution of caustic potash, though less promptly than thickened albumen, but more rapidly than fibrine.

This matter, which is probably the same with that by which all parts of the body are nourished and preserved, but in the case before us secreted in increased quantity and preserving a strong tendency to coagulate, has nothing in it which is necessarily opposed to the healthy action of the animal economy. In fact we may consider exudation as a nutrition, much exalted by inflammatory action, which is itself only an exaltation of the vital properties.

We may admit four periods or states of change to which this material which constitutes the medium of adhesion is subject—a first, the period of development; a second, a period of increase; a third, that of organization; and a fourth, that of mutation; in which it is changed into a cellular tissue.

In the first period, we find that in twenty-four, and sometimes even in nineteen hours after we have irritated a serous membrane, the pleura of a dog, or of a rabbit for instance, that this membrane is much injected, and that there has been formed upon its surface an extremely thin, pulpy stratum, which may very easily be removed: the second period commences when this exudation has assumed a membraniform appearance, and is characterized by an augmentation of thickness and of density: the third period is characterised by still greater density and the presence of vessels. Stoll believed that these membranes might become organised in twelve, nine, or even eight days after the invasion of the disease. Home believed that vessels might appear in twenty-four hours.

In the fourth period, the membrane loses some of its thickness, and every day assumes more and more of the appearance of cellular tissue; and when perfected, there is not only identity of appearance between cellular tissue and these membranes, but also, according to Laennec,* identity of use, and even of disease, except that this tissue very rarely contains adipose matter.†

Nothing in our subject is more curious or more important than the organisation of these membranes; their vessels are thin, delicate, and similar to those of the pia mater; their form and their direction are extremely simple; they are not tortuous, and they proceed, usually, in fasciculi, almost like the lymphatics of the extremities. We may easily convince ourselves that their formation is sometimes very prompt, by the perusal of the following case. A portion of strangulated intestine, which, after the incision of the herniary sac, did not present many bloodvessels, was examined after the death of the individual, which occurred in *twenty-nine hours* after the operation, by Sir Everard Home: he found the portion of intestine which had been strangulated profoundly inflamed, and covered in many points by a "layer of coagulable lymph:" this intestine was injected with very fine size, and two small bloodvessels were found passing along through the new membrane into which the injection had penetrated.

According to Laennec* we may observe the following phases in the organisation of these membranes.

The rudiments of bloodvessels are at first presented under the form of striæ of blood, which are more voluminous than the vessels by which they are to be succeeded. The blood appears to have penetrated into the tissue of the membrane, as if pushed by a strong injection; yet in examining the points of the membrane, on which the layer of "coagulable lymph" is deposited, we find no destruction, nor any orifice of a vessel, but only spots of blood. Soon, according to Laennec, "these lines of blood take a cylindrical form, and ramify in the manner of bloodvessels, still preserving a considerable diameter. If, at this epoch, we carefully examine them, we find that these vessels have an external coat which is soft, and formed of blood scarcely concrete, to which they owe their colour. After having incised this coat, we withdraw a sort of mould, or rounded fascicular body, whitish and fibrous, evidently formed of concrete fibrine, and of which the centre appears perforated and permeable to the blood. However small be the canal, it is these fibrous fasciculi which should, by thinning, form the tunics of the bloodvessels."

These delicate observations have not, so far as I know, been confirmed by other observers: those authors who have spoken of newly developed vessels, among whom we may name Hunter, Monro, Soëmmering, do not speak of this mode of development. Hunter and Home explain it differently; they say there is at first a formation of small ampullæ, containing only a colourless fluid: second, a union of these ampullæ, and production of a vascular network, not yet supplied with blood: third, an inosculation between the newly developed vessels, and those of the inflamed membrane, and next the ingress of blood. Beclard was of the same opinion.† Gendrin thinks that the new vessels are developed by the action of the primitive vessels; he says, "that the blood is excreted by the adjoining capillaries, opening into the soft and fibrinous tissue deposited in the inflamed part; this blood becomes concrete, and the vascular impulsion, *a tergo*, being continued, new blood is pushed into it and hollows it. Thus the little vascular rudiment is prolonged into an irregular, flexuous, and unequal stria, which meets another and unites with it, continuing in this way to prolong itself into the least resistent portion of the fibrinous deposition."‡

To some extent the opinions of Laennec and

* De l'Auscultation Médiate, tom. ii. p. 293.

† Laennec states that he has "quelquefois" seen fat developed in these cellular laminæ. Loc. cit.—Ed.

* Loc. cit.

† Anat. Générale, p. 195.

‡ Hist. Anat. des Inflam. tom. ii. § 1393. and 1571.

Gendrin are alike; they believe that the formation of the new vessel consisted in this, that the little clot was perforated, and that it was penetrated by liquid blood.

The experiments of Brande* would, however, lead to a different conclusion; he shewed that the air contained in the blood had much influence in the formation of bloodvessels. This air is carbonic acid gas, and its quantity appears to be nearly equal in the two kinds of blood; being estimated at a cubic inch for every ounce of blood. This gas may be separated from the blood by the air-pump, and it escapes with a kind of bubbling or effervescence, causing the ascent of the mercury in a barometer attached to the apparatus.

It has been remarked that during the coagulation of the blood, a large quantity of carbonic acid gas escapes; this coagulation, observed under the microscope, has shewn that the gas, by escaping in all directions, forms a net-work of canals, the branches of which anastomose with each other; and that this net-work preserves its form after desiccation. It has also been established that it is this gas which forms those canals in coagulated blood; because, if by means of the air-pump we deprive the blood of it, before it is coagulated, they do not occur.

Sir E. Home has even injected the vessels which were developed in the coagulum soon after the blood was taken from a vein. If the formation of new vessels occur even in a coagulum of blood removed from the living body, but preserving still a certain quantity of its heat, and of its vitality, with more reason might we expect that a similar phenomenon should obtain during life: and this fact has been demonstrated by experiments performed on a rabbit, in which had been produced a hemorrhage from a small branch of the mesenteric artery: after twenty-four hours, the coagulum which was formed was injected.

The formation of vessels in coagulated blood, by means of the carbonic acid gas which traverses it in all directions, is in perfect accordance with the observations which have been made by M. Bauer upon germinating wheat, which were instituted for the purpose of shewing the influence of the globule of air. These globules are manifested below a bud of mucilaginous substance; they push it forward, elongate it, and thus form a filament.

I do not, however, believe that either of these theories correctly explains the phenomenon.

It was for a long time believed that false membranes were never organised; that nature had given to the parts of our economy an almost unlimited power of development, but not the faculty of communicating life to the products of the circulation; that false membranes *appeared* to be organised only because they constituted a kind of frame-work through which vessels from the inflamed tissue *might* be prolonged: ulterior observations, however, have shewn that these media are really organised. We have no general rules as to the time when such organisation shall commence. It seems to be dependent upon inexplicable individual dispositions. It may, however, be remarked, that the greatest analogy exists between the mode of development of vessels in these media of adhesion and their mode of production in the membrane of the yolk in the chick, saving always this remarkable circumstance, namely, the inconstancy, the irregularity of the work of organisation in the former, and, on the contrary, the constancy and the regularity of the occurrence in the latter case.

These media are in fact secreted by a tissue, the vitality of which is exalted to a certain extent, and it appears to impress upon the product of its secretion a commencement of vitality, as in generation. All these circumstances appear to me to demonstrate that these vessels are the product of a spontaneous generation—a true epigenesis; so indeed, to a certain extent, thought Hunter. He says, "In a vast number of instances I have observed, that in the substance of the extravasation there were a great number of spots of red blood, so that it looked mottled. The same appearance was very observable on the surface of separation between the old substance and the new, a good deal like petechial spots. Was this blood extravasated along with the coagulating lymph? In this case I should rather have supposed it would have been more diffused. I have therefore suspected parts have the power of making vessels, and red blood, independent of the circulation."*

If the inflammation be not strictly confined to that state in which the albumino-fibrinous exhalation is accomplished, but proceeds to the next stage, the exhalation entirely changes character; pus is produced, a granulating surface is developed, and union is accomplished by the intervention of another tissue, and by a slower process than that which we have already described. This is the process which is always observed in mucous membranes, scarcely ever in serous; for in the former, the albumino-fibrinous matter never becomes organised, and can therefore never be the medium of a permanent union. In these membranes, if adhesion occur, the inflammation must proceed to the succeeding stage. Adhesion of mucous membranes, however, does not often occur—it is not compatible with the performance of their functions.

Soon after the secretion of pus is established granulations are developed, and a state favourable to adhesion is produced. The development of granulations occurs in the following manner:—upon the surface, about to suppurate, is exuded a layer of "coagulable lymph;" this lymph becomes penetrated by bloodvessels, nerves, and absorbents, which give birth to granulations. These granulations are developed much earlier in some tissues than in others—in a stump, for instance, we see them first upon the cellular tissue, then upon the muscular, then the fibrous, and lastly upon the osseous tissue: they appear to form as much

* Phil. Trans. 1818. pp. 172 and 185.

* Loc. cit. pp. 388-9.

more readily as the tissue may be more cellular and vascular. That these organs are very vascular is evident from the rapidity with which they bleed upon the slightest contact; that they contain nerves is shewn by the pain which is produced in them by the slighest touch: does not their prompt destruction by slight causes seem to indicate the existence of absorbents?

No one has made more interesting researches into the nature of these bodies than Sir Everard Home.* He carefully observed the changes which occurred in an ulcer of the leg. By using a lens which enlarged objects eight times, he saw that granulations were formed in the following manner: first, is seen a mass of capillary vessels differently arranged; secondly, small sinuosities containing pus. The ulcer observed during ten minutes, offered, in the first place, an extremely thin and transparent pellicle, under which were disengaged globules of gas, then canals having a horizontal direction, and containing blood. The tunics of these vessels were so delicate that they were ruptured by the simple motion of the leg. These canals anastomose with each other, taking different directions; those which are developed the first were the next day changed into true vessels. Soon these new vessels have enough of solidity to admit of our passing a needle under them and raising without rupturing them. The formation of all these parts is due, according to Home, to the coagulation of pus, and the development of carbonic acid gas; "for if the puriform matter be wiped off, these phenomena are not produced." When, on the contrary, he employed substances, calculated to coagulate the pus, the formation of those vessels was accelerated. He concludes from his experiments that bloodvessels are developed, almost as it were under the eye of the observer; that they are not a prolongation of pre-existing vessels; that they are formed independently of the action of the subjacent solid parts. So far, therefore, although the processes may differ, yet the general points of union between the two modes is singularly similar.

While suppuration is proceeding, another operation is in progress under the layer of granulations. A stratum of cellular tissue, at first simple and not very resistent, afterwards fibrocellular, and lastly fibrous, is organised insensibly to serve as the base of the succeeding medium of union.

When granular surfaces are brought into contact, and the tendency to secrete pus has ceased, they enter into adhesion. This tendency is marked by a diminution of activity in the granulations; the membrane ceases to secrete pus, and the granulations become firmer and contracted: before union can be effected, the suppurating surface must, therefore, change its nature—must be destroyed. A state like that in simple union by the first intention is produced; the secretion becomes plastic, and somewhat analogous to that which accompanies that mode of union.

* Home on Ulcers.

When these new tissues or media of union are developed between surfaces naturally free, the structure of the two portions of the organ between which they are seated becomes changed. In serous or mucous membranes, as well as in those surfaces which are immediate modifications of these two systems, this may be observed. When, for example, the pleura costalis becomes adherent to the pleura pulmonalis, the point of union is no longer a serous membrane; the free surface having disappeared, an uninterrupted continuity is established between the subserous cellular tissue of the pleura costalis, and the interlobular cellular tissue of the lung. This conversion is frequent in the peritoneum; in the tunica vaginalis a similar effect is produced by the common operation for hydrocele; in synovial membranes a similar effect occurs in what is termed false ankylosis.

Having described the general laws by which the phenomena of adhesion are governed, I shall now point out, generally, the modifications which are impressed upon it in different tissues.

It is upon serous membranes that we may with most advantage study the process of adhesion, not only because it is more rapidly developed there, but because it much more frequently occurs there than in other tissues. If we examine the surfaces of two such membranes which have been recently united, commencing at a certain distance from the point of adhesion, we see the layer of coagulable matter effused between the two surfaces become thinner as we approach the point of contact. If the adhesion be sufficiently recent to admit of our separating the surfaces, we see the intermediate layer tearing, but remaining adherent to the inflamed surfaces. If the inflammation be more advanced, and the pseudo-membrane be more dense and organised, we find that the very thin layer of new deposition by which the union has place is more resistent than the thicker layer of organisable matter by which it is surrounded; and at a later period we may discover vascular filaments attaching the adherent portion of the new tissue to that upon which it has been developed. These filaments are as much more evident as the adhesion is more immediate: of this we may very easily assure ourselves by cutting transversely two portions of digestive tube which have become to a certain extent adherent by their external tunic. The adhesion may be already very solid at the points where contact is so immediate that we can scarcely distinguish the interposed matter. Very delicate red capillaries creep through this matter, whilst perhaps at the distance of some lines, and even at the centre of an already organised point, the contact having been less immediate, a plastic layer of one, two, or more lines in thickness, may be seen uniting the surfaces, but not presenting either the solidity or the organisation of the excessively thin layer which adjoins it.

When these adhesions have existed for a certain time, the serous structure completely disappears. This destruction of serous membranes at the adherent point is very evident around herniæ which have been inflamed; the intestines engaged in the tumour are enveloped by a more or less dense layer of cellular tissue; and hence many herniæ thus circumstanced have been described as having no hernial sac. This sac has, however, originally existed, but has disappeared by the adhesions which have been formed between it and the displaced organs, adhesions by which the cellular tissue which replaces the serous membrane has been developed.

If we consider these adhesions in relation to their frequency in the serous cavities, we see that they exist most frequently in the pleura, existing in nearly half the adult bodies examined. After the pleura comes the peritoneum, then the pericardium; those of the tunica vaginalis are less common, but the arachnoid is, of all serous membranes, especially relative to its extent, that where these adhesions are most unfrequent.

The absence of mobility appears singularly to favour this phenomenon: thus in the pleura they most frequently occupy the superior parts, and in the peritoneum most frequently occur between the viscera forming a hernia, and between the convex surface of the liver and the diaphragm.

The membranes between which such adhesions occur, must usually, of course, be in intimate relation, the one with the other during the time when the process is in progress of accomplishment, though now and then the distance is considerable; but they may afterwards become separated to great distances: those cellular bands which are so commonly seen in the thorax are evidences of this fact.

Some circumstances tend to demonstrate that these bands in serous structure may at a certain period of their existence be absorbed and disappear, and the secreting surface be reproduced. M. Ribes states that occasionally we do not find any trace of such bands, nor any adhesion in the peritoneum of persons who have had penetrating wounds of the abdomen. Beclard examined an insane person who had several times stabbed himself in the abdomen. At the points where the more recent of these wounds had been inflicted considerable adhesions were found; beneath the older cicatrices no vestige of adhesion was found. A case of artificial anus occurred in the practice of M. Dupuytren, by which fæcal matter passed during twelve days. The patient died at the end of seven months. At the examination after death, it was found that the portion of intestine in which the accidental opening had existed, was distant from the abdominal cicatrix between four and five inches. A very attenuated cellular band extended from the cicatrix to the portion of intestine. Doubtless a short time would have sufficed for the absorption of this band, when the intestine would have been set at liberty and the serous surface restored.

In the course of lectures which Bichat delivered only a few months before his death, he maintained that adhesion was never produced between mucous surfaces, and that consequently the cavities lined by this tissue were never obliterated. Few statements have given rise to more extensive discussion than this; few discussions have up to the present moment been attended by less satisfactory results. In his first dictum I believe he was clearly right, in the second as clearly wrong.

Mr. Hunter's opinion was in accordance with that of Bichat: he says, "that in all the outlets of the body called mucous membranes, the order of inflammation differs from that which occurs in cellular membrane, or in circumscribed cavities. In these latter adhesive inflammation is immediately admitted to exclude, if possible, suppuration." In internal canals, where adhesions would in most cases prove hurtful, the parts run immediately into the suppurative inflammation, the adhesive inflammation being in common excluded.*

Mucous membranes, when unchanged by disease, are not capable of becoming adherent the one to the other, and the reason of this is simple. I have already stated that no permanent adhesion can occur in the living body without the intervention of a new tissue, which at a certain indefinite or undetermined period of its existence becomes organized.

A pseudo-membrane of considerable extent may be thrown out upon an inflamed mucous surface; but this membrane, I apprehend, never becomes organised, and union between mucous surfaces cannot therefore be permanent unless some other agency be called into action. But, as soon as inflammation has destroyed the characters from which these membranes derive their name; when the mucus, which like an inorganic layer appears to oppose itself so successfully against immediate contact, thereby preventing the organization of the effused matter, no longer exists; when the cellular element which forms the basis of this membrane is developed, then adhesion by means of the union of granular surfaces is effected with the greatest facility; of this we have evidence in most of the mucous canals. It is not rare, for instance, to meet with complete obliteration of the vagina, of the cystic duct, and so on.

It is stated very generally that the opinion of Bichat is entirely unfounded; that inflammation of the vagina is followed by complete occlusion, without destruction or transformation of the mucous membrane, and that similar effects may occur in the Fallopian tubes, the uterus, and other mucous canals. That these are produced is perfectly true, but never until the disorganization to which I have alluded has occurred.

It is maintained triumphantly as a confirmation of the opinion that no transformation occurs, that when these adhesions are separated, we have the healthy mucous membrane performing its functions as before. This, however, is not the case; the membrane is essentially different, and it is not without difficulty that we can overcome its tendency to enter into adhesion again. That a membrane is produced, which performs functions analogous to

* Loc. cit. p. 305.

the primitive membrane, is true. If we examine a fistulous canal which has existed for a certain time, we find it invested by a membrane similar in appearance, and performing an analogous function to the primitive mucous membrane,—so rapidly does nature under certain circumstances adapt an organ to the performance of the function to which it is destined.

As it is therefore upon the organization of this pseudo-membrane that the species of union of which I am treating is dependent, some remark upon that subject becomes necessary. It has been maintained by Albers, Soemmering, and Larrey, that these new formations upon mucous membranes may become organized. The former of these gentlemen believes that the false membrane of croup is commonly organized. Soemmering, it is said, possessed preparations which demonstrated the fact. Cailleau* supports this opinion, as well as Villermé† and Guersent.‡ I have never seen this membrane present the slightest vestige of organization, nor have I ever found any one, with the exceptions I have named, who has, although, to my knowledge, they have been sought for during many years, by a number of the most competent observers of the present day. And as I believe the investigations of morbid phenomena are more accurately made at present than at any former period, I adhere to the opinion that organization of these membranes upon mucous surfaces never occurs; and that union by "the first intention" can never occur in those canals which are invested by mucous membrane. But when the composition of the mucous membrane becomes destroyed or disorganized by inflammation, and a granular surface is presented, adhesion may be and is frequently produced.

The epidermis with which the skin is furnished forms an inorganic stratum which is opposed to all adhesion; but remove this epidermis, render the surface bleeding, or suppurating, and adhesion may be produced with the greatest facility. It is against this tendency we have constantly to struggle for the purpose of preventing the adhesion of fingers to each other, to the palm of the hand, and so on,—so common a consequence of burns. Adhesion may in this tissue occur, therefore, by the development of the fibrino-albuminous medium, or by that of granulations. The synovial membrane of joints may become adherent, constituting a species of ankylosis, which is termed "false." In these cases the secretion of synovia diminishes and ultimately ceases, the contiguous surfaces lose their polish, become rugous, and contract adhesions. (See Joints.) In osseous tissues, adhesion may be effected either through the agency of the albumino-fibrinous exhalation already described, or that of granulations. (See Bone.) In cartilaginous tissues the mechanism of adhesion is different; and in speaking of the process in these tissues, it is necessary to divide the tissue into those which are invested by a more or less dense fibrous perichondrium, and those which are without it. To the first appertain the cartilages of the ribs, of the larynx, and all those which Bichat termed fibro-cartilages. The second class comprehend the diarthrodial. It is in fact, I believe, upon the presence or absence of the perichondrium, that are dependent the principal differences which are presented in the pathological condition of these organs. The non-diarthrodial as well as the fibro-cartilages, when they are ruptured or divided, are not united by a cartilaginous substance.

In the wounds of cartilages, with loss of substance, there is formed a kind of cellulous matter, which is a secretion from the perichondrium; in fact no phenomena of reproduction are observed where this membrane does not exist; thus it is never observed in diarthrodial cartilages. We may cut and mutilate these latter, and after many days we shall find the wound almost as it was on the first day. When the cartilages of the ribs are ruptured, their union is often effected by an osseous ring which surrounds the two fragments. See the articles Artery, Encephalon, Nerve, Fibrous tissue, Muscle, Vein, for the phenomena of adhesion in these structures.

(Benjamin Phillips.)

ADIPOCERE, from *adeps* and *cera:* a term given to a peculiar fatty matter, somewhat resembling spermaceti in appearance, and supposed to partake of the properties of fat and wax. In the year 1789, Fourcroy communicated to the Royal Academy of Sciences at Paris a curious account of the changes sustained by the human bodies interred in the cemetery of the Innocents in that city; some of these had been piled, for a succession of years, closely upon each other, in large cavities containing from one thousand to fifteen hundred individuals. One of these graves, opened in Fourcroy's presence, had been full, and closed for fifteen years. When the coffins were opened, the bodies appeared shrunk and flattened, and the soft solids were converted into a brittle cheesy matter, which softened and felt greasy when rubbed between the fingers. The bones were brittle; and the texture of the abdominal and thoracic viscera no longer discernible, but lumps of fatty matter occupied their places.

It is not uncommon to find masses of this adipocere in the refuse of dissecting-rooms, especially when heaps of such offal are thrown into pits and wells, and suffered gradually to decay. The carcases of cats and dogs and other drowned animals also often exhibit more or less of a similar change; and Dr. Gibbes (Phil. Trans. 1794) found that lean beef, secured in a running stream, underwent a change into fat in the course of three weeks. Fat, and the adipose parts of animals, also undergo a change in appearance and composition under similar circumstances: tallow becomes brittle and pulverulent, and may be rubbed between the fingers into a white soapy powder.*

Gay Lussac, Chevreul, and some other eminent chemists, conceive that muscular fibre, skin, &c. is not convertible into adipocere, but that this compound results entirely from the fat originally present in the substance, and that the fibrin is completely destroyed by putrefaction. There are cases, however, in which the conversion of muscle and of fibrin into fat can scarcely be doubted, (Annals of Philosophy, xii. 41,) though the propriety of applying the term *adipocere* to such fatty matter may be questionable. The action of very dilute nitric acid upon some of the modifications of albumen is also attended by their conversion into an adipose substance.

The chemical properties usually ascribed to adipocere are the following: it fuses at a temperature below 100°; it dissolves in boiling alcohol, and the greater portion is deposited as the solution cools; the action of ether resembles that of alcohol; it is saponified by the fixed alkalies, but not by ammonia. It would appear, however, from Chevreul's experiments, that adipocere is not a mere modification of fat, or a simple product, but that it is a *soap* composed of margaric acid and ammonia. These combinations of adipose substances and their further chemical history will be given under the article Fat.

* If a portion of the fatty degeneration of the liver be immersed for some time in water, it will furnish an excellent specimen of adipocere. The writer of this note had lately an opportunity of observing the process of the conversion of a large portion of liver into this substance.—R. B. T.

ADIPOSE TISSUE.—(Lat. *Tela adiposa* Fr. *tissu adipeux, tissu graisseux*, Germ. *das Fett*, Ital. *adipe*.

Many of the old anatomists, as Mondini, Berenger, Vesalius, and Spigelius, represent the fat *(adeps vel pinguedo)* of the animal body as entirely distinct from the *membrana carnosa*, or cellular membrane. The separate existence of a proper adipose membrane, however, situate between the skin and the filamentous tissue, or *membrana carnosa*, was first taught by Malpighi, then distinctly maintained by De Bergen and Morgagni, and finally demonstrated by William Hunter. Collins, James Keill, and other anatomists adopted the views of Malpighi, and Haller was disposed latterly to imitate De Bergen and Morgagni, in assigning to the fat of the animal body a situation distinct from that of the cellular membrane. And in this country the independent existence of the adipose membrane was recognized by Bromfield, John Hunter, and others.

It was still, however, confounded with that of the filamentous tissue under the general name of cellular membrane, adipose membrane, and cellular fat, by Winslow, Dionis, Portal, Sabatier, Bichat, and Meckel, and described as a variety or modification of the cellular membrane; and Blumenbach considers it as a secretion into that membrane. Its distinct existence from the cellular membrane was finally admitted by M. Beclard, and its anatomical and physiological relations as well as its chemical properties have been since minutely investigated by M. Raspail.

According to the dissections of De Bergen and Morgagni, the demonstrations of Hunter, and the observations of M. Beclard, the structure of the adipose membrane consists of rounded packets or parcels *(pelotons)* separated from each other by furrows of various depth, of a figure irregularly ovoidal, or spheroidal, varying in diameter from a line to half an inch, according to the degree of obesity in the part submitted to examination. Each packet is composed of small spheroidal particles which may be easily separated by dissection, and which are said to consist of an assemblage of vesicular bags still more minute, aggregated together by very delicate filamentous tissue. These were originally described by Malpighi under the name of membranous *sacculi*, and by Morgagni under that of *sacculi pinguedinosi*.

The appearance of these ultimate vesicular pouches is minutely described by Wolff in the subcutaneous fat, and by Clopton Havers* and the first Monro in the marrow of bones, in which the two last authors compare them to strings of minute pearls. If the fat with which these vesicles are generally distended should disappear, as happens in dropsy, consumption, chronic dysentery, and other wasting diseases, the vesicular sacs collapse, their cavity is obliterated, and they are confounded with the con-

* Osteologia Nova, Lond. 1691, and Obs. Nov. de Ossibus, Amst. 1731.

tiguous cellular tissue without leaving any trace of their existence.

Hunter, however, asserts that in such circumstances the cellular tissue differs from the tissue of adipose vesicles in containing no similar cavities, remarks that the latter is much more fleshy and ligamentous than the filamentous tissue, and contends that though the adipose vesicles are empty and collapsed, they still exist. When the skin is dissected from the adipose membrane, it is always possible to distinguish the latter from the filamentous tissue, even if it contain no fat, by the toughness of its fibres and the coarseness of the web which they make.

The distinguishing characters between the cellular or filamentous and the adipose tissue may be stated in the following manner. First, the vesicles of the adipose membrane are closed all round, and, unlike the cellular tissue, they cannot be generally penetrated by fluids which are made to enter them. If the temperature of a portion of adipose membrane be raised by means of warm water to the liquefying point of the contents, they will remain unmoved so long as the structure of the vesicles is not injured by the heat. If again an adipose packet be exposed to a solar heat of 104° Fahrenheit, though the fat be completely liquefied, not a drop will escape until the vesicles are divided or otherwise opened, when it appears in abundance. The adipose matter, therefore, though fluid or semifluid in the living body, does not, like dropsical infiltration, obey the impulse of gravity. Secondly, the adipose vesicles do not form, like cellular tissue, a continuous whole, but are simply in mutual contiguity. This arrangement is demonstrated by actual inspection, but becomes more conspicuous in the case of dropsical effusions, when the filamentous tissue interposed between the adipose molecules is completely infiltrated while the latter are entirely unaffected. Thirdly, the anatomical situation of the adipose tissue is different from that of the filamentous tissue. The former is found, 1st, in a considerable layer extended immediately beneath the skin; 2dly, in the trunk and extremities round the large vessels and nerves; 3dly, between the serous and muscular tissues of the heart; 4thly, between the peritoneal folds which form the *omentum* and mesentery; 5thly, round each kidney; and, 6thly, in certain folds of the synovial membranes without the articular capsules.

In each of these situations it varies in quantity and physical properties. In the least corpulent persons a portion of fat is deposited in the adipose membrane of the cheeks, orbits, palms of the hands, soles of the feet, pulp of the fingers and toes, flexures of the joints, round the kidney, beneath the cardiac serous membrane, and between the layers of the mesentery and *omentum*. In the more corpulent, and chiefly in females, it is found not merely in these situations, but extended in a layer of some thickness, almost uniformly over the whole person; but is very abundant in the neck, breasts, belly, *mons Veneris*, and flexures of the joints.

It has been long observed that the subcutaneous adipose layer presents considerable differences from the adipose matter found between the folds of the serous membranes; and the older anatomists, aware of these differences, distinguished the former by the name of *pinguedo*, and the latter by that of *sebum*. The subcutaneous adipose membrane is, when viewed as a whole, more elastic, softer, and less granular than the omental fat, and evidently presents the arrangement of vesicular bags much more distinctly than the omental. It is in the subcutaneous adipose membrane indeed, almost exclusively, that the vesicular arrangement can be recognized. The subcutaneous cellular fat also contains a greater quantity of oil than the omental, which abounds chiefly in firm, brittle, granular fat.

The situation where the vesicular structure of the adipose membrane is most easily demonstrated is in the hips between the skin and the gluteal muscles, and at the flexures of the joints generally. In the former situation especially, the constituent fibres of the vesicular bags are tough, firm, and ligamentous, and the bags themselves are large and distinct.

It is a remarkable anatomical character of the sebaceous or tallow-like fat that its distribution is confined chiefly to the external or commutual surfaces of several of the serous membranes; and this arrangement presents a series of interesting anatomical analogies. Thus sebaceous fat is found on the external surface of the *pleura costalis*, between it and the intercostal muscles, and between the layers at the posterior and anterior *mediastinum*. It is also found between the cardiac *pericardium* and the muscular substance of the heart, especially around the vessels of the organ. In some of the large mammalia even this circumstance is connected with peculiar anatomical appearances. Thus, in the heart of the dolphin *(delphinus tursio)* we find the cardiac pericardium formed into broad prominent fringes, consisting each of two folds of the membrane, between which is interposed a considerable quantity of sebaceous fat. In the same manner the several *omenta*, or peritoneal duplicatures in the abdomen, may be recognized as analogous fringes containing more or less sebaceous fat; and the omental appendages *(appendices epiploicæ)* of the colon must be regarded as examples of the same arrangement. Lastly, in the interior of the articular capsules we find the synovial membranes forming large prominent fringes, which, if immersed in water, show to what extent they are made to recede from the capsule and bone, and forming cavities of duplication in which sebaceous matter is contained.

It thus appears that none of the serous membranes is exactly applied either to the *parietes* of cavities or to the surface of the contained organs, but that they form intervals on their outer or attached surfaces, on which various quantities of sebaceous fat are deposited. In all these substances we do not recognize the same distinct arrangement of an appropriate organ, but simply masses of adipose, or rather sebaceous matter, interposed between the attached surface of the serous membranes and the adjoining or the contained organs.

Fat occurs in a third modification in the marrow of bones. The adipose granules, which are soft, whitish-yellow, and oleaginous, are here contained in a peculiar membrano-cellular web, forming numerous vesicles, which may be regarded as an ultra-osseous adipose tissue. It is a remarkable proof of the influence of the vital principle that during life the substance of the bones is never tinged with this animal oil, but the moment life is extinct, the marrow begins to transude and impart to the bones a yellow tint and a greasy aspect.

Fat, though chiefly observed to occur in the bodies of animals, is nevertheless not confined solely to these bodies. Thus not only do various kinds of oil and consistent oleaginous matter occur in certain vegetables, but substances similar even to tallow are found in some vegetable productions. A sort of tallow is obtained from the *vateria Indica*, a forest-tree of the camphor family, indigenous in the Indian Archipelago. In a species of croton indigenous in China, namely, the *croton sebiferum* of Linnæus, the *stillingia* of Michaux, or tallow-tree, the seeds are covered with a quantity of fat, bearing so close a resemblance in all its properties to tallow, that it is used by the Chinese in the manufacture of candles; and the fruits of the *aleurites triloba*, a native of the Sandwich Islands, of the same natural family with the *croton*, are the candle-nuts of the inhabitants of these remote regions.

It is chiefly in the subcutaneous layer that the organization of the adipose membrane has been investigated. The constituent vesicles or bags consist of firm, tenacious, ligamentous, gray, or whitish-gray coloured substance, mutually united by means of delicate filamentous tissue. These vesicles or sacs receive arterial and venous branches, the arrangement of which has been described by various authors, from Malpighi, who gave the first accurate account, to Mascagni, to whom we are indebted for the most recent. According to Malpighi,* the bloodvessels divide into minute ramifications, to the extremities of which are attached the membranous sacs, containing the globules of fat so as to bear some resemblance to the leaves attached to the footstalks of trees. These vesicular or saccular arteries are afterwards divided into more minute vessels, which then form upon the vesicular sacs a delicate vascular network. According to Mascagni, who represents these vessels in accurate delineations, the furrow or space between each packet contains an artery and vein, which, being subdivided, penetrates between minute grains or adipose particles, of which the packet is composed, and furnishes each component granule with a small artery and vein. The effect of this arrangement is that each individual grain or adipose particle is supported by its artery and vein as by a footstalk or peduncle, and those of the same packet are kept together not only by contact, but by the community of ramifications from the same vessel. These grains are so closely attached that Mascagni, who examined them with a good lens, compares them to a cluster of fish-spawn. Grutzmacher found much the same arrangement in the grains and vesicles of the marrow of bones.*

It has been supposed that the adipose tissue receives nervous filaments; and Mascagni conceives he has demonstrated its lymphatics. Both points, however, are so problematical, that of neither of these tissues is the distribution known.

The substance contained in these vesicles is entirely inorganic. Always solid in the dead body, it has been represented as being fluid during life, by Winslow, Haller, Portal, Bichat, and most authors on anatomy. The last writer, indeed, states that under the skin it is more consistent, and that in various living animals he never found it so fluid as is represented. The truth is that in the human body, and in most mammiferous animals during life, the fat is neither fluid nor semifluid. It is simply soft, yielding, and compressible, with a slight degree of transparency, or rather translucence. This is easily established by observing it during incisions through the adipose membrane, either in the human body or in the lower animals.

The internal or sebaceous fat, however, especially that interposed between the fat of the serous membranes, is much more consistent and solid. The reason of these differences will be understood from what is now to be stated regarding the proximate principles of animal fat.

The microscopical and atomical structure of fat has recently formed the subject of investigation by M. Raspail.† By placing a portion of lacerated fat upon a sieve, with an earthen vessel below it, and directing upon it a stream of water, numerous amylaceous granules are detached and pass through the sieve, and after falling to the bottom of the water afterwards rise to the surface, in the form of a crystalline powder, as white as snow. When these particles are collected by scumming, and dried, they form a starchy powder, though soft and somewhat oleaginous to the touch, and which does not reflect the light in a manner so crystalline as an amylaceous deposit does.

According to M. Raspail, when examined microscopically, these granules present forms and dimensions varying in different animals, in the same animal and even in animals of different ages, but in all clearly resembling grains of *fecula*. In the human body these particles are polyhedral and not susceptible of isolation. As they are more fluid also than in other animals, it is necessary to immerse the portion subjected to examination in nitric acid or *liquor potassæ*, either of which has the effect of consolidating the inclosed or central portion

* De Omento, Pinguedine, et Adiposis Ductibus, p. 41.

* De Ossium Medulla, Lips. 1758.

† Repertoire Générale d'Anat. 1827.

of each granule, and disintegrating the granules by the contraction of chemical agency. The borders of these granules appear by refracted light a little fringed—an effect which M. Raspail attributes to the corrosive action of the nitric acid.

When magnified to 100 diameters, they appear like irregular hexaedral or pentaedral bodies, from two to four lines in diameter, and all accurately fitted or conjoined to each other. The actual diameter of these granules in the adult human subject varies according to Raspail from .00117 to .00562 of an English inch. In youth and infancy they are stated to be still smaller.

The chief point to bear in remembrance is that the adipose tissue consists of two distinct parts, one a vital organic and secreting part, the other an inorganic and secreted product, which is void of vital principle. The chemical constitution of fat has been investigated by Chevreul, Braconnot, and more recently by M. Raspail. According to the researches of M. Chevreul fat consists essentially of two proximate principles, *stearine* (*στεαρ*, *sebum*, *sapo*,) and *elaine*, (*ελαιον*, *oleum*.) The former is a solid substance, colourless, tasteless, and almost inodorous, soluble in alcohol, and preserving its solidity at a temperature of 176° Fahrenheit. Elaine, on the contrary, though colourless, or at most of a yellow tint, and lighter than water, is fluid at a temperature of from 63° to 65° Fahrenheit, and is greatly more soluble in alcohol. To the presence of stearine in a large proportion, the intra-serous sebaceous fat owes its solidity and firmness; whereas the elasticity and softness of the subcutaneous adipose tissue, and the marrow, depend upon the predominance of elaine.

It is farther important to attend to the elementary composition of fat. Each variety of fat consists of carbon, hydrogen, and oxygen; and a few, as hog's lard, blubber, nut oil, and almond oil, contain a small trace of azote. The proportion of the carbon is greatest and varies in general from 7-10ths to 4-5ths of the whole. The proportion of hydrogen varies from 1-10th to 1-5th. That of oxygen varies from four or five parts in the hundred to 12 and 13. It appears, therefore, that fat and each of its constituent principles are a highly carbonaceous animal substance.

Little doubt can be entertained that animal fat is the result of a process of secretion. But it is no easy matter to determine the mode in which this is effected. Previous to the time of Malpighi it was a very general opinion that the blood exuding from the vessels was converted into adipose matter. This fancy was refuted by Malpighi, who, departing, however, from strict observation, imagined a set of ducts, (*ductus adiposi*) issuing from glands, in which he conceived the fat to be elaborated and prepared. To this fancy he appears to have been led by his study of the lymphatic glands, and inability to comprehend how the process of secretion could be accomplished by arteries only. The doctrine, though embraced by Perrault, Collins, and Hartsoecher, was overthrown by the strong arguments which Ruysch deduced from his injections; and Malpighi afterwards acknowledged its weakness and renounced it. In short, neither the glands nor the ducts of the adipose membrane have ever been seen, unless we admit the testimony of the Members of the Parisian Academy, who state that they saw them in the civet cat, and to this we must oppose the fact that Morgagni, by anatomical evidence, disproved their existence. Winslow, though willing to adopt the notion of Malpighi, admits, nevertheless, that the particular organ, by which the fat is separated from the blood, is unknown. Haller, on the contrary, aware of the permeability of the arteries, and inferring from the phenomena of injections either of watery liquors or melted tallow, their direct communication with the cells of the adipose tissue, and trusting to the testimony of Malpighi, Ruysch, Glisson, and Morgagni, that fat exists in the arterial blood, saw no difficulty in the doctrine of secretion, or rather of a process of separation; and upon much the same grounds is this opinion adopted by Portal. Bichat, again, contends that no fat can be recognized in the arterial blood, and justly adduces the fact, that none can be distinguished in blood drawn from the temporal artery. To the accuracy of this fact I can bear direct testimony, having repeatedly examined with the view of recognizing the buffy coat, and detecting oily particles, blood, which I had drawn from this vessel,—the latter substance invariably without success. In wounds in the human body during life, and living animals, oily particles may be seen floating on the surface of the blood; but these, it may be said, proceed from the division of the adipose vesicles; and hence it has been inferred that the arterial blood contains no adipose or oleaginous matter.

It may be doubted, however, whether facts of this kind are adequate to prove whether adipose or oily matter does not naturally exist in the blood, and both from the experiments of Chevreul, and those of Lecanu and Boudet it appears that small quantities of adipose or puriloid matter may be obtained from this fluid. M. Chevreul, for example, shows that fatty matter may be obtained from the fibrine of arterial blood; and from a series of elaborate and accurate experiments, estimates the quantity of fatty matter in fibrine at from four to five per cent.* Lecanu and Boudet have also recently shown that crystals of pearly-coloured matter having the characters of an adipose substance exist in, and may be obtained in small proportion from the serum of the blood.† These inferences apply, according to the authors, to blood in its healthy state.

In certain states of the system the blood drawn from the veins has presented serum of an opaque or milky appearance, and which has been proved to depend on the presence of adipose or oleaginous matter. Thus, independent of opaque or milky serum noticed by

* Journal de Physiol. tom. iv. p. 119.

† Journal de Pharmacie, 1830-33.

Schenke, Tulpius, Morgagni, and others, Hewson and several cotemporary observers remarked instances of opacity and milkiness of the serum of the blood, and from ocular inspection as well as experiment and observation, inferred that these appearances arose from the presence of oil in the blood or its serum. Soon after Dr. Gregory, in his *Conspectus*, or View of the Institutions of Medicine, was led to infer apparently from the fact stated by Hewson, that in persons in whom the serum was opaque or milky, this depends on the presence of fat which is undergoing absorption, or resumption into the system. This representation, however, was entirely conjectural; and no direct proof of the fact that oil does exist in certain states in the venous blood was given till Dr. Traill, in 1821 and 1823, furnished accurate chemical evidence on the point. The inferences of Dr. Traill have been since confirmed by the experiments of Dr. Christison, who found that milky serum contains oleaginous or adipose matter, consisting of the two adipose principles elaine and stearine.*

The general conclusions, therefore, that may be deduced from the facts now stated are that in the healthy state adipose matter in small proportion exists in the fibrine of the blood, and in a still smaller portion in the serum; and that in certain morbid conditions of the system, in which there is any process of misnutrition or *paratrophia*, oily matter in considerable quantity may be found in the blood, either in consequence of absorption or non-deposition.

To account, however, for the secretion of adipose matter, it is not absolutely requisite to prove that oleaginous or adipose matter exists in the circulating fluid. Even were it ascertained that oil or adipose matter does not exist, or cannot be detected in any of the elements of healthy blood, the fact would not form a stronger argument against its formation from that fluid, than in the case of several other principles which enter into the composition of the animal tissues, and which nevertheless do not exist in the blood. Thus neither gelatine, which exists abundantly in skin, tendon, cartilage, ligament, and bone,—nor osmazome, which is found in muscle, are contained in healthy blood. But we know that the chemical element of these substances exist in the blood, and we farther know that gelatine consists very nearly of the same chemical elements as albumen; and we must infer, therefore, that it is the faculty of the living tissues or vessels to arrange these elements in that manner and proportion in which they may constitute respectively gelatine and osmazome. The same reasoning may be applied to explain the formation of fat in the adipose tissue. Its elements already exist in the blood, and the living agency of the tissue seems all that is requisite to effect its deposition. Its composition and history would also show that it is a secreted product which consists of superfluous chemical elements not required in the formation of the albuminous and gelatinous tissues.

On this subject the interesting experiments of Berard* and Dobereiner† may, perhaps, furnish some intelligible means of illustration. The former chemist found that by mixing one measure of carbonic acid, ten measures of carburetted hydrogen, and twenty of hydrogen, and transmitting the mixture through a red-hot tube, he procured artificially several white crystals which were insoluble in water, soluble in alcohol, and fusible by heat into an oily fluid. The latter chemist prepared a similar substance from a mixture of coal-gas and aqueous vapour.

It may therefore be inferred that while animal fat is chiefly a combination of bicarbonated hydrogen with oxygen, or, in other words, a highly carburetted hydrate of oxygen, and contains either little or no azote, it is the animal substance which makes the nearest approach in chemical constitution to the vegetable principles. So close, indeed, is this approximation that Raspail thinks it may be in this repect compared with starch; and as the different forms of *fecula* are prepared by the vegetable tissues for the nutritious stores of the vegetable during the process of development, he observes that, in like manner, fat is deposited whenever the nutritious function is in excess in the animal organs.

It was a singular fancy of Fourcroy that the deposition of fat in animal bodies was intended as a sort of vent for the superfluous and unnecessary proportion of hydrogen, since the idea is at variance with chemical facts; and it is not less singular that such a hypothesis should receive any countenance from Blumenbach. Carbon is the principle which predominates most largely in fat; and if any attention is to be given to such views, the adipose tissue ought to be regarded as the outlet for superfluous carbonaceous matter, or at least carbonaceous matter in a much larger proportion than hydrogen and oxygen. The proper physiological view, however, of this question appears to be,—that as the tissues of the animal body consist chiefly of carbon, hydrogen, oxygen, and azote united in variable proportions, and as most of these tissues either contain or seem to require azote, the adipose appears to be destined to receive whatever carbon, hydrogen, and oxygen, are not required to be united with the azote, in the formation of the albuminous, the gelatinous, or the albumino-gelatinous tissues.

On the mechanism of the deposition of fat we possess no exact information. But various facts may tend to throw some light on the circumstances under which it takes place, and the history of the state of the adipose tissue at different periods of life is instructive.

In the fœtus the adipose tissue contains a sort of whitish, solid, granular matter, which resembles adipocere rather than genuine fat.

* Edin. Med. and Surg. Journal, vol. xxxiii. p. 274.

* Ann. de Chimie, 1817, t. v. p. 290.

† Zur Pneumatischen Phytochemie, 8vo. Jena. 1822.

Thus it is less oleaginous, and more brittle and friable than true fat. In the infant this layer continues the same in quantity, but a little more oleaginous, till the period at which the individual begins to exert the muscles of locomotion. The fat then rapidly diminishes in quantity, and after the child has begun to walk and run, the fat has almost entirely disappeared from most parts of the adipose tissue, except the orbits, cheeks, neck, buttocks and the flexures of the joints; but even in these regions it is much less abundant and much more consistent.

The marrow presents similar changes. The bones of the fœtus are void of a distinct medullary canal, and present merely a reddish, homogeneous, vascular pulp, somewhat consistent, but presenting soft compressible portions. This state continues some time after birth. As the individual passes from infancy to childhood, the interior of the bone is formed into *cancelli*, adipose or oleaginous matter is deposited in the intra-osseous tissue within the *cancelli*, and as the vessels of the medullary membrane gradually mould the medullary canal, this oleaginous matter is most abundantly deposited in the interior of the cylindrical bones. The marrow, however, is much less oleaginous, and more like a pulpy paste than it is in the adult.

During the periods of boyhood and youth fat continues very sparing in the adipose tissue, and especially in the male sex. After puberty, however, it becomes more abundant, especially in females. After this period the deposition of fat depends more or less on the habits of the individual, as to eating and drinking and corporeal exertion. In general the deposition of fat becomes more copious and general after the age of forty or forty-two than previously.

From these several facts it appears to result that fat is to be regarded as a secretion by the capillary vessels of the adipose tissue from the blood, and that the tissue and its vessels are to be distinguished from the fat or the matter secreted in the relation of vital agents and organic products. Upon the whole the idea of Haller as modified by Mascagni regarding the origin of the fat appears to be the most probable, viz. that, while the arteries secrete an imperfectly formed oily fluid, the thinner parts are absorbed either by lymphatics or by veins, and the residue is left in a more consistent and solid form.

I think, in conclusion, that, taking all the circumstances already stated into consideration, it may be inferred that adipose matter, or its constituent elements exist in the blood, chiefly as complementary elements of the albuminous, gelatinous, osmazomatous, or gelatino-albuminous principles employed in the nutrition of the several tissues; and that, as the carbon, hydrogen, oxygen, and azote are employed in the formation of the latter tissues, the great excess of carbon, and the smaller excess of hydrogen and oxygen, not employed in the formation of these tissues are arranged by the capillaries in such proportions as to form adipose matter; and that this adipose matter, though fluid, when first formed, becomes more consistent and fixed after deposition in its appropriate tissues.

The pathological conditions of the adipose tissue.

1. *Inflammation.*—From various facts, and especially, observing the phenomena of certain cases of what have been denominated *diffuse inflammation* of the cellular membrane, I formerly inferred that the peculiar phenomena of certain intense and malignant forms of this disorder, depend on inflammation not of the cellular membrane, but of the adipose tissue. This conjecture I have since had opportunities of completely verifying as to certain, if not the majority of cases of diffuse inflammation.

a. In cases of diffuse inflammation affecting the arm, the inflammation has spread along the adipose membrane, producing sero-purulent suppuration and sloughs of the adipose tissue. In cases of inflammation at the verge of the *anus*, the disease spreads along in the same manner, and affects, almost exclusively, the adipose tissue around the *anus* and *rectum*, and along the *glutæi* muscles. It is in the same manner that the adipose cushion, with which the bloodvessels are surrounded, is occasionally the seat of a species of bad inflammatory action terminating in fetid and sloughy suppuration.

That these forms of diffuse inflammation truly depend on inflammation of the adipose membrane, I must further maintain, from the fact that the disease occurs not only in the external adipose cushion, but in the internal or sebaceous fat. I have seen an example of inflammation in the adipose cushion surrounding the left kidney, in which the whole of this substance was converted into an ash-coloured, fetid, semifluid pulp, mixed with shreddy filaments, and in which this suppurative sloughing process had opened a passage from the fat of the left kidney into the interior of the transverse arch of the colon. The instance of inflammation and subsequent mortification of the adipose membrane surrounding both kidneys, detailed by Dr. Thomas Turner, in the fourth volume of the Transactions of the College of Physicians in London, is an example of the same species of disease. In the case witnessed by myself, the disease gave rise to the usual symptoms said to attend diffuse inflammation. Though no great degree of pain was felt, the pulse was quick and small, the tongue brown and dry, the countenance dingy and lurid, and the eyes heavy, the bowels difficult to be affected by medicine, the urine scanty and high-coloured, and at length suppressed; and the patient, after muttering delirium and *typhomania* on the second day of the attack, with *subsultus tendinum*, passed into a comatose state, which terminated on the fourth day in death.

b. This doctrine further does not rest upon evidence deduced from the mere symptomatic characters of the disorder. In fatal instances of diffuse inflammation, we find the adipose membrane not only partially mortified and suppurated, but that part of it adjoining to the skin and to the bloodvessels very much loaded, with injected vessels containing dark-coloured blood.

c. It is chiefly in the corpulent, either by habit or by age, that this disease assumes its most exquisite, intense, and unmanageable forms. In persons of this description, who it is matter of common observation are generally not only plethoric but bloated, and liable to imperfect circulation, and disorders of the circulation and secretions generally, and in whom very slight causes often induce serious disorders, the adipose tissue appears to lose a great proportion of the small degree of vital energy which it possesses, and the more abundant its secreted product is, the less active are its vessels and the inherent properties of the membrane. In consequence of this greatly impaired energy, slight causes, as cold, injury, punctures, &c. produce suddenly a complete loss of circulation and action in the tissue; for it is not increased but diminished action; and this impaired energy continues, until the natural functions of the tissue become extinct. It is thus that the secreted or inorganic matter of the adipose tissue becomes, as it were, a cause of strangulation of the tissue itself, or at least leads so directly to suppress the energies of its organic part, that it is incapable of resisting morbific agents of ordinary power, and hence the organic part either may be smitten with immediate death or is very easily made to assume a very low and imperfect form of morbid action, which speedily terminates in death.

On this subject it is further proper to observe that Mr. Bromfield, surgeon to St. George's Hospital, who sixty years ago maintained the distinct characters and situation of the adipose membrane from the cellular, taught also that the former was liable to inflammation, but erroneously imagined that this inflammation was of the circumscribed kind only.*

2. *Hemorrhage.*—Effusion of blood into the adipose tissue is not very common. It is observed in the same circumstances nearly in which it occurs in the filamentous tissue. Thus it has been seen in land and sea-scurvy. Huxham observed it in fevers with petechial eruptions. And Cleghorn states that one of the appearances after death in the continuous and malignant tertians of Minorca was extravasation of blood in the form of black patches in the adipose layer of the mesentery, omentum, and colon.

3. *Excessive deposition.*—In certain subjects, and in peculiar circumstances, the quantity deposited is enormous. The average weight of the human subject at a medium size is about 160 pounds, or between eleven and twelve stones. Yet instances are on record of its attaining, by deposition of fat in the adipose membrane, the extraordinary weight of 510 and 600 pounds, or from thirty-five to forty stones. Cheyne mentions a case in which the weight was 448 pounds, equal to thirty-two stones. In the Philosophical Transactions are recorded two cases of persons so corpulent, that one weighed 480 pounds and another 500 pounds. And the Breslau Collections contain cases in which the human body weighed 580 and 600 pounds.

In females and in eunuchs it is more abundant than in males; in females deprived of the ovaries it is more abundant than in those possessed of these organs; and it is well known that sterility is frequent among the corpulent of both sexes. In some circumstances this accumulation may be so great as to constitute disease, (*polysarcia adiposa* of several nosologists); and in other circumstances the deposition of fat is a means which the secreting system seems to employ to relieve fulness and tension of the vessels, and if not to cure, at least to obviate morbid states of the circulation. (Parry.) Accumulations of fat are said to take place in some animals in a few hours in certain states of the atmosphere. During a fog of twenty-four hours continuance, thrushes, wheat-ears, ortolans, and red-breasts are reported to become so fat that they are unable to fly from the sportsman. (Bichat.)

4. *Extreme diminution.*—The diminution or disappearance of fat is much more frequent than its extraordinary abundance. This diminution is said to depend on one or other of the following causes. 1st. Long abstinence, as in fasting, and the periodical sleep of dormant animals; 2d, organic diseases, as consumption, cancer, disease of the liver, of the heart, ulceration of the intestines, &c.; 3d, purulent collections or secretions; 4th, leucophlegmatic and dropsical states; 5th, gloomy and melancholy thoughts or passions; 6th, long and uninterrupted effort of the intellectual powers; 7th, preternatural increase of the natural evacuations, as in cholera, diarrhœa, diabetes, &c. mucous discharges, especially from the pulmonary and intestinal membranes, as in chronic catarrh, inflammation of the intestines, and dysentery; 8th, long and intense heat, whether natural, as during hot summers, or artificial, as in furnaces, hot-houses, &c.; 9th, running, riding, and every species of fatiguing exercise long-continued, as is exemplied in the case of grooms at Newmarket, Doncaster, &c.; 10th, states of long disease, not organic; 11th, night-watching and want of sleep in general; 12th, immoderate use of spirituous liquors; 13th, habit of eating bitter and spiced or acid aliments.

Yet even in these states the fat of the animal body is seldom entirely wasted. In several organic diseases, in which great emaciation takes place, a considerable quantity of fat is always found in the orbits behind the eyeball, round the substance of the heart, around the kidneys, in the colon, and in the mesentery and omentum. Thus one or both lungs may be extensively occupied by tubercles and indurated portions giving rise to the usual symptoms of pulmonary consumption terminating fatally, yet without removing the fat from the subcutaneous layer of the chest and belly; and in various organic affections of the brain especially, a considerable quantity of fat is found, not only in the subcutaneous layer, but at the outer surface of the serous membranes.

* Chirurgical Observations, vol. i. p. 94.

According to the observations of William Hunter, anasarcous dropsy is the only disease in which the fat of the adipose membrane is entirely consumed. "This disorder, when inveterate, has that effect in such a degree, that we find the heart or mesentery in such subjects as free from fat as in the youngest children." This, however, is in some degree denied by Bichat, who contends that it is not uncommon to find much subcutaneous fat in subjects greatly infiltrated.* It is obvious that much will depend on the stage of the disease. It cannot be expected that the moment serous infiltration appears in the filamentous tissue, all the fat should be at once removed from the adipose. The process of absorption is gradual as is that of deposition; and the inference of Hunter may be regarded as nearly exact in reference to long-continued, or what he terms inveterate dropsy. It is certain, that while it is very difficult to deprive the bones of ordinary subjects of oil, those of dropsical subjects are the only ones which it is possible to obtain free from this substance.

In certain diseases, especially those the termination of which is attended with serous effusion into the cavities of the serous membrane, the fat is partly absorbed or may be converted into a sort of sero-gelatinous fluid. In chronic dysentery, for example, the subcutaneous fat and that of the heart and omentum, in a great measure disappear, while in their place we find effused an orange-yellow coloured sero-albuminous fluid, of a jelly-like aspect, which coagulates on the application of heat or the addition of re-agents. In the bodies of those, also, cut off by scirrhous disorganization or cancerous ulceration, the greater part of the fat is in like manner absorbed, and in its place appears a dirty orange-yellow coloured sero-albuminous fluid.

The removal of the fat from its containing membrane is effected by the process of absorption, the agents of which are supposed by William Hunter, Portal, Bichat, and Mascagni, to be the lymphatics. According to the results of the experiments of Magendie, Mayer, Tiedemann and Gmelin, Segalas and others, it must, in some measure at least, be ascribed to the influence of minute veins. It is a point of some interest to know in what form it is absorbed, whether as oily matter, or after undergoing a process of decomposition The observation of Dr. Traill, above quoted, would lead to the former view; but it is not easy to conceive that this should be uniform. We want, in short, correct facts on the point at issue.

5. *Adipose sarcoma*.—This consists in an unusual deposition of firm fatty matter in cells, the component fibres of which are sufficiently firm to give it consistence. The tumour, which is generally globular, is always surrounded by a thin capsule, formed by the condensation of the contiguous filamentous tissue. The tumour is supplied by a few bloodvessels, which proceed from the capsule, but which form so slender an attachment that they are readily broken, and the tumour is easily scooped from its seat. This sort of tumour occurs almost invariably in the adipose membrane, and seems to consist in a local hypertrophy of the part in which it is found. It may have a broad basis, but is often pendulous, or attached by a narrow neck or stalk. It is the most common form of sarcomatous tumour, and may occur in any part of the body in which there is adipose membrane, but is chiefly found on the front and back of the trunk, and not unfrequently on two places at the same time.

6. *Steatoma*.—In adipose sarcoma the adipose matter is deposited in cells, and the tumour derives a degree of firmness from the fibres with which it is thus traversed in every direction. In other instances, however, the adipose matter is deposited in a mass in the cavity of a spherical or spheroidal cyst, formed in the filamentous or adipose tissue; and the tumour is soft and compressible, and seems to contain fluid or semifluid matter. When cut open it is found to contain a soft semifluid matter of the consistence of honey, but of oily or adipose properties. In such circumstances the inner surface of the cyst, or at least the vessels of this surface, are the agents which secrete the fatty matter. This tumour may occur either in the filamentous or the adipose tissue, but is to be regarded as an example of local deposition of adipose matter. It may appear in any region of the filamentous tissue, but is most frequent about that of the head and face. Small steatoms are not unfrequent in the eyelids and in the scalp. Larger ones are more frequent about the neck.

7. *Lipoma*.—This name was first applied by Littré to a wen or cyst, filled with soft matter, possessing the usual properties of animal fat. The matter of steatom, according to this surgeon, is either not or imperfectly inflammable, by reason of its degeneration or commixture with some other animal secretion. The propriety of this distinction has been denied by Louis and others, who maintain that these tumours differ in nothing, unless perhaps in degree. It has been favoured, nevertheless, by Morgagni, and adopted by Plenck, Desault, Bichat, and various foreign surgeons, and is defended by Boyer, who represents the steatom as differing from *lipoma* in the matter being white, firm, and changed from its original character, and in possessing the tendency to degenerate into cancer. Plenck had previously distinguished the *lipoma* by its being destitute of a cyst, a circumstance not required by Littré.

Though thus admitted to differ, the anatomical character, as given by Morgagni, and confirmed by Boyer, is in both nearly the same: a cyst, containing unchanged fat, or granular adipose matter, in cells formed by the original fibres of the adipose membrane, according to Morgagni, or those of the filamentous tissue, according to Boyer. At the base or stalk, in the case of pendulous steatom, the cells are compressed, but loose in the body of the tumour.

This description, with the alleged cancerous

* Anat. Gén. vol. i. p. 57.

tendency, accords more with the characters of the adipose *sarcoma* than those of the genuine wen. Personal examination enables me to say, that, in the case of small steatoms of the scalp, eyelids, face, &c. no fibres of this kind are recognized; and to such, if any distinction be adopted, the name of *lipoma* should be confined. In the case of such larger steatoms as I have seen in other regions of the body, though the contents are firmly connected together, and some filamentous threads may be seen here and there, or the tumour may even be separable into masses, I have not been able to trace the distinct arrangement of cells, mentioned by Morgagni and Boyer. Weidmann mentions, that in one case the matter of steatom was a sort of liquefied fat, and in another firm and dense, and not divided into lobes or cells. The other forms of encysted tumours, distinguished by the names of *atheroma*, (*αθηρωμα*, *pulticula*, *ab αθαρα*, *pullis genus*,) and *meliceris* (*μελικηρις*, *mel* and *cera*, honey wax,) are to be viewed rather as varieties of the steatom than as generically different. The substance contained may differ in consistence, but is nearly the same in essential qualities.

8. *Melanosis.*—The adipose membrane is a frequent seat of this singular deposition. The black or melanose matter is found in the subcutaneous adipose membrane, and the subjacent cellular tissue of the chest and belly; it is not uncommon in the fat of the orbit; it is very commonly seen in the adipose cushion on the forepart of the vertebral column, on that surrounding the kidneys, and in the fat of the *anus* and *rectum*; it is found in the anterior and posterior mediastinum; and it is found between the folds of the mesentery, of the mesocolon, and of the omentum. It is also found in the substance of the marrow of bones; and, perhaps, in most cases in which the osseous system appears to be stained with the melanose deposite, the dark matter may be traced to the medullary particles, the situation of which it is found accurately to occupy.

In all these situations it appears in various degrees of perfection, and in different forms. It may be disseminated in black or inky spots, through the adipose membrane; it may be accumulated in spherical or spheroidal masses of various size and shape; or it may be found in the form of brown or ebon-coloured fluid or semifluid, enclosed in a cyst formed of the contiguous tissue, more or less condensed.

The melanose matter is entirely destitute of organization, and is to be regarded as the result of a peculiar secretion. No vessels have been traced into it; and when bodies affected with this deposite are minutely injected, the vessels can be traced no farther than the enveloping cyst. (Breschet.) It is also to be noticed that it is never deposited exactly in the site of organic fibres, but always between them, and very generally in the precise situation of the adipose particles. These several circumstances show that the melanose disease consists not in a degeneration or conversion into another substance, but in the deposition of a new form of matter in the manner of a secretion.

In what form the melanose substance is first deposited we have few accurate facts to enable us to form a judgment. Laennec is of opinion that it is first deposited in a solid form, and afterwards becomes fluid. The former he considers the stage of crudity, the latter that of softening (ramollisement.) Several facts, however, would lead to the conclusion, that when first deposited it was fluid, and afterwards acquired consistence. Thus in several dissections performed by Drs. Cullen and Carswell,* the matter of the small tumours, which are supposed to be of short duration, were found to be softest, and sometimes as fluid as cream. In like manner, in a case recorded by M. Chomel, in which the disease was found in the liver in the shape of large cysts, the melanose matter was more fluid in the centre than in the circumference of the cysts. Upon the whole, if the melanose deposite be, as is supposed, an inorganic secretion, the idea of its being poured forth from the vessels at first in a fluid or semifluid state is most probable, and most consistent with the usual phenomena and laws of animal processes.

AGE.—(Lat. *ætas*. Gr. *ἡλικια*. Germ. *Alter*. Fr. *age*. Ital. *età*.) This word, in its most extended sense, may express any period of duration. In reference to the human body it is used to denote either the whole time occupied by this system in passing through its several stages from birth to decay, or, in a more limited signification, that particular portion of existence commonly designated old age. It is in the former of these meanings that we employ the prefix to the following article; in other words, we propose to give an account of the organic and functional changes which the human system undergoes, from the commencement of extra-uterine life to the period of its dissolution by natural decay.

The term of human existence has been variously divided, and in many instances with a view to adapt its divisions to certain fanciful notions respecting the power of num-

* Trans. Med. Chir. Soc. Edinb. vol. i. p. 264.

bers; but the only rational principle on which we can distinguish certain definite periods, must be that of observing alterations in the condition of the whole body or of its several organs, and the correspondence which they bear to particular epochs. The old Aristotelian division of human life into three stages, growth, maturity, and decline, is founded on this principle; for, viewing man as a whole, the conditions in which he is an imperfect, a complete, or a declining member of his species, are well marked. But these conditions are capable of subdivision according to the changes which particular organs have undergone; in other words, man, in the progress of his *perfectionnement*, makes certain acquisitions in his structures and functions, and in his decline suffers certain losses and impairments; the more striking of these additions to, or subtractions from his resources, suggest the well-known division of existence into infancy, boyhood, puberty or adolescence, manhood, old age, and decrepitude. It is not our intention to discuss the subject of age by describing the characteristics of the stages last enumerated; we think it better to take a view of the general revolutions which transpire in the human economy during growth, maturity, and decline, and under each of these heads to mention the changes which particular organs undergo in the course of time, without limiting ourselves to distinct stages, the determination of which must be, to a certain extent, arbitrary.

The consideration of the alterations which take place in the body during its progress from infancy to manhood might very properly be preceded by some remarks on those ultimate processes which are essential to growth, viz.—nutrition, secretion and absorption; but, for information upon this interesting subject, the limits prescribed to this article compel us to refer the reader to that upon NUTRITION, in which the processes alluded to will be viewed in relation not only to the development, but also to the maintenance, and to the decay of the tissues.

On comparing a young with an adult animal we are at first struck by the difference in bulk; but immediately afterwards our attention is attracted by the difference in their respective capabilities of action,—a difference not merely proportionate to that of size. A closer examination informs us, that in the infant many of the parts of the body are absolutely incomplete, as organs or instruments, and we proceed to investigate whether this imperfection holds with all the organs or only with some of them; and if the latter be the case, whether the parts thus existing only in a rudimentary state belong to a particular class. Now, the organs and functions of man, in common with those of other animals, are divided into those which he shares with organic beings in general, and those which distinguish him as an animal; the former subserving his own independent existence, the latter his existence in relation to external objects of his consciousness; these more or less subjected to the control of volition, those removed, under ordinary circumstances, from the government of this principle. Hence these two classes have been variously named organic and animal, nutritive and relative, automatic and voluntary; and, as life is a term employed to designate the collective functions according to some physiologists, or the cause of them according to others, we have organic life and animal life, &c., &c. But the animal functions are truly supplemental; they could not subsist but by virtue of the organic; while, on the other hand, the latter are perfectly capable of a separate existence, as in the vegetable world, or in those conditions of animal life in which its characteristics are all but suspended, such as profound sleep and apoplexy. Yet, although the functions of relation are thus dependent on those of nutrition, it is evident, at a moment's glance, that the latter viewed collectively in an animal structure, would present an aspect altogether incomplete, and different from that which we notice in the system of a vegetable. In the one case they were obviously intended to act only for themselves and for one another; in the other they have an ulterior object to fulfil, but for which they would not have been called into existence and operation; this object is the production and support of the functions that constitute the animal. If we now look at the new-born infant in contrast with the full-grown man, we at once perceive that the essential difference between them has reference to the life of relations; in other words, the immaturity of the former is not determined by the state of the vegetative organs, which, as organs, are perfect, but by the undeveloped conditions of the parts which are to receive impressions from, and to re-act upon surrounding objects. Thus, on the one hand, we observe that the food adapted to the little being is rapidly converted into chyle, that the blood, after undergoing its requisite changes, performs its circuit freely and effectively, and that the activity of the nutritive, secernent, and absorbent processes is evidenced by the quick increase of growth, and by the abundant fluids contained in the various tissues. But, on turning to the relative functions, we find the case altogether reversed; sensation is dull, faint, and flitting; voluntary motion scarcely exceeds the amount necessary for obtaining nutriment from the parent; while the demonstrations of intelligence are the very lowest compatible with our belief in the possession of such a principle by the being in question. An examination of the organs devoted to these several actions leads to results in accordance with what we observe in the functions themselves; in the one class the organization is complete, in the other much remains to be accomplished. If the apparatus of digestion be inspected, the parts employed in deglutition, viz., the tongue, pharynx, and œsophagus, will be found fully formed; in the stomach the parts required for accommodating the aliment during its stay and for mixing certain fluids with it, are properly developed; no deficiency is observable in the structure of the liver and pancreas; and the chyliferous vessels are pervious, extensile, and perhaps contractile. If we proceed to the organs of circulation, similar conditions are observable. In the heart the several cavities, valves, and fibrous arrangements are duly proportionate to each other, and possess such qualities of firmness, pliancy, distensibility and contractility as are required for receiving, expelling, agitating, and keeping in separate compartments the two different kinds of blood; the arteries are found resistent enough to hold the blood within their calibres, and at the same time elastic enough to adapt themselves to the varying quantity of their contents, while the veins are found so organized both as to the muscularity of their coats, and to the perfection of their valves, as to be quite capable of conveying the fluid back to the heart. Not less complete is the apparatus of respiration, whether we regard the development of the diaphragm, or the elasticity of the thorax, or the cellular and tubular arrangements in the lungs and their appendages. For affording the necessary conditions for the occurrence of those molecular motions which constitute deposition and absorption, and upon which secretion also depends, we find an infinite number of capillary tubes well formed for supplying the fluids from which new particles may be taken, and to which old ones may return, and so disposed as not to interfere with the action of any supposable chemical affinities. If we next direct our attention to the organs of the animal functions, an opposite set of facts will directly meet us. In the locomotive system, the bones are discovered imperfectly ossified, the muscles deficient in fibrin, and the tendons and ligaments in firmness and density. Of the organs of sensation it may be said, in general terms, that the mechanism employed in the application of the appropriate stimulus is, for the most part, incomplete, while a difference is also observable in certain properties of the nervous substance.

From this view it might at first be concluded that, in order to trace the changes that ensue between the commencement of extra-uterine life and the attainment of maturity, we have only to look for them in the organs of the relative life. But the survey that we are about to take of the changes in question will show that the other class of organs are by no means exempt from alteration, although the changes are not those of development. They will be found to have reference to *degree* or *amount* of function rather than to capacity.

The external characters of the infant just eliminated from the uterus at the full period of gestation are as follows:—the integuments are thin, tender, and covered with a white unctuous matter; the nails just reach the ends of the fingers; the trunk and limbs are round and plump; and the articulations are in a state of flexion. The average weight of the body is about six or seven pounds; the length varies from seventeen to twenty-one inches, sometimes falling short of or exceeding these limits. The point which lies midway between the two extremities is at the umbilicus. The dimensions of the head and of the abdomen are very large in proportion to the other cavities, and as compared with their own measurements in after periods of life. The pelvis looks contracted, the thorax flattened at its sides and prominent in front, and the lower extremities are less developed than the upper. A line drawn from the occiput to the chin measures five inches and three lines; from the occiput to the forehead four inches and three lines; and from the vertex to the base of the skull three inches and six lines. The circumference of the head, taken along the course of the median line, is from thirteen to fourteen inches; but taken horizontally, and passing over the parietal protuberances, it seldom measures more than ten or eleven inches. The contrast between this general aspect and that of a full-grown man is too obvious to require any representation of it here.

The characters of the interior will be best described and understood by examining analytically the several apparatuses of the functions. Of the latter the most simple and primitive is assimilation, consisting of certain molecular motions which maintain, repair, and mould the organic tissues. We have already observed that the requisites for this function are perfect in the new-born infant; a copious supply of the fluid from which the textural particles are to be elaborated, a ready ingress for this fluid, and a no less ready egress for that which receives the particles no longer required in the process. All that we know of the mechanism employed is a porous extensile substance, varying in its chemical constitution according to the nature of the tissue. Porosity is resolvable into a collection of infinitely minute tubes, and the degree of porosity is, therefore, determined by the number of the tubes; the extensibility depends on the composition of the tubes. The tissues of the infant are soft, they abound in fluids, and are more capable of imbibition or artificial injection than at later periods of life; this being consequently possesses a complete mechanism of nutrition. But this mechanism can be of little utility unless the nutrient fluid be supplied liberally, and after furnishing the atoms for the formation of the several textures give place to fresh supplies. These conditions are afforded by the arteries and veins.

There is no period of human existence in which the processes of interstitial growth are so active as in infancy, whether they be instanced in the accretion of matter, in the change of composition, or in the modification of form. This fact is in harmony with the state of the capillary system just described, and it will be found to correspond no less with the relative construction of the arteries and veins. The function of the former of these is to convey the blood into the tissue, of the latter to take it away; consequently in a part where the growth is most energetic, we might, *à priori*, expect that the former would be more numerous, capacious, and distensible. This is well known to be the case from actual observation, partly of the effects of artificial injection, and partly of the phenomena of disease. An examination of the textural properties of the two sets of vessels leads to the same conclusion. Sir Clifton Wintringham, in his Experimental Enquiry, fully demonstrated that the venous coats in the young animal far exceed the arterial in density, and that, consequently, they are less subject to distension. When maturity is attained, the disproportion between the résistances of these vessels no longer exists.

However well provided the infant may be with the mechanical apparatus of pores and vessels, these can be of no avail unless the fluid they contain possesses certain chemical properties. Now the blood in early extra-uterine life presents the same general characters as in more advanced periods; but there is yet wanting a comparative analysis of this fluid at different ages.* Inferentially we can entertain no doubt that it is fully adapted to the purposes of nutrition, when we consider the conditions of the chylifactive and respiratory functions, and that, although the differences of its composition in early and in more mature periods have not been defined by experiment, they must bear a relation to the different degrees of nutrition and secretion. The difference, however, between the blood of the infant and that of the aged is perceptible to the senses, and will be noticed hereafter.

Pursuing the channels of the blood to the heart, we find this organ, as stated above, complete in its functions. Its volume, however, is large in proportion to the size of the body. Its parietes are less firm in texture, and of a paler colour than they afterwards become; but their contractility is more active. The pulsations are from 120 to 140 in a minute. The large volume is in harmony with the quantity of the fluid, the comparative weakness of its parietes with the small extent to which their impulse requires to be propagated, and with the trifling resistance; and the quick successions of its contractions furnish the fresh supplies of the nutriment required by the energy of growth. In the progressive development of this organ we notice that the bulk, although increasing so long as general growth continues, is proportionately smaller, a circumstance that corresponds with the diminution of the circulating fluid; the fibres become stronger and of a deeper hue, so that the contractions are more capable of propelling the blood through the greater extent which it has now to traverse, or, more strictly speaking, of communicating a shock to a greater column; but the pulsations are slower, agreeably to the diminished requirements on the part of the capillary actions. We must not omit to observe that at birth the parietes of the left ventricle scarcely exceed those of the right in thickness; but from this period an alteration commences, and rapidly proceeds until the thickness of the latter is to that of the former as 1 : 4. This change corresponds with the closure of the foramen ovale, the obliteration of the ductus arteriosus, and the consequent execution of the systemic circulation by the left ventricle only. The relative capacities of the right and left cavities begin to alter soon after birth. From tables given by Meckel it appears that, while at birth the capacity of the former compared with that of the latter is as 1 : 1¼, at the age of 50 it is nearly 3 : 1.*

The lungs at the moment of birth undergo a more remarkable alteration in their form, their texture, and their contents, than any other organ in the system; but during infancy and childhood they present no appreciable change in their organization, although a change must be inferred from the increase of their function. In infancy there is a smaller consumption of oxygen; and the power of generating heat, a function so intimately connected with respiration, is inferior to that possessed in later periods. Much light has been thrown on this subject by the researches of Dr. Edwards; and practical observations of the highest importance in the management of infants, founded upon the facts which he has ascertained, are to be met with in his valuable work.† The inspirations and expirations are more frequent at this early period, although the chemical actions between the air and the blood are less considerable. This greater frequency is a necessary accommodation to the rapidity of the circulation. At puberty there is a marked development of the organs of respiration; the volume of the lungs increases in conformity with the expansion of the thorax; while the greater determination of the blood to their vessels is indicated by the deeper hue of the parenchyma, by the liability to pulmonary hemorrhage, so characteristic of this period, and perhaps also by certain diseases which affect the nutrition of these organs. The corresponding activity of function is indicated by the increased power of calorification, the energy of muscular motion, and the exaltation of the cerebral actions; functions well known to have a direct relation with that of respiration; while the establishment of the generative faculty appears to own a connexion, though somewhat more remote, with the pulmonary development.

We pass from the system which imparts new properties to the blood to that which supplies it with nutriment. No imperfection is discoverable in the apparatus of digestion in the new-born infant; every organ is complete as an organ, but passes through various changes in adaptation on the one hand to the food that is supplied, and to the mode of receiving it, and on the other hand to the demands of the other parts of the body. The organs employed in conveying and modifying the chyle, viz. the lacteals and the mesenteric

* De Blainville states, on the authority of Fourcroy, that in infancy the albumen of the blood is more abundant, that the fibrin is softer and more gelatinous, and that the phosphates are in smaller proportion than in succeeding periods. Cours de Physiologie, t. ii. p. 262.

* Manuel d'Anat. t. ii. p. 284.

† On the Influence of Physical Agents, &c. translated by Drs. Hodgkin and Fisher.

glands, are in a state of high development, as indicated both by their size and by their tendency to disease. The stomach and duodenum are fully formed, but the sensibility of their mucous membrane is adapted only to the milk of the mother; any other kind of food has a greater or less tendency to produce irritation. This membrane is thick, extremely villous and vascular, and consequently of a rose-colour.* In young persons it assumes a milky or satin-like appearance; in the adult it becomes slightly ash-coloured, especially in the duodenum and in the commencement of the ileum; in the old subject it is more decidedly ashy. Its whitish appearance, according to Andral,† is found either in very old persons or in younger subjects who have died of marasmus. In the adult the small intestines, according to Orfila,‡ bear a proportion of eight to one as compared with the distance from the mouth to the anus; in the infant the proportion is no less than twelve to one.§ The large intestines are longer with respect to the small intestines in the infant than in the adult; but their calibre is proportionally smaller. Ascending to the mouth we might be tempted to say that there is evidence of incompleteness in the absence of teeth; but a moment's consideration assures us that the organs collected in this part are all eminently adapted to their function. The food is already prepared by the mother, and only needs to be extracted and conveyed into the pharynx; actions which are perfectly achieved by the lips, cheeks, and tongue. When the period has arrived at which this food can no longer be furnished with safety to the mother, and when all the purposes are accomplished which were intended in this close connexion between the two beings—purposes in all probability of a moral as well as a physical character—the infant is prepared for a more independent existence by the emergence of teeth. This event generally begins about the sixth or seventh month by the appearance of the two middle incisors in the lower jaw; these are followed by the corresponding teeth in the upper jaw; next are seen the lateral incisors below and above: the rest appear in the following order;—the first molars, the canines, and the second molars; those of the lower jaw having generally the priority of emergence. The milk-teeth, as they are called, by the end of the seventh year have given way to the second and permanent series. For the different characters of the two sets, the order of their appearance, and other particulars, we beg to refer the reader to the article Teeth. That the first series should be only temporary is a necessary provision, in conformity with the change in the conformation of the maxillary bones which ensues at the same time.

We must not leave the alimentary tract without observing that the fibres of the stomach and intestines in infancy and childhood are, like those of the heart and other involuntary muscles, more irritable than in after life; hence the contents of these viscera are propelled more rapidly, and the evacuations are more frequent; their tissue is also softer, and their colour more approaching to white.

The liver undergoes a great change after birth both in form and in function. The peculiar circulation of which it formed so important an organ during fœtal life being abolished, the left lobe which nearly equalled the right in volume, is diminished to a third of its original size. But while the umbilical vein and the canalis venosus are obliterated, the vena portæ is developed, and the bilious secretion becomes the predominant function. Of the further changes which this organ experiences, we have very little knowledge, except that the whole bulk is greatly lessened, and that the colour of its parenchyma becomes darker, and that it is more subject to disease in after periods. Occasionally we meet with instances in which the fœtal proportions of the liver continue through life (Andral). The bile has not been carefully examined with reference to particular ages, but it is known to be less viscid and to contain a smaller quantity of its peculiar principles in infancy; while its greater liability to concretions at more advanced periods indicates an alteration in its composition. The gall-bladder, though small at birth, contains bile, green in colour and bitter in taste, and soon becomes enlarged.

The spleen also increases in volume, but what alteration takes place in the progress to maturity, in its function, must, of course, be doubtful until the function itself be better understood. Probably its enlargement is connected with the distended condition of the venous system. Of the changes in the pancreas and salivary glands, we know little more than that their texture increases in firmness. The lacteals, lymphatics, and their respective ganglions have a very marked development. It is to be regretted that no observations have as yet been made upon the composition of the chyle at different ages. There are doubtless many alterations corresponding to the varying activity of the digestive function, and to the kinds of aliment used at those periods.

So much for the organs and functions which are concerned in augmenting or modifying the nutrient matter. Before proceeding to those of the relative life, we must allude to the organs of excretion. The kidneys at birth have not lost the traces of their lobular formation, but these are soon effaced. The weight of these organs at birth is to that of the whole body as 1·80; in the adult 1·240. The medullary portion is more abundant than the cortical in early life. The supra-renal capsules soon begin to shrink from their fœtal size. The ureters are large, and the bladder has a more elongated form than in after periods; it also occupies a higher situation above the pelvis. The functional qualities of these forms are not so well ascertained as the analogy of their organization to

† Précis d'Anat. Pathol.

‡ Leçons de Méd. Lég. t. i. p. 62.

§ This statement is at variance with that of Meckel, who says that the small intestine is much shorter in the early periods. Op. cit. t. iii. p. 424.

that of inferior animals. The urine is retained a shorter time in the bladder; it is more aqueous and less impregnated with saline and animal ingredients than in after life; there is also a particular deficiency of urea. Of the intestines we have already spoken; their contents are copious but less feculent than they afterwards become. The perspiration affords a similar character to that of the other excrementitious secretions, being more aqueous, less saline, and less odorous. On the whole it may be said that less activity is indicated in the *egestive* than in the *ingestive* system.

Of the defensive organs, or those which are exposed to surrounding agents, we may remark, in general terms, that although fully adequate to the demands of the infant under the circumstances of his existence, they acquire a development proportionate to his growing independence of the care of others. The skin increases in firmness, and the epidermis in thickness; the sebaceous follicles become larger and more numerous, and the hair is more abundant.

There is a portion of the nervous system which we have every reason to consider more related with the functions which have been just reviewed, than with those of the animal life, and which might *à priori* be expected to bear a corresponding ratio of developement. We allude to the ganglions; they appear to be fully formed at birth, but what changes they undergo between that period and maturity we do not profess to know. In old age their tissue is found hardened, shrunken, and of a greyish colour. (Bichat.)

The changes that we have next to take notice of are of a totally different character from the foregoing. They consist not merely in augmentations of size, correspondently with the general increment of the body, or in modifications of organs according to the altered circumstances under which they have to act, but in processes essential to the completeness of certain organs. These are the parts employed in locomotion, voice, sensation, and thought. We shall begin with the osseous system.

Bones are not subservient to locomotion only; they have, in some parts of the body, the important office of enclosing and defending from external injury the more delicate organs of the system. We shall find, therefore, that in the young animal, according as they fulfil the one office or the other, their development will differ. But whatever be the functions of the bones, they require, for the perfection of that function, three mechanical properties,—firmness, lightness, and tenacity. They must not admit of flexion, and, at the same time, the density of their substance must not render them cumbrous by weight, or brittle in texture. To present these three conditions, the organs in question consist of two principal ingredients, an animal matter and an earthy matter, most intimately interwoven; the one preventing such vibrations as would occasion risks of fracture, the other affording the necessary strength in supporting weights, and in resisting the divellent tendencies of antagonist muscles. The proportion which these parts bear to each other varies with the ages of the human subject. Viewed as a part of the system devoted to the life of relations, bones are used as pillars of support, as levers in various attitudes and motions, and as *points d'appui* to the muscles and tendons. On examining the constitution of these portions of the osseous system in the new-born infant, we find the quantity of calcareous salts comparatively small, and even the animal substance softer than in later periods, in consequence of the greater ratio of gelatine. In growth these proportions undergo a gradual alteration; the gelatine is diminished, the cartilage becomes firmer, and both give way to the deposition of earthy particles: in the increase of density produced by this deposition consists the process of ossification. To particularize the incompleteness of the osseous system would require us to enter upon the anatomy of almost every bone in the body, an investigation incompatible with the limits of this article. Some idea of it may be obtained from the fact that all the epiphyses of the long bones, and the greater number of the apophyses are as yet but cartilaginous; they derive their ossification, not from an extension of the process in the bones to which they are attached, but from ossific centres within their own spheres. In the tarsus the only bones in which ossification has commenced are the astragalus and os calcis. The carpus is entirely cartilaginous. The os innominatum of the pelvis consists of three separate bones; ossification has but just commenced in the descending ramus of the pubis, and the ascending part of the ischium; and the consolidation of the pelvis is not complete till after the thirteenth year. The long bones have no central medullary cavity in the early periods of intra-uterine life; but in the fœtus at its full term, the animal matter which occupied that space has begun to be absorbed, and the deposition of osseous matter takes place in the form of a cylindrical sheath, so that the canal exists at this period, though in an incomplete state. The medullary canal is analogous to the cells of the short and flat bones, and of the extremities of the long bones, which are also incomplete in infancy. The shape of the cylindrical bones is manifestly different from that which they afterwards assume; thus there is a much smaller disproportion between the diameters of the extremities and that of the shaft; the surface is less furrowed by sinuses or roughened by ridges; differences exactly corresponding to the imperfeet development of the muscles, which, when more bulky in their middle portions, require a larger space for their accommodation about the body of the bone, and when stronger in contraction, require attachments that will match them in firmness. The osseous system is not complete till after the age of twenty.

There is no part of the skeleton in which we have a more striking illustration of its gradual development than in the bones of the face and in the cranium. It is not till the seventh year that a separation begins to take place between the tables of the skull, that the frontal sinus begins to open, that the nasal bones lengthen, that the cells of the malar and upper maxillary bones are enlarged, that in consequence of this expansion of their cavities the outer lamina projects, and that the lower jaw is elongated. The stationary condition of the tabula vitrea is conformable to the arrest in the increment of the brain; the extension of the outer table to the increasing power and action of the muscles attached to it; the development of the sinuses and cells to that of the voice and certain of the senses; and the projection of the jaws to the increased number of the teeth. But although these changes commence as early as the seventh year, they are not complete till the twenty-first, or even later. At this time the countenance becomes settled, not merely by the full development of the muscles, which express the predominant emotions of the individual, but also by the complete adjustment of the bony arrangements just enumerated.

Those portions of the osseous system which are employed in protecting the organs enclosed by them from external compression or injury, have attained a degree of growth far surpassing that of the bones devoted to locomotion and to the mechanism of sensation. The ribs, for instance, defending the lungs and the heart, and playing so important a part in respiration, are farther advanced in the ossific process than the bones of the extremities. But the most striking fact of this kind is presented in the spinal column. The annular portions of the vertebræ which form the canal of the medulla spinalis, are found strongly ossified at birth, but the bodies of these bones, which are to be used hereafter in supporting the weight of the head and trunk, are very slightly expanded, and all but devoid of earthy particles, while the processes to which the muscles employed in the flexion and extension of the column afterwards contract attachments, are either only shaped in cartilage, or may be said to have no existence.

Passing from the bones to the muscles, we observe the latter no less incomplete in infancy as it regards their physical characters; they are pale, flabby, and easily torn; they contain less fibrine than in after years; their contractility is weak though easily excited; and the fasciculi and fibres are but loosely connected from the want of the fasciæ and aponeuroses which brace them in later periods. As life advances, the fibres become redder, more distinct, and stronger. A readiness to contract is manifested very early, but it is not till maturity that these organs are able to maintain contraction for any length of time. They suffice well for the quick and buoyant motions of the lively child, but fail in those violent and prolonged exertions required by the labours of manhood. The form of the muscles changes materially in the progress of years; thus, they swell out in the middle, and occasion a great difference in the proportions of the limbs. Those portions of the locomotive apparatus attached to the muscles and articulations, viz. the tendons and ligaments, undergo corresponding changes. In infancy they are soft and gelatinous; gradually they become firmer, their gelatine acquires a more glutinous character, and the membrane which envelopes them is more condensed. Every one knows the different products obtained by boiling the tendinous parts of young and adult animals; in the one they have the qualities of jelly, in the other of glue. The readiness with which the joints of a child are strained or dislocated is likewise well known. The immature condition of the infant is strongly marked in the ankles, which are turned inwards, and would never suggest the use to which the feet are to be applied, but for our familiarity with the change that afterwards occurs. The cartilages and fibro-cartilages are subjected to a development corresponding to that of the fibrous tissue.

Into the composition of the vocal apparatus we know that muscular, fibrous, and cartilaginous tissues enter; and, as these are altered by age, the mechanism which they constitute might *à priori* be expected to suffer similar modifications. The larynx of the infant is small and almost circular; consequently the lips of the glottis and the superior ligaments are very short. This configuration, viewed in connection with the immaturity of the muscular tissue, accounts for the shrill wailing cry, which is the only vocal sound produced at this early period of human existence, and the only one required, since the quick instinct of maternal affection can interpret these simple notes into an eloquent language. No very appreciable alteration takes place in these parts at the time when speech is acquired, for this attainment has more connection with the development and command of the muscles of the pharynx and mouth, as well as with the organ of intelligence, which enables the human being to discriminate sounds and to imitate them. Fortunately the oral and pharyngeal muscles are some of the foremost in development, being required in suction and deglutition. A progressive change goes on in the larynx, though it is not very evident till the period of puberty in the male, when the thyroid cartilage is elongated, and with it the thyro-arytenoid muscle. At this epoch occurs the moulting of the voice, or an accession of gravity in the tones, occasioned by the elongation of the parts just mentioned. The projection of the pomum Adami takes place at the same time. In the female larynx scarcely any change occurs, and the voice in consequence remains acute. We have already spoken of the facial bones and their cavities, parts which exercise a very decided influence on the sonorousness of the voice.

We must now hasten to the consideration of the parts employed in that other distinguishing function of animals, viz., sensation. There are two grand divisions of the organs of sensation, those which we understand, and those which we do not. The former consist of the various kinds of animal mechanism whereby the external causes of sensation are modified, the latter of the nervous substance intermediate to the external excitant, and that state of consciousness which we denominate sensation. We know that the eye collects rays of light and concentrates them on its internal surface, but are utterly ignorant of the changes which the retina, the optic nerve, and the brain undergo in producing that condition of our sentient existence which we call vision. It is true that we are aware that certain states of these parts are incompatible with sight; but why they are so is quite beyond our knowledge. We are, as it regards our acquaintance with the adaptation of nervous tissue to the production of sensation, in the same predicament as a man who watches the working of a steam-engine, and knows that a certain quantity of fuel, of water, of valvular compression, &c. is necessary to its motion, but has no idea of the laws of caloric, vaporization, constitution of elastic fluids, &c. Our science demonstrates the fitness of the external and internal ear for receiving, propagating, multiplying, and diffusing vibrations, but why the contact with the auditory nerve produces sound, is an all but impossible inquiry; as well as the reason why the sensation may be absent when the organ is in perfect order, and the nerve to all appearance unchanged; or why the sensation may occur without vibrations, as in dreaming, and many nervous disorders. The same may be said of the skin; it is well adapted for coming in contact with the points or superficies of bodies, but who can say why the nerves spread over it occasion certain feelings? These remarks are premised merely to shew that it must not excite surprise, if we are unable to point out completely the changes which age produces in the human body, correspondently with the changes of its sentient faculties.

It has already, in all probability, struck the mind of the reader, that the great development of the cerebral system in the infant is inconsistent with the principle which we have been endeavouring to demonstrate, viz., that the growth of the human body consists essentially in the elevation of the organs, subservient to the animal functions, from a rudimentary state. The more we grow, the smaller is the proportion of the brain to the rest of the fabric. But it is no less true that the *functions* of the brain grow with our growth. How then are we to reconcile these opposite facts? We must certainly discard the opinion, that the bulk of the organ is proportionate to its power, and examine the composition and the relations of its various parts to each other.

Limited as our knowledge is of the requisite conditions of nervous substance for its function, we are notwithstanding aware of two extremes of softness and hardness, which comprise those states of the tissue which are compatible with the exercise of its peculiar faculty. Pathologists well know that ramollissement and induration of the brain may produce the same lesion of function, viz., abolition of sensation; while it is equally well known that approximations to the same conditions will produce impairment of this faculty. Now in infancy the brain is extremely soft, almost pultaceous, while in old age it is extremely hard in comparison, and the similarity of the two ages in many respects, but particularly as it regards the functions of the nervous system, is matter of universal observation. It might then *à priori* be suspected that one of the changes in cerebral growth would be a tendency to a certain intermediate degree of consistence, and this is found actually to be the case.

From a careful comparison of the size and weight of the brain at different ages, it was ascertained by the Wenzels, and is demonstrated in tables contained in their work, De Penitiori Cerebri Structurâ,* that although the organ increases very sligthly in bulk after the third year, its weight does not attain its maximum till after the seventh, so that up to this time there is a progressive increase of density. After the seventh year there is no great difference either in size or density. (The size of the brain must not be confounded with that of the head, which after the period that we speak of, is determined by the growth of the external table of the skull, correspondently with the projection of the bones of the face.) There must, therefore, be some other change than that of density, to account for the augmentation of intellectual power in the succeeding periods, and herein our information is most at fault. Nevertheless we are not altogether without intimations of organic changes. The majority of physiologists are agreed that the function of the cortical substance is of a higher character than that of the medullary. The lower we descend in the animal series, the less we find of the cineritious matter, which is not apparent at all in the invertebrata, nor indeed in fishes. It is, therefore, not without probability conceived that this matter is more immediately concerned in thought; and, conformably with this view, we find its colour more strongly marked, as boyhood stretches on to manhood.† We may mention as corroborative of this circumstance, that M. Foville, an eminent investigator of the pathology of mental diseases, asserts that the principal lesions in the brains of maniacs occur in the grey tissue.‡ The convolutions again afford us some hints upon the subject before us. Intelligence is in direct proportion to their extent, and we accordingly find that these parts are deeper as age advances. As the existence of the posterior cerebral lobes, and of the corpus rhomboideum in the cere-

* See the notes to Milligan's Translation of Magendie's Physiology.

† This observation refers to the cineritious matter of the convolutions. In certain other parts this substance diminishes after birth. Thus, in the full-grown fœtus, the medulla oblongata is grey throughout, but soon begins to whiten, first in the corpora pyramidalia, and afterwards in the olivaria. The outer surface of the tuber annulare, and of the crura cerebri, is also grey at the commencement of extra-uterine life; but they lose this colour after a few weeks. In the thalami optici and corpora striata there is no distinction of white and grey matter, the latter alone being visible. See Meckel, Manuel d'Anatomie, t. ii. p. 717. Till the functions of these parts in mature age are better understood than at present, it would be useless to speculate upon the physiological relations of the changes which they undergo in earlier periods.

‡ Dict. de Méd. et Chir. Pratique, art. Aliénation Mentale.

bellum, is observed only at the top of the animal scale, we might expect that in the progress of age there would be a change in the relations of these parts to the whole mass, but we cannot find that any researches have been prosecuted in elucidation of these points.

Most of what we have predicated of the progressive actions in the brain, is likewise applicable to the cerebellum and spinal marrow, and nerves. The latter parts, however, are more forward in their organization, being devoted to the more primitive functions of sensation and voluntary motion, while the former is the instrument of the faculties more eminently intellectual. The proportion of the cerebellum to the brain at birth, is, according to Meckel, as 1·23; the former weighing nearly $3\frac{1}{2}$ drachms, the latter 9 or 10 oz. A month after birth the ratio is 1·17; after six months, 1·8.

The proportion between the spinal marrow and the brain at birth, and for five months after, is 1·107 or even 1·112; the brain at the former period weighing 9oz. 4dr., and the spinal marrow 45gr., while at the latter period the cerebral organ weighs 21oz., and the spinal $1\frac{1}{2}$dr. In the fœtus of five months the proportion is 1·63, of three months 1·18. In the adult it is 1·40. The diminishing ratio of the brain to the spinal marrow is in obvious harmony with the elongation of the vertebral column, and with the general growth of the members. The medulla oblongata is proportionally larger in early than in advanced life; the corpora pyramidalia and olivaria being distinct and prominent; a fact which corresponds with the development of the brain.

The longitudinal dimensions of the corpora quadrigemina at birth exceed those of the adult period; after the former period they increase only in their transverse diameter.

The concretions of the Pineal glands have not begun to be formed till the seventh year. They are sometimes wanting in very advanced age, according to the observations of Meckel and the Wenzels, which we have had opportunities of verifying by our own dissections. The number of these bodies increases with the progress of life, and their colour is paler in youth and old age than in intermediate periods.*

So much then for the nervous organs of sensation. Our attention must next be directed to the mechanism intermediate to the nerves, and the excitants of sensation. The simplest kind of sensation is that which informs or reminds us that we are possessed of bodily parts, such as members and internal organs. The mechanism employed, if there be any, is unknown. Nerves are distributed through the tissues, we feel those tissues, and conclude that these feelings result from relations between the nerves and the other textural molecules with which they are in contact. These feelings must of course vary with age because the tissues alter, but whether the susceptibility is increased we cannot say, and only venture to remark that the probability of this being the case is suggested by the fact, that adults are more subject to perversions of sensibility than children; witness the various nervous, hypochondriacal, and hysterical disorders with which adults are almost exclusively visited.

The next order of sensations in respect of simplicity are those of tact, or those by which we are made acquainted that foreign bodies are in contact with our skin. It is perhaps in some respects only a modification of the first-mentioned sensation, but it requires the presence of something not belonging to us. It is true that other parts than the skin may convey the notion of an external body being applied to them, but they do not afford any perception of the qualities of the body; it is merely the affection of themselves which is produced by that body. We are aware that all sensation may be analysed in the same manner with similar results, but it is enough for our present purpose that the sensation excited on the skin is less *selfish*, if we may use the term in this sense, and ought to be so, in order that it may serve its office of supplying some knowledge of the external world. Doubtless the organization of the epidermis and of the skin itself, as well as the greater distribution of nervous matter, occasion the difference. The dermoidal tissue in modifying the external cause stands in the same relation to the nerves of tact, as the eye to the optic nerve, or the nose to the olfactory. The organ of tact is affected by age; the skin in very early life appears less susceptible of impressions, and differs in its tissue, the papillæ being less developed. A change, however, is soon effected in this respect, and as we advance towards manhood, it becomes less gelatinous and more fibrous. It must be confessed, however, that the modifications which it undergoes in reference to its function of sensation, are not well defined. This circumstance is owing to the variety of sensations to which it ministers, such as (in addition to what we have mentioned) feelings of heat and cold, dryness and moisture, &c. and, secondly, to its being also an organ for other and very different functions, such as transpiration, secretion, and absorption.

Touch has a far more complicated mechanism than tact. It is one of the senses properly so called, or the special senses, and like the others of its class *is distinguished by its requiring the assistance of muscles.* Its sensations are compounded of tact and muscular resistance, and the organ is that wonderful instrument the hand. The imperfect state of this organ in infants must have been noticed by every one; it is generally closed and capable of grasping but very feebly; at all events a long time occurs before the little being learns to arrange the sensitive tips of the fingers, and to adjust the thumb in such a manner as to ascertain with nicety the form, consistence, and other properties of bodies. Whether the skin is less sensitive in these subjects we cannot say, but it is quite certain that the muscles, which effect the digital motions alluded to, are not developed any more than those in other parts of the body. Fine-

* For further details see the works of Meckel and Tiedemann.

ness of touch, tactus eruditus, is one of the most difficult attainments of manhood.

Concerning the alterations in the olfactory apparatus we have already spoken, when the development of the facial bones was under consideration. The sense of smell is manifested pretty early, but there can be no great precision and nicety in its exercise, both from defect of surface, and from the want of muscular power and command, in adjusting the quantity and impetus of the air that conveys the odorous particles. Thus, some agents are only appreciated by a sudden inhalation through the nostrils, as if to bring the particles with a certain degree of force upon the Schneiderian membrane. This art the child does not understand.

Taste being a sense so essential to the maintenance of the system, whether by inducing the animal to take the trouble of eating, or by warning him of improper aliment, is manifested very early. The usual description of the mechanism of taste would give just cause for questioning what was said respecting the necessity of a co-operation of muscular action with the five senses. Taste is described as the result simply of the application of sapid bodies to the tongue, palate, velum palati, &c. But these bodies excite no sensation without the aid of muscles. A certain degree of compression is necessary, which is accomplished by pressing the tongue against the roof of the mouth. Any one may assure himself of this fact by placing a strongly flavoured substance on the tongue when projected from the mouth; no taste will ensue till the member is withdrawn and then pressed against the palate. This observation applies not only to the tongue but also to the palate itself, and that sensitive surface the velum. In each instance, however, the effect may be imitated, by compressing with the finger the part where the substance is applied.

Taste must undergo a progressive development correspondently with the muscular organs. It is, to say the least, very doubtful if a child could perform those delicate manœuvres of the tongue and palate, which are practised by gourmands or professed wine-tasters. There is something more than this muscular action, however, to be taken into consideration. The more refined flavours are probably felt and estimated by the lining membrane of the nasal passages. It is common to remark that the scent of a substance is similar to its taste, but in all probability the two sensations are identical; for the taste in question is not perceived if the nostrils be closed; witness the abolition of taste during a catarrh. If therefore so close a connection exists between the two senses, it is clear that the development of the organization belonging to the one must influence the other function; and it has been already pointed out that the olfactory surface increases with growth.

The new-born infant is probably all but deaf; even the loudest sounds produce no sensible impression. The nurse's lullaby, therefore, is for some time superfluous; by degrees, however, the shrill tones, of which such strains for the most part consist, begin to be appreciated; the precise period however we do not know. In correspondence with this obtusity we find the organ incomplete, but the incompleteness has reference rather to the external than to the internal ear. Thus the pinna is very inelastic, and therefore unfitted for collecting vibrations; the same may be said of the meatus auditorius. In like manner, the membrana tympani is very oblique, and scarcely more than a continuation of the superior surface of the meatus, and thus little calculated to receive the vibrations. These parts are also covered with a soft matter very unfavourable to vibrations; the tympanum is very small, and the mastoid cells do not exist. In the progress of age all these parts gradually increase in hardness, and consequently are better adapted to their function. There are muscles attached to this sense also, but we are deficient in observations on their degree of development, though we may infer their condition from analogies in the rest of the muscular system.

Lastly, we come to the organ of vision, of which, however, there is not much to be said. The differences between the visual organ in the infant and in the adult consist more in degree than in kind; thus the sclerotic membrane is less elastic, and the cornea is less conical, in consequence of the smaller quantity of aqueous humour; (the greater thickness of this coat is produced by the serosity contained between its laminæ;) the crystalline lens is less dense, but more convex in form. The pigmentum is in smaller quantity at birth than afterwards; while the retina is thicker and more pulpy than in more advanced periods. The yellow tint of the foramen of Soemmering does not become visible till some time after birth, but deepens with the progress of life, till the stage of decline, when it grows paler. It has been ascertained that perfect images are formed on the retina; and yet for the first few days the child gives no indication of visual sensation, and when objects appear to attract its attention, they are only those which are vividly illuminated. The deficiency therefore must exist in the optic nerve, though we are ignorant of the organic condition on which this insensibility is dependent. We observe, moreover, that the eye is much more passive than in the adult, that it follows the motion of luminous bodies, or is fixed upon them with little or no apparent interference of the will. This muscular incompleteness, then, tallies with what we have noticed with respect to the other senses. The eye is known in its advance towards manhood to increase in the capability of adapting itself to different distances; but as we are ignorant of the mechanism made use of for this purpose, it is useless to look for corresponding organic alterations. We must not omit to notice those appendages to the apparatus of vision, called eyebrows, which become much more prominent as life advances, by the development of the frontal sinuses, and are therefore better adapted for shading the eyes.

The generative apparatus is situated intermediately to the animal and the organic system.

The evolution of the organs connected with this function marks the age of puberty; and the changes in which this evolution consists, both in the male and in the female, are too well known to require their specification here. The influence of this development on the mental and moral characters of either sex, is likewise sufficiently familiar even to the most superficial observer.

The human being is related with the external world passively and actively, independently of those organic actions and reactions that are constantly occurring in his system with regard to outward agents. He derives perceptions from objects about him, and he reacts on them by his power of muscular motion. But in his growth we mark that the perfection of those organs, which are scarcely more than passive in his *relative* life, advances much more rapidly than those which enable him to take a more active part. Thus the eye and the ear attain a certain maturity of organization and function, long before the bones and muscles, which officiate in locomotion. The bones and muscles connected with the organs of sensation, and therefore partaking of the passive character, are also equally forward in their development. What is the probable final cause of this arrangement? If all our voluntary motions were the immediate consequences of our sensations, as some of them undoubtedly are, such as those which close the dazzled eyes, or refuse the bitter food, or withdraw from painful contact;—if all these followed directly on sensations, it would indeed be a strange anomaly, if the systems that belong to each were not precisely on the same level of development. But this is not the case; all the more important motions, important as it regards that world in which man exists, as an intelligent and social creature, though less so as it respects his individual being, are the results of a mental condition, no less distinct from sensation than from muscular motion. This state is desire, or as it is commonly called when the antecedent of action, will or volition. Probably no mental state is more simple than this, and it may follow any other. It is therefore the more necessary that it should be preceded by such intellectual changes as will give it a right direction; in other words, that it should come under the dominion of certain faculties. But in early life the faculties to which we allude are very imperfectly developed; those only have attained any thing like maturity which are in immediate relation with the senses; such are perception, memory, association, and imagination; while the reflective faculties, such as comparison, reasoning, abstraction, all in fact that constitute man a judicious experienced agent, are rudimentary. The consequence is that the desires or volitions are proverbially vain and dangerous. Let us observe a child of seven years old; his senses are sufficiently acute for all ordinary purposes, although they are deficient in precision and delicacy; he has seen many attractive objects, he has heard many wouderful stories, and tasted many exquisite delights; he remembers them vividly, he associates them rapidly, and often in shapes very different from those in which they were formerly combined. Desires follow which would prompt him to execute the most ridiculous and mischievous schemes. But happily the muscular system, by which alone he could accomplish them, is too immature and feeble for his puerile purposes. Here then is the final cause that we were in search of; the *active* corporeal functions of relation must not advance beyond the governing faculty of the mind.

But why, it might hastily be asked, should not the senses, the mental faculties, and the motive powers, all have been equally developed? The question is absurd, if we consider but a moment the manner by which the mind accomplishes its growth; that its higher powers result from the accumulation of innumerable sensations, by which in fact the former are nourished and exercised.

We shall now introduce a brief account of some researches upon the *height*, *weight*, and *strength* of the human body, at different ages, prosecuted by M. Quetelet, of Brussels. Not having room for the numerical tables, or the particular observations, from which his general conclusions are derived, we must content ourselves with a statement of the latter, and refer those of our readers who may be desirous of seeing the former, to the author himself. His deductions as to the growth of human stature are as follows: (1) the growth is most rapid immediately after birth; it amounts in the first year of infancy to about two decimetres (nearly eight inches.) (2) The growth diminishes as the child advances towards the fourth or fifth year; thus, during the second year his increase of height is only half what it was the first year, and during the third year it is not more than one-third. (3) After the fourth or fifth year, the stature increases pretty regularly until the age of sixteen, and the annual growth is about fifty-six millim, (two inch.) (4) After puberty the stature still increases, though slightly; thus, from the sixteenth to the seventeenth year, the increase is about four centim. ($1\frac{3}{5}$ inch); and in the two following years, only two centim, and a half (one inch.) (5) The stature does not appear to be quite completed even at the age of twenty-five.—These observations refer only to absolute growth, but if the annual increase of stature be compared with the height which has been attained, it will be found that the infant, after birth, increases in the first year by two fifths of his height; in the second by one-seventh; in the third by one-eleventh; in the fourth by one-fourteenth; in the fifth by one-fifteenth; in the sixth by one-eighteenth; &c. so that the relative growth continually diminishes after birth.

In addition to these statements M. Quetelet has ascertained that the rules of growth are not the same in both sexes; 1st, because the female at birth is less than the male; 2dly, because her development is completed earlier; 3dly, because her annual growth falls short of that of the male. It appears likewise that the stature of persons living in towns, taken at the age of nineteen, exceeds that of residents in the country by two or three centim (1 or 1¼ inch); and that the children of persons in easy circumstances, and those of studious habits, are generally above the middle height.*

A memoir by the same author devoted to an examination of the weight of the human subject at different ages, contains a series of interesting conclusions, from which we select the following. (1.) At the period of birth there is an inequality both as to weight and to stature, in the two sexes; the medium weight of males being 3 kil. 20, (rather more than 7 lbs.), that of females 2 kil. 91, (about 6½ lbs.); the height of the former Om. 496, (about 19 inch.); that of the latter Om. 483, (about 18 inch.) (2.) The weight of the infant *diminishes* the first three days after birth, and does not begin to increase till the second week. (3.) At the same age the male is generally heavier than the female; it is only about the twelfth year that their weights are equal. Between the first and eleventh year the difference of weight is from 1 kil. to 1 kil. and a half; between sixteen and twenty, about 6 kil. and after this period from 8 to 9 kil. (4.) At full growth the weight is almost exactly twenty times what it was at birth, while the stature is only about three and a quarter more than it was at that period. This holds good with both sexes. (5.) In old age both sexes lose about 6 or 7 kil. of their weight, and 7 centim. of their height. (6.) During the growth of both sexes, we may reckon the squares of the weights, at the different ages, as proportional to the fifth powers of the heights. (7.) After full growth in each sex, the weights are very nearly as the squares of the heights. (From the two preceding statements it may be deduced that the increase in the longitudinal direction exceeds that in the transverse, including in the latter both width and thickness.) (8.) The male attains his maximum weight towards the fortieth year, and begins to lose it sensibly towards the sixtieth. The female does not attain her maximum weight till about the fiftieth year. (9.) The weights of full-grown and well-formed persons vary in a range of about 1 to 2, while the heights vary only from 1 to 1⅓. This statement is deduced from the following table:†

	Maximum.	*Minimum.*	*Medium.*
	KIL.	KIL.	KIL.
Male weight	98.5	49.1	63.7
Female	93.5	63.7	55.2
	MET.	MET.	MET.
Male stature	1.990	1.740	1.684
Female	1.740	1.408	1.579

* Recherches sur la loi de la Croissance de l'Homme, par M. Quetelet. Annales d'Hygiène Publique, &c. t. vi. p. 89.

† Ann. d'Hygiène, t. x. p. 27. To the above memoir M. Villermé has appended some extracts from manuscript notes found among the papers of M. Tenon, and written about the year 1783. They contain observations which correspond, in many respects, with those of Quetelet.

The last researches of this industrious observer have been devoted to the muscular power of man at different ages, and have been but very recently published. In the course of his memoir he refers to two tables; one stating the relative power of draught (la force rénale), at the several periods; the other, the relative manual strength (la force manuelle); in each case estimated by the dynamometer. The results are very much what might be expected à priori. It appears that the maximum of the "force rénale" is at the age of twenty-five; and that the difference in the extent of this kind of muscular power between males and females, is less during childhood than at the adult age. Thus, in the former period the male surpasses the female by one-third, towards puberty by one-half; and at full growth, his strength is double that of the other sex. The manual force is greatest at the age of thirty, and at all ages is greater in the male than in the female; before puberty, in the ratio of 3 : 2, after this period, in the ratio of 9 : 5. The average manual strength of a man is equivalent to 89 kil. and exceeds his weight by 19 kil., so that he might support himself by his hands only, even with a considerable weight attached to his feet.*

This and the preceding memoirs, we are told by M. Quetelet, are extracted from a work which he is about to publish, entitled "Sur l'Homme et le développement de ses facultés; ou, Essai de Physique Sociale." We need scarcely add that we are justified in expecting from the specimens already presented to us, a series of valuable and highly interesting facts, together with deductions of no ordinary importance and originality.

Having thus briefly traced the changes that precede maturity, we may ask what is it that prevents the processes of growth from advancing at the same rate as they have hitherto done? Why, so long as they are undisturbed by disease or unnatural circumstances, should they not advance ad infinitum, or at least why should they not raise man to the strength and dimensions which poets have fabled in their Titans? The same food, the same atmosphere, the same light and heat, the same electric agencies, by which the organs have been maintained or excited, are still around them and exerting their influence. Why, then, should they never transcend a certain point? Why should the stature, however much it may vary between a Boruwlaski and an O'Brien, yet never rise above a certain measure? Why does the strength never exceed the powers of a Milo or a Desaguliers, or the intellect surpass the limits of Aristotle, Shakspeare, or Newton? These are interesting but impossible problems. If we say that a certain quantum of vital power is allotted to the growth of man, and that while a portion is expended in raising him to maturity, the residue must be husbanded for conducting him through the remaining portion of his duration, else he might suddenly stop short

* Ann. d'Hygiène, &c. Oct. 1834, t. xii. p. 294.

in his career without passing those stages that prepare him for the cessation of his existence; —what do we gain by such an explanation? Nothing; for the term vital power which we employ is but a hypothetical cause, or if more closely examined, is scarcely even this; it is but an abstract term applicable to a number of actions that do not occur in the inorganic world. The vital power of a body is but the collective manifestation of its vital actions, and to say therefore that only a certain quantum of vital power is inherent in it, is but to express in other words the simple fact that those actions are circumscribed. Discarding this explanation, shall we say that the fact must be referred to some deficiency in the media of the being's existence; that, although the aliment, the air, the light and caloric are competent to the production of a certain degree of growth, they cannot extend it, and that, were their conditions different, the animal development would be more perfect. It is easy perhaps to suppose this, but we do not see how it can be proved, nor indeed that existing analogies favour it. On the surface of our globe there is every variety in the temperature, in the humidity, and in the electric conditions of the atmosphere, and every diversity in the articles of food employed; in more limited spheres there are the greatest diversities in these several respects produced artificially by the various occupations of mankind; and although we find, both among races and individuals, great varieties of development, which may occasionally be traced to some relation with the media in which they live, these varieties are by no means in proportion to the differences of the media, and in the majority of cases the former are independent of the latter. In the temperate zone, with a due proportion of animal and vegetable diet, man appears to attain his most perfect development, and with however great skill he adapts these circumstances, he never surpasses a certain point, and from what we know of his physiology no great alteration in any one of the external stimuli of his existence could be tolerated. A different proportion of the oxygen, nitrogen, and carbon in the atmosphere, we know full well to be noxious; a larger or smaller quantity of aqueous vapour suspended in it will occasion many well-known maladies; the same may be said of alterations in the balance of the electricity that surrounds us. Great extremes of heat and cold may be borne for awhile, but it is obvious that they are not so well adapted to a healthy state of the system, and therefore to its growth, as intermediate degrees; and consequently it is not easy to conceive any degree either above or below these limits consistent even with existence. Familiar enough also are we with the effects of full and sparing, of simple and mixed dietetics, and with the fact that between certain well-known bounds lie the salutary quantities and qualities. From all which it appears sufficiently evident, that we cannot conceive any difference in the amount or properties of the known stimuli of life, that would be more favourable to the growth of man, than those which are to be found in the range of the known variations, whether natural or artificial. From the beginning there must have been established a direct relation between the organization of the body and the outward elements; the latter are nothing but stimulants adapted to co-existing susceptibilities, or to put it more closely, man is not made by, but for or with, the surrounding agents; his lungs are fashioned in correspondence to the atmosphere which he breathes, his digestive organs to the food that is spread so plenteously before him, and his nervous system to the subtle imponderable agents that play about him; consequently as his organs only act in concert with, and do not result from the media of his existence, a development beyond that which he is known to acquire must proceed quite as much from the former as from the latter; and the supposition, the value of which we have been endeavouring to estimate, thus falls to the ground. If man could become a larger, more powerful, or more sagacious animal than he now is, he must not only live in different media, but must possess a different constitution; in other words, the characters that distinguish him as a species must be altered. The question, then, that offered itself remains to our apprehension unsolved by either of the hypotheses. The limitation of man's development is like the definite period of his duration, and a hundred other circumstances connected with his existence, an ultimate fact; no event that we are able to discover intervenes between its production and the will of the Deity.

Maturity, though varying with every individual, may be said to take place somewhere between the ages of twenty-five and thirty. It is a general opinion that it is a stationary condition; that when such changes have taken place in the frame, as render the human being capable of undertaking the various duties and occupations to which adults alone are adequate, there are no further alterations till the period of declining age; that, in short, growth has entirely ceased. But this idea is not strictly correct, for there is in all probability no period when the system is absolutely stationary; it must either be advancing to or receding from the state of perfection. This is of course more obvious when we know that augmentation of bulk is only a part of that process which perfects the organization. (See Nutrition.) It is true that at the adult age the determinate height and figure, the settled features, the marked mental and moral character, naturally give rise to the idea that a fixed point has been attained; but a little inquiry soon teaches us that the individual is still the subject of some progressive changes. It is the stature only that is stationary, for this depends on the skeleton, which ceases to lengthen before the period we speak of. But the capability of powerful and prolonged muscular exertions increases for some years; there must consequently be a change in the muscular tissue. The intellectual faculties have not attained their maximum, although we do not hesitate to consider them mature; we must therefore infer that there is a corresponding organic development of some kind in the cerebral substance. Maturity then would, according to this view, require to be dated at a period much later than that which is usually assigned to it. It is enough, however, without referring further, to know that although at the adult period the organs of animal life are so developed, that we cannot consider them imperfect instruments, they are even afterwards the subjects of a *perfectionnement*. What is commonly meant then by maturity, is in strictness that period of human existence, during which the processes of growth and decline are passing into each other by such slow degrees as to be imperceptible.

In this important era of the life of man, more important even than the season of adolescence, we must leave him in the full possession of all the faculties and energies which his Maker has allotted him, fulfilling his destiny of good and evil, encountering and triumphing over peril, toil, and pain, scaling the rough steep of ambition, threading the dark intricate paths of gain, labouring for the happiness or misery of his fellow-creatures, supported all the while by the consciousness of a strength that seems never to fail him, of resources never to be exhausted; we must allow a few years to roll by, and then return to him, when weary, wayworn, and broken with the storms of life, he has discovered that there are limits to his powers of action and endurance; that of the objects which he proposed as the ends of his labours, while a few have been accomplished, the majority are either vain or unattainable; and that a race fresh in vigour, and high in hope, the images of his former self, are overtaking and thrusting him away from the scenes of his exertions. What are the revolutions that have transpired in his system?

The formative organs of all the tissues of the body are in reality the tissues themselves; whether it be a muscle, or a gland, or the coat of a vessel, the parts which essentially produce its growth are nothing more or less than its own constituent molecules, the mutual attractions of which in deposition and absorption constitute assimilation; for there is no proof that vessels are used for any other purpose than that of conveying the nutrient fluids to and from the places, where the ultimate molecules arrange themselves in the form of tissue. The altered qualities, then, which are presented by the tissues, in whatever organs, in the decline of life, must depend immediately upon alterations in their own molecular motions and affinities. The nature of these alterations will of course correspond to the nature of each tissue; and unless we mistake, they will all be found to agree in one character, viz. a simpler composition, a lower kind of organization than they formerly possessed. But the discussion of this point will be more conveniently deferred till we shall have briefly recited the principal changes in the more important parts of the body.

As the nutritive secretions of the various structures are supplied with materials by the fluids in those structures, it is evident that they must at any time be increased, diminished, or otherwise modified by changes in the quantity and properties of these fluids. It is therefore a natural commencement of the subject to begin with the circulating system.

Nothing is more obvious in the condition of the aged as contrasted with the young than the different ratio between the fluids and the solids, the former being remarkably deficient. There is not only a notable diminution in the quantity of oleaginous or serous secretions, which are generally contained in the cellular parts of the body, but it is manifest that the tissues are permeated by a much smaller proportion of blood. This fluid moreover is very different in quality from what it was in earlier life; it is less arterial, its colour has not the same bright red it once presented, it has a large proportion of serum, and its coagulum is less firm in consistence.* Correspondently with the deficiency of fluids, many parts which once contained them are shrunk or obliterated. The capillary system becomes infinitely less extended than it once was; many of the extreme branches of the arteries themselves are no longer to be penetrated, and those which remain pervious, are far less distensible than formerly. There is indeed a remarkable change in the coats of these vessels; they are not only contracted in diameter, but are become denser and more rigid in texture. In this respect they differ from the veins, which in old age are more dilatable than in youth, and consequently contain a larger quantity of blood. The final cause of this is evident; in youth the arteries must convey a relatively larger quantity to supply the increasing structures; in the decline of life, when the latter are decreasing, there can no longer be any need for the same supply; the permission, however, of an accumulation in the veins, where it is less likely to be productive of injury, appears to be an accommodation to the diminution of the circulating powers.

If we trace the arteries from their extremities back to the heart, we shall find their calibres every where diminished, their coats less elastic, less capable of adapting themselves to the varying quantity of their contents, in some places resembling the texture of ligament, in some that of cartilage, and in others studded with deposits of osseous matter. The heart itself presents marks of degeneration no less decided; its cavities are shrunk, its fibres pale, and but feebly contractile, and fat will sometimes seem to take the place of the muscular substance. Frequently, also, the coronary arteries are found ossified, and the same alteration is not uncommon in the valves.

All these facts account for the slow, languid, staggering circulation characteristic of advanced life; there is less blood to be transmitted to the various organs, and that which is sent is propelled with a degree of feebleness that shows how little energy is required in its motion, when

* De Blainville is of opinion that these changes are exaggerated. Cours de Physiologie, i. 262.

so few nutritive actions are transpiring. We have spoken of the altered character of the blood, of its being less arterial and of a darker tint: this change is explained by the alteration in the respiratory system. The lungs are become lighter, the cells being relatively much larger,* and the parenchyma, which consists principally of bloodvessels, being greatly diminished. This alone would not explain why the blood is imperfectly arterialized, because, although the respiratory surface is diminished, less of that fluid enters the organ. But the bronchial membrane is always in a more or less unhealthy condition, being covered with a thick and copious secretion, that constitutes the "old man's catarrh," and prevents a due intercourse between the air and the blood. Besides this circumstance, the expansion of the chest is less perfect in consequence of the diminished elasticity of the parietes of the chest produced by the ossification of the cartilages and other causes: the muscles also participate with less energy in the respiratory movements. Every thing in the history of advanced life indicates the diminution in the vigour of the circulation and respiration. The apathy and languor of mind, the deficiency of many secretions, and the general decrease of animal heat, but particularly in the parts most distant from the heart, are all more or less intimately connected with the failure of these vital actions.

On turning to the digestive apparatus we have abundant marks of deterioration. The teeth fall out, the alveolar processes are absorbed, and the gums become hardened. In addition to these there is a change in the muscularity of the stomach; it has become weak, attenuated, and less contractile. The same is true of the intestines. The lacteal vessels are much fewer in number, and scarcely any lymphatic glands are to be met with. Every thing intimates that the food is less perfectly acted upon, and that consequently less chyle is extracted, and transmitted to the circulation.

Since, then, in these several systems, we find marks of diminution, impairment, depravation, it is not wonderful that nutrition, which is performed by means of the materials supplied by those systems, partakes of the same characters. But as nutritive changes must have occurred in the various deteriorated parts just spoken of, it would be incorrect to say that alterations of tissue depend solely on the alterations of these systems, though they are promoted by them; they must, in fact, have assisted each other. The altered tissues could not have been easily thus changed, without a defect in the quantity or quality of the matters out of which they are formed; nor could the latter defects have easily occurred without some alteration in the texture of the parts employed in conveying and elaborating the nutrient fluid. It is an old saying, that the functions of the body form a circle: if this be true of their healthy condition, it is not less so of their diseases and decline.

The organs and tissues subservient to the organic life having undergone vitiation and diminution, we may expect to find equal or even greater decay in the parts which are altogether dependent upon them, or the organs of the supplemental life. These indeed, as they are the last to be developed, are some of the first to present marks of decline, and evidently for the same reason, viz. because they are appended to and generated by the other parts of the system, and also are more open to our observation. The body is indeed, in this respect as in many others, not unlike a political community; no great change can occur in its internal arrangements, such as a failure or derangement of its energies and resources, without a manifestation of this weakness or disorder in its foreign relations.

Let us proceed, then, to examine the ravages which are wrought by the hand of time on the organs of locomotion and sensation, in the same order in which we have traced the developments and amplifications, once lavished by the self-same agent.

And first of the bones. The process of development in these parts consisted of a certain adjustment of the animal to the earthy matter, in order to give the requisite firmness, toughness, and solidity. As life advances, the phosphate and carbonate of lime are found to exceed the proportion of the cartilage and gelatine. The general conformation of the bones is less regular; they look shrunken and worn. When handled they feel lighter, notwithstanding the osseous substance is in excess; a fact, which results from the diminished quantity of the fluids, and one or two other circumstances to be mentioned presently. The processes and ridges, once so eminent and distinct, are comparatively effaced; this alteration accords with the wasting and diminished exercise of the muscles that were attached to these eminences. On looking for the lines and spaces, which are occupied in early life by cartilages or membranes, and which are visible even in manhood, we now find every trace of them vanished. Thus, the divisions between the epiphyses and shafts of the long bones, the line of union between the bones of the pelvis, and, in a still more marked degree, the sutural outlines of the bones of the head, are no longer perceptible. They are all filled up with bony deposit, and the pelvis and cranium form single bones; even the foramina by which the nutrient arteries entered the tissue are contracted or obliterated. The cellular structure between the tables of the cranium is removed;

* M. Andral, in his description of the atrophy of the lung which occurs in aged persons, says, "In some cases the walls of the cells disappear altogether, and we only find in their stead some delicate laminæ or filaments, traversing in different directions cavities of various sizes. In the parts of the lung where these alterations exist, there are no longer to be found either bronchial ramifications, or vesicles properly so called, but merely cells of greater or less diameter, divided into several compartments by imperfect septa or irregular laminæ. Many of these cells bear a perfect resemblance to the lung of the tortoise tribe, and they all approach to it more or less as to a type of organisation, towards which the human being in this case seems to descend. Pathol. Anat. v. ii. p. 528, translated by Drs. Townsend and West.

and the outer plate has approximated and indeed become identified with the inner; hence we see more depressions on the surface of an aged skull.

On inspecting the internal structure of these organs, we find the cavities that contain the marrow much more extensive than formerly, and the medullary tissue reduced to a consistence scarcely exceeding that of oil. The cells also of the short bones and of the extremities are more expanded, and the laminæ which form them are very much attenuated.

The deficiency of animal matter renders the bones of the aged fragile; they are broken by the most trivial accidents. It is also the cause of their slowness to unite; for the activity of assimilative, and consequently of reparative processes, is dependent on the vascularity and fluidity of a tissue. The lightness, however, of these organs produced by the same cause is beneficial, or at all events in harmony with the state of the muscular system.

If we next turn our attention to the articulations, we shall find that similar processes of disqualification for former functions have ensued. The spinal column, which once adapted itself with such ease and flexibility to the motions and curves of the body, has become almost as rigid as a single bone by the drying up of the intervertebral cartilages, and sometimes by the encroachments of ossification.* Scarcely any traces of cartilages between the ribs and the sternum can now be found; one of the causes to which we alluded above, in connection with diminished respiration. The same deficiency of cartilage is observable in the bones of the wrist and of the tarsus. A change, the opposite of mobility, may also be detected in the ligaments which embrace the joints; they are dense, dry, and inelastic. The gelatine which enters so largely into their composition has become altered in its chemical properties; it is less easily soluble in water, and has all the characters of glue rather than of jelly. Ill-adapted as this state of the articulations is to the purposes of motion, it is, we think, not altogether difficult to discern its appropriateness to the human being at this advanced period. Were the joints supple and flexible, while the muscles have so little power, how much greater would be the risks of accidents to the aged man in the slight motions which he achieves. In order to preserve their frames from falling, those whose joints move easily upon each other are compelled to exercise those muscles which keep the limbs in the requisite degrees of extension and stability, during certain attitudes and motions; but this end is accomplished in the feeble old subject by the very stiffness of his articulations.

The muscles are subject to changes no less decided than those in the organs just mentioned. They are pale, flabby, atrophied, and indisposed to contract on the application of stimuli; but the fibre itself is tough and not easily torn, and the true muscular substance seems to have given way in some places to a sort of dense cellular membrane, or a yellowish degeneration of tissue particularly described by Bichat. Their tendons are often studded with calcareous matter, and the sheaths in which they play are rigid and unmoistened with synovia. They obey the stimulus of the will tardily and irregularly; the uncertain tremulous movements, the tottering gait, the stooping posture, the unsteady grasp of the aged, are familiar to every one.

The organ of voice comes next to be considered. The larynx, once composed of several cartilages that moved freely on each other, is now a cavity capable of much less variation in its dimensions, owing to the rigidity of its parietes; the extent of the cavity gives in early old age that depth of tone, which by its gravity and solemnity excites our homage. In more advanced age, however, the tone becomes hoarse, shrill, and piping; this in all probability is produced by the contraction and stiffness of the rima glottidis, but still more by the want of vigour in the muscles of the mouth and throat. The incapability of managing the tone, and the tremulous articulation, are also results of changes in the muscles of the larynx, pharynx, and tongue, similar to those which transpire in other parts of the muscular system. Many senile impediments of speech are also produced by the loss of teeth, by the falling in of the cheeks, and by the disproportion of the lips to the space which they occupy.

In our investigation of the signs of decay in the parts that are subservient to sensation and thought, we shall be met by the same difficulties which formerly opposed our way, when inquiring into the phenomena of their development. We traced the progress of the nervous substance both in the nerves and in the cerebro-spinal centre from the almost pulpy state recognized in the infant, to its firm consistence in the adult. If we now investigate the anatomical quality presented by the tissue in advanced life, we shall find that it has shared the alteration of nearly all the other tissues,—that in short it has increased in density. This fact viewed in connection with another, namely, that ramollissement and induration produce very nearly the same lesion of function, will account for the failure in the sensific powers of old age. Besides this alteration in the substance of the nerves, they are found to be diminished in diameter; their neurilemmes are become, like other membranous parts, much harder and stronger. Moreover, Bichat has remarked that the nervous tissue of old ani-

* "Cependant il est rare que les fibro-cartilages s'ossifient chez les sujets avancés en âge. A la verité on voit souvent les vertèbres se réunir avec les autres au moyen d'une substance osseuse, mais cette soudure dépend bien plus rarement de l'ossification des fibro-cartilages que de la formation de lames osseuses à la circonférence des deux faces par lesquelles se regardent les coups des vertèbres. Cependant j'ai observé quelquefois aussi l'ossification des fibro-cartilages intervertebraux, et j'ai trouvé alors, en sciant longitudinalement la colonne épinière, que plusieurs vertèbres étaient soudées ensemble, et confondues en une seule masse."—Meckel, Manuel d'Anat. t. i. p. 364.

mals is much less easily affected by reagents than that of younger ones; so that there would appear to be an alteration in the chemical composition as well as in the mechanical consistence.

That which has been said of the matter of the nerves is also true of the brain. The whole bulk is diminished and the density greater than in earlier years. Some, however, assert that it is even softer than in manhood. M. Blandin makes a remark of this kind, in commenting upon Bichat's statement of a greater hardness in the tissue, and says that it might be expected *à priori*, since there is so strong a correspondence between the two extremes of life. There is reason, however, to think that this remark, if true at all, applies only to the cerebral organ of persons very far advanced; and it is not improbable that diseased softening has in other cases been mistaken for the natural effect of age. The membranes investing the brain like the neurilemmes (for they belong to the same system) are also thicker and more resistent. The vascularity of the organ is greatly diminished; on a divided surface no red dots are visible as at periods less advanced.

The alterations in the mechanism of the senses must next be considered. The skin, which is the medium between the nerves of tact, and external agents, undergoes great changes in the progress of life. It becomes drier, harder, less flexible, and at the same time looser, in consequence of the absorption of the adipose substance. By the latter qualities the function of the skin is more evidently impaired, in that modification of it more expressly denominated touch, or the sense of tact united with certain muscular feelings in the fingers and hands. By the looseness of the integuments, the slowness and weakness of the muscles, the stiffness of the digital joints, and that dulness of sensation which exists in this as in every other part of the system more or less, the hand is notably deteriorated in old age.

In the olfactory apparatus we find that, although the cavities and sinuses, through which the Schneiderian membrane is extended, are rather increased than diminished in size, the membrane itself is attenuated and less pulpy. The nerve also is mentioned by Rullier* to be evidently contracted and wasted.

The sense of taste so closely connected with that just spoken of survives to the extremest limit of existence; the final cause of which is evident. It is too intimately connected with one of the processes of organic life to be easily dispensed with, although one of the functions of the superadded life. It is, however, feebler than at periods less advanced, and requires the excitement of more piquant aliment; this is partly owing to the diminished sensibility of the gustatory nerve itself, and partly to the diminution of the sense of smell, on the perfection of which depends our appreciation of the more delicate species of sapidity. The surface of the tongue is more rugose than in younger subjects, and there is generally a deficiency of moisture, which is an additional cause of diminished sensation.

* Dict. de Méd. art. *Age*.

The ear, both in its external appendages and in its internal structure, presents certain conditions which very well account for the frequency of deafness among the aged. It is true the cartilages become harder, more elastic, and therefore more vibratory, but the internal surface of the meatus is often thickened, and obstructed by a dense cerumen. The membrana tympani is more rigid and therefore less capable of varying with the degree of the vibrations. In the internal cavity, although the mastoid cells are enlarged as life advances, the deficiency of the liquor cotunnii in the vestibule, the cochlea, and the semicircular canals, must greatly interfere with the production of hearing. In addition to all these circumstances there is probably an idiopathic insensibility of the nerve.

The modifications of the organ of vision are familiar to all who have paid even the most superficial attention to the science of optics. The cornea is less transparent and less convex, partly from the diminution of the aqueous humour, and partly from the condensation of its texture. The latter change is more marked at the circumference, where a nebulosity is often formed, which has gotten the name of gerontotoxon, or arcus senilis. The pigmentum diminishes, and the iris grows paler in conformity with the altered colour of the hair. The crystalline lens is denser, less transparent, and often acquires a yellow tint; the vitreous humour likewise suffers a decrease. The retina is considerably attenuated, but has increased in firmness. The punctum luteum is paler, and not unfrequently altogether effaced; a change which, in the opinion of Meckel,* bears a direct ratio to the diminution of the transparency of the cornea. These several alterations are necessarily followed by two results—diminished refraction of the rays of light, and torpor of the nervous function, both of which produce *presbyopia*. That long sight bears a relation with nervous as well as more mechanical causes is, we think, attested by the fact that this kind of vision is modified by temporary excitement of the brain, as in phrenitis.†

If we now take a retrospect of the revolutions which have occurred in the several structures enumerated, and endeavour to arrange them under specific heads, it will be found that diminution of bulk, deficiency of fluid, and condensation of substance, comprehend them all or nearly all. The attenuation has been generally ascribed to a preponderance of absorption over deposition, or a reverse of that condition in which incremental growth consists. But we cannot enter upon the question here, and must refer to the article Nutrition, contenting ourselves with the remark that it seems a superfluous multiplication of causes to sup-

* Op. cit. t. iii. p. 261.

† See Abercrombie on Diseases of the Brain.

pose that absorption increases, when the cessation or diminution of deposition fully explains the fact, provided the absorption is only maintained in its usual ratio.

Concerning the lessened quantity of fluid we have already made some remarks, and hinted at its relation with impaired digestion and slackened circulation. Here it is sufficient to observe that the fact is a sign of diminished vitality, by which we mean merely a diminution of vital actions, especially of those of nutrition. The abundance of fluid in the young succulent body is adapted to the constant accumulation of new particles, and to the increasing complexity of the organization of the tissues, as well as to the reparation of waste, or to the counteraction of decomposition;—by the still abundant though diminished quantity in the adult the composition is maintained and rendered more exquisite;—in the old man there is only enough required to keep up that degree of renovation, which is necessary to the integrity of the structure, and even this action is less than in former periods, because the organization, from its chemical nature, is less prone to decomposition. This brings us to the consideration of the third general fact, or the condensation of tissue, which will require more particular notice, because great importance has been assigned to it by some writers. The condensation is a result of the deficient humidity just spoken of; but this is not all, otherwise the condensation would be merely that of dryness; the tissue itself is of firmer materials. Thus membrane becomes ligament, ligament cartilage, cartilage bone, and bone increases in its earthy proportions. This hardening of the whole body is spoken of by many writers as the cause of decay, and ultimately of death, by the gradual closure of all the small vessels, and the obstruction to vital motions; while the methods of averting old age, proposed by the same authors, turned chiefly upon an artificial supply of moisture to the body. Galen constantly alludes to this condition when treating of old age, and the means of resisting its tendencies.* Lord Bacon, in his curious and highly interesting treatise, entitled Historia Vitæ et Mortis, has much to say upon desiccation and the methods of preventing it, such as bathing and inunction. The fable of the restitution of old Æsop by the cauldron of Medea, he considers typical of the utility of the warm bath in softening the substance of the body. So much stress does Haller lay on the effect of the universal tendency to induration, that he tells us that one of the reasons why fishes are so long-lived is because their bones are never hardened to the same degree as in the higher animals—"Inter animalia aves longæviores sunt, longævissimi pisces, quibus cor minimum, et lentissimum incrementum, et ossa nunquam indurantur." Primæ Lineæ, § 972. There is, however, we think, but little foundation for the supposition that induration stands in the relation of cause to the general failure of the functions of the body. It is rather a symptom of decline, or one of the phenomena in which decline consists, and is therefore itself the effect of the failure or alteration of some of the functions, more especially of the assimilative. It is a deterioration of interstitial secretion, partly promoted by the changes in circulation, in digestion, and probably in innervation, and partly itself contributing to these changes, but primarily owing its origin, like the latter, to the ultimate law, which determines that at a certain period decay shall transpire. It is in one respect a descent in the scale of organization. This indeed is indicated by the paucity of fluids and by the slow nutritive motions, which conditions are always sufficient to warrant our application of the terms, diminished vitality or less vitalized structure; but the substance itself, independently of these deficiencies of action, belongs to a more simple organization. We examine a bloodvessel, and instead of finding its coats of that complex texture which enables it to accommodate itself by a property, known only in living bodies, similar but superior to elasticity, we mean tonicity, we observe a plate of osseous matter, unyielding, insensible, immobile, possessing no other vital character than bare assimilation or molecular growth. We search for those admirably constructed substances which are interposed between the ribs and the sternum, and by their elasticity give extent and facility to the respiratory movements, and we discover them converted into the same matter as the contiguous bones, with the coarse property of cohesion, and, as in the former instance, with nothing but its growth to redeem it from the character of mere inorganic matter. We untangle the muscle, and instead of the irritable fibre, soft in texture but firm in contraction, we find a torpid substance, scarcely fibrous in form, firm in mere physical cohesion, weak in vital contraction, and consequently of a degraded organization. The processes of induration about the joints, the glands, and the integuments, will all, when examined, be found to approximate more than the former conditions of these parts to the qualities of the inanimate world. Homogeneousness of substance is alone an indication of a low organization, and a body which possesses both this property and hardness, may be considered on the very outskirts of the region of vitality. Such are the properties of osseous deposits. May we not here perceive an analogy with the animals of the inferior classes? In many of the mollusca how trifling a degree of vitality seems adequate to the formation, growth, and reparation of their calcareous coverings and appendages; or to go down to the coralines, madrepores, and porifera, we observe that the very lowest structure that can be considered animal is sufficient to secrete or assimilate those vast collections of earthy matter which pave the ocean, and rise into islands, mountains, and mighty continents. In this hardened constitution, this simplified but degenerate structure, we see that the frame of man, in its natural decay, loses the characters that

* See his treatises De Sanitate Tuendâ, and De Marasmo.

once distinguished it from the dust, and that not less literally than truly it has become more and more "of the earth earthy."

We have now traversed as far and as minutely as our space would allow, the organs and tissues, with their various alterations. It remains for us to inquire whether any one of them may be considered to stand in the relation of cause to the others. We have already dismissed the supposition, that rigidity and concretion are productive of the other alterations, and we also partly entertained the question, when treating of the relations between assimilation, the fluids, and the organs subservient to circulation and digestion. But there are one or two additional points which must be alluded to in this place.

The decay of all the organs, concerned in the *life of relations*, has been shewn to depend on a failure in the actions which are necessary to their generation and maintenance; these organs may, therefore, be dismissed at once from our inquiry into the causation or priority of the processes of degeneration. Yet the observation of the marked declension of the function of the nervous system throughout the body, has led to the hypothesis, that the failure in this power is the ultimate fact in the history of our decline, the fact to which all the others may be traced. This view is suggested by Dr. Roget in his justly-admired article on Age, in the Cyclopædia of Practical Medicine. He considers the general condensation of tissue throughout the system, to be occasioned by a diminished force of circulation, which allows the capillaries to collapse and become obliterated; the weakened circulation this distinguished author is inclined to attribute to a diminution of nervous power in the muscular fibres of the heart; whence he infers that the declension of nervous power bears the priority in the chain of events. We do not feel prepared to adopt the inference; for if we admit this failure in the innervation of the heart, (and whether its fibres are dependent on nerves for their contractility, is still an unsettled question,) are we to pass over the condition of the blood? Might we not say that the enfeebled contractions of the heart are referable to an alteration in the properties of its appropriate stimulus? It is known that this vital fluid has been less affected by respiration than in former periods of our existence; we might therefore, when searching for the earliest antecedent in decay, stop at the imperfect arterialization of the blood. But this would be, in our humble opinion, to pause too soon. The deficient oxygenation of the circulating fluid is sufficiently well known to be the effect of certain changes in the apparatus of respiration. And to what do these changes belong? To a variety of structural, functional, and nervous phenomena, which, if pursued, would lead us into a maze of events, from which it would be impossible to select that which was earliest in its occurrence. Or if we leave the respiratory system, and follow the blood backward to the process of chylification, and ultimately to digestion, we shall, as was shewn above, be equally unsuccessful in obtaining satisfaction. Or finally, if we return to the heart, and investigate the diminished nervous power, admitting this diminution to be alone sufficient for the debility of circulation, is it possible to stop at this phenomenon? Nervous power is nothing but the function of nervous substance, and whether the latter belongs to the ganglionic system, or to the cerebro-spinal, it may have undergone some change, or have been stimulated differently from usual. We know that the sensibility of the nervous system is most intimately connected with the quality of the blood, and with the force of its impulse; so that if it be true that diminished circulation is the effect of diminished innervation, it is no less true that the latter is also the result of the former. Thus it appears that in this inquiry we are constantly arguing in a circle, and it can scarcely be otherwise; the principal structures and functions of the organic life commenced simultaneously; they must decline simultaneously: they assisted one another to grow; they accelerate each other in the way to dissolution. If, however, we are disposed in some measure to qualify this remark, and still hold that there must be some organic changes primary in the work of decay, all analogies must, we think, conduct us to the simple processes of assimilation and secretion, into which all the more complicated functions must be ultimately resolved; but we can go no farther, for we know not what determines or modifies the play of those subtle affinities, motions, and contractions, in which such changes consist.

Some fancy that the enigma is solved by the hypothesis of a diminished vital power; but we have already attempted to show that the interpretation is without value, when applied to the cessation of development; the same reasons render it equally useless as a key to the hieroglyphics of decay. Not less vain were the endeavours of those who could satisfy their philosophy with such a subterfuge of ignorance as was afforded in the theory of a sum of excitability, originally allotted to the system, and gradually exhausted, &c.; as if excitability could possibly mean any thing more than an expression of the collective phenomena of excitement, or vital movement. It is exactly on a par with the doctrine of decreasing vitality.* Some talk prettily and poetically of the vital flame burning out, of oil gradually wasting, of fuel expended,— phrases applicable enough as metaphors, but absurd when propounded, as they too often are, as statements of matters of fact.

When philosophy has failed to discover antecedences, she may still find a prolific source of employment in the study of harmonies. There is no event to be found in the relation of cause to those organic changes which, without the intervention of accidental agents, ultimately affix a bound to the duration of man's existence. As no cause can be elicited for the termination of development, neither can we better explain

* "La gêne de l'influence vitale s'accroit sans cesse."—Cabanis.

why growth does not continue stationary, and maintain the bodily structures for a series of ages, so long as external circumstances remain the same. We live in the midst of agents that both supply us with life and infest us with poison: for a time we resist the baneful tendencies, and then gradually succumb, but in what manner we are at present ignorant. The prevalence of certain functions has been supposed to fortify certain animals against the outward agents or inward processes that would otherwise urge them to dissolution. The influence of respiration upon nutrition is well known, and consequently a large sum of respiration has been alleged to account for the longevity of birds; but there are equal or much greater instances to be found among fishes and reptiles, the amount of whose respiration is extremely small. In the one case the vitality is said to be less rapidly consumed, in the other to be more abundantly supplied; explanations which amount to little more than statements of the same facts in different language. Lord Bacon was of opinion that birds owe their lengthened existence partly to the smallness of their bodies, and partly to their being so well defended by their teguments from the atmosphere; while he accounted for the long life of fishes by the non-occurrence of desiccation in their aqueous element. There is nothing satisfactory to be obtained from speculations of this sort. The most that we can learn is the variation in the term of existence by the influence of various outward agents and modes of life. But whatever variation may be discovered, it will still appear that climate, and time, and custom, and science have never prolonged the date beyond certain limits. The study of these circumstances, and the appliances of art, undoubtedly tend to enable a greater number to attain the extreme goal, but can never give the power of transgressing it. Vain, then, as Boerhaave observes, are the hopes of men who look for an *agerasia!*

Although at present, then, we cannot trace the causes of the bounded nature of our existence, yet it is not difficult to discern its fitness to our constitution, and to the universal frame of things. The brevity of life is an ancient complaint; lamentations have been chaunted over it time out of mind: but its antiquity does not redeem this, any more than many other opinions equally hoary, from the character of a prejudice. Every consideration of the fact in question with reference to the universe must "justify the ways of God to man" in the disposition of this as of every other event. We have only to conceive the circumstance altered, in correspondence to the idle wish of some aspirant to longevity, and we see that every thing else also would require to be changed; that, in short, the beautiful arrangements of the world and of our social relations would be broken. To notice one or two of these: if the life of man were longer than it now is, his progeny would need to be greatly abridged from their present numbers, or they would soon exceed the ratio of subsistence. The time occupied in attaining maturity bears a direct proportion to the period of existence in the mammalia; consequently, if life were prolonged beyond its present limits, that time during which the offspring of man is either helpless or very dependent on the parents, would be also lengthened, and the accidents of disease or other casualties remaining the same, it is clear that confusion, distress, and manifold calamities would accrue to a rising generation. After the attainment of maturity and of its accompanying faculties, it is not clear that any thing would be gained by the possession of these for a longer period than is now allowed; since we know but too well that men, after a time, lose the spirit of enterprise once engendered by the consciousness of increasing or lately-acquired powers, and fall into habits of action which they are unwilling to abandon, but which do not advance the resources of the species beyond a certain limit. Hence the advantage of their giving way to others, to whom they can commit their knowledge, and who, by their unworn energy, will advance it further. "Life is sufficient for all its purposes if well employed," was well observed by Dr. Johnson; and what follower of medicine can forget that the immortal sage of Cos, by the example which he afforded in his well-spent life, disarmed his own antithesis of its woful point: ὁ βίος βραχὺς, ἡ δὲ τέχνη μακρή.

ALBINO. (Syn. *Albinismus, leucopathia, leucæthiopia*).—This term, as employed in physiology, appears to have been first used by the Portuguese* to designate a peculiar condition of the human body, which was occasionally observed among the negroes in the western parts of Africa. It consists in the skin and the hair being perfectly white, while in the

* Vossius, de Nili origine, cap. 19. p. 69; see also Ludolf, Hist. Æthiop. Com. lib. i. cap. 14. No. 100. p. 197. The name by which the African Albinoes are known among their countrymen is Dondos: by the French they are frequently termed Blafards.

form of the features and in all other respects the individuals in question exactly resemble the negro race. Another striking peculiarity of the Albino is the state of the eye, which is of a delicate pink or rose colour; it is likewise so sensible to light as to be unable to bear the ordinary light of the day, while in the evening, or in a dark shade, its functions appear to be sufficiently perfect. We learn from Wafer, who accompanied Dampier in one of his voyages, and who relates his adventures in crossing the Isthmus of Darien, that Albinoes are not unfrequently found among the inhabitants of this district.* We are also informed by various travellers and naturalists that they are often met with in some of the oriental isles, more especially in Java and Ceylon;† in all these cases exhibiting the peculiar appearance of the skin, hair, and eyes, while, in other respects, they conformed to the external and physical characters of the people among whom they are found. The same circumstance occurs in this country and in the other parts of Europe, although, if we are to place any confidence in the accounts of travellers, the Albino is much more frequently met with in tropical climates, especially in the western parts of Africa, and in Darien, than in the more northern regions.‡

We meet with a few seattered remarks in the writings of the ancients, which render it evident that this peculiar state of the human body had fallen under their notice. We have the following passage in Pliny: "Idem" (Isigonus Nicæensis) "in Albania gigni quosdam glauca oculorum acie, e pueritia statim canos, qui noctu plus quam interdiu cernant."* The same circumstance is referred to by Aulus Gellius: ". . . . in ultima quadam terra, quæ Albania dicitur, gigni homines, qui in pueritia canescunt, et plus cernunt oculis per noctem, quam inter diem;"† and by Solinus: he says that the Albanians "albo crine nascuntur;" "glauco oculis inest pupula, ideo nocte plus quam die cernunt."‡ Pliny, in speaking of the inhabitants of a certain district in the interior of Africa, names them Leucæthiopes;§ and, as it has been supposed that in this passage he referred to the Albinoes, the term has been applied to them by some eminent modern naturalists;|| but it appears more probable that the Leucæthiopes were a tribe of negroes whose complexion was rather less dark than that

* Wafer's New Voyage, p. 134..8; Buffon, Hist. Nat. t. iii. p. 500; Wood's Trans. v. iii. p. 419, 10; Pauw, Recherches sur les Americains, par. 4, sect. 1. t. ii. p. 1 et seq.; Raynal, Hist. des Indes, t. iii. p. 288. The earliest account which we have of the South American Albinoes is by Cortez, in the narrative of his conquest of Mexico, which he transmitted to Charles V. In describing the palace of Montezuma, among other objects of rarity or curiosity which were found in it, he says, "In hujus palatii particula tenebat homines, pueros, fœminasque a nativitate candidos in facie, corpore, capillis, superciliis, et palpebris." De Insulis nuper inventis narrat., p. 30 of "Nar. Sec.;" see also Clayton, in Manch. Mem. v. iii. p. 261 et seq.

† Buffon, t. iii. p. 399 and 415: Wood's Trans. v. iii. p. 328, 9 and 344. We have not been able to procure the "Voyages de Legat," which is referred to by Buffon and others, as containing the original account of the Albinoes, or, as they have been termed, Chacrelos, of Java. With respect to the Bedas of Ceylon, as originally described by Riheyro, Hist. de Ceylon, ch. xxiv., and more lately by Percival, Account of Ceylon, ch. 13, and by Cordiner, Desc. of Ceylon, v. i. c. 4, it seems evident that they are not to be considered as Albinoes. The only remark which Ribeyro makes on their physical character is, "Ils sont blancs comme des Européens, et il y a même des roux parmi eux," p. 178. Percival, who saw some of them, states that their complexions are fairer and more inclined to a copper colour, than those of the other inhabitants; while all that is said by these writers respecting their habits and modes of life indicates that they are a distinct race or tribe. The term Beda, or Badah, appears to be a corruption of Vaddah, or Veddah, which Knox informs us is the name of the aborigines of the island; Account of Ceylon, p. 61; see also Brown, in Brewster's Encyc. art. "Ceylon," p. 704; Cordiner and Percival, ut supra.

‡ Vossius and Ludolph, ubi supra; Argensola, Conquist. de las Islas Malucas, lib. ii. p. 71, speaks of Albinoes as not uncommon in these islands; De la Croix, Rélation de l'Afrique, par. iii. liv. ii. sect. ii. §. 13, "Albinos, hommes blancs, ou Mores blancs," informs us that they compose a considerable body of attendants at the court of the king of Loango; the same statement is made by Ludolf, ubi supra, and by the author of the Hist. Gén. des Voyages, t. vi. p. 250 et seq.: Bowdich, Mission to Ashantee, p. 292, observes, that the king had at his court "nearly one hundred negroes of different colours, through the shades of red and copper to white;" he adds that they were "generally diseased and emaciated;" some of these were probably Albinoes. Cook, in his first voyage, saw six Albinoes in the small population of Otaheite, v. ii. p. 188; in his second voyage he saw one in New Caledonia, v. ii. p. 113, 4; and in his third voyage, he met with three in the Friendly Isles, v. i. p. 381, 2. These, it may be remarked, must have belonged to the Malayan variety. See also Winterbottom, Account of Sierre Leone, v. ii. p. 166 et seq.; Stevenson, in Brewster's Encyclopædia, art. "Complexion," p. 41, 2; Bory St. Vincent, L'Homme, t. ii. §. "Hommes Monstreux," p. 143-7; also in Dict. Class. d'Hist. Nat. art. "Homme," p. 166 et seq.; Renauldin, in Dict. des Scien. Méd. art. "Albino;" Lawrence's Lect. p. 287; Is. St. Hilaire, Anom. de l'Organization, t. i. par. ii. liv. iii. ch. i. p. 296, 314, 5, and art. "Mammifères," in Dict. Class. d'Hist. Nat. p. 113. Some of the earlier writers did not hesitate to affirm, that they were confined to the offspring of negroes, Monge, Journ. Phys. 1782, p. 401 et seq. Suppl. We have no very distinct account of Albinoes among the Chinese and Mongols, but they appear to be as frequent among the Malays and native Americans as among the Æthiopians.

* Hist. Nat. lib. 7. cap. 2. See the note of Cuvier, in his edition of 7th . . 11th books of Pliny, t. i. p. 18.

† Noct. Attic. lib. 9. cap. 4.

‡ Polyhistor, cap. 15. p. 25. See the remarks of Saumaise, Exerc. Plin. p. 134, and of Pauw, t. ii. note in p. 13.

§ Lib. 5. cap. 8. We also find the same term in Pomponius Mela, lib. 1. cap 4, and in Ptolemy, Geog. lib. 4. cap. 6; but it is not accompanied by any description of the people so designated.

|| Among others by Blumenbach, Gen. hum. var. § 78. See Is. St. Hilaire, p. 297, note. We may remark that the term is objectionable, as indicating that the Albino is confined to the Æthiopic variety.

of the Africans generally.* It has been likewise supposed that Celsus alluded to the Albino, when he speaks of a peculiar condition of the skin under the name of Leuce;† but this appears to be a morbid cutaneous affection, and to have no reference to the subject now under consideration.

From the number of Albinoes which were supposed to exist in certain countries, as well as from the marked peculiarity in their appearance, an opinion was long entertained that they formed a distinct race or variety of the human species,‡ originating in some unknown cause, and bearing the same relation to the other inhabitants of the countries in which they are found that the acknowledged varieties of the human species bear to each other. But this opinion, although sanctioned by high authority, may be considered as decisively disproved by the well-ascertained fact, that Albinoes are born of parents who do not possess this characteristic peculiarity of the skin, hair, and eyes.§

Although Albinoes are of comparatively rare occurrence in Europe, yet we have had a sufficient number of examples to render us perfectly familiar with the appearance which they present, and with the precise nature of the circumstances which characterize them.* The skin is of a milky whiteness, without the slightest admixture of the brown or olive tint which is found in the complexion of even the fairest European female; the hair is also perfectly white,† and is generally of a soft or silky texture, while all the coloured parts of the eye are of a delicate rose colour. We are informed that the skin of the African and American Albino is not only completely free from any shade of brown or olive, but that it is also devoid of the pink tinge which is found more or less in the complexion of the European. It would appear, likewise, that the skin of the tropical Albino is frequently in a diseased state, being covered with scales of a leprous nature, and with a serous exudation, which proceeds from the fissures or clefts that take place in various parts of the surface.‡

It has been a very general opinion, that besides the peculiar state of the integuments, the Albino possesses a general delicacy of habit and constitution, and that he exhibits a deficiency even of mental power.§ For this latter opinion there appears to be no sufficient foundation, and with respect to the former we may remark, that any general weakness of the physical frame, if it be actually found to exist, may be probably referred, at least in some degree, to the peculiar condition of the eyes and the skin, which are not well adapted either to a

* See the note of Hardouin in loco, Valpy's ed. p. 1285, Le Maire's, t. ii. p. 438; also the remark of M. Marcus in M. Ajasson's Trans. of Pliny, t. iv. p. 185. It is, perhaps, to this lighter coloured negro, rather than to the proper Albino, that we must refer, in part at least, the accounts which are given by travellers of the great number of white Africans that have been collected in certain situations. We may remark that all accounts of Albinoes that are given in general terms only, should be received with a certain degree of caution, unless the peculiar state of the eye is distinctly noticed. Humboldt remarks that the missionaries, when they met with any Indians that were less black than ordinary, were accustomed to call them white; Pers. Nar. by Williams, v. iii. p. 287 et seq. See Prichard, in Medical Cyclop. Art. "Temperament," p. 163.

† De Medicina, lib. 5. cap. 28. § 19.

‡ This appears to have been the case even with Haller, El. Phys. xvi. 4. 13. p. 492. Voltaire maintains this hypothesis, Essai sur les mœurs, Œuvr. t. xiii. Introd. and p. 7, 8. Buffon inclines to it; but his opinion on this point is not decided or uniform, t. iii. p. 501. See Is. St. Hilaire, p. 295.

§ In addition to the authors already referred to, we have a case of this kind by Helvetius, Hist. Acad. Sc. 1734, p. 15 . . 7. The Albiness described by Buffon was born of black parents: see also Castillon, in Berlin Mem. 1762, p. 99 . . 105; Dicquemare, Journ. Phys. 1777, p. 357 . . 0, and 1788, p. 301 et seq.; Hist. Acad. Scien. 1744, p. 12, 3; and Maupertuis, Ven. Phys. p. 135 et seq.: Jefferson, Notes on Virginia, p. 103 . . 5, mentions an instance of three Albino sisters born of black parents; two of these had black children; Firmin, Descrip. de Surinam, t. i. p. 153, 5; Goldsmith's Anim. Nature, t. i. p. 452, 3; Bruc, Hist. des Voyages, t. iii. p. 370, 0. See on this point Is. St. Hilaire, p. 303. We have a decisive proof that the peculiarity of the Albino is merely accidental and individual, and does not constitute a distinct variety, in the state of the offspring of an Albino and a black negro, which is not intermediate between the two, as in the case of the Mulatto; Hunter, on the Anim. Œcon. p. 248; Is. St. Hilaire, p. 305...7.

* We have a copious list of references in Blumenbach, p. 278 . . 0, in Lawrence, p. 281 . . 9, and in Is. St. Hilaire, ut supra and §. 5. One of the earliest of what may be considered as the correct descriptions is that of Buffon, Supp. t. iv. p. 559 et seq. The descriptions of Blumenbach, §. 78, and of Saussure, Voy. §. 1037 . . . 1043, are particularly correct and characteristic: to this we may add the more recent account of Is. St. Hilaire, t. i. par. 2, liv. 3. ch. 1, §. 2 and 5. We are informed by Ludolf, ubi supra, that the first modern writer who distinctly mentions the Albino is Tellez.

† Blumenbach particularly characterizes the whiteness of the hair of the Albino as being "gilva, colori cremoris lactis quodammodo comparanda," p. 275.

‡ See Vossius, Ludolf, De la Croix, Cook's First Voyage, and Winterbottom, ut supra; Blumenbach, p. 274; Buffon, in Hist. Acad. Scien. 1760, p. 17; St. Hilaire, p. 304, 5: Wafer, in his description of the white inhabitants of Darien, p. 134, et seq., says that there is a white down on their skin.

§ Wafer, p. 134-8; Buffon, t. iii. p. 503; Wood's Trans. vol. iii. p. 420; Voltaire, t. xv. p. 269,70; Pauw, t. ii. p. 9, 10; Raynal, t. iii. p. 288; Dubois on the People of India, ch. xv. p. 199 et seq.; Firmin, t. i. p. 153 . . 5; Dalin, in Amœn. Acad. t. vi. p. 74, note; Isert, Voy. en Guinée, ch. xv. p. 199 et seq.; Labillardière, Voyage, t. ii. p. 141; Winterbottom, ut supra; Rayer, sur le Peau, t. ii. p. 193 . . 203; Blandin, Dict. Méd. Chir. Prac. "Albinie;" Breschet, Dict. de Méd. "Albino;" Sonini, in his edition of Buffon, t. xx. p. 355-6, note. So far as regards the state of the intellect, the charge is repelled by M. Sachs, who gives a minute account of the peculiarity in his own person and that of his sister; Hist. Nat. duor. Leucæthiopum. Jefferson informs us, that the Albinesses, of which he gives an account, were "uncommonly shrewd, quick in their apprehension and reply," p. 103-5.

bright light or to a high temperature, and therefore render the individuals less able to bear exposure to the weather, or to perform the ordinary occupations of life. To the same cause may be ascribed the morbid condition of the skin, which, as was remarked above, occurs not unfrequently in hot climates, and which is not observed in the European Albino. Partly from the circumstances stated above, and partly from the idea of imperfection or defect, which is connected with their appearance, the tropical Albino is generally regarded by his countrymen with a degree of compassion or even of contempt;* and hence is derived one of their popular denominations, chacrelas, which is a corruption of kakkerlakken, the Dutch name for the cock-roach, as being, like those animals, able to leave their haunts only in the evening.†

Besides the complete Albino, which we have now described, there are occasional examples of individuals, where the whiteness of the skin exists in certain parts of the surface only, while the remainder of the body is of its ordinary colour.‡ In the majority of cases the peculiarities which constitute the Albino are connate, and continue during life without any change. There are, however, some instances, where the whiteness of the skin does not exist at birth, but makes its appearance at a subsequent period, generally by slow degrees, until the complete Albino character is induced.§ When once formed it does not seem that it ever disappears, or is even in any degree diminished, nor have we any authentic accounts of its being removed by any constitutional change, either natural or morbid, or by external applications.

* Vossius, p. 68, informs us that they are avoided by the other negroes, as supposed to be diseased. De la Croix says the negroes regard them as monsters, and do not permit them to multiply, ut supra. Dubois, p. 199 et seq. observes that they are named lepers by birth, and that when they die their bodies are not buried or burnt, but cast on dunghills. See also Firmin, ubi supra.

† Blumenbach, p. 277; Lawrence, p. 287; St. Hilaire, p. 296.

‡ Phil. Trans. vol. xix. p. 781, and Lowthorpe's Abridg. vol. iii. p. 8; Buffon, t. iv. p. 565. tab. 2, et p. 571, tab. 3; Arthaud, in Journ. Phys. 1789, pt. 2. p. 277,8; Rush, in Amer. Trans. vol. ii. p. 392 et seq.; Gumilla, El Oron. Ilus. t. i. p. 109 et seq.; Ditto, Hist. de l'Oronoque, trad. t. i. p. 150 et seq.; Jefferson, p. 105; Blumenbach, § 48; Rayer, ut supra; Is. St. Hilaire, p. 309 et seq.; Isert, p. 156. Bell, in Travels in Asiatic Russia, p. 217,8, saw a number of persons with white spots on the skin, but it seems probable that this was the effect of some cutaneous disease. The partial Albino appears to have been noticed by the ancients; Lucian, Prometh, t. i. p. 15.

§ Blumenbach, p. 276, says it is "semper connatus;" see, also, Lawrence, p. 285. There are, however, certain well authenticated cases, where the skin of the negro has gradually changed its colour from black to white; sometimes the change has been general, sometimes only partial; Bates, in Phil. Trans. vol. li. p. 175 et seq.; Gualtier, in Journ. Phys. t. lxx. p. 248 et seq.; Le Cat, sur le Peau, p. 112 et seq.; Rayer, ut supra; Fisher, in Manch. Mem. vol. v. p. 314 et seq.; Rush's Remarks on the same, Amer. Trans. vol. iv. p. 289 et seq. In one of the four cases which are mentioned by Le Cat, the change of colour appears to have been the consequence of a severe burn or scald. Besides the partial Albino, we have what has been termed the imperfect Albino, where the peculiarity exists in a certain degree only; Is. St. Hilaire, §. 4. p. 312 et seq.

Although, as has been stated above, this peculiarity occurs in individuals, who did not derive it from their parents, yet, like all those deviations from the ordinary structure of the body, which have been styled accidental varieties, when once produced, it is disposed to propagate itself by hereditary descent. There are also certain individuals, who have a tendency to produce it; so that even among the few European Albinos, of which we have a minute account, we have cases of its occurrence in two or more members of the same family, either as connected by parental descent, or by collateral relationship.* We have no instance on record of the offspring of a male and female Albino.

The whiteness of the skin and hair, both general and partial, is not confined to the human race; it is found in most, if not in all the species of the mammalia, and in some of these, as in the dog, the horse, and the rabbit, is the subject of daily observation;† in most of them, however, the peculiar state of the eye does not exist. These white varieties, like other analogous cases among the lower animals, when once produced, are strictly hereditary, in which respect they differ somewhat from the human Albino.

Various opinions have been entertained by physiologists respecting the nature of this peculiarity, whether it should be considered as a morbid affection,‡ depending upon a diseased state of the constitution, and also respecting its immediate or efficient cause. The first of these points may be regarded as a verbal controversy, depending altogether upon our definition of morbid action; but we conceive, that according to the ordinary definition of the term, we should not consider it as a disease, but as a connate deviation from the perfect structure of the animal frame, not produced by an external cause, and not removable by a remedial agent. For a correct knowledge of its physical cause, we are indebted, in the first instance, to an ingenious conjecture of Blumenbach's, who accounted for the red colour of the eye, and its extreme sensibility to light, by the absence of the pigmentum nigrum.§

* See particularly Saussure's account of the two boys of Chamouni and Sachs's Narrative; also Blumenbach, p. 276 and 279, note; Firmin and Jefferson ut supra; Pauw, t. ii. p. 25; Bory St. Vincent, L'Homme, p. 144, mentions an Albino of the third generation; Is. St. Hilaire, passim.

† Blumenbach, p. 281, 2; Is. St. Hilaire, p. 297..9.

‡ "Ad cachexias referenda videtur affectio," Blumenbach, p. 274; Is. St. Hilaire, §. 6, supposes that there are two species of Albinism, one the effect of disease, the other a true anomaly; but we conceive that the term is not correctly applied to the former state.

§ Comment. de Oculis Leucæthiopum, et De Gen. Hum. var. §. 78.

This conjecture was shortly after verified by Buzzi of Milan, who took advantage of an opportunity which presented itself, of dissecting the eye of an Albino, in which the pigmentum nigrum could not be detected.* He also examined the structure of the skin, which appeared to be deprived of the rete mucosum, that part of it in which its specific colour is supposed to reside; the hair was also found to be deficient in its central coloured part.† Whether, in these cases, the pigmentum nigrum of the eye and the rete mucosum of the skin are absolutely deficient, or are only deprived of their colouring matter, so as not to be detected by the eye, is a point on which different opinions have been formed by anatomists;‡ perhaps, upon the whole, we may be induced to consider the latter opinion as the most probable.

What are the circumstances in the constitution of the parents which should lead to this peculiarity in their offspring is entirely unknown, nor have any conjectures been formed on the subject which can be considered as even plausible.§ The hypothesis of Buffon, which at one time obtained a considerable degree of credit, that white is, as it were, the primitive colour of nature, which, by various external causes, is changed to brown or black, but which the body has always a tendency to resume under favorable circumstances,‖ is completely without foundation: nor does it appear that we can explain it upon the principle, that domestication and the habits of civilized life have a tendency to produce a lighter shade of the complexion, because we trace no connexion between the supposed cause and the effect, and because the production of the Albino is complete in the first instance, and not brought about by any gradual or progressive alteration.

It appears that we must come to the conclusion, that although the anatomical or physical cause of the peculiarity is ascertained, yet that we are entirely ignorant of its remote cause, or of that train of circumstances which leads to its production.*

* For some remarks "on the colour of the pigment of the eye," and its effect on vision, as applicable to the eye of the Albino, see Hunter, p. 243 . . 253; also Blumenbach, §. 51. "Capillorum cum cute consensus," and §. 53, "Irides oculorum cum capillorum colore consentientes."

† Sachs gives us a minute account of the analysis of the hair of the Albino, compared with Vauquelin's analysis of hair in its ordinary state, from which it appears that no iron could be detected in it.

‡ Blandin, Dict. Méd. Chir. Prat. "Albinée;" Rayer, §. 630.

§ Mansfeldt is disposed to ascribe the production of the Albino state to some shock given to the fœtus, by an impression made upon the mother; it is characterized as a "cessation totale, momentanée d'action cérébrale;" Journ. Compl. t. xv. p. 250 et seq. Is. St. Hilaire essentially adopts this hypothesis, ascribing the peculiar state of the skin to an "arrêt de développement," in consequence of which the colouring matter is not formed at the requisite period, p. 319,0. The idea, that it depends upon something peculiar in the seminal matter of the parent, which was maintained by Herodotus, Thalia, §. 101, and was controverted by Aristotle, Hist. Animal. lib. 3. cap. 22, has been revived by Maupertuis, Diss. 2, and by Pauw, t. i. p. 179, and t. ii. p. 21. Le Cat refers the colour of the negro to a peculiar substance, which he names "Æthiope animal," which he supposes is contained in their fluids, analogous to the black inky matter of the cuttle fish; par. 2. art. 1; the absence of this substance converts the negro into an Albino.

‖ T. iii. p. 502,3.; Wood's trans. t. iii. p. 422. We may remark that this speculation of Buffon's is precisely the reverse of that of Hunter, p. 243 et seq.

* "The following cases have not been referred to in the body of the article; De la Nux, Hist. Acad. Scien. 1744, p. 13; Camelli, Phil. Trans. v. xxv, p. 2268; Duddell on the Eye, Suppl. to, sect. iii. §. 30 et seq.; Percival, Irish Trans. v. iv. p. 97, 8; Hunter, Anim. Œcon. p. 250, 1; Traill, in Nich. Journ. v. xix, with an Add. by the editor; Mansfeldt, Journ. Compl. t. xv; Ansieux, in Journ. Méd. de Corvisart, t. xiv, p. 263, 4.

For the following epitaph, which appears to have been written on an Albino child, we are indebted to a literary friend, the Rev. Jos. Hunter.

"Upon Thomas, son of Ric. Elmhurst by Margaret his wife, daughter to Ric. Micklethwaite: whose promising parts, were interrupted by an early death.

" . . . This boy no Albian was, yet gray hair'd borne
Who saw old age and night as soon as morne.
His grave's a cradle; there his God him lay'd
Betimes to sleep lest he the wanton play'd.
Bid him good night! i'th bed of dust sleep on
Until the morne of Resurrection.

"Anagram.

"Lo Earth misseth me, 1632."

(*J. Bostock.*)

ALBUMEN, (Fr. *Albumine*, Germ. *Eyweisstoff*,) is one of the most important proximate principles of animal bodies; it is the leading ingredient of the blood, of many of the secretions, and of muscular fibre, cartilage, and membrane: the white of egg (whence the generic term *albumen*) presents it in considerable purity, and it is from this source, and from the serum of the blood, that we chiefly obtain it for the purposes of experiment. In this article we shall describe the leading properties of albumen; and in others, refer to its principal modifications.

The white of egg may be regarded as a combination of albumen with water; it contains small quantities of saline substances, which are inseparable in its liquid state. When it is evaporated at a temperature below 120°, it dries into a brittle, shining, transparent substance of a pale yellow colour, inodorous and tasteless. Its ultimate constituents, exclusive of saline matters and a trace of sulphur, are carbon, hydrogen, nitrogen, and oxygen; of these the relative proportions have been determined by Gay Lussac and Thenard, who analysed the white of egg dried at 212°; and by Dr. Prout, who employed the dried serum of slightly inflammatory blood; the following table shows its theoretical composition as contrasted with these experimental results:—

	Atoms.	Equivs.	Theory.	G. Lussac.	Prout.
Carbon..	8	48	51.61	52.883	50.00
Hydrogen	7	7	7.53	7.540	7.78
Nitrogen	1	14	15.05	15.705	15.55
Oxygen	3	24	25.81	23.872	26.67
	1	93	100.00	100.000	100.00

White of egg, when heated to about 150°, *coagulates*, that is, it becomes a white, translucent, and somewhat elastic substance, which, when cautiously dried, shrinks up and assumes the appearance of horn, becoming tough, yellowish, and insoluble in water. Two parts of white of egg and one of water entirely coagulate when duly heated; equal parts remain, under the same circumstances, semi-fluid; a mixture of one part of white of egg and ten of water becomes opaque, but is not coagulated; and a milkiness is perceptible when the albumen only forms a thousandth part of the solution.* Fresh-laid eggs, and those which have been oiled upon the surface do not perfectly coagulate when put into boiling water, in consequence, probably, of the dilute state of the albumen. One hundred parts of the fresh albumen of the egg, when carefully evaporated in vacuo, leave a residue = fifteen parts. One hundred parts of the coagulated white of a duck's egg (dried in vacuo with sulphuric acid) leave 13.65 parts, which, steeped in water, acquires its original appearance, but in four days only took up 68 of water, though it had lost 86.35.†

When albumen is made part of the voltaic circuit, it presents appearances dependent upon the power used, which, when considerable, excites so much heat as to coagulate it; but with a feeble power and the poles sufficiently distant, coagulation ensues most plentifully at the negative platinum wire; a coagulum also forms at the positive wire, where acid is also sparingly evolved. These phenomena are much interfered with by the evolution of gaseous matters at the respective poles, which occasion a froth, and the appearance of more extensive coagulation than actually occurs.

When coagulated white of egg is boiled for several hours, it shrinks up and becomes hardened, communicating traces of animal matter to the water. Heated by high pressure steam in a copper digester to 400°, it blackens the interior of the vessel, and dissolves, leaving a small residue of unaltered albumen. The solution is brown, and has the odour of boiled meat (from osmazome?). This action deserves further investigation.‡

White of egg soon runs into putrefaction, and evolves sulphuretted hydrogen. The serum of blood kept for two years in a well-stopped phial, blackened its interior, and became a stinking, pale, yellow liquid, still coagulable by heat, and containing hydro-sulphate, carbonate, and acetate of ammonia, and a fetid volatile matter: a portion of yellowish white purulent-looking matter, containing undecomposed albumen, remained at the bottom of the phial. Coagulated white of egg, even under water, long resists putrefaction.

* Bostock, Nicholson's Journal, vol. xiv. and Medico-Chirurgical Transactions, vol. i. and ii.

† Chevreul, Mém. du Museum vii. 180. Ann. de Ch. et Ph. xix. 46.

‡ Gmelin, Handbuch der Theoretischen Chemie, ii. 1053. 3rd ed. Frankfort, 1827.

One hundred parts of dried white of egg, subjected to destructive distillation, yielded carbonic acid, carburetted and sulphuretted hydrogen, prussic acid, carbonate of ammonia partly in solution and partly sublimed, stinking volatile oil, and 14.9 of spongy difficultly combustible carbon, which, by incineration, left 2.21 of ash composed of carbonate of soda, phosphate of soda, and phosphate of lime, (Hatchett.)

Nitric acid, dropped into a solution of albumen, forms a white, flaky precipitate, which is more or less abundant according to the state of dilution of the solution, and which is soluble in ammonia and potash. When coagulated white of egg is kept for some weeks in very dilute nitric acid, it acquires a yellow colour, and if digested in boiling water it dissolves, and has acquired the properties of gelatine, and is precipitated by tan and muriate of tin. Hatchett.)* Cold nitric acid sp. gr. 1.25, gradually tinges coagulable white of egg of a yellow colour, dissolving a little of it, and forming malic acid, with the evolution of nitrogen; its surface becomes tallowy, and in twenty-four hours it falls into a pale yellow powder, which is acid and composed of nitric, nitrous, and malic acids with albumen; when thoroughly washed with water, it becomes more neutral and of an orange colour, still reddening litmus, and remaining insoluble in water, but soluble in caustic potash.† When coagulated white of egg is digested in hot nitric acid, nitrogen, nitrous gas, carbonic acid, and prussic acid are formed, and a dark yellow solution obtained, which is precipitated by the addition of water and ammonia, and which contains malic and oxalic acids, bitter matter, and fat. (Hatchett.)‡

Sulphuric acid is a less powerful precipitant of albumen than nitric acid. Dilute sulphuric acid dropped into an aqueous solution of albumen occasions a precipitate which is soluble in excess of acid; ferrocyanate of potassa throws it down. When coagulated albumen is digested in sulphuric acid, very slightly diluted, it yields a deep crimson solution.§ Coagulated serum digested in sulphuric acid diluted with six parts of water, converts it into acid *sulphate of albumen*, which, when edulcorated with cold water, becomes more neutral, and is soluble in warm water, forming a gelatinous solution, which is precipitated by sulphuric, muriatic, and nitric acids, and by the alkalies. (Berzelius.)|| Coagulated white of egg digested in hot sulphuric acid becomes carbonized without forming artificial tan. (Hatchett.)

When a solution of recently fused phosphoric acid (pyro-phosphoric acid) is added to solution of albumen, it occasions an abundant precipitate: the acid gradually loses this property, and again acquires it by fusion and ignition. (Berzelius.)

Muriatic acid occasions a precipitate in albuminous solutions, and entirely throws down the albumen when aided by heat; but the precipitate is soluble in excess of acid, and in ammonia and potassa. A muriated albumen may be formed in the same way as the sulphate. (Berzelius.) Coagulated egg-albumen digested in muriatic acid gradually acquires a purple colour. (Hatchett.) Albumen which has been precipitated by muriatic acid, often becomes reddish when collected and exposed upon a filter.

When coagulated seralbumen is digested in acetic acid, it becomes soft and transparent, and, aided by a gentle heat, dissolves with the evolution of a little nitrogen. This solution is precipitated by the alkalies, but a slight excess again renders it clear: it is also precipitated by sulphuric, nitric, and muriatic acids, and by ferrocyanate of potassa. When this acetic solution of albumen is evaporated, it leaves a transparent sour residue, soluble in warm water acidulated by acetic acid. (Berzelius.)

Albumen is slowly soluble in liquid ammonia. In solution of potassa it becomes gelatinous, and yields a pale yellow green solution, precipitable by acids and alcohol, and by acetic acid. Heated in liquid potassa, albumen evolves ammonia.

Alcohol and ether coagulate ovalbumen, but pure ether (free from alcohol) does not coagulate seralbumen. (Gmelin.) When serum is shaken with ether, it soon separates upon the surface, holding fatty matter in solution. (Gmelin.) Coagulated serum digested in alcohol or ether yields a solution of fatty matter.

Coagulated ovalbumen, when long boiled in water, becomes bulky and falls into pieces, and a small portion is dissolved: the filtered solution, evaporated at 212°, leaves a pale brown film, and is alkaline; it is rendered turbid by mineral acids, acetic acid, and tincture of galls, and by many metallic salts.

When albumen which has been cautiously dried at a low temperature (without coagulation) is triturated with four parts of water, it yields a solution resembling fresh albumen.

A solution of the white of an egg in a pint of water occasions no precipitate in lime, barytic or strontia water, nor in solution of sulphate of lime. Some of the neutral salts render it more or less turbid, and it is copiously precipitated by solution of alum. Nitrate, acetate, and subacetate of lead are precipitated by albuminous solutions. One part of fresh ovalbumen in 2000 of water, or one of dried albumen in 10,000 of water is rendered turbid by subacetate of lead. A four-hundredth part of liquid, or a two thousandth of solid albumen is precipitable by corrosive sublimate. (Bostock.) The precipitate is blackened by potassa, and is probably a compound of muriate of albu-

‡ Phil. Trans. 1799.

§ According to Raspail, when sugar is previously dissolved in the sulphuric acid, the albumen is coloured purple, which is deeper in proportion as the acid and sugar are in greater quantity.

|| Lehrbuch der Thier. Chemie.

men and calomel. Nitrate of silver, muriate of gold, and of platinum, also precipitate albuminous solutions. These precipitates are mostly triple compounds of acid, albumen, and oxide, and several of them are redissoluble in excess of liquid albumen.

Albumen is precipitated by tannin in the form of a yellow viscid combination. Water, holding a thousandth part of solid or a two-hundredth of liquid ovalbumen, becomes turbid after some hours by the addition of a solution of galls containing 2.5 per cent. of solid matter. (Bostock.)

The above are the principal chemical properties of liquid and solid albumen as obtained from the egg and from serum of blood; several of their modifications will be noticed under other heads, such as FIBRINE, MILK, BILE, &c.

The cause of the coagulation of albumen is, in many cases, obscure and even inexplicable. It appears possible that the acids by which it is coagulated enter into combination with it so as to form insoluble compounds; the same change probably happens with certain metallic salts, and with tan; its coagulation by alcohol has been ascribed to the abstraction of water. Having remarked the copious coagulation of albumen at the electro-negative pole in the voltaic circuit, I was induced to ascribe the fluidity of albumen to combined soda, the evolution of which seemed to cause its solidification, and it appeared possible that the acids and even alcohol might also occasion coagulation by the abstraction of soda; and that its more enigmatical coagulation by heat only, might be ascribed to the transfer of soda from the albumen to the water. It has been objected to this statement that the addition of alcali to coagulated albumen does not reproduce liquid albumen, and that acetic acid causes no coagulation; but when albumen is once coagulated, its properties are essentially modified, and acetic acid, or even acetate of soda appear to form soluble compounds with it. (Gmelin.) Dr. Turner* supposes that albumen combines directly with water at the moment of being secreted, at a time when its particles are in a state of minute division; but as its affinity for that liquid is very feeble, the compound is decomposed by slight causes, and the albumen thereby rendered quite insoluble. The organization of albumen may certainly be concerned in its singular properties with respect to many coagulants: there are several albuminous fluids, which we shall hereafter refer to, which contain globules resembling those of the blood. In the voltaic coagulation of albumen, that which separates at the positive pole contains globules, which, under the microscope, resemble the blood-globules deprived of their colouring matter.†

The readiest tests of the presence of albumen in fluids are its coagulation by heat, alcohol, and acids; when it is too dilute for such detection, it may be subjected to voltaic electricity, or tested by corrosive sublimate, or by ferrocyanate of potassa; the alcali should, in the latter case, be previously neutralized by acetic acid. It would appear, from Orfila's experiments, that white of egg is an antidote to the effects of corrosive sublimate when taken into the stomach, and that, if administered in sufficient quantity immediately after the reception of the poison, it prevents the progress of the symptoms. The white of one egg appeared sufficient to render four grains of the poison ineffective.

The readiness with which some metallic oxides are received into the system may perhaps be ascribed to their affinity for albumen, with which some of them form compounds not easily decomposable, and in which the metallic oxide cannot be detected by the usual tests, till they have been subjected to heat sufficient to decompose the organic matter. Mercury and silver are thus, in certain cases, detected in the secretions and excretions.

(W. T. Brande.)

AMPHIBIA.—(Αμφις, utrinque, βιος, vita. Fr. *Amphibies.* Germ. *Amphibien.* Ital. *Amphibie.)* A class of vertebrated animals, hitherto almost universally considered as an order of REPTILIA, constituting the *Batrachia* of the later erpetologists. To the retention of the latter appellation, as derived from the Greek name of a single form of the group, and as bearing no reference to any character either of structure or of habit, there is an obvious objection. The term *Amphibia* is therefore here adopted, as designating one of the most striking peculiarities of the class; namely, the change which takes place at an epoch of their life, more or less advanced, from an aquatic respiration by branchiæ to an atmospheric respiration by true lungs, and an equivalent and consequent alteration in their general structure and mode of life.

The *Amphibia* may be characterized as "vertebrated animals, with cold blood, naked skin, oviparous reproduction, and most of them undergoing a metamorphosis or change of condition, having relation to a transition from an aquatic to an atmospheric medium of respiration."

These characters, by many of which the amphibia are distinguished from the reptilia, are sufficiently determinate and important to justify our considering them as a distinct class, according to the generally received principles of zoological arrangement; notwithstanding most even of the modern writers on the subject have retained them as merely an order of reptilia. But it will also be seen that if in the adult state they approach the reptilia in many points of their general structure, their organization, during the early and imperfect condition of the tadpole, partakes no less of that of fishes. As an osculant or intermediate form, connecting two others of higher typical importance, it may be, certainly of greater extent, and consisting

* Elements of Chemistry, 4th ed. 868.

† Prevost et Dumas, Ann. de Chimie et Physique xxiii. 52.

of groups having more striking distinctive characters, there is not, perhaps, a more interesting and satisfactory instance in the whole range of the animal creation than is afforded us in the class of amphibia: a circumstance which can only be fully appreciated by following out the structure of each system of organs, first as it exists temporarily in the tadpole, and ultimately in its permanent condition in the perfect animal.

The class has been variously divided into groups according to the different views of the naturalists by whom they have been arranged. The division adopted by many zoologists of the present day, according to the mere presence or absence of the tail in the perfect state, is not only liable to the objections which belong to all merely dichotomous arrangements, but appears to be far less natural and less consistent with the physiological characters of the groups than that which may be derived from the absence or presence and the duration of the branchiæ. Thus the frogs and toads, which in the adult state have not the vestige of a tail, and the salamanders and tritons, which retain that organ through life, all agree in the early possession of branchiæ, which are subsequently lost and replaced by true lungs, and in undergoing consequently a total change in the medium of their respiration; whilst the proteus and the siren retain their branchiæ, with lungs, (rudimentary at least,) and probably throughout life possess synchronously the twofold function of aquatic and atmospheric respiration. The *amphiuma* and *menopoma* have not as yet been observed to possess branchiæ at any period of their existence, though further observations are necessary to warrant the conclusion of an absolute non-existence of a metamorphosis in these genera.

It appears to me that no one arrangement hitherto given sufficiently distinguishes the different forms; and I venture to propose the following modifications as more consistent with the diversities of structure in the different groups.

Class Amphibia.

Order 1.—Amphipneurta.

Body elongate, formed for swimming. Feet either four, or two anterior only. Tail compressed, persistent. Respiration aquatic by means of branchiæ, throughout life, co-existing with rudimentary lungs. Branchiæ external, persistent. Eyes with palpebræ.

Genera, *Proteus*, *Siredon*, *Menobranchus*, *Siren*, *Pseudobranchus*.

Order 2.—Anoura.

Body short and broad. Feet during the tadpole state wanting; afterwards four, the hinder ones long and formed for leaping. Tail before the metamorphosis, long, compressed; afterwards totally wanting. Ribs wanting. Vertebræ few and anchylosed. Tympanum open. Respiration at first aquatic by branchiæ; afterwards atmospheric by lungs. Branchiæ at first external, but withdrawn within the chest before the metamorphosis. Impregnation effected externally during the passage of the ova.

Genera, *Rana*, *Hyla*, *Ceratophrys*, *Bufo*, *Rhinella*, *Otilopha*, *Ductylethra*, *Bombinator*, *Breviceps*.

Order 3.—Urodela.

Body long, slender. Feet always four. Tail long, persistent. Ribs very short. Respiration at first aquatic by external branchiæ, afterwards atmospheric by cellular lungs. Vertebræ numerous and moveable. Tympanum concealed. Impregnation internal.

Genera, *Salamandrina*, *Salamandra*, *Molge*.

Order 4.—Abranchia.

Body long, formed for swimming. Feet four. Cranium solid. Tail compressed. Respiration by means of lungs only: branchiæ none. No metamorphosis known.

Genera, *Menopoma*, *Amphiuma*.

Order 5.—Apoda.

Body elongate, slender, anguiform. Feet none. Tail very short, almost wanting. Lungs one larger than the other. (The existence of branchiæ at any period of life unknown.) Ribs very short. Sternum wanting. Ears concealed. Impregnation unknown, probably internal.

Genus, *Cæcilia*.

I. *Osteology.*—The changes which take place in the habits and formation of these animals, in their passage from the tadpole or pisciform state to their adult and permanent condition, are not confined to any one system of organs or of functions. The skeleton, the organs of motion, of sensation, and of digestion are not less the subject of these changes than those of respiration and circulation: it will, therefore, be necessary, in treating of each system of organs, to describe not merely their structure in the perfect state, but the less advanced grade of organization from which they emerge in passing from the condition of a fish to that of a reptile.

In the adult state, however, they are found to vary considerably in the form and composition of the skeleton, according to their habits, and to the existence or absence of a tail. The principle of compensation, or, in other words, the extreme developement of one set of organs at the expense of another, which is so often seen to take place in every form of animals, is here strikingly illustrated. In the frogs, whose movements on land, from their feeding chiefly on terrestrial prey, are necessarily extensive, we find the hinder legs developed to an extraordinary degree, for the purpose of enabling them to take enormous leaps, by which they not only seek or pursue their prey at a distance from the water, but rapidly escape from danger, and rapidly regain their place of refuge in the nearest pond or rivulet. As it is evident that a long tail and a generally elongated body, with a flexible spine, would be not only useless but inconsistent with these habits, we find these animals absolutely tailless, the body contracted longitudinally into as short a space as possible, the vertebræ very few, and anchylosed or soldered together into a single immoveable piece, and wholly devoid of ribs.

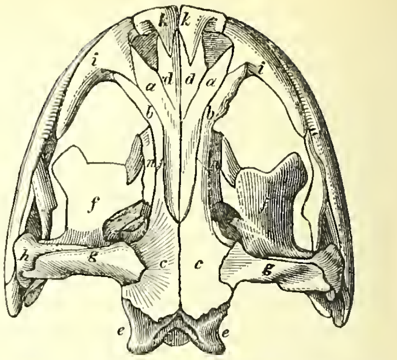
On comparing with this formation, on the other hand, the extensive developement of the tail, the long flexible body, and gracile form of the newts or aquatic salamanders, and reflecting upon the obvious object of this structure in facilitating their motions in the water, we should hardly be prepared to find that the extraordinary extension of the hinder extremities in the frogs, the *primary* object of which is to afford the great powers of leaping just alluded to, is made subservient also to their aquatic life, by enabling them to swim with great facility, aided by a web of skin extending between the toes of the hinder feet.

Now as we shall hereafter see, when treating on the respiration of these animals, that the occasional presence of water, and its application to the surface of the skin, is equally essential to the well-being of both these forms, it is very interesting to observe how admirably this peculiarity in the general requirements is provided for by the very different, and even opposite, construction of their form and limbs, which their individual habits of life demand.

But to return to the detailed anatomy of the skeleton. On examining the general texture of the bones in this class, there is an obvious advance towards the firm calcareous substance of those of the higher forms of vertebrated animals when compared with the bones of fishes, they being more compact, and less transparent and flexible than in the latter animals. The cranial bones, though they retain to a certain extent the character of those of fishes, in the permanent disunion of the different centres of ossification, at least in many instances, yet they do not overlap each other, as in that class, but, on the contrary, remain with their margins at least in contact, and in many cases actually united, though not by true sutures. The elements of which the cranium is essentially composed, and which in a higher grade of organization are found consolidated, are here still exhibited as distinct pieces; a state of things which is strikingly imitated in the progress of the development of these parts in the highest classes during their growth. It is also to be observed that the bones of the face are more closely united to those of the cranium and to each other in the higher than in the lower forms of the class, exhibiting distinct and obvious links in the development of these parts, which we see so beautifully and gradually perfected in the ascending series from fishes up to man.

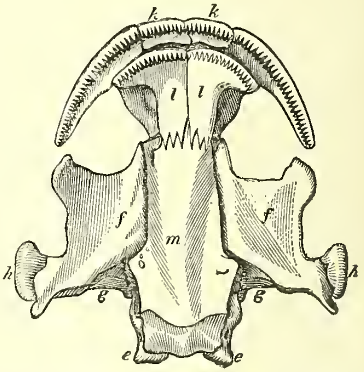
The following enumeration of the separate cranial bones of the amphibia, as existing in the *menopoma alleganiensis*, the gigantic salamander of America, will illustrate the general relations of the distinct centres of ossification, here remaining permanently detached.

Fig. 14.



In figs. 14 and 15 the different elements are thus designated:—*a.* the frontal; *b.* the exterior frontal; *c.* the parietal; *d.* the nasal;

Fig. 15.



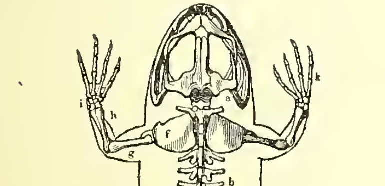
e. the occipital; *f.* the pterygoid; *g.* the tympanic; *h.* the jugal; *i.* the superior maxillary; *k.* the intermaxillary; *l.* the vomer; *m.* the sphenoid; *n.* corresponding to the orbitary processes or alæ of the sphenoid. In the frog and most others the palatine bones are distinct. We here find that the separate portions or elements which in this class are permanently detached, correspond almost exactly with the number found in the cranium of fishes.

It will be observed by a reference to the figures, that the intermaxillary bones—and this is more or less the case in all the amphibia—are much developed transversely, as in the fishes, an affinity which has been already so much insisted on, and which is borne out by the condition of all the other parts of the cranium. The lateral extension of the upper and lower maxillary bones, for instance, as well as of the tympanic and jugal, expands the general form of the skull, without involving any expansion of the cavity of the cranium, which is restricted to a small, central, elongated space. The latter bones also terminate in a condyle, which is received into a shallow glenoid cavity of the lower jaw, a peculiarity which offers a still further illustration of the proximity of this class to the fishes. The lower jaw consists of three distinct pieces on each side, an anterior, a lateral, and a posterior or articular portion. The anterior bone supports the teeth in those genera which have teeth in the lower jaw, and unites with its fellow at the symphysis. In frogs the lower jaw is devoid of teeth, but they are found in the upper jaw, bordering the intermaxillary and the maxillary bones; and the vomers are also furnished, each with a transverse row of teeth; but in the salamander, the menopoma, the proteus, and others, they are found occupying the margin of the lower jaw. In the toads there are no teeth in the lower jaw, but the edge of the jaw-bone is serrated. The second bone of the inferior maxilla occupies the side, and is larger even than the former. It has at the posterior part a coronoid process, behind and within which is placed the third bone, which forms the medium of articulation with the cranium.

It is to the *os hyoïdes* that the principal interest attaches in the present class, as it is that bone which undergoes the most remarkable changes in its form and relations during their transformation, passing from the office of supporting the branchial organs into a true os hyoïdes, and thus offering, as Cuvier has beautifully shewn, an elucidation of the true nature of this apparatus in fishes. As this bone, however, has a direct relation with the respiratory functions, I shall explain these changes while treating on that part of the subject.

The spinal column varies exceedingly in the different forms of the amphibia. In the highest form the vertebræ are fewer than are found in any other animals. In the common frog

Fig. 16.



there are but nine, and in the pipa only eight. Of the nine vertebræ in the frog, the first, the atlas, *a*, has no transverse processes; there are two articular surfaces situated anteriorly, by which it is articulated to the two occipital condyles. In the seven following vertebræ the anterior articular surfaces of the bodies are concave, and the posterior convex. This convex tubercle, which enters the concavity of the next vertebra, consists of the intervertebral cartilage converted into bone. In the tadpole condition of the animal (and this remains permanently the case in the perenni-branchial forms, as the *menobranchus*, the *proteus*, &c.) this intervertebral substance retains the soft consistence which characterises it in fishes; and, as in that class, it is contained in the circumscribed cavity formed by the cup-like hollows of the two articular surfaces of contiguous vertebræ. The elongated fish-like form of those amphibia which retain their branchiæ throughout life, requires that this structure should also be permanent; and we have thus another beautiful example of that perfect chain of organisation which is manifested by this class of animals, from the fish upwards to the reptilia.

The vertebræ of the adult frog have long transverse processes (*fig.* 16, *b*), but are wholly destitute of ribs—a class of bones which would be utterly useless in the particular modes of locomotion to which these animals are restricted, and the absence of which implies a peculiarity in the act of respiration, which will be described hereafter. The spinous processes are very short; the articular are oblique, the posterior of each being placed above the anterior of the following one.

The last or sacral vertebra has large transverse processes (*fig.* 16, *c*) directed a little backwards, to which the ilia (*fig.* 16, *d*) are attached; and to the body of this vertebra is united by two tubercles, a long single bone, extending backwards to above the anus. This bone (*fig.* 16, *e*) is considered by Cuvier as a second sacral vertebra; but by Schultze, Altena, Dr. Grant, and others, it is regarded as the coccyx. The vertebral canal occupies the anterior third of a carina or crest, which runs along the upper surface of this bone, diminishing gradually in its course until it wholly disappears.

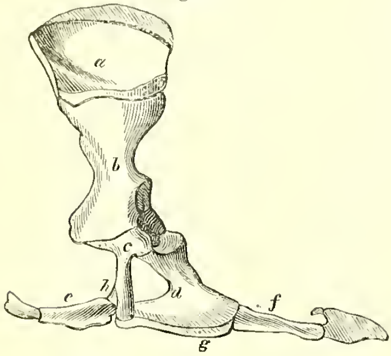
The spinal column in the other orders of the class differs in a remarkable degree from that which has been just described. In the salamander there are thirteen dorsal, two sacral, and about twenty-five caudal vertebræ, which in the genus molge or newt are increased to upwards of thirty. In these the anterior surface of the body is convex, and the posterior concave, a contrary arrangement to that which occurs in frog. The transverse processes are directed a little backwards, each, excepting the atlas, supporting a small rib, which is scarcely curved. The *menopoma* has a similar arrangement. In the *siren* are found forty-three vertebræ in the trunk, and forty-four or more in the tail. They all retain in a great measure the form of those of fishes and of the tadpole of the higher orders of this class, particularly in the existence of the intervertebral cavity or double cone, formed by the apposition of two hollowed surfaces of their bodies, and filled by a semi-cartilaginous mass or intervertebral substance. Eight only of the vertebræ, commencing with the second, bear ribs, which are extremely small, and in fact merely rudimentary. In the tail the transverse processes are only found on a few of the most anterior vertebræ.

The spine of the proteus is not sufficiently different from that of the siren to require any particular description.

The construction of the members, both anterior and posterior, especially the latter, will be found to be arranged on very different plans, according to the habits and requirements of the different groups, and particularly their mode of progression. In the *apoda*, as the *cæcilia*, there are not even the rudiments of limbs. In the other orders they exist under very different degrees of development, according as they are constructed for leaping and swimming, as in the frogs, toads, &c., or for creeping, as in the salamanders; or they are rudimentary, and without any very apparent use, as in the *amphiuma*. It will be necessary to give a cursory description of these forms.

Of the anterior extremity in the anoura.—The shoulder of the frog (*fig.* 16, *f.* *fig.* 17.) consists of the scapula, the clavicle, and the coracoid bone, which all combine to form the glenoid cavity for the head of the humerus. The scapula is composed of two very distinct portions. The upper, (*fig.* 17, *a*,) which is

Fig. 17.



permanently cartilaginous, at least at its margin, is articulated moveably to the inferior and more solidly ossified piece, (*fig.* 17, *b*,) at the inferior and posterior part of which is the articular surface forming its portion of the glenoid cavity, immediately anterior to which it is attached to the clavicle. (*fig.* 17, *c*.) This bone is slender and straight, and is connected beneath with its fellow in the median line. The coracoid bone (*fig.* 17, *d*) is considerably larger than the clavicle, and is also connected with its fellow by its broad median margin. The sternum consists of several pieces, extending from before the clavicles to some distance behind the coracoid bones; the latter terminates in a broad xiphoid cartilage. These parts differ considerably in their relative proportions in different genera.

The arm is developed in a very inferior degree compared with the hinder extremity. The humerus (*fig.* 17, *g*) is short and thick, having a rounded head, received into the glenoid cavity of the shoulder-joint. The opposite extremity forms an almost globular surface for its articulation with the bone of the fore-arm, which is still shorter, and consists of the radius and ulna united, (*fig.* 17, *h*,) having only a slight groove to show their line of union. The carpal bones (*fig.* 16, *i*) are six in number, supporting the four metacarpal bones, (*fig.* 16, *k*.) The index and middle finger have each two phalanges, the others three. The index is particularly large in the male. The thumb is merely rudimentary.

The posterior extremity is greatly developed in the frogs, for the purpose before mentioned, of enabling them to take long leaps, and to swim with great rapidity and energy. The pelvis consists of the three essential bones of this part, the ilium, ischium, and pubis on each side. The iliac bones, (*fig.* 16, *d*,) diverging above, are moveably articulated with the sacrum. They then extend backwards, and form, together with the small ischiatic and pubic bones, (*fig.* 16, *l*,) the cotyloid cavities for the reception of the femur. This bone (*fig.* 16, *m*) is nearly twice as long as the humerus, cylindrical, and having a slight double curve. The leg consists, like the fore-arm, of but one bone, the tibia and fibula being anchylosed through their whole length. This bone (*fig.* 16, *n*) is even a little longer than the femur. It is succeeded by two bones of considerable length, (*fig.* 16, *o*,) having very much the aspect of a tibia and fibula, but which must be considered as bones of the tarsus greatly modified, and are most probably the *os calcis* and the *astragalus*. Between these elongated bones and the metatarsal are four small tarsal bones. The metatarsal bones (*fig.* 16, *p*) are much elongated, as are also the phalanges, (*fig.* 16, *q*,) for the purpose of forming strong oars or paddles with the intervention of a broad web of integument. The inner toe is considerably developed, and the whole structure of the foot and leg thus combines to furnish a powerful and efficient organ of progression.

The elongated forms of the aquatic salamander, the proteus, the siren, &c., in which the vertebræ are developed to so great an extent, present the opposite extreme in the structure of their limbs. These are small, feeble, and appear as it were abortions. In the genus triton and in the salamandra, which possess both anterior and posterior extremities, they differ but little in their general form and development. The bones of the fore-arm as well as of the leg, instead of being respectively anchylosed into a single piece, as in the frogs, are permanently separate, consisting of a distinct ulna and radius in the former, and an equally distinct tibia and fibula in the latter. The toes are four, both before and behind; they are short, slender, and of slight construction.

This imperfect development of the extremities is, however, as we have seen, admirably compensated by the extraordinary extent of the spine both in the body and the tail; and while the limbs afford but very imperfect means of progression on land, the structure of the spine is admirably adapted to the purpose of swimming, which is performed either by a succession of curves, as in the amphiuma and the siren, or by the alternate flexure of the tail, as in the *tritons* and the *menobranchus*.

Having given this general sketch of the osteology of the amphibia in the adult state, it will be interesting to examine the structure of the skeleton in the tadpole. It has already been observed that in this early condition of its existence the animal resembles fishes in all the most remarkable characters of its organization. We find accordingly that the limbs, which are at first scarcely perceptible by the most minute examination, become gradually developed, passing through a rudimentary form beneath the integuments, from which they do not emerge until they have acquired considerable size and a very defined figure. The hinder legs are first seen, and are early employed as a feeble assistance to the more effective tail, as instruments of progression. The tail is developed, however, to a great degree, occupying the same relative size and situation as it is found to do in fishes. The coccygeal vertebræ are numerous, forming a long column, not ossified, but retaining its cartilaginous structure, at least in those forms in which it is deciduous; but in the *salamanders*, the *tritons*, the *proteus*, and all others of the *urodela*, it becomes ossified instead of being absorbed. In the frog and other anoura, as the permanent organs of progression acquire their full development, the tail is slowly removed by interstitial absorption, not suddenly falling off as some have supposed, but becoming gradually smaller and smaller until it wholly disappears. The cranium undergoes no other important change than that of the gradual ossification and expansion of its different elements, the centres of ossification being at first wholly disunited as in fishes, and afterwards assuming the more consolidated structure and closer approximation to each other, by which they approach the reptilia.

II. *Muscular system.*—The similarity which has been already shewn to exist in the osseous system of fishes and of the tadpole and perennibranchiate amphibia, would naturally lead to the conclusion that a corresponding affinity would be found in the muscular apparatus. The muscles which are employed for progression in those early forms of vertebrated beings, are found to consist of oblique layers, abutting upon a median line, and extending along the whole length of the tail on each side. A similar general direction obtains in the muscles both of the trunk and tail in the long-bodied forms of the permanently tailed amphibia. The direction of their action therefore is horizontal, and their progression is effected by the alternate action of the muscles on each side These oblique caudal muscles in the tadpole of the tailless tribe, become absorbed with the vertebræ to which they are attached, as the animal gradually assumes its permanent form; but its aquatic habits are still provided for by the extraordinary magnitude of the flexors and extensors of the thigh, leg, and foot, which are in perfect accordance with the great length of the bones of this extremity, which has been described. The muscles which form this important apparatus of motion are exactly analogous to those which are so peculiarly developed in the human leg. Thus the large glutei extend the femur, the rectus and triceps extend the leg, and by their united and sudden action forcibly throw the whole limb into a straight position, whilst the gastrocnemii, which are here as in the human subject of sufficient size to form a considerable calf of the leg, enable the foot with the wide expanse of its toes, connected as they are by a tense web, to strike with great force and effect the resisting medium in which they live, assisted by the flexors of the toes, which are called into action at the same instant. The same beautiful mechanism is no less adapted for the peculiar nature of their progression on land; by it they are enabled to take those long and vigorous leaps which particularly characterize some of the genera of the acaudate family of this class. It is obvious that the same sets of muscles must be developed for the performance of the energetic and sudden movements abovementioned as are required to sustain the upright form of the human subject in its erect position, those, namely, which extend at once the thigh upon the pelvis, the leg upon the thigh, and the heel upon the leg; and hence arises the remarkable similarity in the conformation of the leg in these otherwise remote forms, and hence too the act of swimming in man must be a tolerably accurate imitation of the same effort as exhibited by the frog.

III. *Organs of digestion.*—The foregoing consideration of the various structures of the organs appertaining to locomotion would prepare us for corresponding differences in those belonging to this important office. These variations, however, are not found exactly to follow those which have been described in the former class of organs. The tadpole condition of the higher amphibia does not correspond in the nature of its food, nor consequently in the structure of the alimentary canal, with the class of fishes, nor indeed with that permanent tadpole, as it may be called, the larviform axoloth.

The teeth, as has been already stated, vary in the different genera not so much in their size and form as in their situation. Thus the whole of the amphibia have teeth in the palate; the salamanders have them also in both the upper and lower jaws, the frogs in the upper only, and the toads in neither. In the two latter genera the palatine teeth are placed in a transverse line, interrupted in the middle. In the salamanders they form two parallel lines, containing not less than thirty on each. In the *menopoma* they occupy the anterior palatine margin of the vomer, forming a line on each side parallel with the maxillary and intermaxillary teeth. In the *axoloth* they are arranged in the quincuncial order, and are numerous. But the most remarkable form and arrangement of the palatine teeth is found in the siren, in which they have the quincuncial arrangement; they are placed on two small bony plates on each side, probably rudiments of the vomer and palatine bones. Each of the larger has six or seven lines of teeth, about twelve on each line; and each smaller bone bears four ranges of five or six teeth; making in all nearly two hundred teeth in the palate. Those of the lower jaw in this animal are placed in similar order. In the proteus the teeth nearly resemble those of the salamander.

The maxillary teeth are always slender, sharp-pointed, and closely set. The frog has about forty on each side of the upper jaw, of which eight belong to the intermaxillary bone. The salamander has about sixty above and below.

In the tadpole state of the frog the mouth is very small, and, instead of teeth, is occupied only by minute horny plates of just sufficient consistence to abrade the soft mixed food which it finds on the surface of animal or vegetable substances in the water. Its stomach and intestinal canal are of very different form from that which they afterwards assume. The intestine is of nearly equal size throughout its whole length. It is very long, being not less than ten times the length of the actual space from the mouth to the anus, and is coiled up in a circular form, occupying the greater part of the abdominal cavity. The canal, as we shall presently see, changes its character materially during the metamorphosis of the animal, becoming gradually shorter until it is not a quarter of the length, in proportion to the size of the animal, which it exhibited in its earlier condition.

In the adult amphibia the whole alimentary canal is of a very simple character. The œsophagus is wide and comparatively short. The stomach single, consisting of a simple sac, elongated in the lengthened forms of the salamander, the proteus, and other aquatic species. The intestine is but slightly convoluted, even in the short tailless family; and there is comparatively little difference in the diameter of its two distinct portions. It terminates, as in the reptilia, in a cloaca, or pouch, which also receives the openings of the urinary and genital organs. The anus in the toads and frogs opens on the hinder part of the back; in the other forms it is situated beneath at the commencement of the tail, as in the reptilia.

The liver, the pancreas, and the spleen are found in the whole of the amphibia; and these organs are observed, in the elongated aquatic forms, to assume a corresponding lengthened shape. The liver is of considerable size, particularly in the salamanders. The gall-bladder exists in all cases, varying, however, in size and form in the different genera.

IV. *Lymphatic and lacteal system.*—This system is highly interesting in the amphibia, on account of its extreme development, and of its presenting several important and remarkable peculiarities in its structure.

The investigations of Professor Muller of Berlin have lately brought to light the existence of pulsating cavities in the course of the lymphatics, constituting a sort of ventricles for the propulsion of their fluids towards the veins into which they are received. In the frog two pairs of these little pulsating sacs are found; at the posterior part one is situated on each side of the extremity of the coccygeal bone, behind the hip-joint, and the anterior ones under the posterior edge of the scapula by the transverse process of the third vertebra. These cavities are of considerable size, and pulsate with some degree of regularity: the pulsations, however, do not coincide with those of the heart, nor are those on the one side always synchronous with those on the other. The posterior ones convey the lymph received from the legs and hinder parts of the body into the ischiatic veins, and the anterior pair, into which the absorbents of the arms and the anterior parts of the viscera, &c. open, convey this fluid into the jugular veins. The internal structure of these sacs is cellular; they communicate freely with each other on each side by anastomosing vessels. On inflating the organ, not only the lymphatic vessels are inflated, but the whole of the veins also. Dr. Marshall Hall had previously observed a somewhat similar pulsating cavity in the eel.

These lymphatic ventricles in the amphibia have still more recently received further examination and illustration by Professor Panizza of Pavia, who published the result of his researches in the year 1833.* Professor Muller's discovery was published in the previous year in the Berlin Annals.

The lymphatic system is developed to an extraordinary degree in the frogs, as well as in several other genera of this class, its vessels being found in numbers and of considerable size immediately under the skin.

The lacteals ramify upon the surface of the intestine in two layers, anastomosing and forming intricate plexuses on the mesentery, and terminating in two trunks, or thoracic ducts, which pass forwards one on each side of the spinal column.

V. *Of the sanguiferous system.*—If the changes, so frequently alluded to, which the animals of this class undergo in passing from the condition of a fish to that of a reptile, have received repeated illustrations in the consideration of the structure of the skeleton, of the organs of motion, and of those of digestion, far more interesting and important are those which occur in the character of the circulation; in which the view which has been taken of the true situation of the amphibia in the chain of animal development receives the most satisfactory proof. Beginning life with all the essential characters of the fishes, even in the functions of circulation and respiration, possessing the single branchial heart of that class, how wonderful and beautiful are the changes which these systems of organs undergo, as the branchiæ become obliterated to give place to pulmonic cavities, and the heart at the same time assumes the compound character and form of a systemic and pulmonic heart, in accordance with the change in the respiratory organs.

The newts, or water-salamanders, afford the most satisfactory opportunity of observing these

* Sopra il sistema linfatico dei rettili. fol. Pav. 1833.

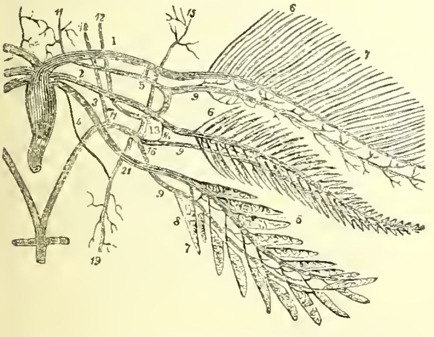
changes, as the branchiæ are large in proportion, and remain external during the whole period of their existence; the animal also acquires considerable size before these organs of aquatic respiration are lost. The heart in the early stage of these animals consists of a systemic auricle, which receives the whole of the blood from the system after circulation, and of a ventricle which propels it through a third cavity, the *bulbus arteriosus*, to the branchial arteries, of which there is one given to each branchial leaf. From the capillary branches of these arteries the aërated blood is received by the branchial veins, which, as in fishes, concur to form an aorta without an intervening ventricle. From the last, or posterior branchial artery, on each side is given off a branch which goes to the rudimentary pulmonic sac, and which ultimately forms the trunk of the pulmonary artery. But the most interesting and important change is that by which the continuous branches of what were originally the branchial arteries combine to form the two trunks of the aorta. This is effected by means of small communicating branches between the branchial arteries and the branchial veins, which, as the branchiæ become absorbed, and their minute branches are obliterated and lost, gradually enlarge until they become continuous trunks; and the artery, which was originally branchial, then becomes the single root of the two descending aortæ, and at its base gives off the pulmonary artery.

The two veins which return the blood from the rudimentary air-sacs gradually enlarge as these cavities become more important, and assume the character of lungs; and at length they receive the name, as they perform the function, of pulmonary veins. These by degrees become, as it were, distended at their point of union with the heart, and ultimately form the second auricle.

This general description will be better understood by a reference to the subjoined figures taken from the tabular views of M. St. Ange, of which an English edition has been published by Mr. Jones.*

The following detailed description of those figures is necessary to the correct understanding of this intricate but interesting arrangement.

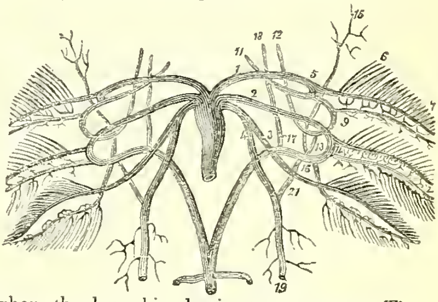
Fig. 18.



The first period, previous to any change having taken place in the branchiæ, is given in *fig*. 18. Four pairs of trunks (1, 2, 3, 4) go off from the heart. The first branch on each side (1) gives off a small anastomotic branch (5); after which it becomes divided into numerous branchial filaments (6); these, by their ultimate subdivision, terminate in a capillary tissue or network (7), from which arise other minute returning vessels, forming, by their junction, a single large vessel (9), which brings back blood into the general circulation after it has been aërated in its course through the branchiæ. The second branch (2) also gives off a small one (14) previously to its subdivision in the second branchial leaflet, which branch enters the returning vessel; thus producing a communication between the two vessels 2 and 9, as in the former case. The returning vessel then terminates in the arch of the aorta, in which the two vessels 13 and 15 also terminate. The third principal vessel (3) is similarly distributed on the third branchial leaflet, and the corresponding returning vessel (16) terminates in the aorta, as in the other case. The arch of the aorta, thus formed, gives off a branch (21), which, after receiving the fourth branch from the heart (4), goes into the lungs (19).

The second period, shewn in *fig*. 19, occurs

Fig. 19.



when the branchiæ begin to contract. The anastomotic branch (5), shewn in the former figure, is not much enlarged, and assumes the character of a continuous trunk with 1. The branches (11 and 12) have increased in size, but the original continuation of 1 going to the branchiæ, has decreased in the same proportion. The anastomotic branch (14) has acquired the size of the arch of the aorta, whilst the continuation of 2 is diminished, and the branchial leaflet is contracted in a corresponding degree. The branch 3 has become exceedingly small; and 4, which was before the smallest, is now the largest of all. By these changes in the relative dimensions of the different vessels, especially in the enlargement of the anastomotic branches, the whole system of the circulation is gradually being altered, until, in the third period, (*fig*. 20,) it has assumed the character of that in the reptile, by the total obliteration of the branchiæ and their vessels, and the enlargement of those branches, which, at first only anastomotic, have now become principal.

In the adult condition of the animal, there-

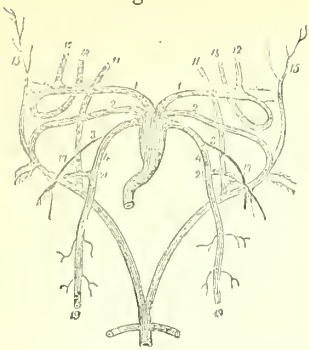
Fig. 20.



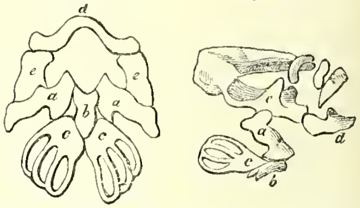
fore, the heart consists of a single ventricle, and of two auricles. The existence of a second auricle was first demonstrated in the higher forms, the frogs and toads, by Dr. Davy,* and, although in the latest works of Cuvier and Meckel the auricle in these forms is described as single, yet the more complicated structure has since been amply confirmed by many other anatomists. Weber† especially has described the biauricular structure in a large American frog; but he failed to demonstrate it in the perennibranchiate amphibia. From a very interesting paper by Mr. Owen, in the first volume of the Zoological Society's Transactions,‡ it appears that the biauricular structure of the heart was ascribed by Hunter to all the amphibia except the perennibranchiate forms; in which, however, the existence of the left auricle has been satisfactorily determined by Mr. Owen, who has also given some very interesting illustrations of the mode in which the coexistence of branchiæ and rudimentary lungs is associated with certain peculiarities of the circulation. The circulation in the adult *amphibia*, then, assumes exactly the character which we find in the *reptilia*, but in the most simple form.

The little pulmonic auricle receives the blood perfectly aërated from the lungs by means of the pulmonary veins. The systemic auricle at the same time receives the impure blood from the system by the venæ cavæ. The blood from the two auricles is sent together into the single ventricle where it becomes mixed, and this mingled arterial and venous blood, thus but half purified, is propelled by the same impulse, partly into the pulmonary arteries to be more perfectly purified, and the remainder through the aorta and the whole circulating system to the different organs of the body. The aëration of the blood, therefore, is but imperfect; a condition which is met with equally in the whole of the reptilia.

VI. *Respiration.*—The preceding observations on the circulation have in some measure necessarily anticipated the account which we have to offer of the correlative function of respiration, and the character of those changes to which its organs are subjected in the transit of the amphibia from the pisciform to the reptile state. Breathing water, in the first instance, exclusively, these animals are furnished in the tadpole condition with branchiæ or gills, of a leaf-like form, considerably subdivided, though far less so than in the fishes. These branchiæ are, in the first instance, in all cases external; but in the higher forms of the class they remain so situated only for a brief space, becoming, as in the frogs and toads, internal at a very early period of their existence. They are supported by cartilaginous or osseous arches, connected with the os hyoides, and the changes which they undergo are accompanied by alterations in the form of that bone, to which allusion has already been made, and an account of which will now be given.

At that period of the tadpole's existence, at which its branchiæ are in full action, and the lungs still restricted to the state of a blackish, rudimentary tissue, we find the tympanic bones, (*figs.* 21, 22, *e*,) developed to a great

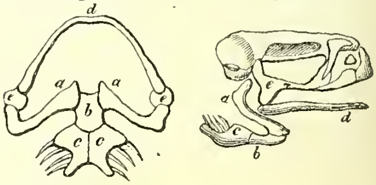
Fig. 21. *Fig.* 22.



extent, and forming the basis to which the branchial apparatus is suspended, by means of a rather thick angular portion, (*figs.* 21, 22, *a*.) This has been shewn by Cuvier to represent what in the fishes is composed of three bones, and is the medium by which in them the whole branchial apparatus is suspended to the temporal, and which bears also the branchiostegous rays. Between these two lateral branches is a single piece, (*figs.* 21, 22, *b*,) which, according to the same authority, corresponds to the chain of bones placed in most fishes between the two first branchial arches. To the posterior point of this bone are attached two rhomboidal portions, (*c*, *c*,) to the external margins of which are suspended the arches on which the branchiæ are supported, and which represent the chain of bones in fishes, bearing the two last branchial arches.

As the age of the tadpole increases, and its metamorphosis is proceeding unseen, (*figs.* 23, 24,) we find the branches which support

Fig. 23. *Fig.* 24.



the branchial apparatus (*a*) gradually lengthening, and becoming more and more slender, and at length exhibiting the two long cartilaginous pieces, by which the os hyoides is

* Zool. Journal, vol. ii.

attached to the cranium; (*fig.* 25, *a*,) the single piece (*b*,) and the two rhomboidal pieces (*c*, *c*,) in the meantime become united and extended, (*figs.* 25, 26,) and gradually lose by absorption

Fig. 25.

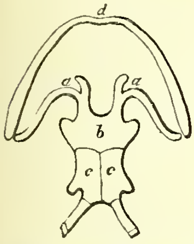

Fig. 26.

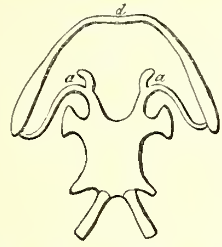
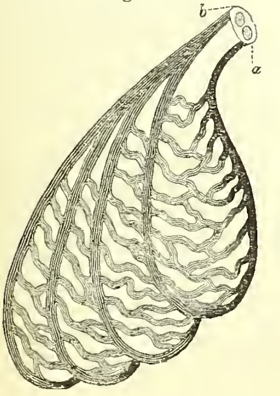


the branchial arches, and ultimately form a broad disc, the body of the os hyoides, the anterior margin of which on each side is dilated into a scutiform process, and the posterior margin bears two bony appendages, which are, in fact, the posterior cornua of that bone.

Such are the changes which this bone undergoes during the gradual passage of the amphibious animal from the tadpole state, in which it represents the class of fishes, to its perfect or reptile condition; and it affords a most interesting instance of the manner in which the true nature of an organ, existing under ambiguous circumstances in one class of animals, is often clearly illustrated by its characters, or, as in the present instance, by its transformations, in another.

The minute filiform branchiæ, which are appended to the tadpole of the frog immediately behind the head, have essentially the same structure as is observed in the gills of the perennibranchiate family, as the *siren* and the *proteus*, though in a different form. In the *proteus* each branchia consists of three principal divisions or branches, from each of which proceed seven or eight leaves, again subdivided into numerous regular leaflets forming the ultimate divisions of the branchiæ, on which the extreme capillary branches of the vessels ramify, and in which the blood undergoes its necessary change. A minute ramification of the branchial artery, conveying the impure blood from the heart, enters each leaflet at its base, (*fig.* 27, *a*.) and passes, along

Fig. 27.



its shorter or inner margin, giving off capillary branches in its course, which, after meandering over the surface of the leaflet, and communicating with each other in various directions, pass over to the opposite margin of the leaflet, and reunite in a corresponding ramification of the branchial vein (*b*), which passes out at the base to combine with the corresponding branches from the other leaflets, and convey the aërated blood back to the heart. This is the general structure, modified however in the different genera, by which this important function is effected in all the amphibia, as long as they are confined to their aquatic life; and whilst the higher groups lose these organs as they advance, and acquire the necessary organs for atmospheric respiration, those of the lower forms retain them throughout life, coexistent with rudimentary lungs; and thus probably exhibit the remarkable phenomenon of a twofold mode of respiration at one and the same time in the same individual.

Such, then, is the general structure of the organs of aquatic respiration, whether in the early and transitory form in which it is seen in the frog and the salamander, or in the permanent character which belongs to it in the perennibranchiate group of the siren, the axolotl, the menobranchus, and the proteus. But as the former of these groups acquires gradually a perfect and unmixed atmospheric respiration, and as the pulmonary cavity serving this office is only slowly developed, so we find in the perennibranchiate forms that the lungs also exist, though in little more than a rudimentary state. The early condition of the lungs in the caducibranchiate genera, in which they ultimately exhibit a somewhat advanced structure, is that of a mere rudimentary sac, without internal cells or any appearance of even the commencement of that more perfect structure which they afterwards acquire. Gradually, however, the inner surface is furnished with small processes, forming little sacs or cells, on which the capillary branches of the pulmonary vessels ramify, and through the infinitely attenuated surfaces of which the impure blood undergoes its essential process of depuration.

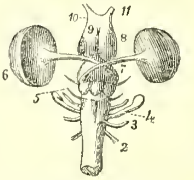
In the lower forms of the class, as in the *proteus anguinus* for instance, the air-bags, for they scarcely deserve the name of lungs in this state, never arrive at this advanced stage of development, but remain permanently in the condition of simple membranous sacs. Every part of the apparatus belonging to that organ is equally rudimentary. The glottis consists of nothing more than a small slit in the lower part of the fauces, placed between the branchial apertures of each side. The margin of this little opening, which has no cartilaginous ring to support it, is furnished with a small soft pair of muscles, by which it is opened. The tube leading from this opening speedily bifurcates, and one passes to each air-bag. In this rudiment of a trachea and of bronchi, there is no appearance of cartilaginous rings; it is a mere membranous canal, each branch of which opens without any other apparatus into its air-cell. From the perfect condition of the branchiæ, and the very simple structure of these pulmonary sacs, it will readily be seen that the function of respiration could be only very ineffectively aided by the latter organs, even were there no other difficulty arising from the imperfect structure of the apparatus which in the air-breathing amphibia serves the office of conveying the air into the lungs. A short description of the means by which the act of inspiration is effected in the frog will enable us to judge how far it may be *possible* that the rudimentary lungs in the *proteus* and *siren* are to be considered as performing any such function.

In the adult frog, toad, salamander, and all others of the higher orders of amphibia, the reception of air into the lungs is effected not by the primary expansion of the pulmonic cavity and the consequent rush of air into it, but by the act of forcing air into the lungs, or in fact by a simple act of swallowing. This is effected in the following manner. The os hyoides and tongue are brought downwards to a considerable extent, and the cavity of the mouth being thus much enlarged, the air enters by the nostrils. The pharynx is then shut at the posterior part, so as to prevent the passage of air into the œsophagus, and the cavity being suddenly contracted by means of the muscles acting on the *os hyoides*, the air is necessarily forced through the glottis and trachea into the lungs, as the posterior nares are closed either by their margins acting as a valve, or by the pressure of the tongue against them. This view of the mode of inspiration explains the cause of the well-known fact, that if the mouth of frogs be held open they perish from actual suffocation; for the motions of the os hyoides being thus impeded, and an external passage being also afforded for the air, respiration by the injection of air into the lungs is obviously impossible. Any other mode of inspiration, connected with the primary expansion of the thoraco-abdominal cavity is obviously impossible in the frog and its congeners, from the total absence of ribs. It may not be out of place to explain here the mode in which the peculiar noise uttered by the male frog, called croaking, is produced.* According to the observations of P. Camper, the inspired air is forced against the inferior surface of the tongue, the protuberance of which divides it as it were into two currents, which pass into the membranous sacs adhering to the lower jaw and existing exclusively in the males. From these sacs it is directed over the tongue, and by its vibration the peculiar sound in question is produced.

It is an interesting question whether in the perennibranchiate amphibia, the organs which have just been described as rudimentary lungs, do ever serve the purposes of respiration in even the smallest degree; and it is one of no small difficulty. The superficial structure of the nares in the siren and the proteus, in which they almost exactly resemble those of fishes, and which would preclude the mode of inspiration practised by the frogs, together with the slight and attenuated character of the membranous tube and sacs, would almost lead to the conclusion, assumed by Rusconi, that in the proteus at least these organs do not exercise any function appertaining to respiration. If these animals be confined for a considerable time in the same water, the branchiæ become purple instead of having the florid red colour which characterizes them in a healthy state, and they die asphyxiated. On the other hand, the very excitement of the two sacs, accompanied by tubes of such length, and opening to the pharynx by a sort of simple glottis, governed by a distinct muscular apparatus, would seem to warrant the opinion that a nearer affinity to true lungs is to be traced in these organs than in the air-bag of fishes, though recent observations have shewn the latter organ to be analogous to the lowest rudimentary state of lungs in the higher animals. The chain of affinities, therefore, is here perfect, as far as regards the pulmonary cavities.

VII. *The nervous system.*—The centre of the nervous system offers a not less striking instance of the progressive development of the amphibia in their passage from the pisciform to the reptile state than those which we have already shewn in the organs of the other functions of the body. The condition of the brain in the early state of the frog tadpole, the genus in which the changes are most strongly marked, is almost exactly that which it possesses in the fishes. The linear arrangement of the different lobes, the broad and lobed form of the medulla oblongata, the small cerebellum, the large size of the optic thalami, with the distinct ventricles which they contain, and the very diminutive extent of the hemispheres, all evince a low degree of development, and one not yet emerged from that which we find in the brain of fishes. The same imperfect character is also observed in the spinal marrow, which even in the frog is continued into numerous coccygeal vertebræ, and as the extremities are not yet in existence, is devoid of those enlargements which afterwards take place where the nerves of the anterior and posterior members are given off. The brain becomes developed, however, in a very short period; the changes which take place being very rapid, though at last not very considerable; the hemispheres become enlarged, expanding laterally and in some measure upwards, constituting the first step towards that superiority in position, as well as in size, over the other lobes, which is so conspicuous a character of these important portions of the brain in the higher animals. *Fig.* 28. represents the brain

Fig. 28.



1, pneumogastric nerve; 2, ninth pair; 3, sixth pair; 4, acoustic; 5, facial; 6, the eye; 7, optic nerve and its tubercle; 8 and 9, base of the hemispheres; 10, anterior portion of ditto; 11, pedicle of olfactory lobe.

in the common frog after Serres. As the limbs begin to make their appearance, the enlarge-

* Comment. Soc. Reg. Scient. Götting. v. ix.

ments of the spinal cord are observed to take place, and the contraction of the coccygeal vertebræ into a single linear bone, is accompanied by a corresponding diminution in the length of that part of the spinal marrow, which at length only extends, in the form of a small filament, into the anterior third of that bone.

The inferior condition of the brain which has been described as existing in the tadpole of the higher species, is permanent in the proteus and other perennibranchiate genera; so that the brain of the animal just named bears a very obvious resemblance to that of the larva of the aquatic salamander or *triton.*

VIII. *The organ of vision.*—The eye differs considerably in its form and magnitude in different genera of the amphibia, and without any very apparent relation to either their habits or their circumstances. In the frogs and some others they are remarkably large and prominent; in the salamanders they are comparatively small, though from their at least equally aquatic habits, this difference might perhaps have scarcely been anticipated, and in the cœcilia, as the name imports, the eyes are scarcely if at all visible. In the latter animal the same object has doubtless been intended by this absence of vision, as in the mole and many other animals, whose common subterranean mode of life would render the possession of acute sight not only generally useless, but an extreme inconvenience on their occasional appearance above the surface.

In some points of their structure the eyes of the amphibia are not remotely related to those of the fishes; as, for instance, in the flattened anterior surface of most of them, arising from the small supply of the aqueous humour, and in the depth of the crystalline. In some of the lower forms, there can scarcely be said to be a true orbit, the eyes being fixed as it were in the integuments, and surrounded by a mass of minute veins, intermixed with extremely small branches of nerves. Rusconi states that in the *proteus* he was not able to discover muscles, nor even the optic nerve; though on carefully and gently raising the hemispheres of the brain a minute nervous filament was seen going towards the foramen which serves for the passage of the ophthalmic artery; but whether this was the optic nerve or not, appears a matter of entire doubt. In fact, the structure of the eye in this animal, on the whole, is very imperfect.

In the frog, on the contrary, the eye is fully developed, and all the essential parts of its structure sufficiently conspicuous. The globe of the eye is large and projecting; the sclerotic is considerably solid and tough, and semitransparent; the cornea is large, and though somewhat flattened, is much less so than in fishes, or in the lower forms of the class. The inner surface of the choroid is extremely black, and the external of a silvery whiteness. The ciliary processes have not with certainty been discovered in these animals, unless, as Altena suggests, a little tubercular mass, occupying nearly their situation, and closely connected with the edge of the choroid and with the capsule of the crystalline, may be a modification of this structure. The iris is covered on its posterior surface with pigmentum nigrum; the anterior having a shining metallic lustre, precisely similar to that which we see in fishes. The contractility of the pupil asserted by Carus is denied by Altena and others. The retina is thick, and covers the whole internal surface to the capsule of the crystalline. The vitreous humour is, in proportion, abundant, and the lens is large and of a spheroidal shape, consisting of numerous concentric laminæ, enclosing a nucleus of extreme density, exhibiting a close relation to the state of this part in fishes. There are in the frog three palpebræ; or perhaps, with greater strictness of analogy, it might be said that there are two palpebræ, and a sort of expansion of the inferior, serving as a *membrana nictitans.* The superior palpebra is small, and is not possessed of any degree of mobility; the inferior is broad, expanded, and semitransparent. It has an internal membranous expansion, which has just been alluded to, and which is capable of covering the whole *eyeball.*

IX. *The organ of hearing.*—The function of hearing exists in very different degrees in the different groups of amphibia. The aquatic habits to which the lower forms are confined by their branchial respiration, would render an acute perception of sonorous impulses as unnecessary as it would be incompatible with the dense medium in which they live; and we find in this sense, as in every other function of the body, the most perfect concord existing between the habits of the animal and its structural arrangements. The pisciform aquatic genera of this class, therefore, are found to possess as near an affinity to the fishes in the structure of the organ in question as in most others; and in this they are also imitated by the tadpole state of the higher reptiliform groups, the adult condition of which exhibits a much more advanced development of the acoustic organ. In the proteus and the allied genera, there is neither a tympanic cavity, nor membrana tympani; it consists of a large cavity hollowed as it were out of the temporal bone, at the bottom of which cavity is the sacculus with its cretaceous body; the fenestra ovalis is closed by a bony lamina, the representative of the stapes. Behind the sacculus are the membranous semicircular canals. The whole organ is covered externally by the integuments, without any possible communication with the atmosphere.

In the frog, on the other hand, the whole structure is more complicated. The sacculus, which is membranaceous, is filled with the cretaceous matter, which is here semifluid, having the appearance of cream. The semicircular canals are contained within the substance of the temporal bone. The ossicula auditus are three, united, and contained within the tympanum, which they traverse, and are attached to the membrana tympani, a broad round membrane, perfectly superficial, and very distinct from the surrounding integument. The cavity of the tympanum is not capacious. It communicates with the external air by means of an Eustachian tube passing from it to the fauces. In all the essential parts of this structure, there is but little variation from that which exists in the true reptilia.

X. *The organ of smell.*—The nares in the perennibranchiate amphibia are, like those of fishes, confined to little more than a slight cavity on the anterior part of the head, and having no continued canal by which they can communicate with the cavity of the mouth. In the proteus the similarity of this organ to that of fishes is so complete, that even the plicated radiations of the lining pituitary membrane are almost exactly imitated. It is of considerable size, and is contained in a lengthened canal or cavity, the parietes of which are in no part osseous. The nostrils terminate immediately under the upper lip. The olfactory nerves are rather large, and no sooner emerge from the cavity of the cranium than they divide into numerous branches of various lengths, which enter every part of the soft pituitary membrane.

In the more highly developed genera the organ of smell has the more advanced structure which is observed in the reptilia. The nostrils are partly cartilaginous, partly osseous, and extend into the cavity of the mouth, though the posterior openings are placed much more forward than in the higher classes of vertebrata. The olfactory nerves enter the nostrils through two openings in the ethmoid bone. The absence of the convoluted and extensive surfaces of the turbinated bones, the entire simplicity of the canal of the nostrils, and the small extent of its surface, must restrict these animals to a very circumscribed enjoyment of this function; and it is probable that the sensibility to odours is much more acute in the aquatic forms, in which the organs of sight and of hearing are so imperfectly developed, than in the frogs, in which the organs of these senses are much more elaborately formed.

XI. *Of the organ of taste.*—The sense of taste, in all the amphibia, as well as in fishes, is probably very obtuse. The tongue in the *urodela* is small, and attached closely at every part. In the *anoura*, on the contrary, it is developed to an extraordinary degree; it is very long, bifid, and the anterior half is not only free, but, in its quiescent state, doubled back upon the posterior fixed part, and capable of being thrown forwards and again retracted with the rapidity of lightning, serving as a most efficient means of arresting the quickest movements of insects, which it conveys into the back part of the mouth to be swallowed.

The application of the tongue as an assistant in respiration, by closing the posterior nares, in all higher groups of the class, has been before alluded to.

XII. *The dermal or tegumentary system.*—The absence of all hard scaly adventitious covering to the skin of the amphibia is one of the most common, or perhaps it may be said, the only universal peculiarity by which they are, as a class, distinguished from *all* reptilia. The amphibious nature of their progressive development, or the existence at the earliest period of even rudimentary branchiæ, can scarcely be said to be without exceptions, as several genera have already been mentioned as not having yet been observed in this condition. But the naked skin is a character belonging equally to all, from the serpentiform cœcilia to the typically amphibious frog, and the pisciform axoloth and proteus.

The skin of the aquatic genera is soft, smooth, and furnished with a secreting surface, by means of which it is kept constantly moist, and in a state suitable for that cutaneous respiration which strikingly characterises these animals. Many of those which are generally inhabitants of the land, as the terrestrial salamanders, the toads, and others, are provided with numerous cutaneous glands, which secrete a tenacious milky fluid, which is somewhat acrid, and may perhaps be deleterious if swallowed in any quantity; though the old opinion of the poisonous nature of these animals is altogether without foundation. The fluid which is poured out from these cutaneous follicles in the common salamander is copious, of a milky colour, and consists of mucus, with the addition of some acrid matter, the nature of which is not yet known. From the quantity which is suddenly secreted when the animal is injured or any part of the surface irritated, it is not improbable that even the effect of fire may for a few moments be arrested by it; and thus may have originated the fable of the salamander having the power of remaining unconsumed and unhurt when thrown upon burning coals. The acrid nature of the cutaneous secretion of the toad was confirmed by the observations of Dr. Davy a few years since.

The cuticle of these animals is frequently shed; that of the aquatic species comes off in shreds, and is washed away from the skin. In the toads a very curious process takes place for its removal. When the cuticle has become dry and unyielding, and a new and softer surface is required, the deciduous layer splits down the median line of the back and of the abdomen at the same time. The whole cuticle is thus divided into two parts. By numerous convulsive twitchings and contortions of the body and legs, this separation becomes more and more considerable, and the cuticle is gradually brought off the back and belly in folds towards the sides. It is then loosened from the hinder legs by similar movements of those limbs, and finally removed from them by the animal bringing first one and then the other forwards under the arm, and by then withdrawing the hinder leg its cuticle is left under the fore leg. The two portions are now pushed forwards to the mouth, by the help of which the anterior extremities are also divested of it. The whole mass is now pushed by the hands into the mouth, and swallowed at a single gulp. The new cuticle is bright, soft, and covered with a colourless mucus; the old skin was harsh, dry, dirty, and opaque. This curious process I have repeatedly watched. I have observed shreds of cuticle hanging about the terrestrial salamander, which would lead to the opinion that this animal does not disengage itself from its deciduous skin in the same manner as the toad; but as the individuals under notice were not in health, the observation is inconclusive.

But the most interesting circumstance connected with the functions of the integuments of these animals, or indeed with any part of their economy, is their cutaneous respiration, or the power which the dermal surface possesses of effecting those changes in the blood, which are essential to life, and which are usually performed by particular organs set apart for that express object, and modified according to the aquatic or atmospheric medium in which the depurating agent is applied to them.

Although the experiments of Spallanzani had long ago demonstrated that carbonic acid was produced by the contact of the atmosphere with the skin of frogs, the subject had never been examined with the care and attention which its importance demands, until the investigations of Dr. Edwards of Paris, given in his work "On the Influence of Physical Agents on Life," set the question at rest, and established the proposition by a series of interesting experiments, so admirably arranged, so satisfactorily conducted, and so logically reasoned upon, as to leave no vacuity in the regular line of induction, nor doubt of the strict correctness of his conclusions.

The existence of a cutaneous respiration in frogs was proved by the simple experiment of tying a piece of bladder over the head so tightly as to produce complete strangulation, and then placing them under water. On examining the air contained in the vessel after an hour or two, a sensible quantity of carbonic acid was detected.

On placing frogs in vessels filled respectively with river water and with water which had been deprived of its air by boiling, and inverted over the apertures perforated in the shelf of a pneumatic trough, containing ninety-eight and a half pints, those in the latter lived on the average little more than half as long as those in the aerated water. On trying the effect of stagnant water renewed at intervals, they were found to live two months and a half, and then died from accidental neglect of renewing the water. Similar results followed experiments made under running water. The effects of temperature in these experiments were very striking, and prove that the duration of life under water is in an inverse proportion to the elevation of the temperature from 32° to about 107, at which point the animals die almost instantly. But these effects of temperature were found to be modified by an increase of respiration, whether by their rising to the surface and breathing the atmosphere, or by the quantity of aerated water being increased.

Such is a rapid glance at some of the results observed by this distinguished physiologist, on the cutaneous respiration of aërated water; those which are connected with atmospheric respiration by the same surface are no less interesting. In order to render the experiments as rigorously satisfactory as possible, pulmonary respiration was prevented by actual strangulation, rather than by keeping the mouth open, a method which appears liable to some degree of uncertainty. A ligature was passed round the neck of six frogs, using the most rigid compression, so as completely to exclude any possible passage of air. One of them lived twenty days; those placed in five ounces and a half of water had died in from one to three days. As the severity of the operation of strangulation might probably have hastened death, another mode was tried, namely, the total excision of the lungs,—an operation which appeared to produce but little suffering; the animals were then placed on moist sand. Of three frogs thus treated, two died on the thirty-third day, and the remaining one on the fortieth.

Other experiments were instituted to resolve the converse of the former proposition, whether life can be prolonged by pulmonary respiration alone, unaided by that of the skin? The result of the experiments made upon tree frogs and upon the *bufo obstetricans*, was that pulmonary respiration is not sufficient to support life, without being accompanied by the influence of the skin.

The results of these experiments are not only highly interesting as regards the habits of the particular tribe of animals which were the subject of them, but still more so with reference to some important questions in general physiology; but as their bearing on these points can only be shown by viewing them in relation with all the other subjects treated of in the admirable work from which they are taken, it would be out of place to consider them here. It is impossible, however, not to be struck with the evidence they afford, that the respiratory organ, that surface through the medium of which the blood undergoes its necessary change by the action of oxygen, whether pulmonary, branchial, or cutaneous, and whether the medium of its access be water or the atmosphere, is in all cases similar, being a modification of the cutaneous surface. And as we see in the instance before us, the same surface capable of performing either atmospheric or aquatic respiration, the inference is obvious, that pulmonary and branchial organs may, and probably do, possess an identity of structure. When it is considered too that moisture is absolutely essential to atmospheric respiration, whether pulmonary or cutaneous, the identity of the two processes becomes still more unequivocal.

This view of the subject receives considerable confirmation from the fact that branchiæ are in many animals capable of exercising the office of atmospheric respiration through the medium of a very small quantity of water; as the land crabs of torrid regions are enabled to traverse immense districts under a burning sun, by means of those little reservoirs of water, described by Dr. Milne Edwards, formed by duplicatures of the lining membrane of the branchial cavity. The eel too, as is well known, will live for a long time out of water, from its branchial cavity being capable of retaining a sufficient quantity of water to bathe the branchiæ for a considerable time, thus preserving those organs in a respirable state.

XIII. *Of transpiration and of secretion.*—The particular condition of the skin already described, naked and consisting of a moist mucous surface, would render it probable that cutaneous transpiration should be exceedingly extensive and rapid in these animals; this is in fact the case to such an extent, that when exposed to too great a degree of heat, the evaporation of transpired fluid is sufficient to produce a very rapid decrease in the weight of the animal; which, if exposed for a sufficiently long period to its influence, becomes almost dried up and dies.

One object, and that not an unimportant one, of the sensible transpiration of fluid in these animals, the frogs especially, is undoubtedly to preserve the skin in a condition fit for the performance of that cutaneous respiration which has been described. But its still more obvious purpose is to afford a quantity of fluid for evaporation from the surface, in order to reduce and equalize the temperature of the body when exposed to a degree of heat, sufficient to incommode or injure it. This will appear very reasonable when we reflect that these animals will die in a few minutes, if placed in water of 107 degrees of Fahr., though respiring freely with the head above the water, whilst, on the contrary, they will support for hours the action of damp air of the same temperature.

The water which is thus transpired is not the result of the absorption of fluids taken in by the mouth, for these animals do not appear to drink. It is received by absorption on the surface of the skin, to which part it is afterwards restored when necessary. But in order to be ready whenever circumstances call for its use, the fluid thus absorbed is conveyed into a membranous cavity, formed generally of two lobes, opening into the cloaca, where it is retained, to be again absorbed, and again conveyed to the surface for the purposes just mentioned. When a frog is suddenly alarmed, or seized, it ejects from its cloaca a quantity of pure, limpid water, for the purpose of lightening itself, that it may leap with greater facility. This fluid is expelled from the sac in question, and is often mistaken for urine, and the sac for a urinary bladder. Hence, if a frog be kept in a moist situation, without having access to water in any form but in vapour, the skin is always kept moist, and the water-bag always filled.

Such is the function attributed in the first place by Townson to the sac in question, and after him by Dumeril, Altena, and others; but Cuvier, Dr. Grant, and many other anatomists consider that it is the true urinary bladder. That Townson's opinion is correct appears, says Altena, "from the circumstance that the ureters do not terminate in the bladder, but in the rectum itself." Dr. Grant states, that on the contrary, "the bladder receives the ureters."

The kidneys are of a lengthened form, in the aquatic genera, but are shorter in the frogs and other *anoura*.

XIV. *On the restoration of lost parts.*—The fact that parts lost by accident, or removed for the purpose of experiment, become reproduced in many of the lower animals, has been known for ages. The actual multiplication of the species in many, perhaps all the polygastric animalcula, by spontaneous separation,—that of the hydra by artificial division,—the restoration of lost arms in the different species of asterias, of the anterior or posterior extremity of the body in the earthworm, of the claws of the lobster, and other crustacea, and of portions of the head in the pulmoniferous mollusca, are, all of them, phenomena which have attracted the attention, and occupied the experiments of physiologists, at various periods. The experiments of Plateretti, Spallanzani, Murray, Bonnet, and others, have shewn that it is not in the invertebrate forms alone that we are to look for this phenomenon, but that the amphibia, and even some reptilia, will reproduce either the limbs or the tail, when removed. This restoration of the tail in the saurian reptiles is indeed a common occurrence, and it often happens that the new tail is double through the whole of the restored length.

Of all the observers of this curious phenomenon in the amphibia, Bonnet* stands preeminent for the laborious and patient zeal with which all his experiments were conducted, no less than for the conscientious strictness with which they are recorded. In many experiments he cut off the anterior or posterior limbs of the common water salamander or triton, which he found to be invariably restored, and even the toes were reproduced, and acquired some degree of motion. The tails were also amputated at various distances from the base, and were always renewed. The same limb was in some cases removed and restored four times consecutively. In all cases it was observed that warmth encouraged and that cold retarded the regeneration of the part. The restored portions were not generally well-formed, but in some instances varied by excess, in others by defect. One of the most extraordinary results was that which followed the extirpation of an eye from one of these animals. In the course of a year this organ was completely restored, and its organization was found to be perfect.

Dumeril records a remarkable experiment of this nature, in his latest work on the reptilia. The subject was the *triton marmoratus*. Three-fourths of the head were cut off, and the animal was deposited at the bottom of a large vessel having half an inch depth of water, which was constantly renewed. It continued to live, and to move slowly. The

* Œuvres, in 4to. Neufchatel, 1769.

nostrils, the tongue, the eyes, and the ears were gone; the animal could therefore enjoy no relation to external objects but by the sense of touch. It nevertheless evinced consciousness, creeping cautiously and slowly about, occasionally raising the neck to the surface as if attempting to breathe. The process of cicatrization at length completely closed the apertures of respiration and of deglutition. It lived three months after the operation, and then died from accidental neglect. After all, this experiment proves only the respiratory function of the skin, a fact already sufficiently established by the observations of Dr. Edwards before detailed, and its cruelty does not appear to be compensated for by its results.

XV. *Of reproduction.*— The impregnation of the ova in the amphibia, is effected without actual coitus; that is to say, it either takes place out of the body, as in the *anoura*, or the impregnating fluid is received by the mere contact of the external opening of the cloaca in the two sexes, as in the tailed forms. The only exception to this statement is in the land salamander, the male of which has a small intromittent organ. The act itself of impregnation therefore differs materially in these two divisions of the class. The generative organs of both sexes are double, and are placed symmetrically in the abdomen. The testes in the higher forms of the class, the frogs and toads, are small globular oval bodies, having externally a bright white appearance, from the tunica albuginea, and internally a somewhat loose texture, and a yellowish colour. They are placed behind the liver, attached to the vertebral column; the vasa deferentia are numerous, disposed in pairs; they form a small epididymis, and passing on the outer side of the kidneys back towards the cloaca, dilate into vesiculæ seminales, just before they terminate in that cavity. These organs, as in many other animals, become much enlarged at the breeding season.

The ovaria are situated in the anterior and upper part of the abdomen, and are internally divided into numerous sacs, by duplicatures of the peritoneum, by which also they are bound to each side of the spine. These sacs are torn at the period of depositing the eggs, whether by the pressure of the arms of the male, as asserted by Prevost and Dumas, or otherwise, appears uncertain. The oviducts are small at their commencement, and become large towards their termination in a sort of dilated sac, which Altena terms the uterus; they are of a pulpy substance, having an internal secreting surface; and the eggs during their passage through them become enveloped in a gelatinous mass. They dilate into a sort of uterine cavity just mentioned, which opens into the cloaca.

The mode by which the eggs of the frog pass from the ovaries into the oviducts appears yet to be doubtful. The observations of Prevost and Dumas on this subject are generally received as correct, but their statements are denied in some particulars by Altena, and doubted in others. They state that the ova, detaching themselves from the ovaries, are seized by the opening of the tube, but they do not state the mode by which this act is effected. It is a question which was long since examined with great care by Swammerdam, and which brought him into a controversy; and he confesses at last his ignorance of the mode in which it actually takes place.

The ovaries enlarge greatly at the breeding season, and the ova at the time of their deposition fill the body almost to bursting. At the time of impregnation the male placing himself on the back of the female, embraces the body with astonishing force with the anterior legs, which are pressed under the axillæ, and the tubercular thumbs, which are at this period considerably enlarged to enable him to retain his hold, are so essential to this object, that if they be cut off, he can no longer clasp the female with the requisite force. The instinct which instigates the male frog to this act at the season of breeding is astonishingly powerful, and sometimes no less remarkably blind. Thus, it is recorded by Walter, and has been often observed by others since his time, though the object of this curious fact has been unaccountably overlooked, that frogs are occasionally found in the spring adhering with great force to different parts of the skin of pike; and a near relative of the writer of this article has seen an instance of the same kind, where several frogs were so closely fixed to a large pike as to require some force to remove them. This instinct of adhesion is, in fact, sometimes fatal to its legitimate object. I have before now taken from the water a large conglomeration of male frogs, amounting to perhaps twelve or more, with one solitary female in the middle of the mass, dead and putrid, and even some of the males, towards the interior, pressed into an almost lifeless and shapeless lump.

While the male is thus closely embracing the female, an operation which sometimes lasts for more than a month, the eggs, to the number of several hundreds, are gradually ejected from the cloaca, either in masses as in the frog, or in double chaplets as in the toad, and impregnated by the sprinkling of the semen, as they pass out under the male. In some species, as the *bufo obstetricans*, the female is assisted in the act of expulsion by the hinder legs of the male. When the eggs are thus deposited in the water, the jelly-like substance in which each is enveloped absorbs a large quantity of it, and the whole mass speedily enlarges to many times the size of the animal from which it was expelled.

The male of the bufo obstetricans just mentioned, when, by his assistance, the eggs are excluded, attaches them to his thighs by glutinous threads, and carries them about with him until the young are ready to leave them, when he seeks a pool of water in which he deposits them, and the young shortly afterwards come forth.

The impregnation of the tailed aquatic

genera, as the tritons, is effected by a totally different mode. During the spring, the males acquire a considerable dorsal membrane, which runs the whole length of the back and tail, and is sometimes curiously indented or fringed at its edge. This membrane is gradually lost after the breeding season, and its use appears to be to assist in the act of impregnation. The male, instead of adhering to the female like the frog, swims by her side pursuing her in all her rapid and changing courses through the water, till at length both remaining for a moment quite still, he suddenly turns up, by the assistance doubtless of the dorsal membrane, and places for an instant the edges of the cloacal aperture in contact with hers. It is at this instant that the semen is ejected and received. The eggs are afterwards deposited slowly, and comparatively few in number, upon some part of an aquatic plant, on which the female supports herself by holding by her hinder legs.

When the embryo has gradually acquired its larva development, and is ready for its aquatic life, it bursts the thin membrane which encloses it, and emerges in the fish-like form which has been so often alluded to in this paper.

XVI. *Metamorphosis.*—The changes which take place in the different organs during the progress of this extraordinary phenomenon, have been already detailed. It remains to trace the general form of the animal from the egg through its larva condition till it receives its permanent form, and to point out some remarkable peculiarities observed in different genera.

In the frog, the toad, and probably all the *anoura*, the respiratory organs undergo a double change, the branchiæ being first external for a very brief period, and afterwards internal during the remainder of its larva existence. In all the other forms in which branchiæ have been detected, they remain external till they are lost.

The tadpole, whether of the *anoura* or of the *urodela*, possesses, at first, as we have seen, the same means of progression as belong to the class of fishes. That of the triton retains its branchiæ, co-existent with four perfect legs, until it is about a third of its ultimate length. In the frog the legs which first make their appearance are the hinder ones; and from the great development of the tail, and the continuous form of the head or abdomen, they appear as if they came through immediately behind the head.

As the terrestrial salamander, though preferring moist places, does not frequent the water, the young have not the opportunity of being developed in that medium; but as the essential character of their organisation requires that the first portion of their existence should be passed in the condition of a tadpole or larva, we find that the whole of its metamorphosis takes place whilst in the oviduct, where it is found with small branchiæ on each side of the neck, which are lost as the animal enters upon its terrestrial existence. Like the viper, therefore, this animal is ovo-viviparous.

The arrest of the metamorphosis in the lower or perennibranchiate forms is confined to the organs of locomotion in part, to those of circulation, and of respiration. The organs of reproduction receive their full development, though even in these there is a considerable resemblance to those of the fishes.

One of the most remarkable peculiarities in the whole of this class, with regard to the subject now under consideration, is the reproduction and metamorphosis of the pipa or Surinam toad. It has long been known that the eggs are developed in cells on the back of the mother; but the facts connected with this curious circumstance have only of late years been ascertained It is now established that the cells on the skin of the female are not persistent, but grow as the eggs enlarge, and are removed after the young leave them. The male impregnates the eggs as the toad, but immediately places them on the skin of the mother's back; here they are attached by a tenacious mucus, and the skin gradually thickens in the interstices, forming at length a cell around each. In these cells the young ones not only leave the eggs, but actually undergo their metamorphosis; and when they leave the back of the parent, they have lost all the characters of the tadpole, and have become perfect animals.

It is impossible to contemplate the structure and habits of this remarkable class of animals without being struck by the many interesting points which they offer for the investigation of the physiologist. Whether we consider the evident and perfect transition which many of them present, from the form and structure of an inferior to that of a superior type or organization, the facilities which they afford us of tracing, as it were under the eye, those mysterious changes and grades of development which in most cases are accessible only at particular epochs, or are wholly concealed during their progress in the hidden recesses of the reproductive organs, or whether we view the modifications which they present of the respiratory and other important functions of life, it is not, perhaps, saying too much to aver that there is scarcely any class of animals which invites the study and contemplation of the lover of physiological science by phenomena at once so varied and so interesting as the Amphibia.

(T. Bell.)

ANIMAL KINGDOM, an appellation given to that great division of natural bodies to which ANIMALS belong. Like the other kingdoms of nature, the mineral and the vegetable, it is divided into numerous sub-kingdoms, classes, orders, genera, and other subordinate groups, according to the properties and forms of the objects which it comprehends. As the primary grand divisions of the mineral kingdom are founded on the primitive forms of crystallization, and those of the vegetable kingdom on the endogenous and exogenous modes of growth, zoologists have endeavoured to find some common principle for their first divisions of the animal kingdom. The most common function in animals, and in all organized beings, is generation, and we find the animal kingdom divided into four distinct groups by the modifications of this function, viz., *fissipara*, *gemmipara*, *ovipara*, and *vivipara*. But as the fissiparous and gemmiparous modes of generation are effected without the presence of distinct permanent organs, as the fissiparous mode occurs in isolated species belonging to classes remote from each other in the scale, and as nearly all the classes of the animal kingdom belong to the oviparous division, the modifications of this system do not present the means of establishing primary divisions suitable for the purposes of zoology. Although the process of internal digestion is not so universal as the *function* of generation, the internal alimentary cavity is the most universal *organ* of animals, and its forms therefore merit a first consideration in the establishment of primary groups. It is found, however, that in animals whose general structure is nearly the same, the alimentary apparatus varies so much according to the nature of the food, as to render hopeless any attempt to subdivide the animal kingdom from its modifications; as from its having one or two apertures, from its being a simple sac or a lengthened intestine, from its having one, two, or more stomachs or glands developed in its course, or other modifications of this kind.

In the circulating system we are presented with better means for such divisions than in the digestive, for the radiated classes have only vessels for their circulation, the articulated classes have a superadded ventricle, the molluscous classes and fishes a bilocular heart, amphibia and reptiles a trilocular heart, and the birds and mammalia have four cavities in that organ. The respiratory organs likewise afford the means of founding primary divisions, as into ciliated, branchiated, and pulmonated classes, in ascending from the lowest to the highest forms of that system.

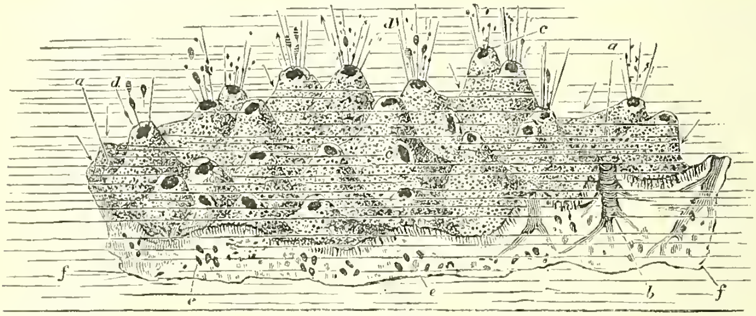
The primary divisions of the animal kingdom adopted by Aristotle, viz., animals with red blood and animals without red blood, are obviously founded on a single principle of classification, and correspond with the more recent divisions of vertebrata and invertebrata; but from the number of distinct classes of animals now comprehended under each of these divisions, they are quite unsuitable as primary groups in the present advanced state of the science of zoology. Considering the functions of the nervous system or the intellectual conditions of animals as a means of classification, Lamarck proposed three great divisions, the lowest of which comprehended the animals regarded by him as *apathic* or automatic, the second the *sensitive*, and the highest the *intelligent*, which, however, are too hypothetical to answer the purposes of the zoologist. Without any fixed principle for the establishment of his primary groups, Cuvier divided the animal kingdom into the *radiated*, the *articulated*, the *molluscous*, and the *vertebrated* divisions, which have been generally adopted by naturalists. From the importance of the nervous system in the living economy of animals, some have sought in its modifications a means of establishing primary or grand divisions of the animal kingdom on principles more uniform and philosophical than those commonly employed. In the radiated or lowest classes of animals, wherever the nervous system is perceptible, as in actinia, medusa, beroe, asterias, echinus, holothuria, &c. it is found in the form of filaments disposed in a circular manner around the oral extremity of the body. This lowest form of the nervous system is expressed by the term *cyclo-neura*, and although, like the radiated and every other character assigned to these classes, it is of partial application, it marks the uniform condition of that system on which the manifestations of life are chiefly dependent, and which principally establishes the relations of animals to surrounding nature. A different form of the nervous system is found in the long cylindrical trunks of the helminthoid and entomoid classes, where we observe almost from the lowest entozoa to the highest crustacea, a double nervous chord or column extending along the whole of the ventral surface of the body. This form of the nervous system, common to the articulated classes of animals, is expressed by the term *diplo-neura*, and it is found to accompany an organization generally more complex than that of the cyclo-neurose classes, and inferior to that of most of the succeeding divisions or sub-kingdoms, especially in the organs of vegetative or organic life, as the vascular, the digestive, and the glandular apparatus. The nervous system is more concentrated around the entrance to the alimentary canal in the molluscous classes, where it generally forms a transverse series of ganglia, disposed around the œsophagus, a character which is expressed by the term *cyclo-gangliata*. The dorsal position of the great ganglia and nervous columns of the cephalopods, and their partial protection by an organised osseous internal skeleton, leads to the condition of the nervous system presented by the vertebrated classes of animals, where its central parts are in the form of a lengthened dorsal nervous chord developed anteriorly into a brain, and protected by a vertebral column and cranium. The vertebrated classes are thus designated *spini-cerebrata*, from the form of the most influential part of their organization.

To the lowest sub-kingdom or cyclo-neurose division belong five classes of animals; viz.,

1. *Polygastrica*, microscopic, simple, transparent, soft, aquatic animals, in which no nervous filament has yet been detected, generally provided with eyes, with a circular exsertile dental apparatus around the mouth, and with vibratile cilia for respiration and progressive motion, and provided with numerous internal stomachs or cœca communicating with the alimentary cavity. (See Polygastrica.)

2. *Porifera*, simple, aquatic, soft, animals, without perceptible nervous or muscular filaments or organs of sense, with a fibrous internal skeleton sometimes supported with silicious and sometimes with calcareous spicula, the body permeated with a soft gelatinous flesh, covered externally with minute absorbent pores, traversed by numerous ramified anastomosing canals, which commence from the pores and terminate in large open vents, as seen in the annexed figure of the *halina papillaris*, Gr. (*fig.* 29), which represents the animal as alive,

Fig. 29.



under water, with the usual currents passing inwards through its pores (*a a*), traversing its internal canals (*b*), and escaping by the larger vents (*c*, *d*.) (See Porifera.)

3. *Polypifera*, aquatic animals, of a plant-like form, generally fixed, of a simple internal structure, for the most part without perceptible nerves or muscles, or organs of sense, and nourished by superficial polypi, which are developed from the fleshy substance of the body, as in the *campanularia dichotoma*, (*fig.* 30), where the irritable fleshy tubular portion of the animal is seen to occupy the interior of the base, the stem, and the branches, and to extend in the form of polypi from the open terminal cells. The polypi of most zoophytes are provided with tentacula around their orifice, as seen at B, (*fig.* 31), and the margins of these tentacula are generally furnished with numerous minute processes, termed *cilia*, (see Cilia,) by the rapid vibration of which, currents are produced in the surrounding water for the purpose of attracting food and of aerating the surface and fluids of the body, as represented in *fig.* 3, A. (See Polypifera.)

Fig. 30.

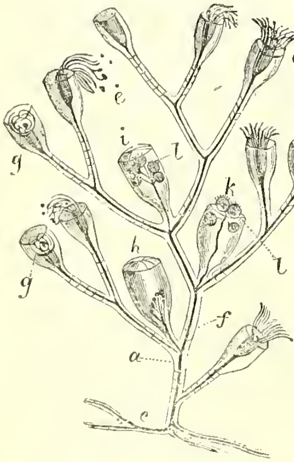


Fig. 31.

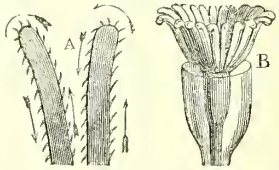
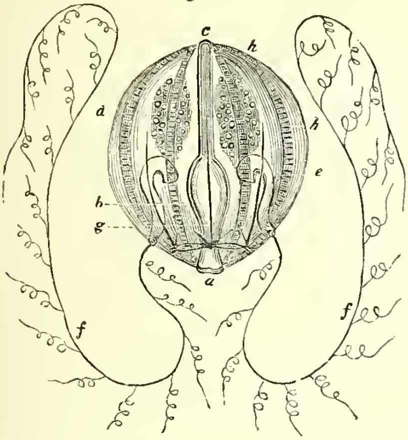


4. *Acalephæ*, soft aquatic free animals, of a simple structure, generally of a gelatinous and transparent texture, and emitting an acrid secretion which is capable of irritating and inflaming the skin like the stinging of a nettle, from which the name of the class is derived. They rarely possess a solid skeleton or a perceptible nervous system. They are all marine, often luminous, sometimes they possess eyes with a crystalline humour, they feed on minute floating animals, and swim by the contractions of a highly vascular and irritable mantle or by means of air-sacs, or by the rapid movement of

external vibratile cilia, as in the *beroë pileus* represented in *fig*. 32. This figure represents

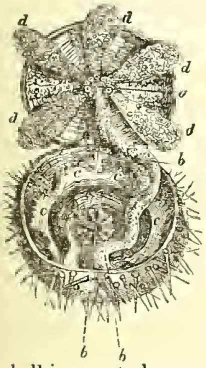
Fig. 32.



one of the ciliograde acalephæ in which the mouth (*a*) is directed downwards, and leads, by a narrow œsophagus, to a wide stomach (*b*), and from this the intestine proceeds straight through the axis of the body to the anus (*c*) at the opposite pole. The longitudinal nerves (*g*), as in *holothuria*, proceed from a nervous ring around the œsophagus. The ovaries (*d*) extend along the sides of the intestine ; the surface of the body is provided with eight longitudinal bands of pectinated broad vibratile cilia (*hh*), and two long ciliated tentacula (*ff*) extend from two curved lateral sheaths. (See Acalephæ.)

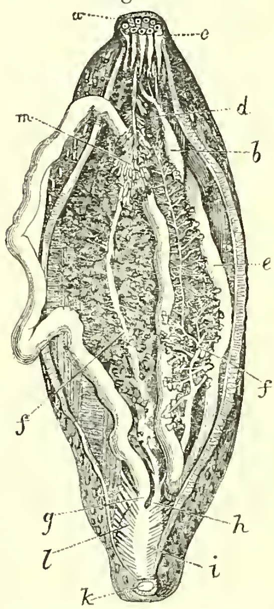
5. *Echinoderma*, simple aquatic animals, for the most part provided with a calcified exterior skeleton or a coriaceous skin, the body for the most part radiated, globular, or cylindrical, often provided with a distinct nervous, muscular, respiratory, and vascular system. These animals have received the names of echinoderma, from the spines or tubercles which generally cover their exterior surface, as seen in the annexed figure of the *echinus esculentus* (*fig*. 33.) The mouth (*b*) is here in the centre

Fig. 33.



of the lower surface, and the intestine (*b,b.*) connected to the shell by a mesentery (*c*), on which vessels are ramified, passes in a convoluted manner upwards to the opposite axis where the anal aperture (*a*) is surrounded by the five openings of the ovaries (*d,d.*) The mouth is surrounded with a maxillary apparatus containing five teeth, and the exterior of the complicated and solid shell is seen to be provided with moveable calcareous spines. These animals are for the most part free, but some are fixed, as the crinoid echinoderma, the vascular system is unprovided with auricle or ventricle, and the digestive canal is seldom furnished with distinct glandular organs. There is sometimes a simple stomach with one aperture and numerous lateral cœca, and sometimes a lengthened intestine with two terminal openings. Some marine animals without an echinodermatous covering are placed in this class from the similarity of their structure in their more essential organs, as is the case with the *holothuria* represented in *fig*. 34. The mouth (*a*) is here surrounded with

Fig. 34.



ramose tentacula (*c*) and an osseous apparatus. The intestine is long, convoluted, vascular, supported by a mesentery, and terminates in a cloaca (*i*) at the opposite axis of the body. The ramified internal branchiæ (*ff*) open from the cloaca ; the great systemic artery receives the aerated blood from the branchiæ, and the organs of generation (*m*) open near the anterior part of the body. The irritable coriaceous skin is supported by five broad longitudinal subcutaneous muscular bands, and five crowded series of tubular muscular feet extend from its surface. (See Echinoderma.)

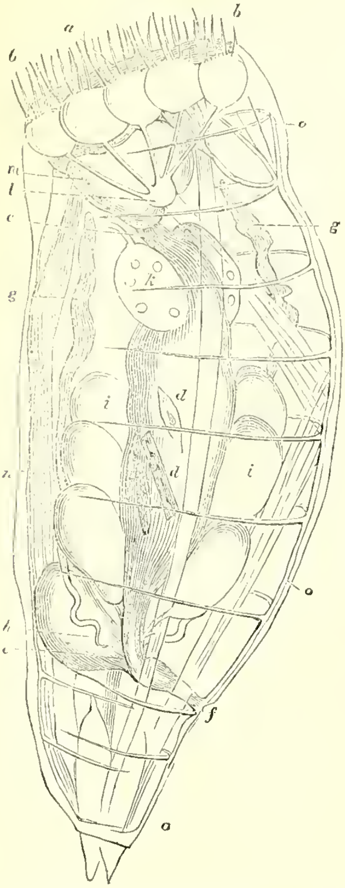
The second sub-kingdom or diplo-neurose division comprehends four classes of helminthoid animals and the same number of entomoid classes, viz.

6. *Entozoa*, parasitic, simple, internal, or fixed animals, for the most part of a lengthened cylindrical form, without distinct organs of sense or any internal skeleton, the mouth or anterior part of the body generally provided with recurved sharp spines, the body generally covered with an elastic white transparent integument, the nervous system seldom distinct, the vascular system without auricle or ventricle, without respiratory organs, and with the sexes generally separate. (See Entozoa.)

7. *Rotifera*, minute aquatic animals with distinct nervous and muscular systems, provided with eyes, lateral maxillæ, a dorsal vessel, an intestine with two apertures, and with vibratile cilia disposed generally in a circular form

around the anterior part of the body. They are termed rotifera from the appearance of revolving wheels produced by the rapid movement of the cilia disposed around the mouth.

Fig. 35.

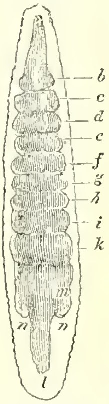


One of these minute wheel-animalcules, the *hydatina senta*, is represented highly magnified in *fig.* 35, where the mouth (*a*) is surrounded with long vibratile cilia (*b b*). The œsophagus (*c*) leads to a capacious stomach (*d*), which becomes a narrow intestine below, opening into the cloaca (*e*), where the genital organs (*i*, *i*, *g*, *g*, *h*,) also terminate. Several ganglia surround the œsophagus, and a dorsal vessel (*o o*) is seen extending along the middle of the back and sending out regular transverse branches. All the rotifera are free, most are naked, many are sheathed or loricated, they exhibit no branchial or pulmonary organs, they are remarkable for their fertility and their tenacity of life. (See Rotifera.)

8. *Cirrhopoda*, aquatic, articulated, diploneurose animals, with articulated cirrhi, and branchiæ for respiration, body covered with a fleshy mantle, and fixed in a multivalve shell. These animals are all marine, the branchiæ are fixed to the bases of the articulated cirrhi, the mouth is provided with mandibles and maxillæ, there is a pulsating dorsal vessel, and a double longitudinal knotted subabdominal nervous chord. The cirrhopoda have been commonly placed among the molluscous classes from the form of their exterior coverings. (See Cirrhopoda.)

9. *Annelida*, with a long cylindrical body generally divided into transverse segments, and covered with a soft skin; the head commonly provided with antennæ and numerous simple eyes, and the mouth with maxillæ; the organs of motion in the form of simple setæ or cirrhi extending from the sides of the body in a single or double row. The vascular system of the annelida consists of arteries and veins, without a distinct auricle or ventricle, and the blood is generally of a red colour. The respiratory organs are generally in form of external branchiæ, sometimes of internal air-sacs, and the alimentary canal passes straight through the body with two terminal openings, and with numerous lateral cœca developed in its course, as seen in that of the leech, *hirudo medicinalis*,

Fig. 36.



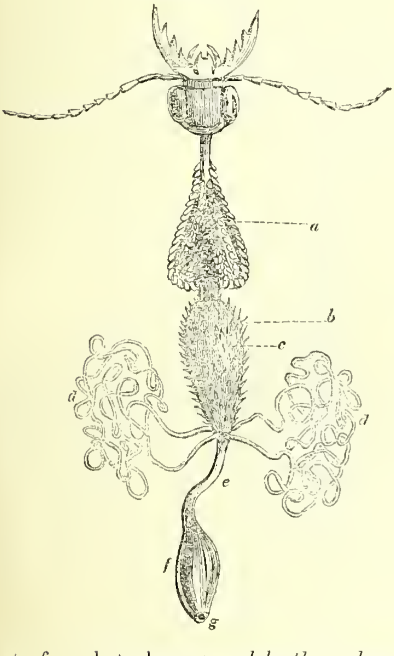
(*fig.* 36.) These lateral cœca (*b*, *c*, *d*, *e*, *f*, *g*, *h*, *i*, *k*, *m*,) increasing in length and size from before backwards, are often much more lengthened and divided, as in the *halithea*. Many of the red-blooded worms are fixed in calcareous, arenaceous, or other tubes, and many are free and naked. (See Annelida.)

10. *Myriapoda*, with a lengthened articulated body equally developed throughout; the head provided with antennæ and simple eyes; the segments of the trunk free, without distinction of thorax and abdomen; the segments furnished with one or two pairs of articulated legs adapted for progressive motion on land; the respiration is aerial, and performed by tracheæ, which ramify from their commencement in stigmata which open along the whole extent of the body. They do not undergo metamorphosis, nor possess compound eyes nor wings, and they have always more than six pairs of feet. (See Myriapoda.)

11. *Insecta*, with six articulated legs extending from an articulated trunk, which is divided into a head, thorax, and abdomen; the head is provided with a labium, a labrum, mandibles, and maxillæ, with compound and often also with simple eyes, and a pair of antennæ and palpi; the thorax supports the six legs, and commonly one or two pairs of wings, and has attached to it the moveable segments of the abdomen, which embrace the principal organs of digestion, circulation, and generation. The respiration is effected by tracheæ, which form continuous lateral trunks before they ramify through the body. The circulation is aided by a pulsating dorsal vessel provided with numerous valves, and the alimentary canal is furnished with salivary and hepatic, and often with pancreatic glands. The sexes are sepa-

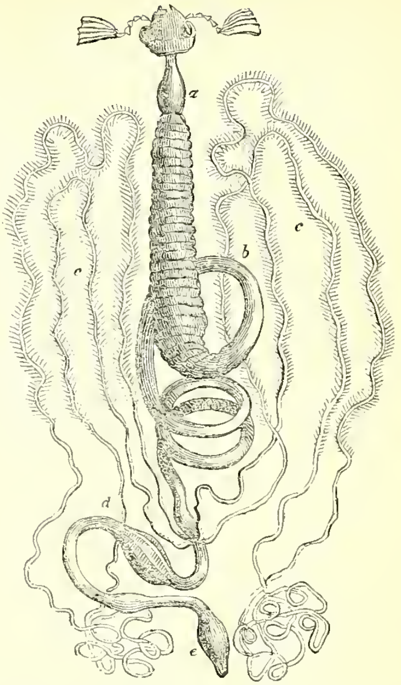
rate, and the genital organs, slow in their development, are highly complicated in the perfect state. These animals generally pass through a series of metamorphoses, and throw off their exuvial covering five or six times during their development. This class is the most numerous in the animal kingdom, comprehending about a hundred thousand species. The greater part of their life is spent in the larva state, during which they are generally most voracious, like the young of other classes. In the adult state the masticating organs and the digestive apparatus vary much according to the kind of food in the different species, as is seen in comparing the alimentary canal of a carnivorous *cicindela campestris* (*fig.* 37.) with

Fig. 37.



that of a phytophagous *melolontha vulgaris*, (*fig.* 38.) In the carnivorous insect (*fig.* 37.) the intestine passes nearly straight through the body with few enlargements in its course, and the glandular organs have a simpler structure. The œsophagus passes down narrow from the head, and dilates into a wide glandular crop (*a*), which is succeeded by a minute gizzard, and this is followed by the chylific stomach (*b*, *c*), which is covered like the crop with minute glandular cryptæ or follicles. At the pyloric extremity of the chylific stomach, the liver, in form of simple biliary ducts, pours its secretion into that cavity by two orifices on each side (*d*). The short small intestine (*e*) opens into a wide colon (*f*), which terminates in the anus (*g*). In the vegetable-eating insect, (*fig.* 38) the alimentary canal is more lengthened, convoluted, and capacious, with more numerous dilatations, and the glandular organs are more developed. The crop (*a*) of the *melolontha* is

Fig. 38.



succeeded by a minute rudimentary gizzard, and to this succeeds a long and sacculated glandular or chylific stomach, which becomes narrow and convoluted below, and terminates in a small pyloric dilatation, which receives the four terminations of the biliary organs. The succeeding part of the intestine is also convoluted, and has three enlargements in its course to the anus (*e*). The liver (*c c*) is here of great magnitude, and has its secreting surface much extended by the development of innumerable minute cœca from its primary ducts. Insects also often present distinct urinary organs, and numerous glands in both sexes connected with the organs of generation. (See Insecta.)

12. *Arachnida*, with the head and thorax united, generally four pairs of legs; without antennæ, or compound eyes, or wings, or metamorphosis; the trunk divided into a cephalo-thorax and abdomen; the head is often provided with two pairs of chiliform manducatory organs; the eyes are simple. The respiration is aërial, sometimes performed by tracheæ, and sometimes by pectinated pulmonary sacs opening on the sides of the abdominal surface of the trunk. In their nervous, respiratory, and circulating systems they indicate a higher grade of development than insects, and like them are generally inhabitants of the land, attaining considerable size and strength, with cunning, cruel, carnivorous habits, and often provided with poisonous instruments. (See Arachnida.)

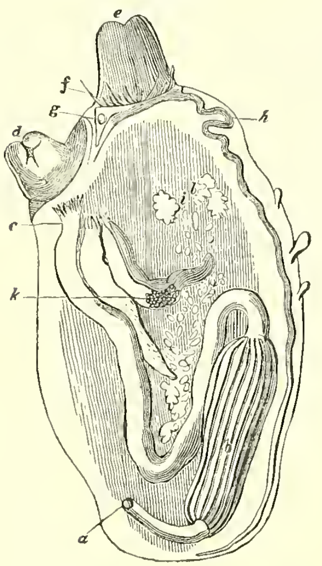
13. *Crustacea*, with the head and thorax generally united, two pairs of antennæ, two

compound eyes, more than four pairs of legs, the respiration effected by gills, and the shell generally hard and calcareous. These entomoid aquatic animals are generally carnivorous, and have a short and straight alimentary canal. Their circulating system is often aided by a muscular ventricle. The sexes are separate, and the organs of generation are double and symmetrical in both sexes. Their biliary organs have a conglomerate form, being composed of minute glandular follicles grouped together into lobules and larger lobes. Some of these animals are fixed and parasitic, and breathe by their general exterior surface; most are free, and respire by means of branchiæ placed under the sides of the carapace or exposed on the under-surface of the post-abdomen. (See Crustacea.)

The third, or cyclo-gangliated or molluscous division of the animal kingdom, comprehends five classes, viz.:—

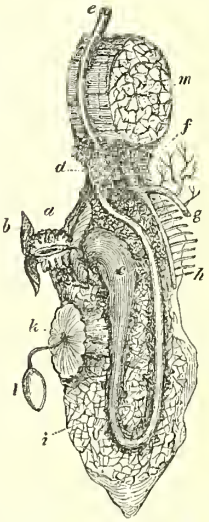
14. *Tunicata*, soft, aquatic, acephalous animals, breathing by internal branchiæ, never in form of four pectinated laminæ, and covered by a close external elastic tunic furnished with at least two apertures. The exterior tunic is lined by a muscular coat; sympathetic ganglia are observed in the abdominal cavity, and the respiratory organs are ciliated as in higher molluscous classes for the production of the respiratory currents. The mouth, unprovided with tentacula or other organs of sense, opens at the bottom of the abdominal cavity, as seen in the *cynthia dione*. (*Fig.* 39. *a.*) The short œsophagus leads to a capacious stomach (*b*), sometimes surrounded by the lobes of a small liver, which pours its secretion into that cavity as in higher mollusca. From the stomach a short wide convoluted intestine proceeds to near the ventral orifice (*d*) of the sac, where it terminates in the anus (*c*). The thoracic orifice (*e*), or the entrance to the respiratory cavity, is generally provided with numerous delicate tentacula (*f*), and a nervous longitudinal filament (*h*) is generally observed to encompass that opening, and to terminate in a small glanglion (*g*). These animals are entirely marine, most are fixed, some are free; they are all female, like the conchifera; the circulation is aided by a muscular heart. Many are organically connected in groups, others are isolated, (See Tunicata.)

Fig. 39.



15. *Conchifera*, acephalous, aquatic animals, covered with a solid calcareous shell, consisting of at least two pieces, and breathing by internal branchiæ in form of four pectinated laminæ. These bivalved animals have the mouth, as in the former class, situated at the bottom of the respiratory or thoracic cavity; the stomach is surrounded and perforated by the lobes of the liver; the circulation is aided by a bifid or a divided auricle and by a muscular ventricle, which is generally perforated by the rectum, as seen in the annexed figure of the organs of the *spondylus*, (*fig.* 40.) The two fimbriated lips (*a*) which surround the mouth are prolonged laterally into four tapering flat pectinated tentacular expansions (*b*). The stomach (*c*) and the intestine are surrounded by the large mass of the liver (*i*), and the rectum, near the adductor muscle (*m*), penetrates the ventricle of the heart (*d*), at some distance from the anus (*e*). The branchial veins (*g*, *h*) return the aerated blood to the two lateral divisions of the auricle, these pour it into the ventricle, by which it is propelled forwards and backwards through the system, so that the heart is here, as in other invertebrated classes, a systemic organ. (See Conchifera.)

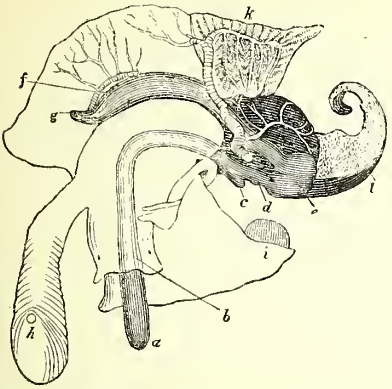
Fig. 40.



16. *Gasteropoda*, body invertebrate and inarticulate, provided with a head which for the most part supports tentacula and simple eyes, and furnished with a muscular foot, extended under the abdomen, and adapted for creeping. These animals are sometimes naked, more generally covered with a univalve, unilocular, solid, external shell. Some gasteropods breathe by a pulmonary cavity, most by branchiæ variously disposed on the surface or under an open mantle. Most are marine, many inhabit fresh waters, and some reside on land. The higher forms are mostly carnivorous, and the lower orders phytophagous, and this difference affects principally their alimentary apparatus,

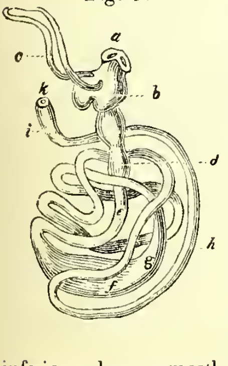
as seen by comparing that of the carnivorous *buccinum undatum*, (*fig.* 41,) with the same

Fig. 41.



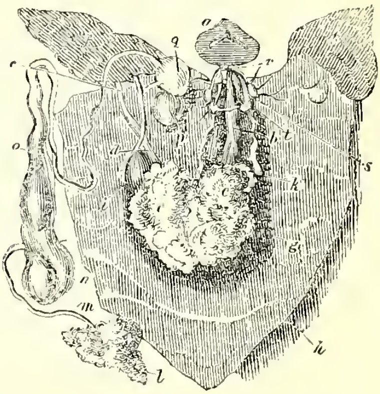
apparatus in the phytophagous *patella vulgata*, (*fig.* 42.) Like most of the predaceous gasteropods the *buccinum* is provided with a long muscular proboscis, (*fig.* 41, *a*, *b*,) capable of being extended to a distance from the mouth, and enclosing a bifid tongue covered with sharp recurved teeth. The œsophagus near the stomach dilates into a small crop (*c*), and to this succeeds a round membranous stomach (*d*, *e*). The whole remaining intestine is shorter than the œsophagus, and dilates into a wide colon (*f*,) before terminating in the anus (*g*), on the right side of the body under the open mantle. The liver, of great size, and accompanying the testicle (*i*) in the turns of the spire, pours its secretion into the stomach as in the acephalous classes. The vas deferens following the right side of the body terminates at the end of the male organ (*h*) in a small tubular styliform duct. In the *patella*, (*fig.* 42,) however, which feeds on marine plants, the mouth (*a*) is provided with a long slender convoluted tongue covered with numerous rows of teeth like a long file. The wide and sacculated œsophagus (*d*) leads to a capacious and lengthened stomach (*f*, *g*), surrounded by the large liver, and the long convoluted intestinal canal (*h*) makes several turns imbedded in the mass of the liver before it arrives at the short dilated rectum (*i*) and anus (*k*). The salivary glands are generally of great size in this class, and present sometimes in the same species both the simple follicular and the conglomerate forms. The pancreas likewise is often present in form of a single follicle opening into the stomach along with the biliary ducts. The inferior orders are mostly male and female, but in the higher forms the sexes are distinct. (See GASTEROPODA.)

Fig. 42.



17. *Pteropoda*, body organized for swimming, mantle closed above, branchiæ external, no muscular foot for creeping, shell, when present, always thin, pellucid, unilocular, and inoperculate. These soft, minute, floating animals are all marine, and are enabled to swim by means of two lateral musculo-cutaneous fin-like expansions, on the surface of which the respiratory branchiæ or vascular plexuses are placed. These lateral fins are never supported by rays. The head is generally provided with retractile or sheathed tentacula, seldom with eyes. The body is sometimes entirely naked, often protected by a delicate thin transparent shell, which encloses the abdomen and is covered with a fold of the skin. They appear to be most closely allied to the inferior testaceous cephalopods in the nature and form of their shells and in their locomotive powers, and also in the general simplicity of their internal structure, especially of their generative organs. The structure of one of the naked pteropods, *clio borealis*, is represented in *fig.* 43, where the abdominal cavity is exposed by the mantle

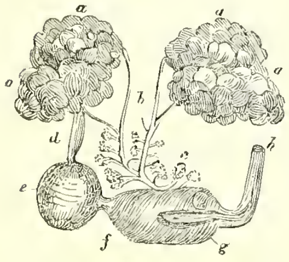
Fig. 43.



being opened from behind. The mouth (*a*) leads to a long œsophagus (*b*), which is surrounded by a circular series of nervous ganglia (*t*). The stomach (*c c*) is imbedded in the lobes of the liver (*g*), which open by numerous short ducts into its cavity. The œsophagus is accompanied by the two long simple salivary follicles (*k*), and at the left or pyloric extremity (*d*) of the stomach is placed the heart (*i*), enclosed in its pericardium, which receives the arterialized blood from the branchial veins, and sends it through the system. The bottom of the abdomen or cavity of the mantle (*h*) is occupied as in the cephalopods with the generative organs, which consist of an ovary (*l*) and long oviduct (*m*, *o*), into which a short wide cœcum (*n*), commonly considered as a testicle, pours its secretion. The oviduct terminates on the left side, near the anus (*e*), in a small glandular sac (*q*), beneath which is the rhenal sac (*p*). The pteropods are commonly found floating in immense numbers at the surface of the water in still warm evenings in tropical seas; some, as the *clio borealis*, figured above, abound in the Arctic seas. (See PTEROPODA.)

18. *Cephalopoda*, free cyclo-gangliated or mulluscous animals, with the feet disposed around the head, respiring by internal branchiæ, and with the abdominal cavity enveloped by a muscular mantle open anteriorly. The cephalopods are all marine animals capable of swimming by means of membranous or muscular expansions, which are never supported by rays. The surface of the body is often naked, sometimes covered with a shell, which is generally polythalamous, rarely monothalamous, and always inoperculate. There is often a concealed, loose, dorsal, calcareous or horny shell contained in a shut subcutaneous sac. The mouth is furnished with two horny or calcified mandibles, and the rudiments of an internal organized cartilaginous cranium and vertebral column are generally perceptible, together with some detached parts of the skeleton of vertebrata. The œsophagus is surrounded by a nervous collar, from which two supra-abdominal nervous columns generally extend along the middle of the back, and sympathetic ganglia are observed in the abdominal cavity as in the inferior molluscous classes. These are predaceous animals, and the alimentary canal, though generally furnished with three enlargements, forming a crop, a gizzard, and a spiral or proper chylific stomach, is always very short. There are two pairs of salivary glands; the liver is of great size, and pours its secretion, with that of the pancreatic follicles, into the stomach, as in the inferior classes. There is always a strong muscular systemic ventricle, and generally a divided auricle placed at the beginning of the branchial arteries. The common form of the chylopoietic organs is seen in those of the *loligopsis guttata*, (*fig.* 44,) where the liver (*a a a a*) pours its secretion by ducts (*b*), which are surrounded and penetrated by the pancreatic follicles (*c c*), and which unite into a single canal before they open by a valvular aperture into the third or chylific stomach (*f g*). The crop (*d*) ends in the strong muscular gizzard (*e*), and from the third stomach (*f g*) the short intestine (*h*) ascends in front of the liver to terminate by a valvular anus at the base of the funnel. The naked species have a glandular sac for secreting a black inky matter, which appears to be wanting in those protected by an external shell, excepting in the argonauta, where the shell is seen in the ovum, and where there is a slight membranous connexion between the animal and its thin delicate calcareous covering. The sexes are generally separate, but the lowest foraminiferous cephalopods appear to approach to the pteropods in the male and female character of the genital organs. (See CEPHALOPODA.)

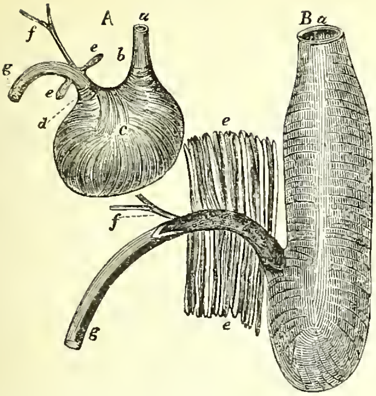
Fig. 44.



The last or highest DIVISION of the animal kingdom, comprehending the vertebrated or red-blooded animals, or SPINI-CEREBRATA, consists of five distinct classes, characterised chiefly by their generative, their sanguiferous, and their tegumentary organs, viz.—

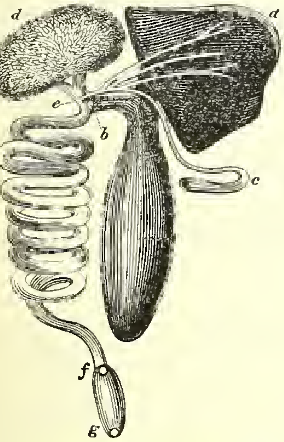
19. *Pisces*, cold and red-blooded oviparous vertebrated animals, with one auricle and one ventricle to the heart, breathing by permanent branchiæ, and with fins for progressive motion. They have a vertebral column and cranium, enclosing a spinal cord, and brain consisting of a medulla oblongata, optic lobes, cerebral hemispheres, olfactory tubercles, and a cerebellum. The hands and feet are always formed like fins for progressive motion in a watery element. The fins are supported by rays prolonged from the skeleton, the body is generally covered with scales, the trunk is organized for the lateral motion of the tail, there is no sacrum, and the pelvic arch is unconnected with the vertebral column. The bones are elastic or cartilaginous, and the centres of ossification for the most part remain permanently detached. The bodies of the vertebræ terminate in two cup-like cavities, they move on elastic tense intervertebral sacs, and the transverse processes are directed vertically downwards in the coccygeal region of the skeleton to facilitate the lateral motion of the trunk. The muscles, of a white colour, are disposed in oblique strata on the sides of the trunk for the movement of the elastic vertebral column. The mouth, destitute of salivary glands, is generally furnished with numerous unequal, irregular, fangless, osseous teeth, and the wide œsophagus, short like the neck, leads to a capacious stomach, from which the intestine, shorter than in the higher classes, and nearly equal throughout, proceeds, without cœcal enlargement, to terminate in a cloacal sac on the inferior surface of the trunk. The liver is large, and pours its secretion generally by a single duct into the duodenum, near the pyloric extremity of the stomach and close to the opening of the pancreatic duct, as shown in the annexed figures of these parts in the frog-fish (*fig.* 45, *A*) and the cod (*fig.* 45, *B*). The œsophagus (*a*) of the frog-fish (*fig* 45, *A*) leads to a large globular stomach (*c*) with a strong muscular cardiac sphincter (*b*). The pyloric extremity is also surrounded with strong muscular bands (*d*), and beyond its pyloric valve two pancreatic simple glandular follicles (*e e*) open into the duodenum (*g*) close to the opening of the ductus communis choledochus (*f*). In the cod (*fig.* 45, *B*) the wide œsophagus (*a*) leads to a long and capacious muscular stomach shut below, and immediately beyond the pyloric valve, formed by a circular fold of the mucous coat, open the ducts of numerous straight and simple pancreatic folli-

Fig. 45.



cles (*e e*) along with the ductus communis choledochus (*f*). The cartilaginous plagiostome fishes, the most complicated of this class, have a conglomerate form of the pancreas opening in the same situation. In the sturgeon and in the sword-fish an intermediate form is seen between the simple pancreatic follicles of the invertebrated classes and the more complicated conglomerate organ in the higher vertebrata. This is shown in the annexed figure of the chylopoietic viscera as I found them in the *xiphias gladius* (*fig.* 46), where the liver (*a*) is raised up to show

Fig. 46.



the three hepatic ducts uniting with the cystic from the curved gall-bladder (*c*) to form a very short ductus communis choledochus. The pancreas (*d*) forms a large reniform mass composed of numerous straight follicles produced by the successive divisions of the great terminal duct (*e*) of this organ. This large intermediate organ is surrounded with a distinct muscular tunic to force its contents into the duodenum immediately beyond the pyloric valve (*b*). The tortuous small intestine ends by a valvular orifice (*f*) in a very short but distinct colon, which presents no cœcum in its course to the anus (*g*). The bilocular heart of fishes is entirely branchial; it is often preceded by a *sinus venosus*, and is always succeeded by a *bulbus arteriosus*, which often presents numerous internal valves in its course. The venous blood is entirely sent through the gills, and the branchial veins, after giving branches to the anterior parts, unite to form the aorta which sends the arterialised blood through the rest of the system without the aid of a systemic heart. The respiration is effected by the transmission of water through the mouth or through distinct spiracula, and over the surface of the branchiæ, which are internal in the adult, and are often preceded by external branchiæ in the young. The lungs are always rudimentary, when present, sometimes in form of a shut single air-bag, sometimes divided or ramified, and most *generally communicating* by a *ductus pneumaticus* with the intestine or stomach, or œsophagus, but seldom employed for respiration. Fishes are oviparous and have the sexes separate; the ovaries are continuous with the oviducts in osseous fishes, and detached from them in the plagiostome chondropterygii, and impregnation sometimes takes place internally and sometimes after the ova are separated from the body. (See Pisces.)

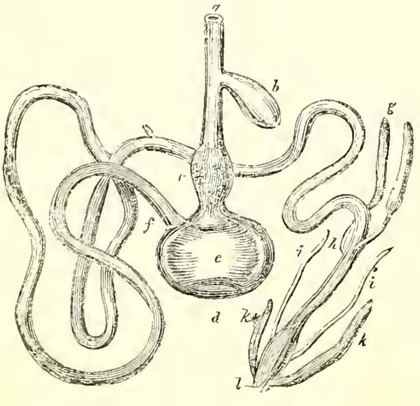
20. *Amphibia*, cold and red-blooded, vertebrated, oviparous animals, with three cavities of the heart, with a naked skin, and breathing, in the young state, by gills. These animals commence their career like fishes with one auricle and one ventricle, which send the whole of the blood through the branchiæ, and they have at this period also double concave bodies of the vertebræ, as in fishes. Many retain the gills through life, accompanied with pulmonic cavities, from which the arterialised blood is sent to a small left auricle. These animals are termed *amphibia* from the metamorphosis to a terrestrial from an aquatic life seen in most of the species. Their skeleton is imperfectly consolidated, their ribs very short or wanting, their pelvic arch free or nearly so, and their atlantal and sacral extremities often very imperfectly developed or partly deficient. Their toes are destitute of claws, as their skin is of scales, and the respiration through their naked, highly sensitive, and secreting surface compensates for the imperfect development or limited use of their lungs, especially during submersion or hybernation. Some reside constantly in the water, others occasionally, and others continue on land. The male organ of intromission is rarely developed, and impregnation of the ova is generally effected externally. The genital organs are double and symmetrically developed in both sexes. The perennibranchiate amphibia, especially the axolotl, have been shown by Weber to possess a double auricle like the caducibranchiate species. (See Amphibia.)

21. *Reptilia*, cold and red-blooded, oviparous, vertebrated animals, with two auricles and one ventricle, not breathing by gills in their young state, covered with scales, and with the means of internal impregnation. These animals, whether aquatic or terrestrial, breathe only by means of lungs, and their pulmonic respiration and the left auricle of the heart are

greater than in the amphibia. Their bones are more consolidated than in the lower vertebrata, their pelvic arch, when developed, is more firmly attached to the vertebral column, the centres of ossification, especially of the cranial bones, generally remain detached, the extremities are for the most part more competely developed, and the toes are generally provided with claws. Their cerebellum is remarkably small, their muscular irritability languid, and they have great tenacity of life. This ventricle, which receives both the venous and arterialised blood, is more or less divided by an ascending imperfect septum. The thoracic and abdominal cavities are not separated by a muscular diaphragm, and the lungs extend backwards over the abdominal viscera. Their organs of generation are double in both sexes, and symmetrically developed on the two sides of the body. The two portions of the corpus cavernosum are often detached and bifid; the chorion of the ova is generally thin or coriaceous, seldom calcified or hard, and the instincts of the parent generally extend to the protection of the young. (See Reptilia.)

22. *Aves*, warm and red-blooded, oviparous, vertebrated animals, with four cavities of the heart, covered with feathers, and with their arms organized for flight. Their bones are the most compact and dense in texture, the most extensively anchylosed, and generally contain air admitted from the cells of the lungs. Their tympanic bone is moveable, they have horny mandibles in place of teeth, their coracoid bones reach the sternum, the sternal ribs are ossified, and they want the tarsal bones. Their diaphragm never forms a complete partition between the thoracic and abdominal cavities. The hemispheres of the brain are without convolutions, the optic lobes are large and hollow, the cerebellum is large and sulcated, and the posterior enlargement of the spinal chord of great size. The great irritability of their muscular system corresponds with the great extent of their respiration, the high development of their nervous system, the rapidity of their circulation, and the increased energy of all their functions. Their alimentary canal is furnished with a crop, a glandular infundibulum, a gizzard, and generally with two cœca-coli, as seen in the annexed diagram (*fig.* 47), showing the

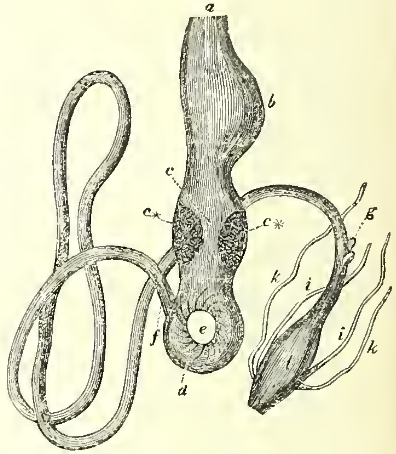
Fig. 47.



common form of these parts in a gallinaceous bird. In these gallinaceous birds the œsophagus (*a*) sends out at a right angle with its course a large crop (*b*), with a contracted neck, and supplied with glandular follicles. Beneath this is the infundibulum or glandular stomach (*c*), with numerous large follicles placed between the mucous and muscular coats, and this opens into the large muscular gizzard (*d*), provided externally with two strong digastric muscles (*e*). The cardiac and pyloric orifices of the gizzard are close to each other (*f*), and towards the lower part of the small intestine a minute cœcum often indicates the original entrance of the yolk-bag. The two long cœca-coli (*g*) commence by narrow entrances (*h*), and the short colon ends in a common cloaca (*l*) for the genital and urinary secretions.

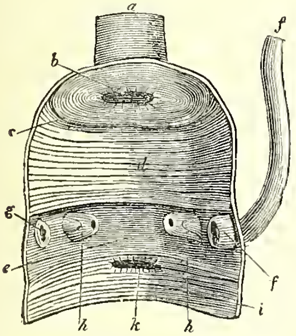
In the predaceous birds, as the eagles (*fig.* 48), the œsophagus (*a*), the crop (*b*), the infundibulum (*c*), and the gizzard (*de*), are capacious, thin,

Fig. 48.



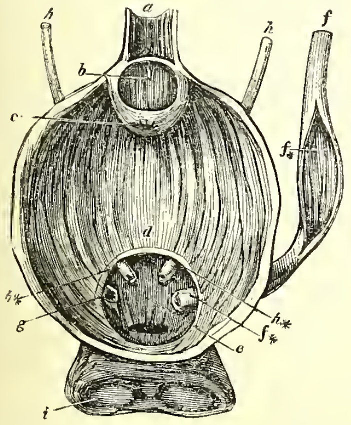
and membranous, and form a continuous cavity for the prey, from which the indigestible parts can be thrown out in a bolus. In these birds the cœca-coli (*g*) are very small, sometimes unequal, or wanting. The urinary (*ii*) and genital organs (*kk*) enter the cloaca (*l*) near the anus. The right ventricle of birds has the tricuspid valve in form of a thick strong muscular fold, and the aorta descends on the right side. The lungs form two undivided, light-coloured lobes, fixed by pleuræ to the back part of the trunk, the last rings of the trachea form an inferior larynx, the bronchi pass in a membranous form through the lungs, and the lungs open into large membranous abdominal air-cells, which communicate with the interior of the bones. This extensive aeration of their systemic as well as their pulmonic vessels gives energy to their muscles for their aerial life and their distant migrations, and a high temperature to their body for the incubation of the egg. Their plumage and their downy covering are the best suited for their aerial life and their high internal heat. Their organs of generation are double and symmetrical in the male, and generally unsymmetrical in their development in the female. The testes are internal, and the vasa deferentia terminate in the cloaca, where there is sometimes a grooved organ of intromission. In the female the left ovary and oviduct are developed, the right for the most part atrophiated and useless. The cavity of the cloaca in most birds, as seen in that of the great *condor* of the Andes (*fig.* 49), receives the end of the rectum (*a*), which forms a wide

Fig. 49.



rectal vestibule (*b*): beneath this lies the part analogous to the urinary bladder (*c d*). Lower than the urinary sac are found the two openings of the ureters (*h h*), with the pervious oviduct on the left side (*f*), and the remains of the impervious oviduct (*g*) on the right side. The *bursa Fabricii* and the clitoris (when present) are placed more posteriorly in the preputial cavity. The most distinct forms of these generative and urinary parts, and the nearest approach to the mammalia are seen in the cloaca of the ostrich (*fig.* 50), where the rectum (*a*) opens into a wide and distinct rectal vestibule (*b*), which extends into a large urinary bladder (*d*). Beneath the urinary bladder is the urethro-sexual canal (*e*), into which the two ureters

Fig. 50.



(*h h h* h**) and the oviducts (*f f* f* g*) open towards the dorsal and lateral part. The preputial cavity (*i*) is the terminal portion in which the distinct clitoris is here lodged. The ova are impregnated internally, their chorion is calcified, and their development is effected by incubation. (See Aves.)

23. *Mammalia*, warm and red-blooded vertebrata, having four cavities of the heart, with a viviparous mode of generation, and possessing mammary glands; with the lungs free in a distinct thoracic cavity, and generally having the body more or less covered with hair. The bodies of their vertebræ unite by flat surfaces, the tympanic bone is fixed, the jaws are generally furnished with teeth lodged in deep alveoli, the coracoid bone rarely reaches the sternum, and the posterior extremities, when present, are always attached by the pelvic arch to a solid sacrum. The thoracic and abdominal cavities are separated by a muscular diaphragm. The hemispheres of the brain contain large ventricles, and rarely want convolutions, the optic lobes are small, concealed, solid, and divided by a transverse sulcus, the commissures of the brain and cerebellum, and the hemispheres of the cerebellum are large. The alimentary canal is of great length, the colon long and wide, with a single cœcum, and sometimes with a vermiform appendix, and the anal opening is generally distinct from the urinary and genital passages. The tricuspid valve is thin and membranous, the aorta descends on the left side, there is no inferior larynx, the epiglottis is distinct, and the bronchi continue cartilaginous into their ramifications in the lungs. The lungs, generally divided into lobes, move freeely in a distinct thoracic cavity, and have no abdominal cells or perforations on their surface, as in birds. There is always a urinary bladder, and the urethra in the male passes through a tubular penis. The organs of generation are double in both sexes, symmetrical in the male, and rarely unsymmetrical in the female. The oviducts commonly unite at their lower part to form a uterus, in which the ovum becomes again connected with the parent, and is hatched. There are mammary glands opening externally for lactation during the helpless condition of the young. (See Mammalia.)

These are the primary and secondary divisions of the animal kingdom, the structure, classification, and history of which it is proposed to consider in this Cyclopædia, under the heads of the several classes as enumerated in the subjoined table.

ANIMALIA.

I. Sub-regnum, Cyclo-neura vel Radiata.
- Classis 1. Polygastrica.
- 2. Porifera.
- 3. Polypifera.
- 4. Acalephæ.
- 5. Echinoderma.

II. Sub-regnum, Diplo-neura vel Articulata.
- Classis 6. Entozoa.
- 7. Rotifera.
- 8. Cirrhopoda.
- 9. Annelida.
- 10. Myriapoda.
- 11. Insecta.
- 12. Arachnida.
- 13. Crustacea.

III. Sub-regnum Cyclo-gangliata vel Mollusca.
Classis 14. Tunicata.
15. Conchifera.
16. Gasteropoda.
17. Pteropoda.
18. Cephalopoda.

IV. Sub-regnum Spini-cerebrata vel Vertebrata.
Classis 19. Pisces.
20. Amphibia.
21. Reptilia.
22. Aves.
23. Mammalia.

For the BIBLIOGRAPHY of this article see that appended to each of the articles on the classes of animals and COMPARATIVE ANATOMY (*Introduction.*)

(*R. E. Grant.*)

ANIMAL (from anima, breath, the living principle. Lat. *animal.* Gr. *ζῶον.* Fr. *animal.* Germ. *Thier.* Ital *animale*). The objects of the material universe were long considered as arranging themselves naturally into three grand divisions, or *kingdoms*, as they were called: the animal, the vegetable, and the mineral. Closer attention, however, and a more careful study of the qualities and actions of the various bodies composing these kingdoms, lead to the conclusion that two of them have much in common, and consequently that a two-fold division suffices to comprehend the whole of the objects in nature,—these are the inorganic, or lifeless, and the organic, or living; the first embracing minerals, fluids, gases, or the various forms in which simple brute matter presents itself to our observation; the second including vegetables and animals.

As the subject ANIMAL may be regarded in the light of the very kernel and epitome of the entire matter treated in the pages of our Cyclopædia, we shall give such extension to this head as its importance seems to demand, studying brevity nevertheless, and embracing in general views the particular points which will be illustrated in detail in the different articles on anatomy and physiology, human and comparative.

COMPARISON OF THE ORGANIC AND INORGANIC WORLDS.

Physical qualities and elementary composition of unorganized and organized bodies.—The organic and inorganic kingdoms of nature are distinguished from one another by many strong features of difference,—first, in reference to their general physical qualities, external form, volume, and elementary composition; and second, in regard to their capacities of action.

The *forms* of the objects composing the inorganic world, indeterminate when they are considered in their masses, are reducible to a very few simple crystalline shapes when they are regarded in their parts. The cube, the hexahedron, the rhomb, the prism, &c. are the elementary forms of the inorganic world: plane surfaces and straight lines uniting under different inclinations, and originating angles that measure certain determinate numbers of degrees are the *accidents*, which give them their characteristic and individual shapes.

But the inorganic world has not absolutely even this limited perfection of form, if the expression may be allowed. In order that the objects which compose it may exhibit themselves under the form of crystals, solution of some kind, rest, time, and space are required; and these or any of these being denied, the objects of the unorganized world present themselves or exist as simple aggregates of molecules, shapeless in their component parts as in their masses. And further, even when the objects of the inorganic world do present themselves under definite forms, these are not necessary and invariable. Carbonate of lime, to take a single instance, occurs crystallized not only in rhombs, but in hexahedral prisms, in dodecahedrons, the several faces of which are pentagons, in solids terminated by twelve triangles with unequal sides, &c. In their material composition, too, unorganized bodies are essentially homogeneous: one part of a mineral does not differ from another.

This is very different from what occurs in the world of organization. From the lowest to the highest of living beings the shape is determinate for the individual, not only as a whole, but even as each of its component parts is concerned. Instead of being circumscribed within angles and right lines like the objects of the inorganic kingdom, those of the organic are mostly rounded in their forms, or they are branched, or articulated and made up of several parts, which present varieties of conformation in harmony with the kinds of offices they have to perform, or the conditions surrounded by which the beings thus fashioned exist. Neither do they consist of homogeneous particles like minerals, but are made up in general of heterogeneous parts: in plants we have roots, leaves, branches, flowers, &c.; in animals muscles, nerves, bones, and a great number of organs besides, each itself reducible to a variety of simpler parts or elements, entitled tissues.

The organic world also presents an immeasurably greater variety of forms than the inorganic: the myriads of animals and vegetables that people and possess the earth differ to infinity from each other in their forms and physiognomies.

Size.—Neither is there less discrepancy between the inorganic and the organic world in the quality of size, which, in the first, is perfectly indeterminate, being greater or less, simply as the constituent molecules happen to be aggregated in larger or in smaller numbers. The volume of organized bodies, on the contrary, is determinate; every animal, every vegetable, has a particular stature, a certain bulk, which is that of its species also, and is within narrow limits alike in regard to all the individuals composing the kind.

Composition.—Contrasted in their chemical nature, organized and unorganized bodies present numerous and striking points of dissimilarity. Modern chemistry enumerates no fewer than fifty-two elementary or simple substances,* besides the imponderables — light, caloric, and electricity. The whole of these are met with in the mineral or inorganic world; but no more than nineteen of them have been detected in the constitution of organized bodies.† Six of this number, indeed,—oxygen, hydrogen, carbon, azote, phosphorus, and calcium, occur in such abundance as to compose almost the whole mass of organized bodies; the remaining thirteen are met with but sparingly distributed, and some of them even appear to be adventitious, and by no means essential to the constitution of the bodies in which they are encountered.

Speaking generally, the chemical composition of inorganic objects may be stated to be the more simple, many of them consisting of a single element only, and when more compound generally presenting binary, and at most ternary combinations of known elements. Organized bodies, on the other hand, are never made up of single elements, they are not even binary combinations, vegetables in the aggregate being at least ternary, and animals at least quaternary compounds. Though the elements which compose inanimate objects, therefore, are more numerous, the combinations they enter into are less complex than those they form in the constitution of living things.

Another difference in the chemical constitution of unorganized and of organized bodies consists in the *mode* or *form* in which the chemical elements exist in each. In the former they present themselves *immediately* as it were, the chemist in his analyses coming upon them at once; in the latter they occur under two forms, the one immediate as in minerals, the other *mediate*, or arrauged under a variety of new and peculiar shapes, which, with reference to the bodies they mainly constitute, are conveniently and fairly spoken of as *elements*, with the prefix organic, they being exclusively the products of life and organization; these are also frequently spoken of as the *immediate principles* of vegetables and animals.

In the inorganic world, again, the constituent elements of bodies are always united by virtue of, and in harmony with, the general laws of chemical affinity, whilst in the organic the compounds formed are very often even the opposites of those that would have been originated under the dominion of these laws. From this it comes that, whilst the chemist finds almost as little difficulty in recomposing as in disintegrating inorganic objects, he has hitherto failed in compounding any one of the higher organic products or immediate principles of plants and animals.* Chemical analysis we may therefore imagine to be a process of a very different nature as applied to inorganic objects from what it is when applied to organic substances. With reference to the former it signifies a simple disintegration, with an inherent capacity in the elements separated to reunite into the compound analysed; in the latter it constantly implies destruction, without any such continuing power of recombination among the constituent elements. Chemical synthesis, consequently, is an expression that can only be logically used in connection with inorganic objects.

Considered with reference to their intimate texture, organized beings are no less strikingly different from unorganized bodies. The last are either solid, or fluid, or gaseous; they never occur commingled, each subserving the existence of the other. The water of crystallization, and the globules of this and other fluids occasionally found included within the substance of minerals, are but adventitious, being in the first instance entangled among their component molecules, in the second imprisoned within accidental cavities in their substances but contributing in nowise to the existence or duration of the matter that surrounds them. Organized bodies, on the other hand, consist uniformly of solid and of fluid parts: whilst the vegetable has its woody fibre and constituent parenchyma, it has its sap also; and animals with their firmer bones, muscles, cellular substance, &c. have likewise blood circulating through their bodies, or various fluids deposited within their tissues, which are just as essential to their constitution and continuance as the containing parts themselves. It is even by the mutual play of the solids and fluids which enter into the composition of organized beings that they manifest themselves in action or exhibit the phenomena which are peculiar to them, and which we denominate vital. It were indifferent whether we took away the solids (were such a thing possible) or the fluids of a vegetable or an animal; in either case it must perish. The solids and fluids of organized beings consequently are in intimate and inseparable relationship one with another.

Consistence.—From this admixture of solids and fluids in the world of organization results the variety of *consistence* which its objects present. In the inorganic kingdom, *rigidity*,—rigidity, too, which is uniform,—is one of the distinguishing characteristics. In the organic, on the contrary, *pliancy* and *softness*, which vary as well in every individual as in almost

* Oxygen, hydrogen, carbon, phosphorus, sulphur, borium, silenium, iodine, fluor, chlorine, bromine, azote, silicium, zirconium, aluminium, yttrium, glucynium, magnesium, calcium, strontium, baryum, potassium, sodium, lithium, manganese, zinc, iron, tin, arsenic, molybdenum, tungsten, columbium, chromium, antimony, ciranium, cerium, cobalt, titanium, bismuth, cadmium, copper, tellurium, lead, mercury, nickel, osmium, silver, gold, platinum, palladium, rhodium, and iridium.

† Oxygen, hydrogen, carbon, azote, phosphorus, sulphur, iodine, bromine, chlorine, fluor, silicium, aluminium, magnesium, potassium, sodium, calcium, manganese, iron, and copper.

* The exceptions to this position are scarcely worth noticing—one or two of the more simple organic elements, oxalic acid and urea, for example, have been formed synthetically, and a substance bearing a remote affinity to fat has also been produced. No one, however, has ever succeeded in forming fibrine, neurine, fecula, gum, &c. synthetically.

every part of the same individual, are no less strongly marked and inherent features. Solidity or hardness may be looked upon as the term of perfection of a mineral; softness, on the other hand, often appears to be the term of perfection among vegetables and animals, the parts in these being generally softer in proportion as they have more important or noble offices to perform. The tender fibrils of the root, the leaves, flowers, stamina and pistilla in plants; the brain, vessels, viscera, &c. in animals, are softer than the bark and woody fibre, than the bones, ligaments, skin, &c. which form, as it were, but the frame and covering of the proper fabric. This quality also varies in the organic world according to the age of the individual: the nearer any organized being is to its birth or origin, the softer will it generally be found to be; the longer it has lived, the harder will it as uniformly be ascertained to have become. Many organized beings, indeed, in the first stages of their existence, are wholly fluid; they only acquire consistence as they are evolved and approach maturity.

It is almost needless to speak of the extent to which inorganic bodies differ from organic in these respects; they are rigid and hard in all their parts alike, and never vary in consistence from the moment of their formation to that of their disintegration or decomposition.

The *elementary particles* or *molecules* entering into the composition of organized and unorganized objects, also differ in their essential nature. All organized beings, in fact, whether their solids or fluids are regarded, appear to be made up of or to contain globular or oval and sometimes flattened corpuscles. The simplest plants,—the confervæ, tremellæ, &c., and the simplest animals,—the infusoria, polypi, &c., are alike composed of globules and a fluid; nor is the case different as regards the most complicated vegetable or animal that exists. The elementary globule has now been discovered in almost all the solids and fluids both of vegetable and of animal bodies,—in the sap and cambium or succus proprius of vegetables, and in the blood, chyle, milk, and other fluids of animals; in the fecula, albumen, parenchyma of the leaves, cells of the flowers, &c. of plants, and in the cellular membrane, muscle, brain, nerve, gland, &c. of animals.

Nothing of the same kind has yet been detected among inorganic bodies. Angular particles separable to infinity into others of a like description are the elements of composition in minerals.

Globules, then, are to be regarded as the elementary constituents of organized bodies, as the ultimate molecules possessing a distinct form, which by their aggregation compose them. The first step, indeed, in the singular process by which infusory animals are eliminated during the decomposition of organized substances, is the formation of globular corpuscles; these, by their subsequent aggregation in some cases and individual evolution in others, appear to give birth to the organized atoms that by-and-by make their appearance; and, as we have said, globules are now admitted to form the basis of the different tissues which enter into the composition of the very highest among animals. These various tissues, in fact, would seem to result from the different modes in which the elementary globules are disposed; and it is not improbable that the difference of function they exhibit may yet be found in harmony with, and perhaps depending on, peculiarity of arrangement in their constituent molecules.

This aggregation of the organic molecules into a variety of tissues and peculiar organs forms another essential feature of difference between the organized and the unorganized world. Minerals, indeed, as they manifest no variety of phenomena analogous to those of life, required no diversity of elementary constitution in their different parts; they are consequently homogeneous. In minerals the component molecules are arranged in layers placed one upon another, so that their crystals can be readily cleft in a variety of directions, according to the elementary arrangement of these. In vegetables and animals, on the other hand, the constituent molecules always form tissues, the fibres of which interlace or cross one another; in no living or organic thing do we observe aught similar to what is called the cleavage in minerals.

From this it comes that minerals are as complete in their parts as they are in their masses: the minutest spark of carbonate of lime has all the properties of a crystal of this substance, were it as large as a mountain. The case is very different in regard to organized beings; these consist of a number of organs, the sum of whose actions constitutes the peculiar vitality of each being, and no individual part or organ enjoys capacity to manifest itself abstractedly from the system to which it belongs. All the parts of organized bodies are mutually enchained by bonds of the strictest causality; this even follows necessarily from the manner in which they originate and are evolved. The radicle that bursts from the fecundated seed of a plant determines the growth of the stem, which subsequently and in its turn plays the same part with reference to the leaves and flowers,—the parts that appear first are the cause of the appearance of those that follow at later stages. No relation of this kind exists among inorganic bodies. When a crystal is formed in the midst of a fluid, the particles composing it unite, in conformity with the mere laws of cohesion and affinity, not in consequence of any determining influence in the particles which cohered the first,—each stage or period of the process of crystallization is independent of that which preceded it. Whilst the parts of an inorganic body, therefore, can exist with all their qualities, as well in a state of disintegration as in one of aggregation, the component parts of organic bodies can only exist with their distinguishing properties when united to the entire being. Individuality in the organic world, far from existing in the integral molecule as it does in the inorganic, can only be said to exist in the mass of integral molecules united into that congeries of organs which constitutes a particular being. As a consequence of this independence on the one hand, and dependence on the other, we find, that whilst in the inorganic world the several parts may be modified without the others feeling the influence of the change induced, in the organic, implication of one part and modification of one action are communicated to and manifested in the state and actions of all the other parts.

Considered with regard to their *duration*, the objects composing the organic and the inorganic world differ essentially. In the former this period is determinate and definite, and, although it varies greatly, it depends in a great measure on circumstances inherent in the individuals; in the latter it is indeterminate and indefinite, and when the objects composing it cease to be, it is generally in consequence of circumstances exterior to themselves. Organized beings exist for a limited time and in opposition to many of the physico-chemical laws; unorganized beings exist indefinitely, and only in harmony with the whole of these laws. Organic beings continue to exist in consequence of a kind of reciprocal action with external things, and especially by virtue of an incessant change and renewal in their constituent elements. The very condition of existence of an unorganized body is quiescence; any new action between its molecules themselves, or between these and others external to them, any addition to, or subtraction from, its component parts, implies the destruction of its individuality.

In the organic world, new forms result from the actions of forms already existing, which have the wonderful property of producing others similar to themselves; and this in virtue of no general physico-chemical law, but of an especial power inhering in each organized being individually. There is nothing like this faculty of *procreation* or of *generation* in the inorganic world. When a crystal is produced, it is necessarily at the expense of one or of others that have already existed, or of a combination of the elements of these; destruction is here a necessary preliminary to production, and the process is simply one of *re*-formation, not of *genesis* or creation. Neither in the *re*-formations of the inorganic world do we find that the forms are always necessarily the same as those which preceded them: the crystalline form does not depend on the nature of the integral molecules, but on their mode of aggregation and number. In the organized world, again, nothing is more certain and fixed than that the form of the new being shall resemble that which gave it birth.

The last distinction we shall mention under this head of material composition and physical qualities between organic and inorganic bodies is, perhaps, less striking, though not less interesting on that account: it is this,—that whilst in inorganic bodies the composition is quite determinate, in organised beings, although constituting particular species, the composition may present individual differences or modifications. These are designated by the titles *temperament, constitution, &c.* There is no corresponding modification recognizable in the inorganic world.

From what has now been said, it appears that organized and unorganized bodies differ essentially from one another in their general physical qualities and material constitution. The form of the organized being is determinate, and its outline is rounded or undulating; its size is limited; its duration is temporary; its composition is an assemblage of heterogeneous parts, of solids and fluids, arranged so as to compose a variety of fibrous and cellular tissues, and aggregates of *organs* or parts differing from one another in their form, structure, and functions, but all nevertheless mutually dependent one upon the other, and concurring to a common end,—the preservation of the individual, which has place by virtue of an internal activity denominated *life*, amidst incessant changes and renovations of the matter entering into its composition, and the continuation of the species, which is a genesis or creation, implying neither destruction nor alteration in the mode of being of the individual or individuals from whom the new formation springs.

Actions of unorganized and of organized objects.— But form, size, material composition, duration, mode of origin, &c. are not the only particulars in the history of organic and inorganic bodies which are capable of being contrasted, and in which differences may be made to appear.

All that exists is *active;* every entity performs *actions*, or manifests forces by which its own existence is continued, and by which it participates in the various phenomena of the universe. Of these actions or forces there are two grand classes, the one *general*, the other *special:* the first are the physico-chemical laws which pervade space and include the universe; the second are the vital laws, which embrace within their dominion plants and animals, or things organized and having life.

The most general of all the forces possessed are those of attraction and repulsion, which inhere in, and are manifested by, all existing things, organic as well as inorganic. Every object gravitates or has weight, coheres in its several parts, exhibits chemical affinities, and yields to the expansive influence of caloric. Inorganic objects exhibit these general forces alone, and are absolutely under their control. Organized bodies are also subjected to the same general forces; but they are often modified, nay, they are sometimes even abrogated and set at nought by vegetables and animals alike, in virtue of the special powers inherent in themselves. These special powers have, in fact, the singular property of subtracting, in various degrees, the beings they actuate from the influence of the general laws of creation. Instead of obeying the universal law of gravitation, vegetables, for instance, shoot upwards, and propel their juices from the roots to the leaves; animals also distribute their blood in opposition to the laws of gravitation, and by their powers of motion overcome the universal physical law that tends to fix them in one place. The force of cohesion is not a merely passive property in the organized as it is in the unorganized world, and the laws of chemical affinity are especially set at nought both by plants and animals, their constituent elements being even generally united into combinations the contrary of those which these laws ordain. Animals and vegetables are farther abstracted from the general law of caloric, the more perfect of them at least having a specific temperature, independent of that of the medium which surrounds them, and which varies in conformity with changes in the peculiar actions of which in them it is the product.

There is even a distinction between the organized and unorganized world to this extent, —that while the physico-chemical laws dominate the inorganic world rigorously, and the bodies that belong to it seem to have begun to be as they continue to exist through, or in harmony with, their prescriptions, no organized body known has either sprung into being or continues to exist through the agency of purely physical or purely chemical forces. The whole of the special properties of organized beings consequently must be held to be effects of the agent denominated *life*, and of the laws which this agent originates. The organized world is, therefore, a creation within a creation, a something superadded to the material universe and to the generally pervading forces that keep its parts in their places, and endow them with what may be called their necessary properties.

Nor is it only whilst endowed with life that organized differ from unorganized beings. Many of the distinguishing and peculiar properties of these remain for a season at least after life has left the organization it had built up. The extensibility and elasticity of the tissues of animals especially, were held by the distinguished Bichat as even independent of life, which he owned increased their energy, but which he denied as their cause, seeing that they continue to exist after death. These properties are undoubtedly peculiar, and are at all events effects of forces which life has called into play, both the tissues which possess elasticity and contractility, and these qualities themselves having been engendered under the influence of vitality.

In these properties, forces or capacities of action common to all the objects of nature, unorganized as well as organized, we see the objection to the old denomination of *inert*, which was applied to one of the great classes. Nothing that exists is inert or inactive; but organized have an infinitely wider field of action than unorganized bodies. Let us, in illustration of this position, examine in succession the various actions by which bodies generally *originate*, *continue their existence*, undergo such *modifications* as they present in the course of their existence, and by which they *come to an end* or *die*.

Origin.—Unorganized bodies, minerals for example, commence their existence from the instant that circumstances exterior to themselves detach them from the mass of some other mineral, precipitate them from a state of solution in a fluid, or bring their constituent elements into a position in which they can combine together. In this, it is evident, there is nothing like *generation*, as the term is applied to organized bodies, which all alike, vegetables as well as animals, spring from a molecule, an atom, which has once belonged to, and which has proceeded from, a being similar to themselves. Vegetables spring from seeds, animals from eggs. Organized beings, therefore, are *engendered*, their existence is a consequence of that of other beings like themselves; and in their succession they depend one upon another. Minerals, on the contrary, have no powers of reproduction; they cease to be, if at any time they originate another mineral, and they are individually in a state of perfect independence.*

In the mode in which organic and inorganic bodies *continue their existence*, there is also a striking dissimilarity. In the inorganic world we observe no actions tending to preserve the individual, other than those which have presided over its formation: it continues to exist through the continuing agency of the affinities and of the attraction of cohesion which called it into being. Animals and vegetables, on the contrary, have special powers for their preservation superadded to those by the peculiar

* It were long to enter here into the discussion of what has been called *equivocal generation*, which, if admitted, militates against several of the inferences just deduced. It is quite certain that infusions of any organized substance do speedily become filled with animals distinct in their kinds and lately shown to be much more complicated in their structure than was long supposed. It is almost as difficult to conceive that these infusory animals proceed from eggs contained in the fluids in which they appear, as to imagine that they proceed from the combination, *per se*, of their constituent elements. Did we incline to admit the reality of equivocal generation, it is certain that its occurrence must be referred to other than the general laws of nature, with which we have already had occasion to show the laws of life to be in opposition, much rather than in harmony. It would be absurd to believe that these general physico-chemical laws, absolutely inimical to life, should at any time call it into being. Equivocal generation being acknowledged, therefore, it would seem necessary to infer a third order of laws besides the physico-chemical and the vital, the nature of which is altogether unknown to us. The number of creatures which were presumed to owe their being to equivocal generation, has been very much curtailed by the progress of science in modern times; and it is not impossible that the mystery which still overhangs the genesis of the infusoria may one day be dissipated, and their production demonstrated to be in harmony with those laws which are known to preside over the origin of higher classes of vegetables and animals.

agency of which they have been created. Inorganic bodies exist through the absence of all change in their interior; organized beings exist by force of change: there are two processes, one of renewal, the other of decomposition, perpetually going on within them; they are continually appropriating from bodies exterior to themselves a quantity of matter which they have the singular faculty of elaborating into their proper substance, and they have at the same time the power of withdrawing portions of the matter which already forms them, and rejecting these from their interior as no longer fitted for their preservation. Vegetables, by means of their roots and their leaves, draw from the earth and from the air materials which they elaborate into juices fitted for their nourishment, at the same time that they throw off, especially by means of their leaves, a portion of the matter which had been absorbed, either as superfluous or as improper to enter into their composition. In the same manner animals appropriate to themselves various amounts of matter in the shape of atmospheric air and food, from which they prepare a fluid proper for their maintenance, at the same time that they, by virtue of peculiar processes, withdraw from their bodies such portions of matter as have already fulfilled their destination, and cast them out under the form of excretions. Organized bodies, consequently, are preserved as individuals by a process of *nutrition*, a process which implies dependence on other bodies, and alternate appropriation and rejection of the particles of these; the existence of an organized being, in fact, only concurs with the presence and appropriation of substances external to itself, with a perpetual accession of matter on the one hand, and of its rejection on the other, whilst unorganized bodies are more certainly continued, as their state of isolation or abstraction from all external influences is more complete. Organized beings, in a word, continue to exist by virtue of certain inherent especial powers; unorganized simply by virtue of the general powers that pervade the universe in harmony with which they were originally framed.

The *modifications* undergone by organized and unorganized bodies are peculiar and characteristic in each class. In the first place modification or change is no necessary condition to the existence of an unorganized body, as it is of one that is organized. A mineral in a state of complete isolation might remain eternally unchanged; a plant or an animal, on the contrary, cannot be conceived as existing for a moment abstracted from the universe around it, and without undergoing change. A mineral, in the instant of its formation, acquires all the properties that distinguish it at any after-stage of its existence; in plants and animals, on the other hand, as we witness an origin, so we observe a series of modifications denominated *ages*,—they commence their existence, they increase in size, they attain maturity, and they decline and ultimately die.

Any change which unorganized bodies exhibit is accidental, and happens under the influence of agencies external to themselves; the changes which organized beings undergo in the course they run from incipience to their end, are on the contrary necessary, and take place in consequence of powers inherent in themselves.

Any change which an unorganized body experiences happens on its surface: its mass is increased or diminished by simple addition to or subtraction from its particles; it does not increase, neither does it shrink and decay in all its parts like plants and animals, in which increase and diminution take place at one and the same time from within and from without. Increase in the unorganized world happens through *juxta-position*, in the organic through *intus-susception*. Organized bodies, consequently, as they alone are *generated*, as they alone possess powers of *self-preservation* and of *reproduction*, so do they alone *grow*, advancing necessarily from *infancy* to *maturity* and *old age*, or exhibit what are called *ages*. (See AGE.) Organized bodies further meet our observation in two different states,—those, namely, of *health* and of *disease*, nothing corresponding to which is encountered in the inorganic world.

Whatever has a beginning has also an *end*. But the mode in which organized and unorganized bodies cease to be, and the influences that determine their periods of being, are extremely different. A mineral ends when the affinities that combined it, and the attraction of cohesion that held its particles together, are overcome. This language implies that its destruction is effected by agencies external to itself—by the action of other bodies, and of circumstances over which it has no controul. The destruction of a mineral is, therefore, in nowise *necessary*, neither is it *spontaneous*: abstract a mineral, as we have said, from all external agency, and its endurance is indefinite.

Very different is the case with regard to animals and vegetables; as their continuance depends on the process of nutrition, their end hangs upon the cessation of this act; and as the tenure by which they enjoy existence is temporary, the machine of organization being calculated to endure but for a season, their *death* or destruction is both *spontaneous* and *necessary*. Organized bodies which alone owe their being to *generation*, which alone *continue their existence*, *reproduce* their kinds, *grow*, *attain maturity*, and *become aged* by virtue of powers inherent within themselves, so do they alone *die*.

The period of endurance of unorganized bodies may often be calculated approximatively according to their masses, their densities, the aptitudes of their elements to enter into new combinations, &c.; that of organized bodies cannot be inferred from these or any other merely mechanical principles. Indeed, data from which the duration of organized bodies may be estimated are altogether wanting. We only know that every species has within narrow limits a period which it cannot pass; but why this period should, in particular instances, be confined to a few weeks, months, or years, or be extended to centuries, we cannot tell.

Nor is it only whilst endowed with all their peculiar and inherent properties that organized differ from unorganized bodies. No longer manifesting their especial powers, organized bodies begin to be disintegrated; their constituent elements, held together in opposition to the laws of chemical affinity, become amenable to these, and forthwith enter into new combinations, which imply the utter destruction of the organization as it had been formed, and hitherto preserved. Organized beings, as they alone *die*, so do they also alone undergo *putrefaction*— a process nothing precisely similar to which occurs in the inorganic world.

From this review of the distinguishing peculiarities of organized and unorganized bodies, it appears that organization implies vitality, and that organization and life are inseparable conditions. It would be going too far to say that they were synonymous terms: *organization* is the mode of structure proper to living beings; *life* is the series of actions they exhibit. And this in fact appears to be about the least objectionable definition of life than can be given: *life is the series of actions manifested by organized beings;* would we go farther, we must condescend upon an enumeration of these actions,—namely, incipience by a *genesis* or creation; temporary endurance as individual by *nutrition*, and indefinite continuance as species by *reproduction*, modification during the term of existence known by the title of *age*, and end by *death*, to which specific acts or phenomena must be added the peculiar inherent power which living beings possess of overcoming the general physico-chemical laws that dominate the rest of the universe.

Thus far we have discussed and contrasted the physical qualities and phenomena common to organized or living beings at large, with such as inhere or are manifested by unorganized bodies generally, more especially minerals; we have still left untouched those that severally pertain to the two grand divisions of the organized world, and that are peculiar to each living thing individually; and here we shall find that the manifestations of vitality are almost as various as the species that people the earth. In the same manner as we have hitherto gone on contrasting first the material composition, and then the actions of organic and inorganic bodies, we shall still proceed by comparing the material composition and the capacities of action of the different classes of organized beings first, and next of the several individuals composing these classes one with another.

Comparison of animals and vegetables.

Animals and vegetables were longheld essentially and irreconcilably distinct from one another. We have already had occasion, however, to observe in how many particulars they are identical. The material composition of both is often in opposition with the general physico-chemical laws, both are made up of a combination of solids and fluids, both consist of a variety of heterogeneous parts, and both have determinate sizes which they cannot exceed. Moreover, both are possessed of vitality,—in other words, both commence by a genesis, preserve themselves as individuals by nutrition, and as species by reproduction; both grow by intus-susception, undergo the mutations which are denominated ages, endure for a time, present themselves in health or labouring under disease, and both decay and die. How intimately animals and vegetables are associated, how nearly they resemble one another, will farther appear as we advance in the following

Comparison of the general physical qualities and material composition of Vegetables and Animals.—As a general axiom the material constitution of vegetables may be said to be less complex than that of animals; this at least is more especially the case as the individuals at the top of the two scales are concerned.

No distinguishing feature of either class is derivable from general diversity of *Size*. Between the microscopic lichen and infusory animal, and the gigantic adansonia and whale, plants and animals of every intermediate magnitude are encountered.

Neither is there much to be said upon the differences which vegetables and animals present when their *Forms* are contrasted. The forms of many are alike amorphous, or simply globular; certain pulverulent fungi in the one class, and monads in the other, resemble each other greatly. Among both, individuals also occur whose parts are disposed around a centre; yet we do not advance far before we discover a peculiarity in animals, namely, composition by the union of two similar or symmetrical halves along a middle line or axis, nothing similar to which has even been imagined in the vegetable world, the members of which on the contrary often exhibit a horizontal division, but without anything of symmetry, into root and branches. As a general law the animal kingdom may be said to affect the globular or simply produced form, with radii in the shape of extremities sent off from a central part; the vegetable to exhibit a greater tendency to ramification or division into branches.

In point of *chemical composition* animals and vegetables consist very nearly of the same elements: oxygen, hydrogen, carbon, nitrogen, phosphorus, sulphur, iodine, bromine, chlorine, potassium, sodium, calcium, silicium, magnesium, manganese, and iron have been detected in both; aluminium and copper have hitherto only been discovered in vegetables, and fluor only in animals. But these elements are united in each in very different relative proportions. Carbon predominates greatly in the more solid parts of vegetables, nitrogen in the bodies of animals generally, although to this rule there are many notable exceptions; albumen, fibrine, and gelatine all contain much more carbon than nitrogen, and certain fungi include a very large proportion of nitrogen in their composition. Several elements, met with abundantly in animals, occur but sparingly distributed among vegetables, phosphorus, for example, and sulphur. The earth afforded by animal bodies incinerated, is mostly lime in a state of saline combination; whilst that yielded by vegetables, besides lime, consists of alumina, with an admixture, greater or smaller in amount, of scilica.

The peculiar combinations which form what are called *immediate principles*, are much more numerous in the vegetable than in the animal kingdom, and are also generally more simple in the former than in the latter, the immediate principles of vegetables being mostly ternary compounds, whilst those of animals are generally quaternary, nitrogen being added in these last to the carbon, hydrogen, and oxygen, which form the organic elements of the first. The immediate principles in both classes are divided into acids and oxides; and many of these they have in common. Vegetables, however, have a third order of substances entering into their composition, of which we discover no traces among animals; these are the vegetable salifiable bases.

There are but few *acids* which exist in the vegetable and animal kingdoms in common; and whilst their number is small among animals, it is very great among vegetables.

The hydrocyanic acid has only been discovered in vegetables; when it is procured from animal substances, it is always formed under peculiar circumstances, or during their decomposition.

Of the organic *oxides*, some—albumen, osmazome, sugar—are common to both animals and vegetables; but they occur in very different proportions in each: sugar, which is so abundant among plants, is scarcely to be detected among animals; and osmazome, which is so universally distributed among animals, has only hitherto been discovered in a few fungi. Of the ternary compounds of carbon, hydrogen, and oxygen, such as *starch, gum, sugar, the resins, woody fibre, fixed oils, volatile oils, camphor, extractive matter, &c.* which enter so largely into the constitution of vegetables, there are but a very few to be discovered among animals, such as the sugar of the milk and urine, the resin of the bile and of the urine, the elaine and stearine of the fat, the volatile oily principle of castoreum, &c. and the camphor of cantharides.

The quaternary organic compounds of carbon, hydrogen, oxygen, and nitrogen, which form the principal elements in the composition of the bodies of animals, are, on the contrary, very rare among vegetables. The most common of these are albumen, gelatine, fibrine, animal mucus, and osmazome; the less common enumerated are the matter of the saliva, caseous matter, urea, and the pigmentary matter of the eye.

Still vegetables are not without several of these quaternary compounds, such as albumen and osmazome, and they even possess others which are peculiar to themselves, such as gluten, the matter of the pollen of flowers, indigo and several extractive colouring principles; to say nothing of the whole exclusive class of salifiable bases, quinia, cinchonia, veratria, strychnia, morphia, &c., &c., which appear to be compounds of carbon, united in large proportion with a little oxygen, hydrogen, and nitrogen.

Comparison of the organic composition or texture of animals and vegetables.—We find many and much more striking differences in the texture than in the chemical composition of the two great classes of organized beings. Both are made up of solids and fluids; but with a few exceptions, the proportion which the solid bear to the fluid parts is much greater in vegetables than in animals.

The fluids contained in the bodies of the higher animals, the blood, chyle, spermatic fluid, bile, urine, &c. have in general a very different character from those that constitute the sap of the more perfect vegetables, or that are deposited as secretions in the nectaries and various cavities of their flowers, leaf-stalks, stem, &c.

But the solids, entering into the composition of each class, are still more widely dissimilar both in their outward and in their intimate characters. The most simple vegetables, the cryptogamia, appear to consist of a homogeneous tissue, forming rounded or oblong cells filled with fluids or a granular substance, without any trace of proper tissue; it is only when we come to the phanogamous vegetables that we find any distinction of tissues, namely, a cellular and a tubular tissue, the whole body of the plant being surrounded with a distinct integument or bark.

The *cellular* tissue of vegetables, whilst still young, is soft, homogeneous, and contains cellules filled with a fluid often charged with globules; when full grown, this tissue is made up of cells properly so called, being spaces surrounded with solid membranous parietes of various forms and sizes containing different matters. These cells appear composed of vesicles placed side by side and running one into another, surrounding the spiral and nutrient vessels of the stem and bark, and opening so as to form reservoirs filled with air, or resinous, oily, or mucilaginous fluids.

The *tubular* or vascular tissue of vegetables occurs under two different forms—spiral vessels, and nutrient vessels. The former present themselves in great abundance amidst the woody fibres, but penetrate also into the leaves, and even into the stamina, pistilla, and fruit. They are not met with in the bark. These vessels seem specially destined to include and conduct the sap, which from the root ascends to the extreme branches and leaves of all vegetables. The nutrient vessels, so called from containing a fluid, the cambium or succus proprius, different from the sap, prepared from this by elaboration in the leaves, have now been demonstrated in a great number of vegetables; they are principally contained in the soft inner layer of the bark, but they also penetrate every part for the purpose of conveying the essentially nutritive juice or blood of the plant.

These elementary tissues, combined and arranged in a great variety of modes, constitute the root, trunk, leaves, flowers, and fruit of all vascular vegetables; and it is wonderful how nearly the whole of this tribe, however dissimilar in their outward appearance, resemble one another in their intimate structure.

The tissues that enter into the composition of animals are much more numerous than those of vegetables. The most universally distributed of these in the more perfect species of animals are the cellular, the vascular, the nervous, and the muscular, to which must be added the tendinous or fibrous, the osseous, the cartilaginous, and the horny, which are less uniformly diffused among the individuals composing the animal kingdom.

The *cellular* is the tissue the most universally encountered among animals; it is demonstrable from the very lowest to the very highest. Its general appearance is that of a soft, homogeneous, whitish, semi-transparent, extensible, and during life slightly contractile substance. It is permeable to air and liquids, and is easily distended by either of these, when it forms a series of continuous cavities or cells, strangers at first to its constitution, but so readily produced as to have given the tissue its distinguishing title. The cellular tissue is dispersed abundantly through every part of the animal body; it enters as a principal element into the composition of many other tissues; it pervades the innermost parts of almost all organs, and in a modified shape forms a covering for them externally; it may be said to constitute the frame-work of the organs generally, supporting them in their particles as it does in their masses; it connects them together also, includes and accompanies the bloodvessels that supply them with nourishment, fills the intervals between them, and establishes continuity between every part of individual organized beings. The cellular tissue consists of filaments and laminæ, mingled and entangled together; the interstices it contains, and which may be blown up into cells, appear to be moistened during life by a thin vapour, or a variable quantity of serous fluid.*

The cellular substance appears to constitute the element of the various *membranes* encountered in animal bodies: the fibrous membranes, the skin, the mucous membranes, the serous membranes, and the synovial membranes, are all readily resolvable into cellular tissue; they in fact appear to consist of this tissue in different states of condensation.

The *vascular* is another tissue extensively distributed among animals. Three modifications of the vascular tissue have been reckoned by anatomists, occurring respectively in arteries, veins, and lymphatics.

The third tissue which is peculiar to animals is the *nervous*. This may be held the most eminently distinctive of this class of organized beings, as it is by its intermedium that they exhibit almost all the faculties which place them so immeasurably above vegetables in the scale of creation, and as, generally speaking, they may be reckoned by so much the more perfect as particular portions of this system are more fully developed. The element of the nervous tissue is a soft, whitish, and little consistent substance, composed of minute globules surrounded by a semifluid substance, and connected together by a tissue of cellular membrane of extreme tenuity. The globules are mostly disposed longitudinally, when they form the medullary fibres of the brain; surrounded by denser sheaths, they take the form of nerves. In all the higher animals at least, two orders of nerves are distinguished, each, however, being intimately connected with the other,—the nerves of *animal*, or, better, of *phrenic* life, and the nerves of *organic* or *vegetative* life. The nerves of the first order are connected in the higher classes of animals with a brain and spinal cord; those of the second proceed from small bodies of a reddish grey colour, and irregular shape, named ganglions. The functions of the first take place with consciousness, those of the second without this mental phenomenon.*

The fourth tissue peculiar to animals is the *muscular*. In several of the very lowest tribes of these, indeed, the existence of this tissue cannot be demonstrated; yet its actions begin to be manifested at a very low grade in the scale. The element of the muscular tissue is a fibre, on the ultimate constitution of which there have been many disputes. The ultimate muscular fibre would appear to consist of a series of solid globules longitudinally disposed, and connected into larger and larger fasciculi, which at length compose the distinct bundles denominated muscles. Fibrine is the organic element of the muscular tissue. Its peculiar and distinguishing property is its capacity to contract or to become shorter, and to relax again or return in its quiescent state to its first lentgh.

The muscles, like the nerves, are divided into two classes or orders, the one under the influence of the will, the other independent of it. The texture is different in each of these two orders: in the voluntary muscles, the fibres and bundles of which the peculiar tissue consists are very regularly disposed, and generally in straight and parallel lines relatively to one another; in the involuntary muscles again, the fibres appear of different degrees of density, run parallel or obliquely with regard to one another, are superposed in layers, intermingled and entangled like a kind of felt, &c.

* Rudolphi assigns as a distinction between animal cellular tissue and that of vegetables, that the latter exhibits cells of a more or less regular form with firm walls, nothing of which kind exists in the former: Rudolphi Anat. der Pflanzen, S. 26, quoted in Tiedemann, Physiologie, 1ster Band, S. 182.

* Some physiologists have gone so far as to suppose a rudimentary nervous system among vegetables, which would imply consciousness on their parts of their existence. This, at least, is a very doubtful presumption, but we are not without abstract arguments which might be adduced in favour of the supposition. How immensely would the sphere in which the bounty of the Creator had displayed itself then appear enlarged! The number of beings conscious of the joys of existence would be increased a thousand fold; and it is even delightful to imagine these lower partakers of organization with ourselves and animals, also enjoying the light and sunshine, the sequence of day and night, the freshness of spring, and the fulness of autumn.

The fifth tissue which prevails among animals is the *fibrous*. This is or may be divided into the *tendinous* and *ligamentous*. These are alike subservient to the muscular tissue and to the function of voluntary motion. They consist of fibrous, parallel bundles, of a white colour and pearly lustre, of great strength, and possessing little elasticity.

The sixth tissue which is peculiar to animals (the first of those less universally distributed) is the *osseous*. This forms the frame-work or skeleton which gives form and fixity to all the other parts entering into the constitution of the higher animals. The essential organic element of bone is a cellular net-work consisting of gelatine, within the meshes of which certain calcareous salts, the phosphate and a little carbonate of lime especially, are deposited in order to give them greater solidity.

The *cartilaginous* is generally reckoned as the seventh among the elementary tissues of animals; it may and has been very properly assimilated to the osseous: the bones are cartilaginous at first, and with the progress of years many of the cartilages show a tendency to, or do actually become, converted into bone. The cartilages that cover the articular heads of the bones are almost the only ones that show no disposition to undergo this change. The organic element of cartilage is gelatine.

The *fibro-cartilaginous* is a mere modification, although an interesting one, of the cartilaginous or rather of the fibrous tissue. The fibro-cartilages are very strong, and particularly elastic.

The horny and calcareous coverings of insects, and the crustacea have uses corresponding to those of the bones. The calcareous shells of the mollusca, too, bear a certain, though a very remote analogy to the skeletons of the higher animals.

The *horny* or eighth tissue peculiar to animals might with propriety be reckoned among the number of those that are very widely distributed. We meet with it in the epidermis of man, and as low in the scale at least as the molluscs and annelides; it is the most universal clothing provided by nature for the bodies of animals.

So much for the simple tissues entering into the composition of animals, to many of which nothing analogous can be discovered among vegetables. But these are by no means the only solid elements that make up the aggregate of animal bodies. The *organs*, as we entitle them, for the performance of certain functions so generally encountered among animals,—the lungs, liver, stomach, kidneys, testes, ovaries, &c., &c., are so many peculiar compounds of the more simple tissues, occasionally with additions denominated *parenchyma*, nothing corresponding to which has ever been discovered among vegetables. These various organs are associated in animals into groups, denominated *systems*, which severally tend to the accomplishment of the individual functions manifested by the creature examined,—the teeth, tongue, salivary glands, œsophagus, stomach, liver, pancreas, and intestinal canal, constitute one great and important system, subservient to the conversion of food into nourishment, and the preservation of the individual; the testes, penis, vagina, uterus, and ovaries, in the two sexes, compose another great system by which the species is continued, and so on.

Besides these solids we have a great variety of *fluids*, which in animal bodies subserve various and important purposes: we have, for instance, the general nutrient fluid distributed to all parts of their bodies, denominated *blood*. We have a variety of fluids prepared for aiding or accomplishing the act of digestion,—the *saliva*, *gastric juice*, *pancreatic juice*, and *bile*; we have various fluids as emunctories of the worn-out parts and particles of the system,—the *perspiration* and the *urine*; and we have a peculiar fluid prepared as a means of continuing the species—the *spermatic* fluid. Fluids corresponding in their destination to one or two of these are also met with among vegetables, but there they are greatly modified.

Comparison of the vital manifestations, or actions of vegetables and animals.—In considering generally the manifestations of vitality in vegetables and animals, we immediately become aware of very distinct and peculiar tendencies in each class. A disposition to produce diversity of parts, and a symmetrical arrangement of these, are as striking features in the acts by which animals are evolved, as the opposite or a disposition to reproduce to infinity similar parts without symmetry is a character inherent in vegetables. The liver, spleen, heart, intestinal canal, pancreas, and vertebral column, are the principal asymmetrical parts in animals; the organs of the senses, the lungs, kidneys, testes, ovaries, lateral bones of the head, and extremities, and the muscles, are the principal symmetrical parts; and these severally cannot be said to be repeated,—they only exist in pairs, on either side of the mesial plane. Such accessory and unessential organs as hair, scales, feathers, &c. are the only ones that are found repeated among animals. The very opposite of this tendency prevails among vegetables; we find nothing like symmetrical arrangement on either side of a middle plane, and we see the same parts repeated again and again to infinity, so that any single part, a branch, for instance, becomes an epitome of the entire tree.

Another peculiarity in the mode in which the vital processes build up vegetables and animals consists in the situation and disposition assigned to the various organs entering into their composition. Whilst in plants the whole of the organs destined to the manifestation of particular functions,—the leaves, flowers, stamina, pistilla, roots, &c.,—are placed externally, and their interior or trunk is a mere prop upon which these parts are hung, in animals the whole of the essential organs destined for the preservation of the individual and continuation of the species are concealed, so that their exterior is the shell, their interior the receptacle for the especial lodgement and protection of these.

Such diversity in the arrangement of the parts composing vegetables and animals does away with the necessity for the existence among the former of any thing like those *central organs* found in the latter, which, from the interior of the body, and generally from the mesial plane, send off radii of communication to every atom of the organization, and prove the media that unite their several and often widely separated parts into a whole. We discover nothing like prolongations from central organs—from a heart, an artery, a stomach, and a spinal cord or ganglionic system, among vegetables. Hence the independence of the several parts of vegetables one upon another, hence their susceptibility of being multiplied by cuttings, and even of some species arising complete from their leaves.

A third and very important peculiarity in regard to the mode in which the vital processes are performed in the animal and vegetable kingdom is that many take place with *consciousness* or knowledge of their occurrence, in the one, whilst they all occur *unconsciously* in the other. In vegetables the whole of the acts whose sum constitutes their vitality are perfectly irresistible, and take place in them without their knowledge, and uninfluenced by their will. A great many of the vital acts, indeed, take place without consciousness among animals also, such as the circulation of the blood, the digestion and assimilation of the food, &c., but the moment the animal passes the sphere of its individual existence, whenever it has to act beyond itself, we find consciousness of the action superadded to the capacity to act. The very lowest animals *select* their food, search for and appropriate their aliment as it presents itself to them; the most perfect vegetable, on the contrary, absorbs irresistibly, and without perception or will, the materials brought into contact with its roots in the earth, and its leaves in the air. The same wide differences are apparent in the act by which the species is continued: animals search for, and, by an inherent virtue denominated *instinct*, implying consciousness, distinguish the other individual of opposite sex, of which they have need in order to procreate their kind; in vegetables, on the contrary, all is passive; the pollen or fecundating powder is projected or falls upon the pistillum, or is even left to be brought into contact with this part by accident, without participation in the act, without consciousness of or will in its performance.

These two last named manifestations, the one subservient to the preservation of the individual, the other to the continuance of the species, are accompanied with such circumstances in animals as presuppose in them other two peculiar faculties: these are *perception* and the *power of locomotion*. To preserve themselves as individuals and as species, they required powers which should make them acquainted with and enable them to establish relations between their own bodies and the world beyond them. By the faculty of *perception*, which may be taken as synonymous with *sensibility* in its widest acceptation, an animal is made aware of his individual existence, as well as of that of the material universe without him. This faculty also takes cognizance of all the internal sentiments, feelings, or desires of which by his constitution he is susceptible, and which are always in harmony with the part he is destined to play in creation. Sensibility may therefore be defined: the faculty by which impressions from without as well as sensations, emotions, and intellectual acts from within are perceived. The organ of this faculty is by universal consent admitted to be the nervous system. The faculty itself, as the above definition indicates, is susceptible of being considered under two heads: as the impressions perceived or perceptions come from without, or as they emanate from within. The organs of the senses are the media through which external impressions reach the percipient principle which resides in the brain and medulla oblongata in the higher animals, the nervous ganglia in the lower, and these same parts are the instruments or elaboratories of the internal sensations. Both of these kinds or modes of perception were alike necessary to the beings endowed with them. The external sensations are the watchmen of the system, admonishing animals of the presence of the objects they require for their preservation; the internal feelings, in like manner, are centinels which admonish them of their wants and lead to the employment of the organs by which these may be supplied.

By the faculty of *locomotion*, again, an animal accomplishes all the promptings of his inward nature; he places himself in relation with the beings and the things which he is admonished by his instincts or internal faculties are necessary to him for his preservation as individual and continuance as species. Made aware of his wants by perception, by the faculty of locomotion he is enabled to minister to them. These two powers, let us observe, always exist together; the one, indeed, necessarily supposes the other. Sensibility or perception is the monitor, locomotion the agent. Without perception locomotion could have subserved no end; without some capacity of locomotion perception would have been a vain inheritance.

Vegetables evidently possess no power of locomotion analogous to that inherent among the higher animals,—where the seed falls there the plant springs, there it attains maturity, and there it dies. Neither do they manifest any thing like sensibility in outward act that can be ascribed to volition or consciousness: their nature, in fact, made perception unnecessary to them; and having no power of locomotion, it would have been useless in the two great acts by which organized beings minister to their preservation as individuals and to their existence as species. Still it is impossible to deny every thing like capacity of outward motion to vegetables. Although they have no power of transporting themselves over the surface of the earth or through its waters like animals, many of them exhibit motions in their leaves and flowers in relation with the state of the atmosphere, and the diurnal revolution of the earth; the sexual organs in several species move the one towards the other; and about the foot-stalks and petioles of the mimosa *pudica* and other plants we observe particular organs that contract when stimulated, very much in the same way as the muscular fibre among the higher animals. Moreover, the motions by which the radicle constantly seeks the ground or tends downwards and the plumula shoots into the air, that by which some of the higher phanogamous plants twist in spirals around objects near them, and by which all preserve one side of their leaves towards the light, cannot be held as accidental or merely mechanical acts. Several genera of the confervæ and tremellæ even exhibit such remarkable oscillatory movements as have induced different naturalists and physiologists to reckon them among the number of the animals.

With all this, however, locomotion among vegetables is a very limited power contrasted with the faculty among animals. These exhibit all the automatical motions of vegetables, and have in addition a particular system, the muscular, superadded to their organization, by which many of the most important offices of the economy are performed: not only instrumental in procuring the food by which they are maintained, but in putting into play the digestive and respiratory apparatus by which the nutritive juices are prepared and assimilated, and finally distributed among the higher tribes to every part of the body. The existence of this system is in fact one of the grand characteristics of the more perfect animals. By its means they react upon the external world and modify it according to their wants; by its means they guide their senses and enlarge the sphere of their acquaintance with things beyond themselves; by its means they impress the air with the tones and articulate sounds, or execute the signs by which they make known the various states of their affective or moral and intellectual being to one another; finally, by its means the sexes approximate, and those acts take place which lead to the engenderment of new individuals and the continuance of species.

The best informed among physiologists, however, do not confine the motions of all animals to the act of the particular tissue we denominate muscular. The polypes and many even of the massy acalephs, to say nothing of the smaller infusories, rotifers, &c. though they move freely, cannot be shown to possess muscular fibres in their constitution; neither indeed can any nervous system, upon which muscular contractions and voluntary motion have always been held dependent, be demonstrated in these creatures. It is consequently probable that the means by which spontaneous motion takes place in these lower animals are peculiar, as indeed we must acknowledge the evident motions which occur under many other circumstances in the world of organization to be.

But let us now turn to the *special* manifestations of vitality of the two great classes of organized beings we are engaged in examining. These we shall consider in the following order, which is also that we have adopted in contrasting the manifestations of activity of unorganized and organized beings,—namely, *origin* or *reproduction*, *nutrition* or self-preservation, *changes* undergone during the period of existence, or the *ages*, and *death*, or end.

Origin, *or the acts by which species are continued.*—Vegetables and animals alike derive their origin from a birth or genesis accomplished in two different modes, either without the concurrence of opposite sexes, or with such a concurrence. When organized beings are produced without the concurrence of opposite sexes, the parent either divides into several pieces, each of which becomes an independent individual, or throws out burgeons or buds from its surface, which, being detached in due season exist as self-sufficing types of the species. When organized beings spring from the concurrence of sexes, again, two sets of organs minister to the generation, the one denominated *male*, supplying a fecundating matter, the other entitled *female*, furnishing a germ, which subsequently to its impregnation by the male organ undergoes a series of evolutions that end in the issue of an individual resembling the parents, and fitted by its own acts to preserve itself and to continue its kind.

Both of these modes of reproduction are common to vegetables and animals. Confervæ and polypi alike exhibit the first mode, almost without a difference: buds or sprouts arise from the surface of both; these adhere for a time, acquire a certain size, and are finally detached to become independent beings. Again, the polype divided into several pieces, gives origin in each of these parts to distinct polypi, exactly as the cuttings of vegetables take root and grow into perfect trees, shrubs, &c.

The second mode of reproduction—that by the concurrence of sexes, or of organs denominated respectively *male* and *female*,—is also exhibited by vegetables and animals indifferently; but there are numerous circumstances distinguishing this manner of reproduction in the two classes of organized beings. In the first place, the sexual organs do not exist from the earliest period, and during the whole course of the life of vegetables, as they do in animals; the sexual organs, in fact, only occur among vegetables at the time of flowering, and perish whenever the end of their evolution has been accomplished, never serving oftener than once for the generative act. The sexual organs of all animals, again, that live for more than a year, suffice repeatedly for their office; and if they are not required to accomplish this oftener than once in the short-lived tribes, it is probably from no inherent incapacity to serve again, or any destruction of the organs themselves, but simply because the term of existence of the organism of which they formed a part is complete,—they perish with the system to which they belonged.

Another grand though not an invariable distinction between vegetables and animals is the mode in which the sexes, or sexual organs—for these may be taken as synonymous terms—are distributed among the individuals of each class. Speaking generally, it may be said that the sexual organs are as commonly divided between *two* individuals among animals by whom the species is represented, as they are confided to *one* among vegetables, which is, therefore, singly the type of its kind. In both classes, indeed, there are exceptions to this general law: the flowers of all vegetables do not contain stamina and pistilla, or male and female organs, neither are the opposite sexes invariably represented by two different individuals among animals. In many plants the male organs are known to exist in one flower, the female in another, but both developed on the same branch; in many others, again, they exist on different stems, and are often evolved widely apart from one another. In the same manner, many of the lower tribes of animals include within their individual organisms male and female organs; this is the case with several tribes of the genus mollusca, gasteropoda, the helix, limax, and lepas, for instance, with the whole of the extensive classes of the annelida, entozoa, echinodermata, &c.

But though there be resemblance to this extent among vegetables and animals in regard to organs, in the act by which fecundation is accomplished there is a wide and essential difference; for whilst vegetables impregnate themselves, or, rather, whilst the impregnation of vegetables is a purely passive process, without perception of or concurrence in its accomplishment on their parts,—the pollen of the anthers of those flowers that have male and female organs being simply shed upon the pistilla, the impregnation of animals, so far as our knowledge goes, appears to be almost as generally a consequence of a connexion between two different individuals, and of volition with consciousness on their several parts. Although many animals have both male and female parts included within the same organism, it would seem that comparatively few have the power of impregnating themselves: two individuals of the like species meet, and *give* and *take* reciprocally; so that there is, in fact, much less difference between the highest and the lowest tribes of the animal kingdom in the essentials by which races are continued, than at first sight appears, much less certainly than there is between the vegetables and animals that are most nearly allied. The modes in which fecundation takes place in vegetables at large, and in animals probably without exception, are inherently and essentially distinct: an hermaphrodite animal is still a very different thing from an hermaphrodite flower.

Another difference between vegetables and animals, less important, indeed, but still interesting, lies in the *number* of the organs possessed by each destined for the continuation of the species. In many vegetables the organs are *single*, one flower being taken as a representative of the sexes; in a much larger proportion of plants, however, the organs are *multitudinous*. Among animals, on the contrary, with a few exceptions in the very lowest tribes, the asterias, &c. where they are multidinous, the essential male and female organs, the testes and ovaria, exist singly or in pairs only.

A third diversity, and one that is striking and almost universal, between those species of plants and animals in which the sexes are represented by two individuals, lies in the difference of conformation, size, and general character of the individuals in the one class, and their perfect similarity in the other. There are very few diœcious plants the males of which are distinguishable from the females; there are very few tribes of animals, on the contrary, in which the distinction of sex is not extremely apparent, the males being generally larger, stronger, and more courageous; the females smaller, more delicately formed, and more timid in their disposition.*

A fourth distinction which deserves to be noted betwixt animals and vegetables is in the diversity of the act by which the new being is separated from the parent, and commences its independent existence. The period at which this happens, indeed, is determinate, and fixed in both alike, but it is accompanied with consciousness among animals, whilst it is altogether unwittingly accomplished among vegetables.

From this review of the mode in which animals and vegetables are called into being, or of the acts which lead to their creation, the main and most striking differences observable in the two classes are these: whilst in vegetables the whole of the acts that constitute reproduction,—the union of the sexes, the fecundation of the ovum, and the birth of the new being are accomplished without the will and without the consciousness of the individual, but irresistibly and necessarily, they are left in some particulars, at least, to the will, and take place with the consciousness of the individuals among animals.

Nutrition, *or the acts by which the individual is preserved.*—Every thing in nature changes, and organized beings only continue their existence with their aptitudes to manifest the acts that draw so wide a line of demarcation between them and unorganized bodies, by a perpetual renewal or recomposition, and as incessant a rejection or decomposition of their elements. Nutrition is, therefore, at least, a two-fold act, implying *absorption* or *appropriation* of nutritive matter, and *excretion* or *rejection* of the old and worn-out particles that have already served their office in the economy: it consists, in fact, as we have said, of an incessant decomposition and reconstruction of the fabric of the living organized being. Nutrition, however, is a very comprehensive term, and includes the whole of the vital acts by which the individual continues

* One of the most striking exceptions to this law occurs among some especially of the smaller species of the birds of prey. In many of these the female is much more powerful, heavier, and even more courageous than the male. The care of the offspring, by one of nature's ordinances, devolving principally upon the female, the supply of flesh for the brood—a supply procured by violence—might often have failed had she not in these tribes been provided with superior strength and courage to insure its regularity and abundance.

its existence,—namely, among the higher tribes of living things, the absorption or ingestion of food or alimentary matter; the preparation of this food by the processes of digestion and respiration; the distribution of the nutritive matter fitted for its ends, to every part of the system by means of a circulation; the conversion of the nutritive matter into the solids and fluids or proper substance of the individual, and finally the depuration and rejection of the worn-out parts and particles by means of certain secreting organs. These various processes in themselves will be particularly considered in the article Nutrition, to which the reader is referred. Meantime let us contrast these different functions as they manifest themselves in each of the two grand divisions of the organized world.

Assumption of aliment. — The earth and the atmosphere, and the carbonic acid and water they contain, are the sources whence vegetables derive their food. Here they find aliment ready prepared for their use, or rather, as passive agents, they depend on the earth and the atmosphere for a supply of the elements required for their continuance. Those physiologists are now admitted to have been mistaken who supposed that the food of vegetables was furnished by the inorganic earth, air, and water, with which their roots and leaves are in relation; more accurate experiments have shown that plants are as dependent as animals on supplies of substances that have once had life for their support. When plants are made to grow in pure earth and in distilled water, they appear to do so by a kind of decomposition of themselves, one part perishing and affording food to that which continues to live. To base a distinction between animals and vegetables, consequently, on the presumption that the one lived on organic, the other on inorganic substances, was incorrect: animals and vegetables are alike in this respect; both feed upon organized matter, and this not always or necessarily in a state of decomposition, as we observe among parasitic tribes, which subsist on the living juices of the individuals they cling to. The food of animals, however, may be stated generally to be both more various and also more complex in its chemical composition than that of vegetables, and whilst vegetables take all their food in a liquid shape, animals much more commonly live on a mixture of solids and fluids.

The assumption of food by vegetables and animals takes place under very different circumstances. In vegetables it is necessary and independent of the individual; it is also incessant; and, farther, it takes place from the external surface, inasmuch as it is with this that the materials which supply the nutriment are in contact.

Animals, however, have not generally their food prepared for their use brought into contact with their bodies, neither are they passive in its assumption; they have mostly to search for it abroad, and are provided with special organs for this purpose. The act by which they take it is not necessary, neither is it incessant. They have also to select their food, and are, therefore, furnished with faculties which guide them in their choice; namely, taste and smell. Lastly, the absorption of the truly nutritious matter is accomplished from their interior, the crude material assumed as food having been first prepared by elaboration in a cavity called a stomach.

As organized living beings, the soundest philosophy and best ordered experiments lead us to infer that there is little if anything *mechanical* in the mode in which either vegetables or animals absorb nutriment. The absorption of their aliment by vegetables is influenced by the seasons, their state of health or disease, their age, and external circumstances generally,—the temperature, state of dryness or moisture, &c. of the air with which they are surrounded; the cause of the absorption of their food by vegetables is, therefore, something different from what is called capillary attraction, or the law by which fluids ascend in tubes of small calibre.

The proper passage of the nutriment into the bodies of animals occurs from their interiors, and in a very large proportion (probably in every somewhat perfect member) of the class, by means of a special set of vessels denominated lacteals or lymphatics, no system corresponding to which exists among vegetables.

The very lowest tribes of the animal kingdom, the entozoa, acalephæ, polypi, &c. having no proper vessels of any kind, the cellular membrane of which they consist absorbs, and by virtue of a peculiar vital process, distributes the nutritive juices extracted from the matters received into the stomach and alimentary canal to all parts of their bodies. Those tribes of animals which have naked skins have the faculty of absorbing by their exterior also.

Still less than in vegetables, can we suppose that the process by which in animals nutriment is ultimately absorbed into the body, whether from the exterior or the interior, is akin to mechanical or capillary attraction. The tissues of which animal bodies consist are, indeed, permeable to fluids, but this does not explain the collection of these fluids in so many tribes into particular canals, and still less does it solve the problem of the continued motion onwards in determinate directions within these channels.

Absorption of alimentary and other matters, therefore, in both of the grand divisions of the organized world, must be held as a vital act,—as one of the particular laws superadded in organized beings to the general system of physico-chemical ordinances that rule the universe and its parts. This quality is common to vegetables and animals.

By far the greater number of animals have one or more special openings,—a mouth or mouths, by which they take in such substances as are fitted for their nourishment. Even the greater number of animals as low in the scale as the infusoria, have been recently demonstrated (by Ehrenberg) to be provided with an opening of this kind. Several, however, seem to receive aliment by the way of absorption alone. The mouth is a cavity of extremely varied character and construction adapted universally to the circumstances in which animals exist. Nothing analogous to a mouth is met with in any vegetable.

The food having been selected and seized is next transferred to the cavity in which it undergoes an elaboration that fits it to be received into the proper system of the animal and converted into its own substance. We do not find anything like the pouch denominated a stomach in any member of the vegetable kingdom. The matter fitted for its nourishment, absorbed by the root, is transmitted to the stem, and from thence makes its way into the leaves of the vegetable. It does not pass unchanged, however, from the earth into the root, or at least it has advanced but a very short way on its course to the leaves, before it is found to have undergone certain changes, which are also known to be greater in amount as it is examined at a greater height or distance from the root. Although growing from the same soil too, the sap of vegetables, i. e. the fluid which is passing upwards through the woody fibres, is found to be universally different. Whether the peculiar qualities thus acquired by the simple moisture holding certain salts, &c. in solution, which is the food all vegetables derive through their roots, be the effect of vital elaboration within the cells of the woody fibre, or result from an admixture of the cambium or fluid which has already undergone assimilation in the leaves, is still uncertain. We are inclined to believe that a process analogous to digestion does actually take place within the woody conduits of the sap of vegetables;—why should it not, or why should any new properties acquired by matters subjected to the influence of the peculiar laws of vitality be held as resulting from mere admixture?

The very same thing, in fact, happens among the lowest tribes of animals which takes place in all vegetables: the substances fitted for their nourishment penetrate or are absorbed into their systems, and are there assimilated without the intermedium of any special apparatus. We mount but a very short way in the scale of the animal creation, however, before we meet with a peculiar pouch, destined for the reception of the aliment, and accomplishment of the first steps in the processes by which, in the more perfect animals, it is finally assimilated. This pouch is the *stomach*, and with the rest of the *digestive* apparatus with which it is connected, is in intimate and uniform relationship with the kind of food upon which animals are led by their instincts to live.

All the accessaries of the assimilating cavity or stomach which we find in animals, from the organs of sense that guide them in their choice of aliment, to the lips that seize it, the teeth or jaws that bruise it or destroy its vitality, the muscular actions by which it is swallowed, and the chemico-vital processes by which it is dissolved, and the purely vital sensibilities by which such parts as are proper for nourishment are retained, and such as are improper for this purpose are expelled,—all of these are wanting among vegetables.

There are yet other processes which form an essential item in the acts by which organized beings universally continue their existence, which it is necessary we should include in this summary of the common, particular, and distinguishing attributes of vegetables and animals. One of the most important of these is

Respiration.—The leaves in the more perfect vegetables are the instruments of respiration; their place is supplied by the general surface in those plants that are aphyllous. Vegetables that live in air act immediately by means of their respiratory organs upon the ambient medium; those that live in water, upon the air held in solution by the fluid around them.

Vegetables are well known to *exhale* abundantly from the surface of their leaves, or stems, in case they have no leaves. The matter exhaled is principally water. They have also the farther property of decomposing one of the elements of atmospheric air, namely, carbonic acid gas. In the sunshine the leaves of vegetables fix the carbon which enters into the composition of this gas, and set the oxygen at liberty; in the dark, however, a very different process goes forward; they then actually absorb oxygen and exhale carbonic acid gas; the balance, however, in the aggregate is not equal between these opposite processes, a much larger quantity of carbon being fixed by the decomposition of carbonic acid gas and oxygen set at liberty, than there is of oxygen absorbed and carbonic acid gas set free. These acts are essential to the life and health of vegetables; their end and object appear to be the preparation of their proper nutritive fluids or cambium: the sap which reached the leaves, colourless, not coagulable, without globules, mere water holding carbonic acid, acetic acid, a muco-saccharine matter, and various salts in solution, is in them converted into a greenish fluid, partly coagulable, and full of globules, which special vessels then distribute for the growth and maintenance of the different parts.

The respiratory act is necessary, and goes on without the aid or concurrence of the individual among vegetables.

Animals are no less dependent than vegetables on communication with the air of the atmosphere, either immediately or mediately, for a continuance of their existence, or the manifestation of those acts whose sum constitutes their lives. In the very lowest tribes the communication between them and the air of the atmosphere takes place over the surface of the body generally, without the intermede of any particular organ or organs for the purpose. The fluids absorbed into their bodies are brought into contact with the atmospheric air in those points where they approach the external surface, and there appear to undergo the changes necessary to fit them for being converted into the substance of the animals themselves. Simple as this process may appear, slender as the means of accomplishing it may seem to be, it is nevertheless *essential*: interrupted for any length of time, the animal inevitably perishes. A process of such importance, as may be imagined, is not long left without its appropriate and special apparatus. This varies extremely in its structure, in the different tribes of animals, and according to the circumstances surrounded by which they live. Some have lungs, branchiæ or gills, and tracheæ opening by spiracula, of infinitely varied construction.

Respiration is also carried on vicariously in a very large proportion of animals, if not perhaps in all to a certain extent, by means of the skin, and in some even by the instrumentality of the alimentary canal.

The changes effected in the atmospheric air by the respiratory apparatus of all animals are similar, but they differ from those that are produced by the corresponding implements in vegetables: the proportion of oxygen it contains universally diminishes, and the quantity of carbonic acid gas it holds in solution as invariably increases in amount. A quantity of water or of watery vapour is at the same time thrown off. This is exactly the opposite of what we have seen to be the effect of respiration among vegetables; in these the quantity of oxygen is augmented, whilst that of carbonic acid gas is diminished. The nutritive fluids newly prepared by the apparatus of digestion, or that have already gone the round of the system, are by a variety of means exposed, in the special or common apparatuses mentioned, to the influence of the atmospheric air, from the contact of which they undergo certain important and often manifest changes that fit them for their ultimate office in the animal economy, — the maintenance of its parts, with their inherent capacities to execute the various functions imposed upon them.

The respiratory act among animals takes place with the knowledge and with the assistance and implied will of the individual. Animals are informed of the necessity of respiring by the feeling of a want, an uneasiness, just as they are admonished of the necessity of taking aliment by the painful sensations denominated hunger and thirst.

The essence of respiration in the two grand classes of organized beings would therefore appear to be different, and might be made the ground of a definitive distinction between the members of each kingdom. *Carbon* is the object for which the respiration of plants is instituted; *oxygen* the end for which relations are established between animals and the atmosphere. Another grand difference between the respiration of plants and animals is the involuntariness of the act in the one, and its voluntariness in the other, its occurrence with unconsciousness in the one, and with consciousness in the other.

The nutrient juices thus prepared have now to be distributed; this is done by means of a peculiar motion impressed upon the fluids in virtue of a vital law with the nature of which we are still very imperfectly acquainted. Let us use the word *circulation* in a sense implying motion generally, not motion in a circle to designate the act by which in the organized world the nutritive juices are distributed through the frames of the objects composing it.

Circulation.—There can be no doubt of the existence of a circulation among vegetables; in many species currents in opposite directions have even been seen with the aid of the microscope, and this not only among the lowest and most simple in their structure of the class, but also in the highest and most complicated. The circulation of vegetables appears to take place within two different congeries of vessels, extremely numerous, and disposed according to their nature in different parts of the plant. The vessels that pump or transmit the sap from the roots to the leaves, for instance, as we have already had occasion to state, run within the woody parts of plants; those that receive the modified juices of the leaves, again, take their course downwards within the bark. These two sets of vessels anastomose within the substance of the leaves, but no where else; the second set can alone be said to have a distribution throughout the vegetable, for every part appears to depend on them for its supply of nourishment, even the extreme points of the roots, which were themselves the first instruments in collecting the aliment still unfit for the purposes of nutrition. The best informed vegetable physiologists are of opinion that the nutritive fluid once sent off from the leaves never finds its way back to these orgaus again; it is absorbed or fixed by the different parts or structures to which it is distributed, ministering to their increment generally, and enabling each to manifest its specific function in the vegetable economy.

In this motion of the fluids of vegetables it is evident that there is little analogous to what we find within the bodies of animals somewhat elevated in the scale. But let us first cast a hasty glance at what does take place within this other division of the organic kingdom before instituting a comparison between the functions of circulation in the two. All animals, from the mammalia downwards to the entozoa, —birds, reptiles, fishes, the mollusca, crustacea, arachnida, insecta, and, among the radiata, the holothuriæ, echini, and asteriæ, include within their organisms particular canals or vessels for containing and distributing their nutrient juices, and within which, moreover, these are in motion in a circle. In the acalephæ we still find canals branching off from the digestive cavity and distributing the nourishment there prepared to the different parts of the body: in these, however, we no longer find any contrivance for establishing a circular motion in the nourishing juices. Still lower in the scale, among the polypes and actineæ, for example, we discover no branched appendages or canals for the distribution of the nutrient fluids; those prepared in the stomachs of the animals appear to penetrate their substance directly, and to permeate the homogeneous cellular tissue of which they consist.

In the tribes which have a *circulation*, in the strict sense of that word, we find two orders of vessels,—arteries and veins, in which the nutritive juices, or blood, moves respectively in opposite directions, from the trunks towards the branches in the one, from the branches towards the trunks in the other. These vessels anastomose freely by their extremities, which terminate and originate in every part of the body, and, farther, meet in a common central cavity, which, when furnished with muscular parietes, is entitled *heart*. Within the circle of vessels thus established, the nutrient fluid of animals is in perpetual or next to perpetual motion during the term of their lives. In the higher classes the main agent in producing this motion is the central organ in which the veins and arteries meet; but it is not the only cause of the circulation, this act going on vigorously in circles and in situations wherein the heart's action can have very little influence, and in some tribes where the heart is even altogether wanting.

The circulation in the greater number of animals, however, is a more complicated process than that which has just been described; it consists, in fact, of two parts perfectly distinct from each other; one whereby the blood is exposed to the action of the air in the apparatus which, in connexion with the respiratory process, we have denominated lungs, gills, &c., another by which it is finally distributed for the uses of the system. This double circulation is accomplished by a great variety of contrivances (vide articles Heart and Circulation). In some tribes we find more than one vessel,—two, or three, each apparently independent of the other, though communicating together, which are subservient to the distribution of the nutrient fluid to the different parts of the body of the animal.

The chief differences between vegetables and animals with respect to their circulation, consequently, appear to be these: in vegetables the motion of the sap or aliment takes place through the whole of one of the tissues of which they consist; that of the cambium or proper nutritive fluid through the whole of another of these tissues, in opposite directions simply, and by the intermedium of fasciculated, very numerous, and independent vessels; whereas the aliment of animals does not circulate through their bodies, but the nutritive fluid prepared from it is collected and confined within *peculiar* channels, connected at both extremities in such wise as to form a continuous circle. In vegetables we perceive nothing like tendency towards or distribution from a central reservoir, nothing like ramification from larger to smaller branches, &c.; consequently nothing like a heart, as we do in animals above the very lowest. In vegetables, again, we see nothing like the two-fold distribution of the nutrient fluid within different orders of vessels, the one to the organs of respiration, the other to the system at large, as occurs among all animals possessing a somewhat complicated organization.

We have recognized the heart as the principal cause of the motions performed by the fluids within the bodies of animals; but as neither all animals have a heart and yet exhibit their nutrient fluids in motion; indeed, as a distinct circulation of the blood may be demonstrated in many animals, and probably takes place in all at periods of their evolution anterior to the existence of a heart; and further, as vegetables exhibit a motion or circulation of their fluids without the agency of any special organ, it is necessary to acknowledge a new law by virtue of which the fluids of organized beings generally go their round or reach their destination. This law has been designated as the *propulsive*,—a power inherent in the nutritive globules of living beings, and one of the special laws superadded to the general and all-pervading forces that regulate the universe.

One fundamental distinction between the bodies of the organic and inorganic kingdoms we have found based upon the permanence of the parts, the constancy of the relations, affinities, &c. of the component elements of the one, and the incessant changes or renewals and decompositions which these parts or elements undergo in the other. The various processes by which the aliment of vegetables and animals is converted into a *succus proprius*, the final means of their individual conservation and evolution we have now examined; we have only farther to discover this nutrient juice converted into the different tissues and substances of which organized beings consist, to have a complete view of the vital act of nutrition. But here we are compelled to pause. Of the processes by which this transformation is accomplished we know next to nothing; all we are assured of is, that each tissue and organ seizes upon and converts into its proper substance those particles enveloped in the general mass of circulating fluids brought into relationship with it, and which are adapted to this purpose, at the same time that the particles which have already been consolidated and served their office are reduced to the fluid state, absorbed back into the torrent of the circulation, and afterwards either abstracted and thrown out of the body by the operation of certain organs charged with this duty, or being subjected to the action of the atmospheric air in the lungs, gills, skin, &c. are restored to their fitness once more to enter as temporary constituents of the organization. It is evident, therefore, that we are only acquainted with this operation in its effects. The act of ultimate nutrition has been happily entitled one of continuous generation in each living being and its parts; it takes place in conformity with the laws of vitality instituted, and probably originating and ending in living organized beings.

This subject, however interesting, we must reluctantly forsake, referring to the article on Nutrition, and to the consideration of what has been called the *nisus formations*, or plastic power in our article on Fœtal development.

Vegetables and animals, from this review, appear to differ little from one another in all that regards their *nutrition*. The processes that lead to this conclusion may be, and, indeed, are more complicated among animals than among vegetables; but the essence of the final act is very nearly the same in both. Neither shall we be able to demonstrate any great want of uniformity between these different classes of organized beings in several of the actions which we shall next discuss; in others, however, we shall discover an impassable line of demarcation between them. The first of these actions which we shall consider is

Secretion.—We have already had occasion to mention the watery exhalation and oxygen thrown off by the leaves of vegetables. Divers other substances are excreted by the same parts, —water, various acrid, glutinous, saccharine, and balsamic substances. It is even by means of the leaves that vegetables throw out those substances which they may have absorbed by their roots, and which seemed calculated to injure them. We are at no loss, moreover, to demonstrate numerous apparently glandular organs in vegetables for the elaboration of a variety of substances, many of them very acrid. The flowers of vegetables secrete, in the first place, certain matters, the infinite variety of whose odours proclaims them to be different; the nectaries are also filled with fluids, which are sweet in many tribes. Lastly, in the flowers, the male fecundating matter, and the fluid that moistens the pistillum are secreted. Nor are vegetables without *internal* secretions, among the number of which certain aeriform fluids are not the least curious. The other secretions of vegetables are of infinite variety, —gummy, oleaginous, balsamic, camphoric, &c. &c. These are all stored up in cells contained in different parts of each individual plant, and undoubtedly either subserve important purposes in their several economies, with the nature of which we are very imperfectly acquainted, or are in relation with some other system in the universe, affording food to numerous tribes of insects, or materials which stand in relation to animals and man as means of accomplishing a variety of ends, the impulses to which they bring into the world with them, though they are launched upon existence unfurnished with the materials.

We have also hinted at the watery and gazeous products of the respiration of animals, and consideration for a moment enables us to make a long catalogue of other secretions both with reference to individuals and to species. We have, for instance, the limpid fluids that bedew the cellular and serous membranes, serum and synovia, and fill various cavities in the body—the chambers of the ear and of the eye particularly; those that moisten and defend the surfaces of the mucous membranes, the tears and mucus; those that are subservient to digestion, the saliva, gastric juice, pancreatic juice, and bile; those that lubricate and prevent the surfaces exposed to the air from drying, the sebaceous or oleaginous fluids of the skin, and cerumen of the ears; those that are laid up as reservoirs of nutriment or defences from the cold, the fat, marrow, &c.; those that are the vehicles for the worn-out particles of the body, the urine and perspiration; those that minister to the reproduction of the species, the fluids of the female germ or ovum, the spermatic and prostatic fluids of the male; and finally, those that are poured out among the mammalia as the first aliment for the newly-born being, the milk. Nor is the list exhausted, for numerous species of animals have peculiar fluids which are useful to them in the places they hold in the system of creation; among these are the venomous fluids of serpents, and of the stings of numerous insects, the inky fluid of the cuttle fish, the fetid fluids of the anal glands of the carnivora, rodentia, &c.; the fluid with which spiders weave their web; the wax with which bees build their cells, &c. Secretion is, therefore, a much more extensive function among animals than among vegetables; the products are still more various, and the apparatus by which they are eliminated is, generally speaking, far more complicated among the former than among the latter. Certainly, in the very lowest tribes of animals, secretion is an exceedingly simple process contrasted with what it becomes in the higher, whose organization is more complex. Among the polypi, medusæ, and entozoa, the whole of this function seems to consist in a kind of transudation, or exhalation from the surface of their homogeneous bodies, without the intermedium of any special organ. Among animals higher in the scale we find secretion performed in two modes,—by vessels, when the act is entitled exhalation, and by means of certain special organs named glands, an arrangement which we also find among vegetables. The skin and pulmonary surface are the great implements of exhalation among animals, as the leaves are among vegetables; almost all the rest of the secretions take place by the instrumentality of glands.

In vegetables secretion seems to be limited to the preparation of the nutrient fluid by the elimination of certain matters, and, so far as our knowledge extends of the end to be answered by any act, for the formation of the generative fluids; we do not, in fact, find among vegetables any apparatus set apart for the excretion of matters derived from a change in the constituent particles of the organs once formed. Among animals, again, the apparatus by which this depuration of the system is accomplished is one of the most important of all to the preservation of the individual. Secretion among vegetables is a function much more under the influence of external circumstances than it is among animals; it is also more subject to periodical changes among the former than among the latter, and whilst the function is mostly called into activity by the stimulus of light, heat, &c. in the one, it rather obeys certain internal and peculiar stimuli transmitted through the medium of the nervous system in the other.

Like all the other special modes of activity manifested by organized beings, secretion is one of the products of the laws of vitality with the essence of which we are altogether unacquainted.

Besides the secretion of the various gaseous, fluid and solid matters mentioned, vegetables and animals appear in common to possess the power of disengaging certain imponderable elements—heat, light, and electricity.

Heat.—There has been considerable variety of opinion among physiologists with regard to the extent to which vegetables have the power of maintaining a temperature of their own independently of that of the surrounding media. Nor is this question, in our opinion, yet completely set at rest. It is certain that trees in high northern latitudes endure a cold many degrees below zero without injury, whilst in intertropical countries they are frequently exposed even in the shade to a heat above that of any animal without perishing; actual experiment, indeed, proves that they preserve a temperature intermediate between that of the extreme heat and extreme cold of the diurnal variations of those latitudes in which they are indigenous. This circumstance is explained variously, some attributing it to a vital property in plants to regulate to a certain extent their own temperature, others alleging that it is merely owing to the indifferent conducting qualities of the materials of which vegetables are composed. The thermometer has been seen several degrees below the freezing point of water within the trunks of fir trees, without their vitality being affected; but it is probable that the constitution of this tribe renders them capable of enduring such a reduction of temperature with impunity as would prove fatal to other trees with simple watery sap.

On the other hand, it is quite certain that the flowers of many vegetables have the power of disengaging heat, a difference of ten, twenty, and even more than thirty degrees having been observed at sun-rise between the temperature of the atmosphere and that of the flowers of different vegetables in southern latitudes, and the same thing is known to occur, though to a less extent, in northern countries.

It would therefore be unfair, with such facts before us, to deny altogether to vegetables the faculty of disengaging caloric. Arguments, indeed, *à priori*, might be adduced to show that they must almost necessarily possess such a property: they are the subjects of incessant change; and one of the most universal of the physical laws involves a change of temperature on any change of constitution.

If the faculty of vegetables generally to secrete or eliminate caloric be doubtful, however, it is indisputable that among all animals a little raised above those at the very bottom of the scale, there is an inherent power of generating caloric, which in their state of maturity is nearly determinate as regards each particular species. Mammalia and birds have universally the highest temperatures.

Reptiles or cold-blooded animals, as they are improperly called, have also the power of engendering heat, and of regulating their own temperature: this faculty, however, and the degree of heat they possess at different times, are influenced to a very considerable degree by the heat of the media in which they live. The same statements may be made with regard to fishes. The temperature of these creatures is generally several degrees above that of the water they inhabit; but it also varies with the temperature of their native element.

Many insects have a very decided power of engendering heat and of regulating their temperature; and similar faculties have been demonstrated in the crustacea, the mollusca, and the annelida. These tribes, however, are all very much influenced by the temperature of the media surrounded by which they live.

No great difference is therefore discernible between vegetables and animals in the faculties they possess of engendering caloric and regulating their own temperature; the faculty is only much more decided, and possessed to a far greater extent among the more perfect classes of animals generally than among vegetables at large. It may very fairly, in the present state of our knowledge, be ascribed as a common property.

As to the mode in which heat is engendered, opinions are still very much divided. The chemical and mechanical explanations that have been given of the phenomenon are not universally applicable. All we can say at the present day is that the production of heat and the power of regulating their temperature possessed by organized beings is another of the hidden and singular laws or properties introduced into the system of the universe with their creation.

Light.—Many unorganized bodies have the property of shining or giving out light for some time after they have been exposed to the bright rays of the sun, or have been heated in the fire, or when they are struck together or smartly compressed, and this certainly without any decomposition of their substance. The disengagement of light, again, is a very uniform accompaniment of the decomposition and composition of inorganic substances, and it appears to be a very constant attendant upon electrical phenomena.

Various organic substances and products of organization have a similar property; living vegetables, too, particularly the flowers, have been seen to give out light by authorities so respectable, that though the fact has been called in question by others of great name, there seems no sufficient reason for treating all that has been said on the subject as illusion: in the physical sciences negatives cannot be received as evidence of equal value with positives.

No one thinks of calling in question the luminousness of animals; most of the innumerable inferior tribes that live in the sea, appear to possess and to manifest this property at different seasons. The luminousness of the ocean itself, so familiarly known, seems to depend on the presence of multitudes of infusory animals within its bosom. Many tribes of insects shine in the dark. The phenomenon is not certainly known to be manifested by any of the class of reptiles, birds, or mammalia. It appears to depend, in insects particularly, on the presence of a peculiar matter, secreted by their bodies and stored up in particular points, which, under the influence of a temperature elevated in a certain degree, and the contact of atmospheric air, enters into a kind of combustion during which light is emitted. Is the phenomenon dependent on one common cause in both vegetables and animals, supposing that it does really occur among the former?

Electrical phenomena are extensively exhibited by the objects composing the unorganized and the organized world. In fact, wherever there is composition and decomposition going on, there are electrical phenomena manifested. The action of the immense mass of vegetables on the air, the evolution of oxygen in the sunshine, and the formation of carbonic acid during the dark, has even been supposed by an ingenious natural philosopher of France (Pouillet) to be the principal source of the electricity of the atmosphere.

Galvanic electricity is excited by the contact of the different parts of which animal bodies consist, particularly of the nerves and muscular flesh; the nerve of a frog's thigh exposed and isolated, touched with a piece of quivering flesh from the body of a bullock just slain, also isolated, causes the muscles to which the nerve is distributed to contract energetically (Humboldt). The same phenomenon occurs when different other parts and fluids, particularly the blood, are used to form a chain. But the electrical phenomena manifested by animals at large, are weak when contrasted with those exhibited by certain fishes provided with special voltaic piles or galvanic batteries by which they give at will, but not otherwise, electrical shocks of such violence as to stun larger animals and even to deprive smaller ones of life. This electricity of animals must be held as a vital phenomenon; several of them have indeed a peculiar apparatus for the preparation of the shock, to speak of the phenomenon by its effects, in our ignorance of its essence or efficient cause, but this loses its power when the nerves that are abundantly distributed to it are divided.

Electrical phenomena are not so obviously displayed by any other tribe of animals as by fishes; but it has been rendered next to certain that muscular contractions are uniformly accompanied by a kind of electrical discharge from the nervous fibrils distributed to the special organs of voluntary motion.

Animals, from this brief review, appear to possess electrical capacities in a much higher degree than vegetables, in which the phenomenon is even explicable on ordinary chemical principles, whilst among animals it is unquestionably one of the effects of vitality.

We have already indicated the existence of two faculties among animals which become necessary or complemental to them as agents entrusted with their preservation as individuals, and their continuation as kinds; these are voluntary motion and sensation. But motion in the abstract is a phenomenon of much more extensive occurrence among organized beings than the notion we form of the act as connected with the existence of a muscular system. Motion is in fact a quality inherent in organized beings; they cannot be conceived as existing without change, and change implies motion. In most, or indeed in the whole of the actions which we have glanced at as manifested by them, we have supposed motion. The simplest of all animals, the infusoria, move about in many cases with great briskness; the polypes, composed of an uniform gelatinous mass, also move in various directions; the acalephs, with a similar structure, rise from the bottom and propel themselves through the waters of the ocean by a succession of contractions of their disc, of their tentacula, or of the fringe-like or foliaceous bodies with which several orders of the genus are provided. Many of the entozoa too, whose bodies consist of a simple gelatinous or mucous tissue, execute motions in various senses.

But it is not only as a whole that a body endowed with life and organization possesses a capacity of motion. Many of its parts, and particularly the globules which enter as essential and integral parts of the fluids contained in organized bodies, have inherent powers of motion: the globules of the blood, for instance, those of the spermatic fluid, and perhaps also the germ included within the ova of the polype, mollusc, &c., have all been observed in motion, and the means by which it is accomplished even demonstrated in many cases. But there is nothing absolutely peculiar in such individual instances, for we must need conceive motion in the first constituent elements of all organisms without exception, long before a muscular, a cellular, a nervous, or any other distinct system has existence.*

Motion of all kinds, therefore, automatic as well as that which is voluntary, must be held as a quality inherent in organized or living beings. The cause of this phenomenon, as of so many others manifested in the world of organization, has been the subject of much difference of opinion and of much dispute among physiologists, and many titles have been imagined by which the agent or primary cause of the act has been sought to be designated, or the act itself to be explained.

It is quite certain that the capacity to commence and to continue the phenomena which we designate as vital, or the motions which constitute these phenomena, depends first on a variety of external conditions, such as a

* Such motion is indubitable. The organic globule has capacities of motion inherent in itself, different from the motions of unorganized objects in a state of extreme division, as is proved by the motions of each kind of body being different, and those of organized globules being interrupted by the electric spark, or whatever destroys their vitality —acids, alkalis, poisons, &c.

certain temperature, intercourse with the air of the atmosphere, supplies of aliment, and the access of light, and it is indubitable that organized beings exhibit phenomena that may be designated excitability, irritability, vital force, &c., which are only other names for these manifestations; but it is also certain that external conditions are of themselves inadequate to originate manifestations of vitality, and that the phenomena of living organized beings, generally designated excitability, irritability, incitability, &c., are *consequences* of a state of things to explain which they have been conceived as *causes*, under the title of *life*, *vital principle*, *soul*, &c. The term *excitability* should be used in physiology, in the very widest sense, to signify a property inherent in organized matter generally, to be determined to manifestations of activity under and in conformity with external influences (Tiedemann). We in fact see organized matter of every description—the green matter of Priestley, confervæ, infusory animals, &c., acquiring organic forms under the dominion of outward influences, and every species of organized being existing within a determinate circle of external agency.

It were a grave mistake to suppose this agency either *chemical* or *mechanical* in its nature; when of such potency as to act either chemically or mechanically it is destructive instead of productive of vital phenomena. These phenomena, therefore, and external influences are rather in opposition to one another than identical. External influences excite organized beings to manifest their inherent capacities; they do not bestow these capacities; all organized beings, indeed, and each particular tissue of every individual among them, are excited in different modes by the various influences from without; the stimulus is identical, the effects are infinitely different.

But organized beings, and especially animals, are not dependent on external influences alone for the manifestation of their peculiar properties; they have themselves the additional power of engendering stimuli proper to arouse into activity the various organs and systems of which they are composed. The fluids circulating through every part of their bodies may be regarded in the light of the most generally distributed stimuli of this description. The nrevous system is another and important source of excitation, the influence of which is felt in every part of the organism of all animals above the very lowest. The various instincts, appetites, propensities, sentiments, and intellectual faculties, also, which all emanate from the nervous system, are inherent causes of a vast variety of manifestations of activity among the more perfect animals. There are yet other stimuli of a mechanical, or chemical, or peculiar nature, which excite unusual or anomalous manifestations; in this category may be placed contagions of different kinds, the causes of epidemic diseases, medicines, &c.

With regard to the essence or cause of this property of the organic globule to commence, and of the perfectly developed organism to manifest the various phenomena whose sum constitutes their vitality, and endows them with their various cognizable properties, all we can say is that it appears to inhere immediately in the particular state of matter which composes them. What this state is in itself we cannot tell; but we are familiar with the phenomena which ensue from, and which indeed reveal to us its existence. It is evidently as diversified as species, and as the systems or organs possessed by the individuals severally composing these: there is a power—the *nisus formations*, the *vis plastica*, in the matter susceptible of formation,—the *organic globule*, the *germ*,—which presides over and regulates its acts; and there are powers inherent in the parts or organisms to which the plastic force gives rise, in accordance with which they manifest the special acts that distinguish them. It would be improper, however, to regard this power or these powers as forces apart from and other than the globules, germs or organisms themselves; in the present state of our knowledge we cannot separate exciting causes from manifestations of activity; all we can venture to say is that germs exist, that organisms exist with inherent capacities of action in harmony with the peculiar states of their constituent elements, thus: the germ of the infusory animal exists with its inherent capacity to engender an infusory animal, the germ of the polype with its inherent power to produce a polype; in the same way the various tissues, vessels, glands, &c. of vegetables and animals exist with their special capacities of excitation, which are manifested in the particular functions they severally perform. Excitability is therefore a multiform property and a consequence, not a single peculiar power inherent in organized beings, the fundamental cause of their actions and identical with or itself the living principle. Dependent on the integrity and continuance of the functions of nutrition, how can it be the cause of these? Only manifested in kind, with the occurrence of specific organs, how can it be the cause of their several manifestations?

We are altogether in the dark with regard to the mode in which the motions and other actions of organized beings are performed, how or by what law the globule that in the infusion of organic matter is to become an infusory animal moves, as well as of the manner in which the contractility of a muscle is excited by the stimuli fitted to call this quality into action. The contractility of the infusoria, polypi, medusæ, and other similar tribes appears to be peculiar. The motions exhibited by the confervæ, tremellæ, and simplest vegetables are also peculiar to them, they differ from those manifested by the simplest animals in being entirely under the influence of external influences, and showing nothing like spontaneity. The tissues of all animals, even the most complicated, show traces of a vital tension or contractility, different from simple elasticity and not depending on muscularity; the cellular membrane, skin, fibrous tissues generally, excretory ducts, and vessels of all descriptions tend to contract upon the parts and fluids they surround and include. This tonicity or peculiar contractility disappears in great part with the cessation of life: a wound made in a dead body never gapes as it does in a living one. Something of the same kind exists in vegetables; the sap ascends with greatly increased velocity in the young shoots under the influence of stimuli of different kinds, and its flow is checked by narcotics and altogether arrested by poisons; it is probable, therefore, that it takes place in consequence of a vital tonicity or contractility in the sides of the sap-vessels which contain it.

From this general review of the physical construction and vital phenomena of the two grand classes of organized beings, vegetables and animals, it is impossible not to remark the strong features of resemblance, and yet the numerous points of difference they exhibit. Both have a beginning, which happens very much in the same way in each; both live as individuals by the susception of aliment and its prepration by a variety of processes, which, in their essence, differ but little from one another; both continue themselves as kinds in a surprisingly similar manner; both exhibit the changes denominated age; both have a merely temporary existence, consequently both exhibit the phenomenon entitled death, and both are decompounded after the cessation of life, their constituent elements assuming new shapes, in obedience to the general laws of chemical affinity, which had been set at nought during the existence of the individuals in either class.

Notwithstanding these striking points of resemblance between vegetables and animals in all that is essential or general, it is impossible, as we have seen, to condescend upou particulars without immediately detecting differences that distinguish in the most marked manner the individuals of the one class from those of the other. It is always in their lowest or most simple species that we remark the most striking similarity between vegetables and animals, and it is among these that we constantly find ourselves most at a loss for characters distinctive of each. We observe no evidence of anything like a connected chain of being from the lowest or most simple, to the highest or most complicated vegetable, and from this through the most inferior animal upwards to man; it is, on the contrary, in the extremes or lowest grades of each that the greatest similarity prevails; here vegetables and animals approximate very closely, here they literally inosculate, but from this common point they begin to form two distinct series, which diverge ever more and more widely from one another as they ascend. Without attention to particulars, it would seem impossible to adduce as ultimate terms of distinction between vegetables and animals, other faculties than those of voluntary motion and sensation as peculiar to the latter, in virtue of the one of which powers they are rendered in a great measure masters of their own existence, whilst by the other they are endowed with consciousness of many of the various acts that take place within, and of the phenomena that occur without them. Even this distinction, however, is only applicable as regards species considerably raised above the lowest; would we indicate the differences between the most inferior members of either series we must condescend upon particulars, and, in some instances, even call in analogy and inference to our aid in laying down the chart of their resemblances and dissimilarities.

COMPARISON OF ANIMALS WITH ONE ANOTHER.

This head is also comprised within that of our entire Cyclopædia. The glance we shall cast over the field it embraces will, therefore, be very cursory, and the views taken of the objects it presents extremely general.

Physical qualities and material constitution of animals.—In point of *size*, animals differ most widely from one another. The existence of some is only made known by the aid of a powerful microscope, the length of others exceeds a hundred feet, and their weight amounts to many tons. These extremes include animals of every intermediate bulk.

The *form* assumed by animals presents many more interesting particulars for study and investigation than the mere bulk of their bodies. The consideration of this accident has even been made the ground of a classification of the objects included within the animal kingdom by several naturalists, and although not adopted as the sole basis of any one now generally received, it nevertheless furnishes the element upon which several of the classes even of the most recent are established. Some animals present themselves in the likeness of a *globule*, others of a *filament*, and others of a small *flattened* membrane (the cyclides). Various animals, again, from exhibiting no uniform or regular shape, have been entitled *amorphous* or *heteramorphous*.

Animals which exhibit a determinate form naturally arrange themselves into two classes; their bodies are either disposed around a centre, or they consist of two similar halves cohering along a middle plane or axis; the first are the *radiata*, the second the *binaria* or *symmetrica* of naturalists. The radiata are not a very extensive class of animals, neither is their organization extremely complicated. The symmetrical is a much more numerous class than the radiated, and includes within its limits creatures of such simple structure as the entozoa, and of such complicated fabric as quadrupeds and man. Of the symmetrical animals, some consist of a mere trunk without appendices or limbs; those that are provided with limbs, again, have them in the shape of feet, fins, wings, or hands, according to the media in which they live. In some the body forms as it were a single piece, in others it is divided into portions, such as head, trunk, and tail. Sometimes it is naked; at others it is covered with shells, scales, spines, hair, &c. Sometimes the general integument is continuous, unpierced by any opening that leads to the interior, at others it is reflected inwards, and lines extensive cavities there contained.

With regard to *structure*, as may be imagined, the amorphous tribes, at the bottom of the scale, are the most simple of all. The bodies of some of these are without any internal cavity, and without any division of parts; they are homogeneous masses, generally gelatinous in appearance, and simply cellular in structure, without arrangement into tissues or particular organs. The external surface of these animals imbibes the matters which are fitted to subserve the purposes of nutrition, and we may presume that it throws off by transpiration such particles as are worn out or have accomplished this end. The external surface is also the organ of respiration in these animals. They procreate by the evolution of gemmi from their surface, and if they possess sensibility the element to which it is attached must be generally diffused throughout their substance.

The organization of the radiata becomes considerably more complicated. Fluids are no longer absorbed from the external surface of the body; we meet with an internal cavity, the rudiment of a digestive apparatus, having a single opening in some of the species, which serves consequently for both mouth and anus, but in others presenting two openings, a mouth properly so called on one side of the body, and an anus on the other. Through the walls of this cavity the nutritive fluids make their way, and infiltrate the general mass of the animal's body. In this class we also discover the rudiments of a nervous and of a muscular system. The nervous system consists of rounded masses of a soft whitish substance, equal in number to that of the radii composing the animal, connected together by slender white cords, and sending off filaments of the same description to all parts of the body, but especially to the outer integument, and to the internal digestive apparatus. The muscular system consists of reddish and whitish fasciculated fibres disposed in the line of the motions. The external surface of these animals is still the only organ of respiration they possess.

The three systems now enumerated—the digestive, the nervous, and the muscular—are readily demonstrated in the majority of the symmetrical animals, and are even very soon found to have acquired complication, and to have sundry other parts and organs superadded to them. The digestive apparatus consists of a mouth for the susception of aliment, of a stomach for its elaboration, of an intestinal canal from which the nutrient juices are absorbed, and of an anus from which the undigested residue is expelled. Whilst in the radiata the nutritious fluids passed through the parietes of the digestive cavity to impregnate the body of the animal, and be assimilated with its substance; in the binaria we find vessels, the rudiments of a circulating system, employed in receiving the juices prepared in the digestive apparatus and transmitting these to all parts of the body. Digestion, too, in this class becomes a more complicated process than in the radiata, and various secreted fluids, *saliva* and particularly *bile*, the special products of large and evidently important organs, are added to the alimentary mass in its progress through the intestinal canal.

In addition to the digestive apparatus and general external respiratory surface we by-and-by find an especial system dedicated to the aeration of the juices prepared for nutrition; this is the *respiratory apparatus*. Of extreme simplicity in the first instance, being little or no more than a fold of integument turned inwards, and forming a simple cavity or sac within the body of the animal, it is soon rendered more complex in its structure, being distributed in the manner of vessels under the name of *tracheæ* or *canals* to different parts of the body, or being confined to a particular district, and entitled *lungs* or *gills* as it is fitted to receive the atmospheric air immediately, or to make use of this elastic fluid suspended or dissolved in water.

The existence of this separate respiratory apparatus presupposes that of another system, namely, the *circulatory*. The fluids prepared by the organs of digestion are not yet fitted to minister to the growth and nutrition of the organization; to be made apt for this purpose they require exposure to the air in the lungs or gills wherever these organs exist, and these being distinct, or contained in a particular region of the body, a series of conduits were required, first to carry the fluids thither, and to transmit them subsequently to every part of the organization for its support. Like all the other systems of animals, the circulatory exists of various degrees of complexness; when first encountered it consists of a series of simple canals or vessels, which diverge on every hand; by-and-by it has several, and finally one, forcing piece, or heart superadded to it, which impels the fluids by its contractions to every the most remote part of the organization.

Among animals, however, nutrition is not a process simply of addition or composition; it is also, perhaps universally, one of subtraction or of decomposition. We have seen the composition provided for by special systems in animals occupying very low grades in the scale of creation; we mount but a short way before we encounter an apparatus which presides over the decomposition also in the shape of another system of vessels, the *veins* and especially the *lymphatics;* these collect the superfluous and worn-out particles from every part, pour them into the general current of the circulation, wherein being exposed in the vital elaboratory of the lungs they are either assimilated anew and made fit once more to form an integral part of the organization, or, being subjected to the action of certain glands, they are singled out, abstracted, and finally ejected from the system entirely. In the most complicated animals therefore a peculiar apparatus for the depuration of the system is superadded as complementary to the absorbents. This we find in the glandular bodies familiarly known as the *kidneys;* the vehicle in which the decayed particles are withdrawn is the urine.

When we examine the instruments of *sensation*, we find them becoming gradually more and more numerous, and the nervous system generally more and more complicated as we rise in the scale of animal creation. The nervous system is before long found to consist of other parts than a series of similar ganglions supplying at once the organs of sensation and those of digestion; it has a central part superadded, from which issue immediately the nerves that supply the organs of the senses,—sight, hearing, taste, and smell, which at the same time make their appearance with their especial capacities. This central superadded portion is the *brain*, with its prolongation in the vertebrata entitled *spinal marrow*. Nor in the more perfect classes of the animal kingdom is the nervous system even thus simple; among them it consists essentially of two grand divisions, the one including the brain and spinal cord and the nerves thence proceeding, the other constituted by the system of the *great sympathetic*, or that series of ganglions which, situated on either side of the vertebral column, from the head to the pelvis, are connected with one another, and with the cerebro-spinal system, by branches of communication, and furnish the digestive apparatus with almost the whole of the numerous nerves it receives.

The nervous system in its relative degree of development and complexity becomes the ultimate standard by which the perfection of animals is estimated, and their place in the scale of creation assigned to them: if man stand alone and unattended, as he undoubtedly does, upon the summit of the pyramid, it is only because he possesses in his brain the organs of certain moral and intellectual faculties which occur in no other living thing; these confer on him his humanity; these are the material parts to which the soul is wedded during his existence.

In intimate connection with the functions of phrenic or animal life, and developed nearly in the same ratio, is the *muscular system*, the most universal agent of locomotion. Exceedingly simple at first, and operating at great disadvantage through a want of levers and points of support, we trace it becoming gradually more complicated as we ascend, and, finally, provided with a complementary *skeleton* or frame-work by means of which it acts to the best advantage. The skeleton among animals is of two kinds,—external and horny, internal and osseous. In the first case the muscular system is inclosed within the resisting pieces which it has to move; in the second it is without these, and is arranged around them. The bones and muscles together compose the numerous and variously fashioned instruments with which animals accomplish the promptings of their inward appetites and instincts. They form feet, fins, hands, the prehensile tail, &c. The muscular system, and a modification of the osseous, the cartilaginous, moreover, compose the most universal instrument by which animals communicate their vicinity, their states, their dispositions or affectious, &c. to one another—this is the *larynx*.

The means by which species are continued, are extremely varied. The very lowest tribes of animals we have seen shooting forth buds exactly like vegetables, and these being in due season detached from the body of the parent, find themselves fitted to commence an independent existence. At the next step we take in ascent, however, we meet with particular organs of reproduction; and, singular enough, the moment these exist they are not of one, but of two kinds, denominated male and female. Sometimes these organs are possessed by single individuals, far more commonly, however, they are divided between two, whence the so uniform division of the beings composing the animal kingdom into sexes. The simplest form of the male organ of generation is a gland secreting a fecundating fluid (the testis) and an excretory duct: the simplest form of the female apparatus of generation is a gland or body producing germs (the ovary) and an excretory duct. In a greater state of complication or development these essential parts in the male have an instrument superadded to them by which the fecundating fluid is carried directly into the body of the female, and in the female the ovary has a dilatable cavity superadded in which the germ remains for a season, and until its included embryo attains such a state of development as is compatible with its more independent existence surrounded by the circumstances amid which it is afterwards to live. In the higher classes, the connection between the parent and offspring does not cease immediately on the birth of the latter, and in the highest of all we find the female furnished with a complementary apparatus (the mammæ), from which she furnishes her young with food during the first period of its existence.

Actions of animals.—The foregoing rapid sketch of the grand features of distinction among animals with reference to their structure naturally leads to the inference of diversity of function in harmony with the peculiar organization possessed by each. In the lowest grades of animal existence we have seen to how simple a process the act of nutrition—this act so complicated among the more elevated tribes,—is reduced. It consists merely of imbibition or absorption by and of exhalation from the general surface of the body. The matters absorbed appear to be assimilated incontinently, or to be made a part of, and to receive the form proper to, the animal in the instant of their assumption: applied immediately to the homogeneous organism, the nutriment is forthwith made a portion of its substance. The vital decomposition of the bodies of these lower animals is accomplished with the same simplicity and directness: the surface that absorbs is also that which exhales the worn-out particles of the system.

The first step by which nutrition becomes more complex, as we rise in the scale of creation, is the institution of a process of solution (digestion), by which the matters appropriated as aliment are prepared for reception into the body. This process of solution is accomplished by powers inherent in the animal itself, within a cavity destined for the purpose. In our survey of the structure we have already seen to how great an extent the organization became complicated as a consequence of this centralization of the office of digestion, and with what variety of superadded function this complication was attended, namely, *external absorption*, *sanguification* or the formation of a fluid, the pabulum of nutrition, confined within vessels, *respiration*, *circulation*, and, finally, *assimilation*, in regard to the composition; whilst with reference to the vital decompositions we have discovered another species of interstitial or *internal absorption*, and *depuration* of the system by one principal apparatus, the kidney, to which the cutaneous and pulmonary exhalations may be added as supplementary.

But every one of these functions, and its organic apparatus, are themselves modified, according to internal aptitude, and in conformity with the circumstances surrounded by which animals commence and continue their existence. *Digestion* is a very simple process in those cases in which it takes place within a single cavity, having but one opening, and no complementary apparatus of any kind, compared with what it is when connected with an apparatus for bruising the food, for mixing it with saliva, for macerating it in a crop or a series of reticulated and foliaceous pouches, mixing it with bile, pancreatic juice, &c. &c., and transmitting it along a muscular canal, of six, eight, or ten times the length of the body to which it belongs.

Absorption, in like manner, among the most inferior classes is essentially one and undivided either in kind or destination. It is in itself adequate to the entire office of nutrition, seizing and transmitting the matters which are fitted for this end, elaborating the food and atmospheric air at the same instant of time, and effecting immediately the composition of the whole animal organism. In animals higher in the scale, we perceive, in the first place, that there are several species of absorption: there is, in the first place, the absorption from the surface of the digestive passages and that from the surface of the lungs, gills, skin, &c. or of the respiratory apparatus. Again, absorption is not limited to furnishing materials for the composition of the organism; it is also entrusted with the office of abstracting from its interior the particles which are worn out and no longer fit to continue the ends of their existence in the places they occupy. Nor is this all; for it is by absorption that the amount of those exhaled fluids which moisten internal cavities, having no external communications, is regulated, and by which, as it would appear, many of the secreted fluids, the bile, and the spermatic fluid in particular, are inspissated and rendered more fit to accomplish the important ends they subserve in the economy. Absorption in the highest classes of all is even performed by two, and perhaps three different orders of vessels, the lacteals, namely, the lymphatics, and the veins.

Further, absorption is not in the higher as it is in the lower classes of animals a function effecting immediately the composition and decomposition of the parts and particles of the organization. It is intermediate to the preparation of the nutritious juices and their appropriation or assimilation by the organism. The lacteals or absorbent vessels of the intestines collect the fluid called *chyle* from the pultaceous alimentary mass in its progress through the intestines. But this fluid is not yet fitted to subserve nutrition; as a preliminary it has to be subjected to the action of the atmospheric air in the gills, lungs, &c., where, being converted into arterial blood, it first becomes apt to minister to the growth and reparation of the body and its parts. So also in regard to decomposition: the fluids collected from all parts by the lymphatics and veins, are not immediately rejected from the economy, as useless and having already accomplished all of which they are susceptible, but being first exposed to the contact of the atmosphere, and then made to undergo the scrutiny of the depurative organs, they are either retained, being restored to their pristine capacity to subserve nutrition, or are abstracted from and thrown out of the body as no longer fit to aid in its growth and maintenance.

Intercourse with the air of the atmosphere is essential to every living thing, and we should *à priori* have anticipated very considerable variety in the means by which, as well as the mode in which this intercourse is established. Among the inferior tribes which are nourished by absorption immediately from the surface of their body, and which find the materials of their nutrition ready prepared for their use in the circumambient media, we may presume that the matters absorbed have either undergone the needful changes by exposure to the air previously to their assumption, or that these changes take place at the time they are appropriated. Where digestion is a preliminary to absorption and assimilation, it is evident that this could not have been the case; and hence the necessity for that modification of the function of *aeration* entitled *respiration*. Looking generally, we observe two principal varieties in the mode by which aeration is accomplished: in some classes there are a number of holes arranged symmetrically along the sides, and communicating with air-vessels entitled tracheæ, which are subsequently distributed to every part of the body. The air in this case is evidently brought into communication with the nutrient juices already arrived at their destinations; and the necessary changes are wrought in them at the instant of their assimilation. Here the respiration is very properly said to be *diffuse* or *disseminated*. In other classes, again, in which the respiration is *local* or *concentrated*, in harmony with the existence of a special apparatus, which we have spoken of under the title of lung or gill, aeration is accomplished by the access of the air on the one hand, and the exposure to its action of the nutritive fluid on the other, the effect of which is to convert the latter into arterial blood, and to make it fit, upon its distribution by appropriate channels, to accomplish the ultimate and immediate nourishment of every part of the organization.

The differeut media in which animals live involves the supposition of another modification as to the mode in which the blood or nutritive fluid is aerated. Those that live in air respire this elastic fluid immediately; those that live in water, again, respire it mingled with or dissolved in the surrounding medium. The tracheæ of those animals whose respiration is diffuse, and that exist on the surface of the earth, consequently are filled with air; those of the creatures that exist in water are conduits for the constant transmission of this fluid. When the respiration is concentrated, corresponding modifications in the function are encountered according to the medium in which animals live: the air is either received immediately into the body, when the apparatus is known as a *lung*, or, suspended among water, it is passed over the surface of the respiratory organ, which is then denominated *gill*. Quadrupeds and birds respire universally by means of lungs, fishes and the mollusca by means of gills. In certain reptiles the function is carried on by means both of lungs and gills, and as it would appear even by the general surface of the body either vicariously, or at one and the same time. These are the only true amphibious animals.

A *circulation*, properly so called, is the appanage of an organization already somewhat complicated, consequently of an animal considerably raised in the scale of creation. This function, it is evident, as implying in its simplest sense a progressive motion of the general nutritive fluid or blood, can only exist where such a fluid is encountered. It is altogether wanting, therefore, among those animals in which nutrition is accomplished immediately. We ascend but a little way in the scale before we find the function consisting not only of an outward or progressive motion of the nutritive fluids, but of a retrograde motion also of these same fluids modified in their nature, and requiring exposure to a greater or less degree in some form of respiratory apparatus to fit them anew for distribution to the organization at large. The fluid in this instance parts from a centre, and returns thither after having made the round of the system. Circulation in this acceptation only occurs among those animals that have a separate respiratory apparatus, and in which we meet with absorption of nutriment from without, and of lymph, &c. from within. The pabulum of nutrition is taken up by lacteals and veins from the digestive apparatus, and by veins and lymphatics from the rest of the organism for transmission, under the name of venous blood, to the apparatus of respiration, whatever its form. In this the fluid, still immature and unapt for assimilation, is exposed in vessels of infinite minuteness and extreme tenuity to the action of the atmospheric air, and having undergone in these a certain change, it begins to be collected by another set of vessels, which form branches successively of larger and larger size, until finally it is projected from the respiratory apparatus in one or more trunks, under the name of arterial blood, fitted for assimilation by the organization at large, and proving the principal stimulus under the influence of which its various particular organs accomplish their offices.

Circulation, however, as a function, is complicated in the same degree as the apparatus by which it is effected. In some classes we find the circulation taking placing through *vessels only*, one set distributing the blood from the respiratory apparatus to the body generally, another collecting this fluid again, and the newly-absorbed matters from the body at large, and transmitting these for elaboration anew in the organ of respiration. In other tribes, and this invariably after the very lowest grades of the scale are passed, we find the hollow muscle, or forcing apparatus, which, in glancing at the differences of structure, we have spoken of as the *heart* superadded to the circle of vessels, which even in its simplest state consists of at least two cavities communicating with one another, one for the reception of the blood from, the other for the projection of this fluid to the general system.

But the blood does not follow the direct and simple course here supposed in almost any case. There is the aeration of the fluid in the way, and means to accomplish this important end must of course be provided. Among many animals it would appear by no means necessary that the *whole* of the blood should undergo exposure in the respiratory apparatus, in order to fit it for the wants of the organization; a *part* only is sent thither, and this on admixture with the remainder suffices to revivify the mass. In this case it is not imperative that the two kinds of blood—the unaerated or venous, and the aerated or arterial—should be kept distinct; there is consequently no occasion for more than one recipient cavity or auricle, into which the aerated blood from the organ of respiration, and the unaerated blood of the system are poured in common and mingled, and one projecting cavity or ventricle from which the mixed current is distributed partly to the respiratory apparatus and partly to the system at large. Here the blood in its course describes no more than a single circle, beginning and ending in the heart, which is then characterized as *simple*, consisting, as has been said, of a single auricle and a single ventricle. Among other tribes of animals, however, the whole mass of blood requires to undergo aeration in the respiratory apparatus each time it completes its round before it can again subserve the wants of the organization. In this instance it is evident that the aerated and unaerated blood require to be most particularly prevented from commingling, and that a single or simple heart will no longer suffice as the implement of circulation. This complex circulation is met with among animals so low in the scale as to be unprovided with a heart, when of course it is accomplished by means of vessels only. In some tribes the one portion of the function is performed by the medium of vessels, the other by the agency of a heart which is now connected with the general systemic circulation, now with the pulmonic, being situated in the one case in the course of the aerated, in the other in that of the unaerated current of blood. In the most elevated classes of animals, finally, the double circulation is effected by means of *two* hearts, one dedicated to the projection of the unaerated blood into the lungs, the other to the propulsion of the aerated fluid through the general system. These two hearts, indeed, adhere to one another, and are usually spoken of as if they constituted no more than a single organ, having however four cavities, two auricles and two ventricles, but they are not less distinct on that account, and are severally the centre of a particular circulatory system, one of which commencing in the cavities for the venous or unaerated blood, extends through the respiratory apparatus (then uniformly a lung), and back to the cavities for the arterial aerated blood; the other, commencing in the cavities just named, extends to every part of the organization, and terminates in the cavities for the unaerated blood, where the lesser round recommences, to be followed in its turn by the greater, and so on, during the whole period of existence.

Assimilation appears to be identical in all animals; it is the ultimate term of nutrition, and however varied the apparatus that ministers to the act, the act itself we may presume not to differ in its essence in one animal from what it is in another.

Akin to assimilation we have *secretion*, and this is a function that offers extensive differences in every class of the animal kingdom. It is generally spoken of as of two kinds, *excretion*, and *secretion*, properly so called. In the lowest tribes excretion is quite simple, consisting of a mere exhalation from the general surface of the body. In the more elevated we find another and very important form of excretion superadded, that, namely, of the urine, the nature of which, and the mode in which it takes place, we have already indicated in speaking of the structure. Secretion, however, even in the classes but a little raised above the lowest, is a function of much more varied import, and consists of a great many other processes than that by which the bodies of animals are depurated and their blood maintained in a state fit to supply all the wants of the system. We advance but a little way before we begin to detect distinct organs destined for the secretion of peculiar fluids from the general mass of circulating nutriment, evidently subservient in many cases to the most important ends of the economy, and by no means destined to be rejected from the system as useless, like the excretions properly so called. It seems even that it is by a process analogous to secretion that the imponderable matters—the heat, light, and electricity, which we have acknowledged as elements in the constitution of organized beings, are eliminated.

All animals possess *sensibility* or *sensation*, though evidently in the most dissimilar degrees. Some have been supposed to possess the faculty of perceiving impressions made upon them by external objects, but to have no power of reacting upon external nature, they being without the faculties which in the higher classes prompt to action. This state, however, of animal existence is rather hypothetical than demonstrable, and in animals generally we observe not only the aptitude to be impressed, but inherent capacities inducing reaction upon the world around them. The sensitive life of these beings consequently consists of two items—the senses and their organs, external and internal, by which impressions are received and cognized, and the affective and intellectual faculties by which the motives to action, the propensities, sentiments, instincts, appetites, &c., are originated, and the means and modes of accomplishing their promptings are supplied.

Animals evidently differ immensely in the degrees in which they are endowed with external and internal senses. Some appear to possess none of the external senses save touch; others, in addition to this, have taste and smell; the most perfect besides these three reckon sight and hearing. The internal senses, in like manner, are more or less acute, more or less numerous, according to the consitution of animals: those of hunger and thirst are probably universally distributed, and the most keenly felt; then come those which induce the respiratory act, the sexual act, &c.; and here we find ourselves among the *propensities* which exist in very different numbers and kinds in every different species of animal. Some tribes tend their offspring, others leave their progeny to the care of accident, which in this case always suffices for their protection; some congregate in herds or shoals, others live solitary or in pairs; some are bold and rapacious, others timid and gentle, &c. When we examine animals generally, with reference to the sentiments or *moral faculties*, we find them still more or less like each other in many respects, some being cautious or cowardly, proud or haughty, persevering or obstinate, &c., in various proportions. When we contrast all other animals with man, however, in regard to moral endowment, we immediately perceive the broad, the impassable line of difference that runs between the lord of creation and all the other beings that with him partake of life. The feeling which leads man to view his actions in their bearing upon others or in relation to justice, is extremely weak among animals, if indeed it do actually exist among them at all. The same may be said of the sentiment which leads mankind to wish well to all, and to succour and relieve those that are suffering and unfortunate. The feeling, again, that raises man to the imagination of a something beyond nature, the sentiment that inclines him to reverence and adore his Maker, thus in one way revealed to him, and the wonderful impulse that leads him to look beyond time and his merely temporary existence, and thence to conceive infinity and eternity, are so many moral attributes which man alone, of all created things, possesses.

Similar diversities in intellectual endowment are apparent when we survey the animal kingdom at large. Intelligence appears utterly wanting in numerous and extensive classes, and it varies conspicuously in the members of every tribe among which it is apparent. In his intellectual powers man is not less eminently raised above all the other beings of creation than in his moral constitution: he alone takes note of the phenomena that pass around him with ulterior views, and he alone perceives the relation between effect and cause, preparing and foreseeing consequences long before they happen.

Locomotion is a function so evidently in relation with the circumstances surrounded by which animals exist, and with the apparatus by which it is accomplished, that it is enough to refer back to the structure for proof and illustration of its infinite modifications among the various genera and species of the animal kingdom. Some, by their constitution, are incapable of motion from place to place, but they still perform those partial motions which their preservation as individuals require—taking their food, respiring, voiding their excretions, &c. Those that can move from one place to another have organs in relation to the mode in which this motion is accomplished, whether it be by creeping, by swimming, by running, leaping, flying, &c. &c. Every partial movement executed by the higher animals has, farther, its own special apparatus: the intestinal canal has its muscular parietes; the necessity that is felt to communicate internal sensations and ideas has its pathognomonic means in the looks, gestures, sounds of the voice, and so on.

Nor is it only in the greater or less degree of complexity of their general structure, in the number and diversity of their particular organs, or in those of the actions whose sum constitutes their vitality, that animals differ from one another; they vary farther in the degree in which these organs and these functions are enchained or mutually dependent. In the most simple animals so complete is the independence of the several parts, that their bodies may be divided into numerous pieces without injury to the vitality of any one of them, each possessing in itself the capacity to commence a separate existence. In animals somewhat more elevated in the scale we observe very extensive powers of reproduction at least, of parts that have been lost, and even of continuing existence in very insignificant remainders of their bodies. In the most elevated tribes, however, the dependence of every part upon the whole becomes such that neither will the body essentially mutilated survive, nor will any part of the slightest consequence continue to live. Among the beings at the bottom of the scale we have in fact found the organization to be homogeneous, or without distinction of parts, and nutrition to be accomplished by means of an immediate absorption and exhalation; and as every part possesses the structure which makes it capable of these two acts, every part, it is evident, suffices for its own existence. In the higher classes of animal existence, however, nutrition requires the concurrence of a multitude of peculiar acts; and in order that life may be continued in any fragment of one of the members of these, it is plain that this fragment must contain the organs of every one of the functions essential to nutrition. Further, it is certain that the nervous system, when once it has fairly made its appearance, strictly dominates the nutritive function, and that every part of the nervous system itself becomes progressively more and more dependent on one of its portions, the encephalon or brain, as animals stand higher in the scale of creation, and as the functions over which the nervous parts preside respectively are themselves of a higher order. These are new and additional reasons for the centralization of life, or for the complete dependence of the organs and their functions one upon another among the more perfect animals—man, the quadrumans and quadrupeds, birds, &c.

So much for the acts that minister to the preservation of the individual. Let us now turn to the interesting series by which species are continued. In the very lowest grades this end is accomplished without the concurrence of sexes: at a determinate period of its life the animal either separates into several fragments, which become so many new and independent individuals, or it throws out a number of buds or germs from its external surface or from a particular internal cavity. The first of these modes of reproduction is entitled *fissiparous*, the second *external gemmiparous*, and the third *internal gemmiparous*.

When we examine animals in the next grade, we find reproduction taking place by the concurrence of sexes, or rather of two kinds of organs which we afterwards discover divided between different individuals, who are then said to be of opposite *sexes*. When the male and female organs are united in the same individual it is denominated an *hermaphrodite* animal, and in some cases seems to suffice for its own impregnation; more generally, however, hermaphrodite animals are not capable of performing this act upon themselves, but require the concurrence of another individual of similar constitution: the two hermaphrodites meet and severally impregnate one another.

Among the more perfect classes of the animal kingdom the organs of reproduction are universally allotted to two different individuals, *males* and *females*, which consequently become in their dualism representatives of their species. Agreeing in this single feature, the modifications in the process of reproduction are nevertheless extremely numerous. In some cases the fecundating fluid of the male is only applied to the egg or germ of the female after its extrusion from her body, as happens among fishes, several reptiles, &c.; in others the male fluid is injected into the body of the female, and made to fecundate the germ still attached to its parent. This act is generally, though not invariably, accomplished by means of a *penis*, or male external organ, with which many birds and all the animals above them in the scale of animal creation are then provided.

With this contact or intermixture of bodies we have the following varieties in the after-parts of the process: the egg or germ now fecundated is either forthwith expelled from the body, and it is only subsequently, under the influence of a certain temperature, and after the lapse of a certain time, that the young being bursts the shell and commences its independent existence; this is the case among *oviparous* animals. Or otherwise: the fecundated egg makes its way so slowly through the passages that lead from the ovary outwards, that it is hatched before it can escape, so that the young one passes from the body of the mother immediately. Animals in whom this happens are justly said to be *ovo-viviparous.* In the third and last place, the fecundated ovum is immediately loosened from the ovary, but instead of being laid, or extruded from the body immediately, it only passes along a canal to a certain distance from the ovary, where it meets with a reservoir or cavity (the uterus) to which it attaches itself, and within which it commences a series of evolutions, at the expense of the mother, preliminary to its final expulsion with instincts ready formed, and an organization so perfect as enables it to begin its separate existence. The classes in which this mode of reproduction obtains, and they are the highest of all, including quadrupeds and man, are entitled *viviparous,* so that in these, besides the connection of the sexes and the fecundation of the germ, we have the phenomena of utero-gestation and labour.

And here the proper work of reproduction ends; but the young are so generally born in some sort immature, that in the higher classes the connection between the offspring and parent does not cease immediately. In the class of mammalia, indeed, the connection is little less intimate during the earlier periods of extra uterine life than it was during the whole term of intra-uterine existence; the young being still depends upon its mother for the whole of its nourishment, and very generally for the supply of warmth it requires and the protection needful to it till able to provide for itself.

Many of the particulars now merely glanced at, and numerous others, the mention of which has been omitted entirely, will be found detailed, and their bearing and importance illustrated in the article on Generation, to which the reader is therefore referred.

(R. Willis.)

ANKLE, REGION OF THE, (surgical anatomy), (*region tibio-tarsienne*, Velp.) The relative positions and other particulars connected with the parts found in the region of the ankle, owing to the numerous accidents which occur here, are matters of great interest to the surgeon. The extent and boundaries of this region are by no means so distinctly defined as those of many others; hence, in isolating it for special description, the surgical anatomist is obliged to assign to it arbitrary or imaginary limits. We propose to adopt the following boundaries for this region, viz. superiorly a horizontal line drawn round the leg two inches above the malleoli, and inferiorly a line drawn across the dorsum and sides of the foot at the same distance from those bony prominences. In this space are comprised the ankle-joint and several important vessels, tendons, and other soft parts well worthy of attention.

In examining the external characters of this region we notice four well-marked prominences, one on either side, termed *malleolus*, (*internus* v. *externus*); a third posteriorly, which corresponds to the tendo Achillis; and a fourth in front, resulting from the projection of the astragalus. The malleoli do not accurately correspond either in situation or shape to each other: the internal lies upon a plane superior and anterior to the external, and in a well formed person is much less sharp and prominent,—a fact, the recollection of which is of great importance in estimating deformity or dislocation of the joint. The cylindrical prominence behind, as it depends upon the tendo Achillis, will of course vary in size and tension according to the relaxation or contraction of the gastrocnemii muscles. Upon either side of the tendo Achillis, between it and the malleolus we meet with a deep groove, called by some the calceo-malleolar furrow: that upon the outside is extremely well marked, and we may here distinctly feel through the integuments two of the peronei tendons: the internal calceo-malleolar groove is broader and shallower, but of much greater interest, for through it, in addition to certain tendons, we have transmitted the principal vessels and nerves destined for the sole of the foot. The anterior prominence, named in popular language, "the instep," is rounded in the transverse direction, and in some individuals projects much more than in others. On throwing the foot and toes into action, as in walking, we can here distinctly recognize the tendons of the tibialis anticus, extensor pollicis, extensor digitorum longus, and peroneus tertius, and almost in the mesial line may be felt pulsating distinctly the anterior tibial artery.

Having thus examined the landmarks which are to guide us in our anatomical investigation of this region, we may next proceed to inquire into the nature and relations of its constituent parts. Besides the bones, cartilages, and ligaments which immediately constitute the joint, and form the basis of the region, we have likewise several other structures entering into its formation; integuments, muscles, vessels, nerves, and fasciæ are here arranged in successive layers beneath each other. We shall accordingly describe four layers,—namely, 1. the skin; 2. the subcutaneous cellular tissue; 3. the fasciæ; and 4. the tendons, vessels, and nerves, which lie in immediate contact with the articulation.

1. *The skin* forms a complete investment for the whole region, but its structure and properties differ considerably in different situations. Upon the inner ankle it is smooth and thin, and possessed of but little extensibility; so that in operating here, if we look forward to union by the first intention, it becomes a matter of great moment to preserve as much

of the skin as possible. Owing to the same peculiarities of the integuments in this situation, no less perhaps than to the frequent motion of the part, wounds and ulcers occurring upon the inner ankle are extremely tedious and troublesome, in many instances laying bare the bone, and finally even occasioning its destruction. Upon the outer ankle, the skin is more pliant and extensible; hence the greater facility of healing wounds and ulcers in this part; and hence, too, the more frequent occurrence of abscess and extravasation beneath the surface. At the posterior part of the region the skin acquires great strength and thickness, becoming as it passes downwards still more dense and unyielding, approximating in fact to the character of the plantar integument. Upon the instep it is also of tolerable thickness, particularly in those individuals whose feet are usually uncovered. In this situation, however, it is soft and extensible: its natural pliancy being still further increased by the secretion of numerous sebaceous follicles thickly scattered throughout its substance. It is here, owing to the frequent motions of the joint, thrown into transverse rugæ, and hence, in making an incision, to give exit to matter, it may be proper to prefer a transverse to a vertical direction.

2. *The subcutaneous cellular tissue.*—The structure and properties of the subcutaneous cellular tissue are not the same throughout the whole region, but like the skin, which we have just considered, its characters vary in different situations. Thus, upon the instep, it is at the upper part loose and distensible, full of adipose cells, and similar in every respect to the subcutaneous tissue of the leg, of which it is a prolongation: as it descends, however, it becomes more dense and unyielding, and adheres more closely to the skin which covers, and to the annular ligament which is placed beneath it. This anatomical fact at once explains why it is that when subcutaneous abscess or infiltration occurs on the anterior part of the leg or foot, the passage of the fluid either upwards or downwards is, for a time at least, impeded at the ankle-joint. It is likewise owing to the density of the subcutaneous tissue across the ankle, that its cells do not permit the accumulation of adipose substance here; hence in very fat persons and also in children whose subcutaneous fat is usually abundant upon the leg and foot, the instep is as it were strangulated by a deep transverse furrow. Upon the malleoli the characters of the subcutaneous tissue present great differences: upon the inner one it is scanty and delicate, but of a compact structure, and contains few if any adipose cells. Upon the outer one it is, on the contrary, much more copious, of a loose and yielding texture, and usually contains a greater quantity of fat. These differences of texture will explain why, after severe contusion, extravasations so frequently occur upon the outer part of the joint and so seldom upon the inner; why abscess is so much oftener met with in the one situation than in the other; and why the transmission of pus and serum from any of the neighbouring regions takes place so much more easily about the outer than about the inner ankle. At the posterior part of the region, the subcutaneous tissue assumes again new characters: losing here its soft lamellated texture it becomes suddenly dense and filamentous, adhering with great firmness to the integuments above, and to the fascia beneath: as we trace it down it becomes more dense and elastic; the cells formed by the decussation of its filaments become loaded with a firm granular fat; in a word, it already begins to put on the characters of the dense fibro-adipose cushion, which is found in the sole of the foot. Hence it is that wounds and abscesses of the part we are now considering, approach in character those of the plantar region: hence the slight swelling, the severe pain; hence in both cases the necessity of a prompt and free evacuation of the matter.

Before leaving this subject we should observe that the subcutaneous tissue of the region we are now considering transmits certain vessels and nerves. In front of the inner ankle we meet with the incipient branches of the great saphena vein and the ultimate filaments of the saphenus nerve: the venous branches are here of such a size that they have frequently been selected by the phlebotomist as the seat of operation. Anteriorly we find the filaments of the musculo-cutaneous nerve, and externally the roots of the lesser saphena vein, and its accompanying nervous filaments.

3. *The fascia* or *aponeurosis* forms the next stratum we have to examine: it is placed between the subcutaneous tissue and the tendons. The fascia, like the two preceding layers, forms a general investment for the whole region. Its structure and properties, like those of the preceding layers, vary considerably, according to the situation in which we view it. Upon the instep it becomes continuous, above with the aponeurosis of the leg, and inferiorly with the dorsal aponeurosis of the foot, but, for very obvious reasons, surpassing both of these in strength. This additional strength is owing to the accessory band of fibres which passes transversely across the instep, interlaced with the proper oblique fibres of the fascia, and to which is given the name of *anterior annular ligament*. Arising from the anterior edge of the inner ankle this annular ligament passes outwards and soon meets with the tendon of the tibialis anticus: at this point it splits into two layers; the one passes before, the other behind the tendon, and they unite again at its outer edge. The same mechanism is repeated in the case of the extensor pollicis tendon which lies immediately external to the last-named tendon; and lastly in those of the extensor digitorum longus and peroneus tertius. In contemplating the mechanism and uses of this ligament, the surgical anatomist cannot but perceive that certain inconveniences must result from its division: its use being obviously to bind down the tendons in this situation, and to form canals for their free and separate transmission, it is clear that after its division in the

living subject, when the individual attempts to flex the foot or extend the toes, these tendons will not only form an unseemly projection upon the instep, but also the accuracy and perfection of these motions will be much impaired. Upon the lateral parts of the region, the fascia is so intimately united to the periosteum, that it is almost impossible to separate them from each other, and hence some have denied its existence here. Behind both malleoli, it becomes however again very distinct, forming in both situations a band similar to that which we have just seen upon the instep. The *internal annular ligament* arising from the posterior edge of the inner malleolus passes backwards to the os calcis; it is thrown like a bridge across that deep gutter which divides the heel and ankle from each other, and it is destined like the anterior ligament to form a covering to the tendons and other parts which pass through this region. Like the anterior, the internal ligament also consists of two layers closely united to each other. To express more distinctly the mechanical disposition of these layers, we may say that the bridge formed by the internal annular ligament consists of two arches; through the anterior arch are transmitted the tibialis posticus and the flexor digitorum longus tendons, wrapped each in its own synovial theca: the posterior arch is occupied with the posterior tibial vessels and nerves, and the tendon of the flexor longus pollicis muscle. Having thus safely conducted these important organs, the superficial layer of the ligament fixes itself into the os calcis, while the deep one passes backwards and upwards to become continuous with the deep fascia of the leg. Behind the external malleolus, the fascia forms another but less remarkable ligament, which Blandin calls the "external annular:" this passes from the fibula to the astragalus, and forms with the posterior edge of the malleolus a deep osseo-fibrous canal for the transmission of the peroneus longus and brevis tendons.

At the back part of this region, the fascia is also found covering the great tendo Achillis; this tendon also, like the smaller ones we have just spoken of, is not merely covered superficially, but is contained within a sheath, formed by the splitting of the fascia into two layers: the posterior layer we may regard as the continued fascia itself; the deep one passes in front of the tendon, and if we trace this upwards, we shall find it becoming ultimately continuous with the deep fascia of the leg. An acquaintance with the disposition and structure of the fascia we have thus described, will enable the surgical anatomist, in almost every instance, to explain the time, situation, and progress of abscesses occurring in this region: he will at once comprehend that three distinct sorts of abscess may form here:—one in the subcutaneous tissue, and which being superficial to the fascia can hardly penetrate deeply toward the joint; another, occurring between the two layers of that membrane, in those situations where it splits to include the tendons; such an abscess will have little tendency to point in front, being bound down by the superficial layer of the fascia, or to penetrate deeply for a similar reason; but to its free passage upwards or downwards in the course of the tendons, little or no obstacle is presented. Lastly, matter may accumulate under both layers of the fascia, where its deep position and close confinement render it alike dangerous, and of difficult detection.

4. The next stratum is perhaps less entitled to that name than those we have hitherto described. Instead of forming, like them, a general investment for the whole region, it consists of several distinct and independent organs scattered irregularly about the joint: we shall enumerate them in the order in which we propose to treat of them, viz., tendons, muscles, arteries, veins, lymphatics, and nerves.

a. *Tendons.* Upon the instep we find no fewer than seven tendons passing towards the foot: the internal is the largest of all, it is that of the tibialis anticus running obliquely forwards and inwards to the inner cuneiform bone. Close upon its outer side is the tendon of the extensor pollicis; still more outwards we meet with the four tendons of the extensor digitorum longus, and most externally of all, or nearest to the outer ankle, that of the peroneus tertius. We need not revert to the subject of the fibrous sheaths furnished to these tendons by the fascia or annular ligament; but we should here carefully observe, that both sheaths and tendons are completely lined by a synovial apparatus. He who is at all acquainted with the general pathology of synovial membrane will understand why it is that effusions so frequently form about the instep; why adhesion of the opposite walls of these synovial sheaths will almost destroy the power of extending the toes and of flexing the foot; and, lastly, he cannot but draw the important practical deduction, that in operations about the instep we should avoid, if possible, cutting into these synovial sacs.

Behind the inner malleolus we meet with three tendons, — that of the tibialis posticus most anterior, and in close connexion with the posterior surface of the malleolus internus; that of the flexor digitorum longus a little further back; and still more posterior, and at a little distance from the others, the tendon of the flexor pollicis longus. These are included, as we have already explained, in fibrous sheaths formed by the internal annular ligament, each sheath and tendon having its own synovial lining. We may here observe a good anatomical reason, why inflammation affecting the sheath of the flexor digitorum will, *cæteris paribus*, be more likely to prove dangerous than that of the tibialis posticus: for, as the synovial sheaths of the former extend along the whole sole of the foot, little or no obstacle is presented to the disease extending itself into that region: whereas the tendon of the tibialis being inserted, not upon the sole, but rather upon the inner edge of the foot, its synovial membrane forms here a cul-de-sac, no doubt presenting some obstacle to the inflammation extending beyond this point. Behind the outer malleolus there exists a deep groove, in which two important tendons are contained, those, namely, of the peroneus longus and brevis. They are lodged in a canal which we have already described as formed by the bone and the external annular ligament, and this canal is lined by a distinct synovial membrane reflected upon it from the tendons. Having passed over the ligaments of the outer ankle, the peronei tendons are next applied upon the surface of the os calcis; and here, though previously in close apposition, and indeed contained within the same synovial sheath, they become separated by a ridge projecting from the bone. The peroneus longus tendon plays behind it as upon a pulley, and instances have occurred, where, owing to the fracture of this little osseous septum, the peroneus longus has been dislocated forwards upon that of the brevis. It has also happened that both peronei tendons have been dislocated forwards from their groove behind the malleolus, and thrown in front of that eminence. Were such an accident left without surgical interference, it is interesting to reflect how completely altered would be the action of these two muscles, if that action were not completely suspended by the inflammation and obliteration of the synovial sheath consequent on the accident; instead of extending the foot and pointing the toe, as they do in their natural state, they would become converted into flexors and abductors of the foot. At the posterior part of the region, the tendo Achillis forms a remarkable projection. In our account of the fascia, we have described the sheath within which this tendon is contained. We may further observe that this tendon is separated from the joint, and also from the deep vessels and nerves of the leg, by a considerable interval, so that it has frequently been cut across without injury to the articulation or wound of any other important part. Its mode of insertion into the os calcis is also worthy attention; instead of being fixed into the whole posterior surface of that bone, it occupies by its insertion merely the lower half of it; superiorly the bone and tendon are not even in contact, for here a distinct synovial bursa is interposed between them. The liability of this large bursa to inflammation and effusion should be carefully borne in mind by the surgeon: and he who is aware of its office, placed as a friction roller between the tendon and bone, will duly estimate how much disease of this bursa will impede the motions of progression. Owing to the interposition of the bursa, rupture of the tendo Achillis has occurred even below the upper edge of the os calcis; and if, having cut across the tendon, we forcibly extend the foot so as to elevate the heel, we shall at once comprehend how indispensably necessary it is to maintain the extended position in our treatment of this important accident.

b. *Muscles.*—There are but few muscular fibres met with in the region of the ankle: the flexor digitorum brevis arises upon the instep; and posteriorly we find some of the fibres of the flexor pollicis longus, which are here continued down a considerable way upon the tendon.

c. *Arteries.*—The arteries about the ankle, from their liability to injury and disease, become of great interest. Upon the instep the course and relations of the *anterior tibial* artery demand particular attention; the vessel here does not run exactly in the median line of the foot, but is somewhat nearer to the inner than to the outer malleolus: we may always reach it with perfect certainty, by cutting between the tendon of the extensor digitorum longus, and that of the extensor pollicis; these overlap it upon either side, and afford considerable protection against wounds or other injuries. Notwithstanding the facility of reaching the vessel in this situation, it is by no means advisable to do so when it is at all possible to avoid it, inasmuch as to expose the artery here it is necessary to wound the synovial sheaths, and inflammation and adhesion would be the probable consequence of such an injury. The branches of the *internal malleolar* artery are found upon the inner part of the region, running upon and in front of the inner ankle, and anastomosing with others passing forwards from the posterior tibial, thus insuring a sufficient supply of blood to the joint, even when the trunk of the anterior tibial itself has been tied. But these vessels are of much inferior importance compared with the posterior tibial, whose main trunk lies in the fossa between the heel and the malleolus internus. It is here occasionally the subject of operation, and hence its course and relations should be very carefully noted. We have already enumerated the tendons passing beneath the annular ligament in this situation; the most anterior is that of the tibialis posticus, immediately behind it lies that of the flexor digitorum, and still more posteriorly, at the interval of about an inch, is found the tendon of the flexor pollicis; in this interval between the two latter tendons runs the posterior tibial artery, not however equidistant from both, but nearer to that of the flexor digitorum; it rests upon the tibia and internal tibio-tarsal ligament, and is covered by the integuments and annular ligament; its venæ comites run one upon either side; and the posterior tibial nerve lies close behind it, but as the vessel descends getting gradually to its inner side. Notwithstanding the few coverings of the artery in this situation, yet owing to the heel, the ankle, and the tendo Achillis projecting around, and bearing off as it were those coverings from it, the vessel is here at a considerable depth from the surface; and any one who supposes it can be easily found in the living subject, will form a very erroneous idea of its true position:—hence it is that all good writers on surgical anatomy recommend us to take up the artery in the lower third of the leg, rather than in the calceo-malleolar groove. Several small vessels ramify about the outer ankle, the external malleolar coming from before meets here with the terminating branches of the peroneal artery from behind, but these small vessels are interesting to the surgical pathologist rather than to the regional anatomist or operative surgeon.

d. *Veins.*—Two veins, the "venæ comites," accompany each of the larger arteries: in all operations upon the artery, the close apposition of the veins, and the possibility of mistaking one for the other, should be remembered by the surgeon. In front of the inner malleolus we observe one or two openings in the fascia, through which small branches of communication pass between the superficial and deep veins; these, no doubt, are the principal channels through which the venous blood of the integuments about the foot and instep is returned, after the operation of tying the great saphena vein.

e. *Lymphatics.*—The lymphatics consist likewise of two sets; the one lying beneath the integuments and scattered irregularly over the region; the other lying beneath the fascia, and for the most part accompanying the blood-vessels. Some anatomists speak of a lymphatic gland lying upon the instep, and receiving several of these deep absorbents; in the majority of cases there is no such gland, and its existence in any appears to us extremely doubtful.

f. *Nerves.*—The nerves in this region have the same general distribution as the arteries. In our account of the larger arteries, we have already minutely assigned the relation which their accompanying nerves bear to them. We may thus briefly enumerate them:—in front, the musculo-cutaneous and anterior tibial; on the inner side the terminal ramifications of the internal saphenus and the posterior tibial; and on the outside, the terminal branches of the external saphenus. For further particulars respecting the nerves, we refer to the articles LUMBAR NERVES; SACRAL NERVES.

For the BIBLIOGRAPHY of this article and all others on surgical anatomy, see the Bibliography of ANATOMY (INTRODUCTION.)

(*John E. Brenan.*)

ANKLE, JOINT OF THE.—(Normal anatomy.) (Fr. *articulation du coude-pied.* Germ. *Fussgelenk.* Ital. *caviglia.*) The ankle-joint, or tibio-tarsal articulation, results from the junction of the leg and foot. For reasons which will appear when we come to explain its motions, it is ranked in the excellent and comprehensive classifications of Bichat and Cloquet as a perfect angular ginglymus. The security of the ankle-joint, more perhaps than of any other in tbe body, is owing to the peculiar form of its bones, and to their exact adaptation to each other; in this respect it has aptly been compared to the *tenon* and *mortise* joint, so frequently used by mechanics, the strength of which, as is well known, is chiefly owing to the peculiar form and close fitting of its component parts. Upon the upper part of the foot, we meet with, it is said, a true and well defined tenon, and upon the lower part of the leg a tolerably perfect mortise for the reception of the tenon. The comparison, though perhaps not strictly correct, will however assist us in understanding how much the security of this joint depends upon the form and fitting of its bones; and will explain to the beginner why, in treating of the ankle-joint in particular with a view to demonstrate its use and mechanism, a brief account of its bones becomes part of our description no less essential than of its ligaments themselves. In our account, therefore, of this articulation, we shall, in the first place, describe its bones; next its ligaments; and, lastly, shall offer some remarks upon its mechanism and uses.

a. *The Bones.*—Three bones contribute to the formation of the ankle-joint; the tibia and fibula form, by the union of their inferior portions, a deep depression, into which the head of the astragalus is received. The *tibia*, as it approaches the joint, looses gradually its prismatic shape, and assumes a well-defined cubical or quadrangular form. On its lower extremity it presents a quadrilateral articulating cavity, covered in the recent state with cartilage; this cavity is transversed from before backwards by an obtuse ridge which subdivides it into two smaller cavities. Of the four sides or margins of this articulating cavity, the anterior is almost straight transversely, but convex or rounded off in the vertical direction, with the obvious design of permitting a greater flexion to the foot; the anterior tibio-tarsal ligament arises from this margin. The posterior margin is also straight transversely, but vertically convex, to permit an increased extension to the foot; the posterior tibio-fibular ligament is connected here: a shallow oblique groove is met with upon the outer part of this surface, for the transmission of the flexor longus pollicis tendon. The external side presents a depression for the reception of the fibula; this articulating portion is prolonged upwards for nearly an inch, is of a triangular form with the base below; the sides of the triangle give attachment to the anterior and posterior tibio-fibular ligaments; and the area of the triangle is rendered rough, except at its lowest part, by the attachment of the inferior interosseous ligament,—another strong bond of union between tbese bones. The inner edge is prolonged downwards nearly an inch in length, forming the prominence known by the name of *malleolus internus;* this is placed upon a plane superior and anterior to the malleolus externus; it is somewhat flattened in shape, and has one surface looking inwards or towards the mesial line; this in the living subject is covered only by the integuments; the outer surface enters into the formation of the joint, hence it is tipped with cartilage to permit the astragalus to play upon it; the anterior edge is sharp and gives origin to the anterior tibio-tarsal ligament; the posterior edge is traversed by a broad and generally well-marked groove, which transmits the tendons of the tibialis posticus and flexor digitorum longus; the apex of the malleolus is below, and gives attachment to the deltoid or internal tibio-tarsal ligament.

The *fibula*, as it approaches the foot, becomes suddenly enlarged in size, applies itself firmly to the tibia, and then descends nearly an inch and a half below its point of union with that bone. The prominence formed by the fibula in this situation is named the *malleolus externus;* it is much larger than the internal, and placed behind and somewhat below it. The external surface of this fibular malleolus is covered merely by the integuments; the internal surface is tipped with cartilage, and convex in the vertical direction, being received upon a corresponding concavity on the outer side of the astragalus; upon the lower and back part of this inner surface may be seen a deep depression, where the posterior fibulo-tarsal ligament arises; the anterior edge of the malleolus is sharp, and gives origin to the anterior fibulo-tarsal ligament; the posterior edge is marked by a deep groove, which transmits the tendons of the peronei muscles, longus and brevis. The apex of the malleolus is below, and gives origin to the middle fibulo-tarsal ligament.

The *astragalus* enters into the formation of the ankle-joint by its superior surface, and a portion of its two lateral surfaces. On the superior surface we observe, anteriorly, a well marked groove forming part of the neck of the astragalus; into this groove the anterior tibio-tarsal ligament is inserted. Immediately behind the groove we meet with an articulating eminence of an oblong quadrilateral form, an inch and a half in its antero-posterior, and about an inch and a quarter in its transverse measurement; (this transverse measurement is, however, a little greater in front than behind;) the eminence is remarkably convex from before backwards, and concave from side to side; the outer edge somewhat more elevated than the inner; it is completely covered with cartilage, and corresponds to the articulating cavity upon the inferior exremity of the tibia. Upon the inner side of the astragalus, we find a small articulating surface of a triangular form, with the base above and apex below; it is convex in the vertical direction, and is tipped with cartilage prolonged ftom the superior surface: upon the triangular surface the internal malleolus plays; the remaining portion of the inner side of the astragalus is rough, and occupied chiefly by the insertion of the internal tibio-tarsal ligament. The external side of the astragalus is also marked by an articulating surface of a much greater size for the reception of the external malleolus: it too is of a triangular form with the base above; concave iu the vertical, and slightly convex in the antero-posterior direction.

b. *Ligaments.*—We have already compared the mechanism of this joint to that of the tenon and mortise; the mortise cavity, however, is not, as we have seen, cut out of a solid bone, but being formed in great part in the lower extremity of the tibia, is completed on the outer side by the fibula, which is firmly united with the tibia by strong ligaments, formiug what is called the *inferior tibio-fibular* articulation. We shall not now describe the ligaments which here unite the tibia and fibula, referring to the article on the Tibio-fibular Articulation; but we must observe that, however it may be advisable, in anatomical descriptions, to separate this last named articulation from the ankle-joint, they are perfectly inseparable in their functions, the integrity of the latter being essentially dependent on that of the former: indeed it may be said, that, by virtue of the great strength of the ligamentous connexion between the tibia and fibula in the former articulation, the mortise is as strong, nay, in some respects stronger, than if it had been formed out of solid bone.

The ligaments which connect the tenon and mortise together, or to speak more literally, which tie the tibia and fibula with the tarsus, are five in number, namely, two tibio-tarsal and three fibulo-tarsal ligaments.

1. The *internal tibio-tarsal ligament* is also called the *internal lateral,* and by Weitbrecht the *deltoid* ligament. There is, however, no reason why we should not apply to it likewise that principle of nomenclature which is so generally and with such advantage applied to other ligaments. It arises by a truncated apex from the point of the inner malleolus, and from the little fossa at its outer surface; its fibres change as they proceed downwards and are fixed into the inner surface of the astragalus and os calcis, some proceeding as far forwards even as the scaphoid bone. The posterior fibres are strong but short; the anterior are much larger and not so thick. Its internal surface is lined by the synovial membrane of the joint; and on its internal surface it is covered by the tendon of the tibialis posticus, and it sends some of its fibres to the sheath of the flexor longus digitorum tendon. In flexion of the leg the anterior fibres are relaxed, and the posterior are rendered tense: in extension the reverse of course takes place. 2. The *anterior tibio-tarsal* ligament *(lig. tibio-tarsal,* Cloquet) consists of a few loose fibres scattered over the synovial membrane, and in some instances so delicate and so separated by pellicles of fat as to be scarcely perceptible. They arise from the fore part of the inner malleolus and the adjacent anterior portion of the tibia, and descend obliquely downwards and outwards to be inserted into the neck of the astragalus. This ligament is covered anteriorly by the tendons of the tibialis anticus, extensor proprius pollicis, and extensor digitorum longus: posteriorly it is in contact with the synovial membrane. 3. The *anterior fibulo-tarsal* ligament *(lig. fibulæ anterius,* Weitb., *anterior external lateral,* Boyer) arises from the anterior edge of the outer malleolus, a few lines from its extremity; it descends obliquely forwards and inwards, and is fixed into the astragalus immediately in front of the articulating surface which receives the fibula: it is scarcely an inch in length, of an oblong quadrilateral form, and is frequently subdivided into two distinct parts. In extension of the foot it is rendered tense; in flexion it is relaxed. 4. The *middle fibulo-tarsal* ligament *(lig. fibulæ medium perpendiculare,* Weitb., *external lateral ligament,* Cloq.) is a round fasciculus of fibres having almost the appearance of a tendon which arises from the apex of the external malleolus, descends obliquely backwards, and is attached to the outside of the os calcis. It does not appear to us that in any position of the joint this ligament takes a perpendicular course, although that epithet has been applied to it by Weitbrecht. It is related superficially to the peroneus longus tendon, and by its deep surface to the synovial membrane, to the astragalus, and os calcis. In flexion of the foot this

ligament is rendered tense; hence it appears designed to limit motion in this direction: in extension it is of course relaxed. 5. The *posterior fibulo-tarsal* ligament (*lig. fibulæ posterius*, Weitb., *posterior external lateral*, Boyer) arises from the little fossa upon the inner and back part of the outer malleolus; it passes backwards and inwards almost horizontally, or at least descends very slightly, and is inserted upon the back part of the astragalus into the outer edge of that groove which transmits the flexor longus pollicis tendon. This ligament is stronger than either of the two preceding, and is frequently divided into several distinct fasciculi. From its superior edge an accessory band sometimes passes upwards and inwards over the synovial capsule to be fixed into the tibia. Walther has described this band under the name of the oblique ligament, and it is well represented by Weitbrecht (*fig.* 65, tab. xxii.)

The *synovial membrane* of the ankle-joint is of very great extent: it lines not only the articular surface of each malleolus, the several ligaments we have just described, and the articulating cavity upon the lower portion of the tibia, but it is prolonged upwards between the tibia and fibula, forming in that situation a little cul-de-sac: this, however, is merely for the extent of a few lines, for its further progress upwards is interrupted by the inferior interosseous ligament, (*fig.* 61.) From the circumference of the tibio-fibular mortise the synovial membrane passes downwards upon the astragalus, covers its superior articulating eminence, and sends prolongations upon its lateral articulating surfaces. It is remarkably loose upon the anterior and posterior parts of the joint, and is said to contain a greater quantity of synovia than any other synovial membrane in the body. Certainly its strength is much increased by those scattered fibres to which we have given the name of anterior tibio-tarsal ligament: posteriorly it is weakest, for here few if any ligamentous fibres can be detected, though Boyer and Weitbrecht speak confidently of such.

c. *Mechanism and function of the ankle-joint.*—To understand properly the mechanism and function of the ankle-joint, we must carefully contemplate it in the opposite conditions of rest and motion.

1. Viewing it, then, in the first place, as the individual stands at rest, we observe that the leg and foot meet each other in the ankle-joint at a right angle, and we are particularly struck with this fact upon finding that this disposition occurs in scarcely any other animal than man. This interesting fact in comparative anatomy is by no means an accidental arrangement; its design is obviously in reference to the proper position of the body in each animal. It has, for instance, frequently been alluded to as one of the many anatomical proofs that the erect position is natural to the human subject: had the leg and foot been articulated at any other than a right angle the upright position of the body could not be maintained, at least without great and incessant muscular exertion. Another point worthy of our attention is that when the ankle is at rest and the body in the upright position, the fibula plays no part in the function performed by the joint: it is the tibia alone which receives the weight of the body, and transmits it to the astragalus. This fact should be carefully borne in mind, for it has considerable influence upon the accidents so frequently occurring here. The astragalus, from the way in which it supports the body, has often been compared to the key-stone of an arch, the arch being represented by the foot. That the foot presents an arched concavity at its lower part cannot be doubted; but it is by no means so certain that this is designed upon the principle of the architectural arch to support the weight of the body: in fact, the astragalus, which receives the entire weight, does not correspond to the centre of this arch. The true design of the vaulted form of the foot is to permit its accommodating itself to the several irregularities of surface which, both in standing and progression, it must encounter.

The motions of flexion and extension are the only ones permitted at the ankle-joint. In *flexion* the astragalus rolls from before backwards in the tibio-fibular mortise; it may be continued until the foot and leg form with each other an angle of about sixty degrees; at this point further flexion is prevented, partly by the tension of the middle fibulo-tarsal ligament, and still more effectually by the neck of the astragalus coming into contact with the lower edge of the tibia. In flexion the anterior tibio-tarsal and fibulo-tarsal ligaments are both relaxed; the posterior and middle fibulo-tarsal are rendered tense; the internal tibio-tarsal ligament has its posterior fibres stretched and its anterior ones loosened. 2. In *extension* the foot not only returns to its rectangular position with the leg, but may even be carried beyond this, so as to form with the tibia an obtuse angle of about one hundred and fifty degrees.* Further extension is at this point prevented by the tension of the ligaments which lie in front, and also by the astragalus behind coming into contact with the lower edge of the tibia. During extension the astragalus rotates forwards in the tibio-fibular mortise; the posterior ligaments are relaxed, the anterior are put upon the stretch, the state of each individual ligament is, in short, reversed from what we have just described as its condition in the opposite motion of the joint. 3. A slight degree of *lateral motion* of the ankle is perceptible in the dead subject, but during life it cannot be said to exist: hence, in the classification of Cloquet and Bichat, the joint is properly ranked under that variety of ginglymus to which we apply the term "perfect."

The ankle is the analogue of the wrist-joint in the superior extremity, and accordingly, though there are certain points of difference between them, the general character of both is

* According to Hildebrandt the angle of flexion is 45°, and the angle of extension according to Rosenthal (Handb. der Chir. Anat.) is 175°.—Ed.

the same. It is no less interesting than instructive to contrast these two articulations with each other, for in doing so we find that the modifications of structure here, as well as in all other instances, are referable to the peculiar function which each part is destined to perform. The hand in the human subject is exclusively an organ of prehension; the foot is one merely of support:—now this simple fact at once furnishes us with a clue to all difficulties. The great strength and sudden expansion of the tibia and fibula at the ankle, are evidently a provision to sustain the weight of the body and to increase the basis of its support; in the radius and ulna such size and strength would have been to no purpose, and hence these bones at the wrist are comparatively thin and delicate. At the ankle we should naturally have expected frequent dislocations, owing to the great weight from above, and to the great mobility which for the purposes of progression must at the same time necessarily exist here; these are two most formidable causes of displacement; but, as if in compensation, we find two strong buttresses (the malleoli) projecting one upon either side of the joint, and rendering such displacement, under ordinary circumstances, almost impossible. At the wrist, where there is no weight to be supported, such lateral splints would have been superfluous: hence the imperfect and almost rudimental malleoli of the radius and ulna; hence the shallow and imperfect cavity; hence, in a word, the anatomical conformation which constitutes the ankle-joint a ginglymus, and the wrist an arthrodia. In the motions of the ankle and wrist-joints we observe likewise a striking difference: in the former, lateral motion would have been superflous in reference to the function of the foot; at the wrist, on the contrary, a free lateral motion is indispensable to increase the sphere of action of the hand.

For the BIBLIOGRAPHY of this article, see that of ARTICULATION.

(John E. Brenan.)

ANKLE-JOINT, ABNORMAL CONDITION OF THE.—The deviations from the natural or normal condition of the ankle-joint may be classed under those which are referable to accident and to disease: any defects which may be considered to result from congenital malformation shall be elsewere treated of. (See FOOT.)

Accidents.—The different structures which immediately compose the ankle-joint, as well as those which surround this articulation, and are merely accessary to its functions, are, each and all, liable to numerous accidents, the most important of which we shall here advert to.

These accidents may affect the *tendons*, the *ligaments*, or the *bones*.

Tendons.—Those tendons which pass behind the inner and outer malleoli are occasionally displaced; and, although the accident must be considered a rare one, it ought not here be overlooked.

"The two peronæi extensor muscles," says the late Mr. Wilson,* "where they pass behind and below the fibula over a smooth lubricated surface of that bone, are bound to it by a strong ligament; but should the ligament give way, one or both of these tendons may escape from the groove or pulley in which they usually play, and being thrown forwards over the edge of the bone, in this new situation their action on the foot will be to bend it on the leg, when in their natural position it was to extend it. The peronæi having been habituated to act with the extensor muscles, continue to contract at the same time with them, but now they oppose the effect which formerly in conjunction with the extensor muscles they produced upon the foot, and by so doing excite much pain and irritation in addition to the lameness. When this situation of the tendon is discovered early, the tendon can be readily restored to its proper place, but if this is not done, it forms a new groove on the fore part of the bone, and the old one is filled up, or otherwise so altered that it cannot receive the tendon, and thus the pain and lameness may continue for life. I have seen this occurrence sometimes in the living body early enough to return the tendon, and have been consulted in cases where it could not be returned; in one, where the pain was so violent that I recommended the division and removal of part of the tendon; the muscle then contracted to its full extent, and afterwards shrunk, and no inconvenience was felt after the operation. I have met with two or three instances of this kind of displacement of tendons in bodies brought into the dissecting-room; but of the previous history of the cases I could know nothing." Mr. Wilson adds, "Those tendons which pass in grooves behind the inner ankle are liable to a similar displacement." Of the latter accident we have known but one instance, but of the former several.

Ligaments. — Accurate anatomical investigations of the actual condition of the various structures which compose the ankle-joint, when affected by a sprain, have shown that in slight cases of sprain of this joint nothing unnatural has been discovered, as the bonds of union between the bones have been merely stretched or strained. In others more severe, the ligaments have been found broken or torn from their attachment to the bones, the synovial sac opened, and its fluid to have escaped from the cavity of the joint; the cellular tissue around has been filled with extravasated blood, and with synovial and serous fluids. In these cases the nerves, bloodvessels, tendons, even the skin itself, have been subjected to a degree of stretching and extension, more or less considerable. Baron Dupuytren, from numerous observations on the living subject, from post-mortem examinations, and experiments, is of opinion that a slight accidental torsion of the foot inwards or outwards, amounting to a sprain, only produces an injury, in which

* Wilson's Lectures on the Bones, &c.

the ligaments are merely stretched; but that a greater effort produces a separation of the lateral ligament from one or other of the malleoli by laceration of its compact tissue, or of the periosteum which covers it, while the ligaments themselves remain unbroken. Opportunities do not often occur of discovering the effects of sprains on the joints by anatomical examination made at various periods after the accident; but although Dupuytren's opinion may be correct as to the majority of cases, still others have found the lateral ligaments ruptured across, instead of having been torn from the bone. Mr. Wilson found, in a case where the patient died five days after a severe sprain of the ankle-joint, that the deltoid ligament binding the tibia to the foot was lacerated, and that the synovial membrane of the ankle-joint was also much torn. In older cases he found evidences of chronic inflammation in the ligamentous structures around the joint; that these structures were thickened and vascular, and had lost much of their pliability.

The pain and inability to walk, the sudden effusion around the injured ankle, the ecchymosis, tenderness of the skin and tension, the signs of this injury expressed by the living structures, are all accounted for by the lesions which an anatomical examination of these injuries of the ankle-joint discovers. This also explains what practical writers have noted of sprains, viz. that sometimes the ankle-joint which has been affected by this accident, rapidly and perfectly recovers,—that, on the other hand, it is not unfrequently so weakened by the injury, as to become peculiarly susceptible of a renewal of the sprain from slight causes; sometimes the articulation contracts a rigidity, by which for a time, or even for life itself, its proper functions are interfered with, and a permanent œdema of the soft parts around the joint is too often in these cases established.

Bones. — The bones which contribute to form the ankle-joint are liable to fracture and to luxation. These bones, we know, are the tibia, fibula, and astragalus; for an account of the accidents which affect the latter particularly, we refer to the article Foot, and shall here, as succinctly as we can, notice the various displacements of the bones of the leg at the ankle-joint, which have been observed to be the result of a fracture through one or both of the malleoli, or of an accidental rupture of the ligaments which tie these eminences to the foot.

When we reflect on the great strength of the ligaments which connect the astragalus to the tibia and fibula, and the support which the articulation derives from the prolongation downwards of the malleoli, we can easily perceive that a luxation of the foot must be the effect only of some very violent cause, and that this accident can very rarely (in a true sense) be a simple one. Effusions of blood, rupture of all the surrounding ligaments, fracture of the external or even of both the malleoli, wounds of the soft parts, and even protrusion of the bones, are contingences which frequently render the dislocation of the tibia at the ankle-joint a very complex accident.

The most superficial view of the structure of the ankle-joint will convince any one that no lateral displacement of the bones of the leg can occur, without its having been immediately preceded by a fracture of either the tibial or peronæal malleolus; but such a view would warrant the conjecture, that a luxation in the direction forwards or backwards may possibly take place, simply from the rupture of the ligaments of the joint alone, and the action of muscles. Such a luxation as this last, when no fracture exists, should be best entitled to the name of simple; yet those luxations of this articulation (such is the vagueness of surgical language), whether accompanied with fracture or not, are all called simple, provided there be no wound through the integuments communicating with the cavity of the joint. In this latter case alone the luxation is denominated compound, of which it is not our intention here to treat.

We shall arrange the luxations of the bones of the leg at the ankle-joint in the above sense called simple luxations, into those which occur in the direction *inwards*, *outwards*, *forwards*, and *backwards*, and each of these, it is believed, may be a partial or a complete luxation.

Luxation of the Tibia inwards.—This luxation may be complete or incomplete: we shall first treat of the most common form of it or that termed partial Dislocation of the Tibia inwards from the Astragalus, or Pott's luxation. Mr. Pott, in describing this accident, observes, "that the support of the body, and the due and proper use and execution of the office of the joint of the ankle, depend almost entirely on the perpendicular bearing of the tibia upon the astragalus, and on its firm connexion with the fibula. If the former bone is forced from its just and perpendicular position on the astragalus; or, if it be separated by violence from its connexion with the latter, the joint of the ankle will suffer a partial luxation internally: this is the case when, by leaping or jumping, the fibula breaks in its weak part, within two or three inches of its lower extremity. When this happens, the inferior fractured end of the fibula falls inwards towards the tibia, that extremity of the bone which forms the outer ankle is turned somewhat outwards and upwards, and the tibia, having lost its proper support, and not being of itself capable of steadily preserving its true perpendicular bearing, is forced off from the astragalus, inwards, by which the ligaments are torn, thus producing a perfect fracture and a partial dislocation."*

If we are called to examine a patient who has recently suffered this accident, we find that the ankle-joint now possesses some degree of lateral mobility. In the normal state of the ankle-joint we know that the quadrilateral cavity formed by the tibia and fibula for the

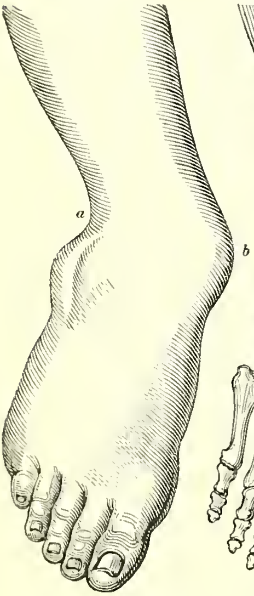
* Pott's Works by Earle, vol. i. p. 327.

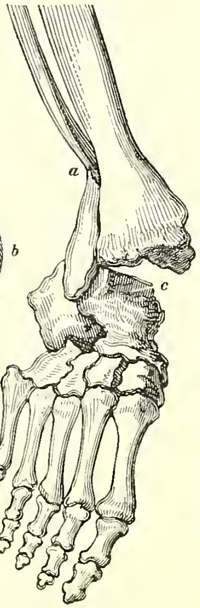
reception of the astragalus, makes with the latter a perfect mortise joint, which admits of motions of flexion and extension, but allows of no motion whatever laterally or horizontally; for it must be recollected that those motions of inclination of the foot, known under the names of adduction and abduction, are not movements in the ankle-joint, but take place in the joints of the tarsus: but the unnatural mobility in question is very great when the fibula is broken at its lower part; this is shewn, when, after the surgeon has bent the limb to relax the muscles, the leg is fixed by one hand placed at its lower extremity, whilst the other moves the foot from within outwards; the foot is then seen to move in a transverse line and to quit the axis of the leg; the malleolus internus projects inwards, and the malleolus externus is moved upwards and outwards, and all these appearances vanish, when by a contrary movement we bring the foot to its natural position.

When we leave the limb for a moment to itself, we notice that there is a remarkable change in the point of incidence of the axis of the leg upon the foot. The tibia and upper fragment of the fibula, although really remaining in their natural position, *appear* driven inwards, while the foot is rotated outwards.

The changes of direction of the leg and foot are such, that if the axis of the leg were prolonged inferiorly, instead of falling on the astragalus, it would leave this bone, and consequently the whole foot, more or less on its outer side; hence the impossibility patients experience of bearing upon the foot, which only presents its inner edge to the ground.

Fig. 51. *Fig.* 52.





Partial luxation of the Tibia inwards, or Pott's luxation.

This change is a necessary and constant effect of the displacement of the foot, when the fibula ceases to support it on the outer side, and when the peronæi muscles begin to contract. The foot and external malleolus which make part of one system, move in one direction; the tibia and upper fragment of the fibula move, or, to speak perhaps more correctly, remain, in another. The centre of this new motion is no longer in the articulation, but, in an oblique line, passing through the joint, and extending from the malleolus internus to the point of fracture of the fibula: this line is well expressed in *fig.* 51, representing the fracture of the fibula, and taken from the engraving which accompanies the work of Pott.

The retiring angle seen *(fig.* 51, 52, *a)* in this partial luxation of the tibia inwards, on the outer part of the articulation, and the projecting one *(b)* existing at the inner, constitute the most striking features of the accident; these angles correspond exactly to the extremities of the line above-mentioned, in the direction of which the weight of the body aets, when the foot being turned outwards this line may be seen to traverse the leg obliquely from the lower part of the upper fragment of the broken fibula to the malleolus internus.

We cannot omit to notice also, that there is in all these cases a remarkable rotation of the whole foot on its long axis, in such a direction that the upper surface of the astragalus looks obliquely upwards and inwards, *(fig.* 52, *c,)* the inner edge of the foot is turned downwards, the sole inclined outwards, the outer edge raised, and the dorsum turned directly upwards. The extent of this rotatory motion is besides always proportioned to the displacement outwards; both are attributable to the same causes, viz. the weight of the body, and the action of the peronæi muscles, when the patient has attempted to walk after the fracture has occurred.

It is on these combined movements when not corrected by a proper mode of treatment, that the deformity of the foot, and all the consequent difficulties in walking, depend.

Complete luxation of the tibia inwards from the astragalus, complicated with a simple fracture of the fibula.—This is a very severe, and, fortunately, a very rare accident. In alluding to it, Dupuytren says,* that "the foot is not only susceptible of being carried outwards, but also upwards at the same time;" a double displacement, which he had observed to occur only once in 200 cases of fractures of the fibula treated in the Hôtel Dieu for fifteen years, "but the case was so marked," he says, "that in future it cannot be mistaken or passed over in silence." It cannot occur unless the fibula is fractured; for this condition is indispensable to any displacement of the foot inwards or outwards; it requires besides a complete laceration of the short thick ligaments placed between the tibia and fibula, the strength of which is such that, in most experiments on

* Sur la Fract. de l'Extremité inferieure du Peroné, in Annuaire Med. Chir. des Hopitaux de Paris, 1809, 4to. and folio.

the dead subject, they resist more powerfully than the structure of the bones themselves.

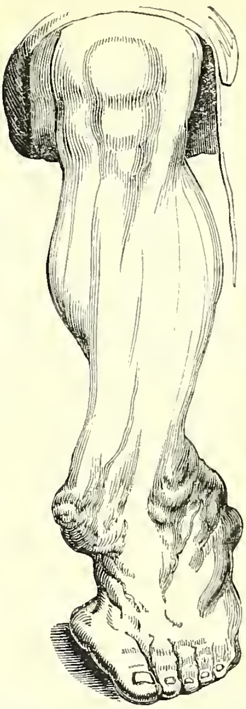
It was as a consequence of the fracture of the fibula and a rupture of these ligaments, that, in the case alluded to, the astragalus was seen dislocated outwards, and then drawn up on the outer side of the tibia. In short, the astragalus, the malleolus externus, and the foot, which formed but one system of parts firmly connected, were drawn first to the outer side of the leg, and then two inches upwards on the tibia.

A carpenter, aged fifty-four years, was admitted into the Hôtel Dieu, in February, 1816. His right leg presented all the signs of fracture of the fibula at its inferior part, such as deviation and rotation of the foot outwards, prominence of the tibia, and of the internal malleolus inwards, depression and crepitation above the outer ankle; but that which most attracted the attention was, 1st, the shortening of the limb, and, 2dly, the enormous increase in breadth of the space which should naturally intervene between the two malleoli. The sinking down of the lowest part of the tibia, even to the level of the sole of the foot, where the projection of the internal malleolus could be felt, the elevation of the astragalus, of the peroneal malleolus, and the whole of the foot along the external surface of the tibia, even to two inches, were all symptoms quite unusual in fracture of the fibula, and left no doubt that the ligaments which stretched inferiorly from this bone to the tibia had been lacerated, and that the foot, yielding to a violent effort from within outwards, and from below upwards, had been luxated in these directions, and had carried with it the peroneal malleolus. This then is evidently a case of complete dislocation of the tibia inwards, or, as the French writers would call it, a luxation of the foot outwards and upwards.

Although this species of luxation has not been specially described in any of our English works, I doubt not but such an accident has been observed, although it is possible that its nature was not always clearly understood. Sir A. Cooper, in his valuable work on Dislocations and Fractures, states that the foot has also been known to be thrown upwards, between the tibia and fibula, by the giving way of the ligament which unites these bones; but he adds that this accident is only an aggravated form of an internal dislocation.

We find but little difficulty in comprehending how the accident described by Dupuytren may occur, because, the fibula having been first fractured, the broken bone and ruptured ligaments permit the foot to yield to the powerful action of the muscles on the back part and outside of the leg, which draw it at first outwards, and then upwards; but on the contrary, it is not easy to imagine any force capable of overcoming the resistance of the many inter-osseous ligaments which exist, and of the fasciæ and annular membranes which surround the bones of the leg: a force must be great indeed which can overcome the muscles also, and cause a divarication of the bones of the leg sufficient to permit the astragalus and rest

Fig. 53.



Complete luxation of the tibia inwards or of the foot outwards and upwards.—(Dupuytren.)

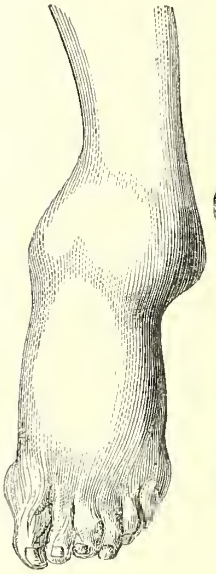
Fig. 54.

Dissection of a case of the same class as fig. 53, *from the museum of St. Thomas's Hospital.*

of the foot to be thrown upwards between the tibia and fibula. Supposing this last case possible, the shortening of the limb and its newly-acquired breadth between the malleoli might lead to error, and the two cases here alluded to be at first sight confounded; but in Dupuytren's case, the fracture of the fibula, the overlapping of its fragments, and above all the ascent of the external malleolus, so much above the level of the internal, will always constitute such characteristic marks, that when such an accident presents itself, we conceive it cannot be confounded with any other injury of this articulation.

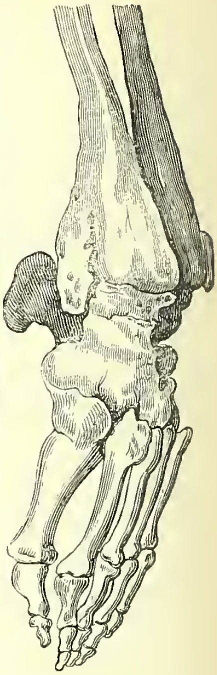
What are the anatomical characters of this complete luxation of the tibia inwards, with displacement of the foot and outer malleolus upwards and outwards? It is evident that there must be very extensive injury done in such cases to the ligaments and bones; the fibula must be fractured near the ankle, and it is probable that some fragments of the tibia may be carried off with the fibula, for such is the strength of the ligaments between the lower part of the tibia and fibula, where these unite for the reception of the astragalus (*vid. fig.* 61), that there is reason to believe that the bone itself would break before the ligaments would yield. If a portion of the tibia, however, is not broken off and carried with the fibula, these transverse fibrous bands must be torn, as well as those oblique ligaments which pass before and behind from the fibula to the tibia. The proper interosseous membrane itself must be detached from between the bones to allow the astragalus to ascend along the outside of the tibia. While the ligaments which connect the outer malleolus to the tibia must be torn, those which unite it to the foot remain entire, the deltoid or internal lateral ligament must be completely torn across, as well as the synovial sac of the articulation; nor should it be forgotten that the annular ligaments and strong fasciæ at the lower part of the leg, must, in so severe and extensive an injury, be lacerated; the tendons, muscles, and other structures may escape injury, the astragalus and outer malleolus are dragged up (*fig.* 54, *a*, *b*), their ascent being only limited by the lower point of the upper fragment of the fibula (*c*), which remains in its natural relation to the tibia, except that it must be somewhat approximated to it; the lowest point of the superior fragment of the broken fibula rest upon the summit of the articular pulley of the astragalus, as is well seen in a preparation preserved in the collection of St. Thomas's Hospital Museum, the delineation of which we have borrowed from Sir A. Cooper's work. The preservation of this specimen, which in our mind is a true example of the complete dislocation of the tibia inwards, and of the external malleolus astragalus and foot upwards and outwards, is a new proof of the truth of the observation we have above made, that this severe accident had not altogether escaped the notice of English surgeons, although the "*Annuaire*" contains the first accurate account of the external signs by which it may be recognized in the living subject.

Fig. 55.



Luxation outwards of the tibia and fibula with oblique fracture of the tibia.

Fig. 56.



Dissection of the luxation outwards (Museum of St. Thomas's Hospital). [*Fig.* 55.]

Luxation of the tibia outwards, complicated with simple fracture of one or both of the malleoli.—This, it is said, is one of the most dangerous of the dislocations to which the ankle is liable, for its production has been noticed to be attended with greater violence, and to be accompanied by more contusion of the integuments, more laceration of ligaments, and greater injury to bone, than we have occasion to observe in the production of the other luxations of this joint.

The astragalus in this accident is carried towards and below the external malleolus (*fig.* 55), whilst the outer edge of the foot is turned downwards, its inner edge upwards, and the sole inwards, the tibial malleolus disappears, and is hidden at the bottom of a retiring angle formed by the inner side of the leg and foot, and the peroneal malleolus forms, with the astragalus, a salient angle rounded off on the outside. Looking only to the change of form, situation, and relative position of the leg and foot, we might suppose the case one of congenital club-foot.* The luxation of the tibia outwards, with inversion of the sole of the foot, is one of the most rare and most difficult cases to explain. Its production must be the result, we suppose, of coincidences rare and unusual. There may be a certain obliquity in the line of direction of the fracture coinciding with a considerable degree of resistance in the lower fragment of the fibula: thus, if we can suppose that a fracture shall traverse the tibia obliquely from above downwards, and from within outwards, so that the point of the upper fragment be directed downwards and outwards, and the lower fragment point upwards and inwards, and if to this obliquity we suppose added a certain resistance on the side of the lower fragment of the fibula, it is plain that the foot being unable to turn outwards, must be carried inwards by the action of the muscles, and with this inversion, &c. some little shortening of the limb, at least when measured on its inner side, may be expected.

If this accident be neglected, the cure which nature attempts is very imperfect, the ankle-joint becomes stiff and rigid (*fig.* 56), the interval between the internal and external malleolus is much increased, the latter presses heavily against the integuments, which, when the limb is much exercised, have a strong tendency to inflame and suppurate, the outer edge of the foot throughout its whole line presses the ground, whether the patient be standing or walking, while the inner edge is somewhat elevated and curved inwards. In the dissection of this accident, it will be found that the

* Dupuytren, Annuaire.

malleolus internus is fractured, and in general, we suppose, with the obliquity from above downwards, and within outwards, above described. The deltoid ligament remains unbroken, the capsular membrane is torn in front, the fibula has been found obliquely fractured, as well as the tibia, or the three ligaments which connect it to the tarsus have given way; none of the tendons suffer, and hæmorrhage to any extent in these cases seldom or never occurs, as the large arteries generally escape injury.

Luxation of the tibia and fibula forwards, and also luxation of these bones backwards from the articular pulley of the astragalus, without fracture.—In the simple and complete luxation of the bones of the leg forwards at the ankle-joint, (without fracture,) the articular pulley of the astragalus is placed behind the inferior extremity of the tibia, which last rests partly on the superior surface of the neck of the astragalus, and partly on the os naviculare.

In the simple and complete luxation of the tibia backwards, (without fracture,) the inferior extremity of the tibia is placed behind the articular pulley of the astragalus, and corresponds to the posterior part of the superior surface of the os calcis. In both these luxations, the natural connexion with each other of the bones of the leg remains undisturbed, and the two malleoli advance or recede together, according to the direction in which the displacement has occurred. In both, the capsular membrane and the posterior and lateral ligaments must be extensively lacerated, and most of the flexor and extensor tendons, in some degree, put upon the stretch.

The luxation of the bones of the leg forwards cannot take place, but in a forced and sudden extension of the leg on the foot, when the latter being retained by some obstacle, and solidly supported, we fall backwards.

The luxation of the tibia backwards, on the contrary, cannot happen unless when the foot is strongly flexed, the toes being elevated and retained in this position, we fall forwards.

Authors have seldom failed to notice these simple luxations forwards and backwards of the bones of the leg, yet for our part, no matter to what source we apply for information, we cannot satisfy our minds that we can adduce a single well-marked example of luxation of the bones of the leg at the ankle-joint, *unaccompanied by a fracture of one or both of the malleoli;* we would not, however, be understood to deny the possibility of such an occurrence, but merely to state our conviction that such an accident must be exceedingly rare.

We have now to consider luxations of the tibia from the astragalus, forwards and backwards, when complicated with a simple fracture of the fibula or tibia close to the articulation: these may be complete or partial.

Complete luxation of the tibia forwards from the articular part of the astragalus complicated with a simple fracture of the fibula.—This accident may arise from the same causes nearly as those which may be supposed to influence the more simple luxation in the same direction; and as we know that when the fibula is fractured near its malleolus, the peronæi muscles may under certain circumstances effect a luxation of the tibia inwards, so that displacement which we are now considering may be the result of the action of the gastrocnemius and solæus. These acting on the foot, which in consequence of the fracture is no longer fixed by the malleolus externus, cause the astragalus to slip from before backwards, and the lower end of the tibia forwards, and move the lower fragment of the fibula in such a manner that its malleolar extremity is carried backwards, and the upper part forwards. This action of these muscles, however, only produces a very incomplete dislocation whenever the internal malleolus is uninjured, or the foot in this case being carried outwards and backwards at the same time; but when, as often happens, either the internal malleolus or deltoid ligament is broken, this displacement may be as complete and direct as the simple dislocation forwards of the tibia. We then find the foot lengthened behind and shortened in front; a semicircular excavation occurs in the former direction, and an osseous tumour raises the tendons and ligaments on the front of the ankle, but it is to be particularly remarked that, whilst in the simplest form of luxation of the tibia, i. e. where there is no fracture, the external malleolus follows the tibia and fibula, and forms a projection corresponding to that of the internal, it is in this case dragged backwards with the foot to which it is attached by the lateral ligaments, and no longer has the same direction as the bones of the leg.

In the dislocation forwards of the tibia (whether simple or complicated with a fracture of the fibula) from the astragalus, the articular pulley of this bone is placed behind the inferior articular cavity formed for it in the tibia; but this latter bone at the same time, it will be recollected, must now rest on the dorsum of the tarsus, where it is formed by the upper part of the neck of the astragalus and os naviculare. When the tibia has thus once advanced before the articular pulley of the astragalus, the luxation forwards is as complete as it well can be; in our opinion, to imagine any more complete luxation of the tibia forwards, we should be obliged to presume that this bone in its advance on the dorsum of the foot had completely cleared the astragalus, and then rested "on the *os naviculare and os cuneiforme internum*,"* which last form part of the anterior

* The weight that so justly attaches to any observations from Sir A. Cooper, induced us to consider well the account he gives of the dissection of this complete luxation of the tibia forwards, in his work on Dislocations and Fractures; and we find that we cannot reconcile it with our ideas of the anatomy of the injury. We are sorry in this instance to be obliged to differ from an authority, to which we feel indebted for many observations copied into these pages; but we think there must be error in the following passage taken from the valuable work to which we allude, page 178, 8th edition.

"On dissection, the tibia is found to rest upon the upper surface of the os naviculare and os cuneirange of the tarsus, a situation which the tibia could not well occupy, without a previous lesion of the tendons of the tibialis anticus, and stretching of the other extensors: from such a relative position of the bones of the leg and foot would result a shortening of the dorsum of the foot and an elongation of the heel to an extent which, we believe, has never been noticed.

Partial luxation of the tibia forwards, with simple fracture of one or both of the malleoli.—The complete luxation forwards of the tibia from the astragalus, which we have described in the preceding section, all writers look upon as the more common form of dislocation forwards; while the partial luxation in this direction is considered a rare accident. My opinion upon this subject is quite different; for some experience in these accidents leads me to say, that a complete luxation of the tibia forwards from the articular pulley of the astragalus is rare, but that a partial luxation in this direction accompanied with a simple fracture of one or both of the malleoli, is an accident by no means uncommon.

The signs of this partial luxation of the tibia forwards are nearly the same as those we have stated to belong to the complete luxation in this direction; they are, however, as might be expected, more faintly marked, and, consequently, may more easily be neglected; but, after all, these signs are so evident, that it is wonderful how with common attention they can be overlooked. It may not be amiss to subjoin the following case as illustrative of the common partial luxation forwards:—

A man, aged twenty-two years, was admitted into Jervis-Street Hospital, at three o'clock, A.M. of the 26th of December, 1833. He stated that he and a *friend* had been drinking together in a public house, that in the middle of the night they quarrelled, that he was knocked down, and was unable to rise, in consequence of his having received a severe injury of his left ankle: his friend then procured some assistance and carried him to the hospital; at my visit, I found him in bed, complaining of much pain, his leg extended and resting on its outer side; the heel was retracted, and between it and the calf of the leg, instead of the ordinary line which marks the course of the tendo Achillis, there was a conspicuous semicircular curve, (*fig.* 57, *a*, *b*); in a word, the heel was lengthened, and the dorsum of the foot seemed much shortened; in the situation of the ankle-joint in front, there was a remarkably hard, prominent, transverse ridge made by the advance of the lower extremity of the tibia and extensor muscles of the toes, while beneath this there was a marked depression, where the skin and annular ligament seemed, as it were, pinched in, drawn under the lower edge of the articular part of the tibia; the foot was pointed downwards, no movement of flexion or extension could be communicated to the ankle-joint, but it admitted of some little motion in a horizontal, and also in a lateral, direction, when the leg was firmly grasped with one hand and the foot moved with the other.

It was remarkable that, although the man had no power whatever over the motions of the joint, he could, while he lay in bed, move his whole limb about with much freedom, and (as there was probably a locking of the bones with each other) these voluntary movements were not accompanied by any increase of pain.

The fibula could be felt to be fractured about an inch and a half above the lowest point of the outer malleolus, "the foot, the outer malleolus, and short portion of the broken fibula, formed one system of parts," and were carried for the length of an inch or more horizontally backwards, while there was a projection forwards, of the lower articular part of the tibia, and the internal malleolus itself was advanced in the same proportion: it is to be observed, that there was no crepitus, because it was the deltoid ligament only which was torn; the tibia was not broken, and the ends of the fractured fibula were evidently far separated from each other. When the luxation was reduced, which was effected without much difficulty, crepitus could be felt, proving the restoration to its place of the lower fragment of the fibula.

This is a species of fracture and luxation, which can, by proper management, be readily redressed, and no deformity remains, if time be not lost after the accident has occurred; but if the fibula become solidly united in its new situation, the motions of the ankle-joint are for ever lost, and the patient is doomed to lameness for life.

In the month of September 1833, a woman, aged fifty-three years, was admitted into Jervis-street Hospital, whose left ankle-joint presented all the characters above assigned to the partial dislocation forwards of the tibia, combined with a simple fracture of the fibula; she stated that she had, two months previously, broken her leg close to the ankle joint, and had been attended at her own house, from a dispensary, by a pupil, who applied pads and lateral splints, but when after a time all the splints were removed, she found that her limb was deformed, her ankle stiff, her foot rigidly extended, and pointed downwards, so as to be nearly useless to her; as two months had elapsed since the accident, before she applied, no promise of relief could be held out to her. She therefore left the hospital, but not before I was enabled, through the kindness of Mr. Sutton, to obtain a cast of the leg and foot, from which figures 57 and 58 are copied. As I

forme internum, quitting all the articulatory surface of the astragalus, excepting a small portion on its fore part, against which the tibia is applied." Now, a single glance at the skeleton of a foot will shew us, that a portion, however small, of the articulatory surface of the astragalus, together with, secondly, the upper part of the neck of this bone; thirdly, the os naviculare; and, fourthly, the os cuneiforme internum, nearly form a space equivalent to a third of the length of the whole foot, an extent of surface, which, manifestly, the articulating portion of the dislocated tibia could not occupy.

Partial luxation forwards of the tibia at the external ankle, with fracture of the fibula near the malleolus.

was anxious, before these pages went to press, again to examine this case, I requested Mr. S. to make inquiry about her; he learned that the woman died dropsical a few days before, and with much difficulty procured for me an opportunity to examine the limb, which on careful dissection presented the following appearances:—the whole extremity was somewhat wasted, the skin on the sole of the foot was smooth and fine, shewing that she had been able to walk but little since the accident; the foot was in a position of almost rigid extension, the toes were directed downwards, the range of motion of flexion and extension did not exceed one inch, in short, all the usual characters assigned to the partial dislocation forwards of the tibia and displacement of the foot backwards were seen; when the skin was removed from the fascia of the leg and foot, the intervening cellular membrane was found infiltrated with serum, the skin was adherent to the inner malleolus, the vena sapbena and the nerve of the same name were thickened and firmly connected together, the extensor tendons were stretched over the tibia, and were somewhat flattened, and the grooves which transmit the tendons that play behind the inner and outer malleolus were deepened. We now directed our attention to the state of the bones; we found that the tibia was displaced forwards, that its anterior edge was advanced more than one inch beyond its natural situation, and that it much overhung the os naviculare, but such was the direction and state of obliquity of the tibia with respect to the foot, that it could not be said to rest upon that bone; between the os naviculare and the inferior articular extremity of the tibia there intervened much fat of a yellow hue and fibrous texture, like intervertebral substance; the internal malleolus itself had not escaped injury, the deltoid ligament had not in this instance as in the former given way; the internal malleolus itself had been broken, and a small portion of the back part of the edge of the articular cavity of the tibia was detached, and both malleoli were retracted, or carried backwards with the foot; the fibula above the fractured portion was directed downwards and a little forwards, and was somewhat parallel to the tibia, yet more tban naturally approximated to it, a circumstance which accounted for the contracted rounded form the middle of the leg possessed; the lower frag-

Fig. 60.

Viewed on the internal side.

Skeleton preparations of fig. 57 *and* 58.

ment of the fibula was directed from below upwards, a little inwards, and very much forwards, so as to make with its shaft a remarkable angle salient anteriorly; this bone had been traversed by the fracture obliquely, from above downwards and from before backwards. The external malleolus was placed about one inch and a quarter behind its usual situation, and was consequently dislocated at its tibio-fibular articulation, having burst those strong ligaments which connect these bones together, and which are so seldom found to yield.

Luxation of the bones of the leg backwards at the ankle-joint.—A luxation of one or both bones of the leg at the ankle-joint backwards, whether the accident be what has been called complete or incomplete, whether accompanied with a fracture of the fibula, or merely with a rupture of the ligaments, is a displacement which must be considered exceedingly rare. Boyer, in his valuable work, gives no case of it from his own observation; and in alluding to such an accident, states that no author, to his knowledge, has given a single example of it. Sir A. Cooper evidently has not seen it; for he says, " I have seen the tibia dislocated in three different directions, inwards, forwards, and outwards; and a fourth species of dislocation is said sometimes to occur, viz. backwards." Baron Dupuytren states that he has never seen this accident.*

Mr. Colles has given me the notes of one case, and it is the only one he can, in his extensive experience, recollect to have met with, of a partial dislocation of the lower part of the tibia and fibula backwards, and has also shewn me the cast he had taken of the leg. In this case the tibia seemed thrown partially backwards, from the articular pulley of the astragalus; the fibula was unbroken, and was also carried backwards with the tibia; the foot, measured from the instep upon its dorsum, was longer than that of the opposite side, the heel was shorter and less pointed, the space in front of the tendo Achillis, near to the os calcis, was partially filled up, and a hard swelling occupied the lower and back part of the tibia, which was evidently formed by a quantity of callus, which had cemented together the fragments of a fracture of the lowest part of the tibia; the leg was shorter than the opposite limb.

It would have been interesting to have learned the precise manner in which this accident had occurred; but as to this, or the immediate symptoms which followed the injury, I could get no satisfactory information. The man did not apply to Stevens's Hospital until the bones were united in their new and faulty position. Besides the partial dislocation backwards of the tibia, this bone with the outer malleolus of the fibula was inclined somewhat outwards; and the man walked lame and most awkwardly on the outer edge of the heel and foot, the inner side of which was somewhat curved inwards.

I have had occasion to notice a displacement of the tibia backwards on the os calcis, in a case where the astragalus sloughed in consequence of a compound injury to the external malleolus and ankle-joint; but such a case is different from that now under our consideration, although the possibility of such an occurrence should not be lost sight of.

2. *Morbid anatomy.* a. *Acute inflammation of the synovial membrane* of the ankle-joint produces changes in the synovial fluid of the articulation both in quantity and quality, and alterations very generally in the appearance and structure of the membrane; I say very generally, for I have known an exception to the rule, in a case* of acute synovitis of the ankle-joint which caused the death of the patient in fifty hours from its first onset; during the whole of the time the patient never slept nor ceased to complain of the agonizing pain of the ankle-joint. At the post-mortem examination, before the skin was removed, the extensors of the toes were observed to be displaced by the fluid which distended the synovial sac of the articulation, and fluctuation was now, as during life, to be felt in two tumours which existed in front of the two malleoli; the interior of the joint was occupied by a turbid oily synovial fluid; no false membrane existed, and if there had been increased vascularity during life, no trace of it was discoverable at the time of examination: increased quantity with altered quality of the synovial fluid were the only deviations from the normal condition which could be noticed. Portions of the synovial membrane are, however, occasionally found covered with false membrane. Pus has also been found in the joint, sometimes laudable, sometimes fœtid, and of a brownish red colour; the membrane has been found thickened, and has afforded evidence of increased vascularity, and even in some points has presented a villous appearance. In very young subjects I have known acute inflammation of the ankle-joint in a few days extend itself to the epiphysis, and produce separation of it from the shaft of the tibia; and in such cases a displacement of the shaft inwards, and of the epiphysis and foot outwards, occurs from the action of the muscles, as in Pott's luxation. Acute inflammation commencing in the synovial membrane of the ankle-joint sometimes extends farther than this: there have been cases in the Richmond Hospital, and the specimens have been preserved in the museum, of acute synovitis of the ankle in which the inflammation extended through the vascular junction of the epiphysis and shaft of the tibia, and having occupied the cellular junction of the periosteum with the anterior and inner surface of the tibia, soon ended in the formation of pus and lymph, which detached from the bone its immediate covering, and produced effects which terminated in the death of the patient. I have seen this detachment of the lower epiphysis of the tibia in an infant six days old, the result of acute

* Je n'ai jamais vu de luxation du pied en avant, dans les fractures du peroné et de l'extrémité du tibia.—Annuaire Médico-Chirurgical, 1819, Paris, p. 159.

* See Dublin Journal, vol. iv. p. 1.

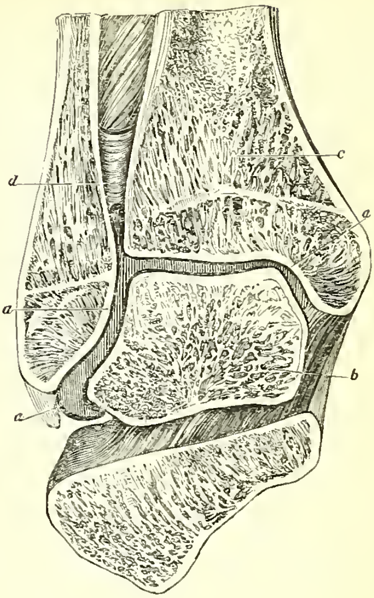
synovitis, with purulent deposition in the joint, and in a young man aged twenty, but have not observed it ever to occur in older subjects; and conclude that it is one of the consequences synovitis of the ankle-joint, which is only to be noticed at an age when the epiphyses are not yet consolidated with the shaft of the tibia.

In these very acute attacks of inflammation, its ravages are seldom confined to the structure which seemed to be the '*point du départ*' of the disease; the cartilages are in some cases removed from the tibia, fibula, and upper surface of the astragalus with astonishing rapidity; the porous surface of the bones has also been found exposed, and their substance to afford evidence of its having been in a state of inflammation. Surgeons should ever bear in mind, that the synovial membrane of the ankle-joint passes very far forwards on the upper surface of the astragalus, even as far as within a few lines of the junction of this bone with the os naviculare, so that an accidental wound high upon the instep might very readily give rise to a fatal synovitis of the ankle-joint. Moreover, by an experiment on the dead subject, it may be shown that a very slight direction too much upwards of the edge of the knife when the operation of partial amputation, according to Chopart, is performed, may wound the most anterior part of the synovial sac of the ankle-joint, and the consequences of such a mishap might prove fatal, or at all events greatly aggravate the ills which even without such cause too frequently follow Chopart's operation.

Again, the synovial membrane extends very low down, even to the lowest point of the inner side of the peroneal malleolus, along the outer or fibular surface of the astragalus (*fig.* 61, *a*).

It has very frequently happened to the writer's knowledge, that inflammation commencing in the body of the os calcis, or in the fibrous or synovial tissue of the articulation between the os calcis and under surface of the astragalus, has crept up to the ankle-joint by this route between the fibula and astragalus; when, therefore, operations and cauterizations are performed by surgeons to cure the carious state of the os calcis, the close contiguity of such an important articulation as that of the ankle should be recollected. The great proximity of the ankle-joint to that between the under surface of the astragalus and os calcis can only be estimated by making a vertical section of the tibia, fibula, astragalus, and os calcis, passing transversely across these bones and through the malleoli, as may be seen in *fig.* 61; and if a subject be selected in which the epiphysis has not been consolidated with the rest of the bone, a useful view may be had illustrating many of the preceding practical observations, and explaining clearly how inflammation, traumatic or idiopathic, once established in the ankle-joint, can pass through the epiphysis to the periosteum of the tibia; and originating either in the body of the os calcis, or in some of the structures composing the articulation between this bone and the under surface of the astragalus, can be propagated to the ankle-joint: such a view as this will shew the necessity of considering, in connexion, the normal and abnormal state of these important articulations.

Fig. 61.



b. *Chronic disease.*—The effects of chronic diseases on the tissues composing the ankle-joint are next to be considered; these are various, and may be referred to the influence of specific diseases, such as gout, syphilis, struma, rheumatism, &c.; but the effects of most of these on this particular articulation need not here be discussed, as they will be sufficiently dwelt on elsewhere in this work (see JOINT): we deem it, however, right to enter somewhat into detail in the description of those morbid appearances of the ankle-joint which are supposed to be of a scrophulous origin, and which are denominated white swelling of the ankle-joint. The external characters of the affection are pretty much those in common with the same melancholy disease, in whatever articulation of the extremity it is situated; the swelling, at first soft, and appearing in front of each malleolus, seems divided into two by the extensor tendons; after a time it becomes more solid, and assumes somewhat of a globular form; here as elsewhere, however, it does not completely surround the joint. The limb above is wasted and the heel is retracted; the foot is œdematous, and the toes are pointed downwards, no motion of flexion or extension can be communicated to the foot; but when the bones are moved laterally, an unnatural motion is communicated to the foot, and a grating of rough and carious surfaces in advanced cases can be felt: the sides of the swelling are studded over with numerous fistulous orifices, from which even now a thin sanious matter can be pressed; a probe introduced passes either directly through one or other of the malleoli, or by a circuitous route into the interior of the joint through the sinuses, which are, as it were, the excretory ducts leading from the interior, and conducting out the sanious and sabulous matter which proceed from the degenerated cartilages, synovial membranes, and bones of the diseased joint. The skin is thin, soft, and shining, and moveable on the surface, except where the fistulous orifices exist.

The anatomical characters of this disease in its advanced stage affecting this articulation we have many opportunities of observing. When the superficial coverings of the swelling are removed, the fat is remarked to be consistent and yellow, the cellular tissue interposed between the ligaments, tendons, and muscles is infiltrated with a viscid, semi-fluid, spongy, homogeneous mass; sometimes this tissue becomes so thick, and is so connected with the lateral ligaments of the ankle-joint, and so interposed among their softened fibres, as to render a clean dissection of these last impracticable; so that the ligamentous and cellular structures around the joint appear to have undergone a species of fibro-cartilaginous degeneration; the viscid glairy matter infiltrated around the joint with the tumefied ligaments are the parts which cause the principal swelling, and give to the fingers examining it that deceptive feeling of fluctuation which characterises the white swelling wherever situated.

The few muscular fibres to be found near this joint are pale and of a gelatinous appearance, being infiltrated with the same matter as that which pervades the more superficial structures. The tendons, nevertheless, preserve their natural colour and consistence. The periosteum will be found much thickened and easily detached from the bone.

The bones of the joint, and those in its vicinity, are very usually more or less atrophied, and have undergone a process of degeneration; notwithstanding, however, what has been said on high authority to the contrary, these bones are occasionally enlarged and expanded; they have lost much of their specific gravity, their spongy tissue is softened, yellowish, and easily penetrated by a knife, and filled with a matter resembling adipocere, or a yellow semi-fluid fat.

The heel it has been noticed is elongated, and the foot measured from the tibia to the toes on the dorsum is shortened very generally, and pointed downwards. Dissection discovers the cause of this frequent phenomenon in a partial dislocation of the tibia forwards on the astragalus, the softened ligaments allowing the action of the gastrocnemii and solæi to drag the whole foot backwards. In the interior of the articulation, a more or less considerable quantity of a sanious matter is found; while the cartilages covering the end of the tibia and fibula, and surfaces of the astragalus, are softened, adhere but slightly to the bones, and have been partially removed, leaving exposed the porous structure of the latter.

The arteries, veins, and capillaries present no peculiarity, except that the naturally white ligamentous tissue is more freely supplied than usual with red vessels. The neurilema of the posterior tibial nerve is evidently much thickened, so as to give it an appearance of enlargement; the small nerves around the joint seem also hypertrophied.

(R. Adams.)

ANNELIDA, (a generally adopted, but barbarous latinization of the French term 'Annélides,' from 'Annellus,' a little ring; ought rather to be written 'Annulata' or 'Annellata.')—The natural group of Annelida comprehends all the invertebrated animals which have a soft body divided into transverse segments or rings; a distinct central nervous system disposed in the form of a longitudinal gangliated chord, blood coloured (generally red), and contained in a system of appropriate and very distinct vessels; and, lastly, organs of locomotion, consisting either of fleshy appendages provided with bristles, or of bristles only; or of a prehensile cavity situated at each extremity of the body; but never of articulated members, as in the Arachnida, Crustacea, and Insecta.

The establishment of this class is due to Cuvier. Prior to him, Pallas, Müller, and Otho Fabricius, had made observations of great interest on the animals of which it is composed; and we find in the writings of the author of the Miscellanea Zoologica the most happy ideas respecting the natural relations which these animals bear to one another. Nevertheless, these works had at first but little influence on the classification of the Invertebrata, and for a long time naturalists persisted in following the method of Linnæus, who united under the term Vermes, the Mollusca, Zoophyta, and Annelida, and dispersed the latter in three different sections of that great class; confounding some with the Entozoa (intestinal worms), others with the Acephalous Mollusca, and others again with the Testacea.

It was in the work entitled "Tableau Elementaire de l'Histoire Naturelle des Animaux," published in the years 1797-8, that M. Cuvier laid the first foundation of a natural distribution of invertebrated animals. He collected together in the class Vermes the species which more lately have constituted the groups of Annelida and Entozoa, and established in it the two divisions corresponding to those which are generally adopted at the present day. Having subsequently determined the presence of red blood in the leech, and having investigated the circulating apparatus in these animals, Cuvier separated the "red-blooded" from the "intestinal" worms, and constituted for the former a distinct class, to which Lamarck afterwards gave the name of "Annélides," which has been generally adopted, and is used at the present day by most naturalists.*

This classification being based essentially on anatomical structure, has been adopted by Lamarck, Dumeril, Savigny, Leach, Latreille,

* See Cuvier, Bulletin des Sciences par la Société Philomathique, an vii. et x. Lamarck, Discours d'ouverture du cours des Animaux sans Vertèbres prononcé en Mai 1806, et Histoire des Animaux sans Vertèbres.

&c., but is not received by all zoologists of the present day. M. De Blainville, in his methodical distribution of the animal kingdom, has adopted another plan. Taking the exterior organs for the base of his system, this naturalist divides the articulate animals, which he terms "Entomozoaires," into seven classes, of which the penultimate, viz., the "chétopodes," comprehends the Annelidans provided with locomotive bristles, and of which the last, viz, the "apodes," is composed of the Annelidans destitute of those organs, together with the planariæ and intestinal worms.*

The general plan of organization exhibited in the animals which are grouped together by Cuvier under the name of "vers intestinaux," and the numerous affinities which connect the planariæ and several helmintha to the Annelida, appear to us fully to justify a partial adoption of the innovations introduced by M. De Blainville, and to indicate that the natural position of the white-blooded worms is by the side of those with red blood, at the bottom of the sub-kingdom of articulate animals; whilst in the system of Cuvier the Annelida are placed at the head of that great division of the animal kingdom, and the entozoa are left among the zoophytes. But, on the other hand, similar reasons appear to us to oppose the adoption of the divisions which M. De Blainville has proposed for the articulate animals. That zoologist, in fact, establishes a distinction between his chetopoda and apoda as wide as between the former and the insecta, arachnida and crustacea, and thus separates from the setiferous annelidans to place among the intestinal worms the hirudines, which approximate to the former and deviate from the latter in many of the most important points of their organization; for example, in the existence of a gangliated nervous system.

This arrangement does not appear to us to accord with the spirit of a natural classification, in which the several divisions ought to be indicative of the different degrees of importance which the modifications of the animal organization present.

In the present state of science the class Annelida ought in our opinion to be preserved nearly as it was established by Cuvier, but should be joined with the entozoa and rotifera, to form a great division of the sub-kingdom articulata, distinct from the natural group, consisting of insecta, myriapoda, arachnida, and crustacea. The affinities, indeed, between the setiferous annelidans and the hirudines are too close to admit of their being arranged in separate classes; and, on the other hand, every day discloses new facts of a nature which demonstrate that the vermiform animals pass from one to another by almost insensible gradations. Thus the researches of M. Dugès on the planariæ show how closely their structure approaches that of certain red-blooded worms, and the distinction founded on the colour of the nutritious fluid no longer suffices to separate them; for on the one hand it is proved that the colour of the blood is yellow and not red in some of the annelidans properly so called; while on the other hand I have recently observed on the shores of the Mediterranean an animal which differs from the genus prostoma only in the possession of red blood. We now know intestinal worms which have a circulation and a vascular system as well formed as that of the annelida, which they already resemble so much by their outward form. The absence of a rudimentary nervous system in the entozoa is called in question by skilful anatomists. Lastly, the excellent works of Ehrenberg on the infusoria of the class rotifera prove the analogy that exists between these minute beings and the articulate animals generally, but more especially to the annelida.

The differences which the annelida present among themselves have necessitated their division into many secondary groups or orders. In the latest work* that has been published on the classification of these animals, they have been divided into four orders, under the names of *Annelida errantia*, *Annelida tubicola*, *Annelida terricola*, and *Annelida suctoria* (suceuses). This classification is based on the combination of the modifications which exist in the structure of these beings, and does not materially differ from that proposed by M. Cuvier in the Règne Animal, and by M. Savigny in the great work on Egypt.

The following is a table of the principal characters which distinguish these groups.

First Order.—Annelida errantia.

Body, with soft appendages (cirri, branchiæ, or antennæ), generally disposed over the whole length of the animal, and not collected towards the cephalic extremity.

Feet generally very distinct, armed with *setæ* or bristles, which have very rarely the form of hooks.

Head generally distinct, and provided with eyes, antennæ, and a retractile proboscis, often with jaws.

(This order, which nearly corresponds to that of the *Annelida dorsibranchiata* of Cuvier, comprehends the genera *Aphrodita, Polynoë, Polyodontes, Acoetes, Sigalion, Palmyra, Amphinome, Chloeia, Euphrosyne, Hipponoë, Eunice, Onuphis, Diopatra, Lysidice, Lombrinereis, Aglaura, Œnone, Nereis, Syllis, Hesione, Alciope, Myriana, Phyllodoce, Nephtys, Goniada, Glycera, Aricia, Aonis, Ophelia, Cirrhatulis, Peripatus, Chetopteras, Arenicola.*)

Second Order.—Annelida tubicola.

Body, with soft appendages, for the most part collected together at the cephalic extremity.

Feet, almost always of two kinds, generally deprived of cirri, and armed with hooked bristles.

Head not distinct, without eyes, antennæ, pro tractile proboscis, or jaws.

(This order corresponds to that established by Cuvier under the same name, and includes the

* See the Bulletin de la Soc. Philomathique, 1818; De l'Organization des Animaux par M. de Blainville, tom. i. table 7; and the article 'Vers' of the Dictionnaire des Sciences Naturelles, tom. lvii.

* See Classification des Annelides et description des espèces qui habitent les côtes de la France, par MM. Audouin et Milne Edwards, tom. ii. des Recherches pour servir a l'Hist. Nat. du littoral de la France.

genera *Serpula, Sabella, Terebella, Amphitrite, Hermella*, and *Siphostoma.*)

Third Order.—Annelida terricola.

Body, completely destitute of soft appendages.

Feet, scarcely or not at all distinguishable, and represented only by some bristles.

Head not distinct, without eyes, antennæ, or jaws.

This order comprehends the genera *Clymena, Lumbricus, Naïs, &c.*

In the classification of M. Cuvier it is united to the Hirudinida to form the order *Annelides abranches.*

Fourth Order.—Annelida suctoria.

Body destitute of bristles for locomotion, completely apodous, and without soft appendages. A prehensile cavity in the form of a sucker at each extremity of the body.

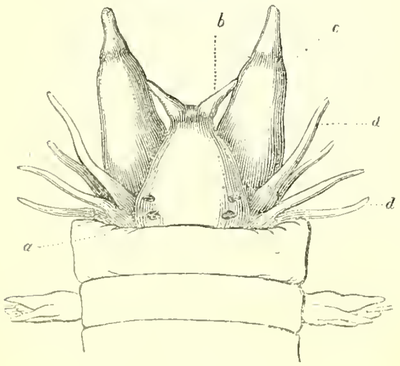
Head, not distinct, but generally provided with eyes and jaws.

This order is composed of the family of *Hirudinida*, and of the genus *Branchellion.*

External conformation.—The Annelida have always an elongated, generally cylindrical, and vermicular form; sometimes, however, they are flat or more or less oval. The body is composed, as we have already observed, of a series of rings, not of a horny or calcareous texture as in the majority of insects and crustacea, but membranous and separated from each other only by a transverse fold of the integument; as is seen in certain larvæ. The number of these rings is occasionally very considerable (some *nereida* have more than 500), and in many annelida it varies considerably in different individuals of the same species, and seems to increase with age. In some instances these segments are subdivided into two or more transverse bands by furrows.

In general each ring supports a pair of members, and when an apparently single segment gives origin to a greater number of these organs, it is easy to perceive that it results from the union of many rings blended together. The two extremities of the body are sometimes dilated in the form of suckers (in the suctorious annelidans), but in general nothing of the kind exists, and the anterior extremity either resembles the rest of the body, or it terminates in a head more or less distinct (as in the nereida, see *fig.* 62), often supporting eyes (*a*), and filiform appendages called antennæ, (*b,c*), the number of which is generally three, four, or five.

Fig. 62.



The *mouth* is situated at the extremity of the body, and in the acephalous annelida is directed forwards, but in the cephalous species this opening is situated below the base of the head. The anus is placed at the opposite extremity, and is almost always found on the dorsal aspect of the body. A certain number of Annelida are completely apodous, and do not present the least trace of an appendage on any of the segments of the body (the hirudinidæ). Others exhibit on either side many rows of bristles, which fulfil the office of feet (the terricolæ). In others, again, the bristles of which we have spoken are supported on a fleshy tubercle more or less prominent, and more or less complicated in structure, and to these organs the name of *feet* is applied.

The feet of the Annelida, when they present the maximum of development of which they are susceptible in that class of animals, are composed each of two very distinct portions, placed one above the other, and appertaining the one to the dorsal, the other to the ventral arch of the ring. (See *fig.* 63, which represents one of the feet of an amphinome.) M. Savigny, who was the first to study with due care the zoological characters furnished by these appendages of the annelida, gave to these portions of the feet the names of dorsal oar (*a*) and ventral oar (*b*) (rame dorsal et rame ventral). Sometimes these oars are pretty distant from one another, (*fig.* 63.) sometimes they are separated only by a shallow fissure (*fig.* 64. which represents the foot of a nereid), and occasionally they are so intimately blended together that they can hardly be dis-

Fig. 63.

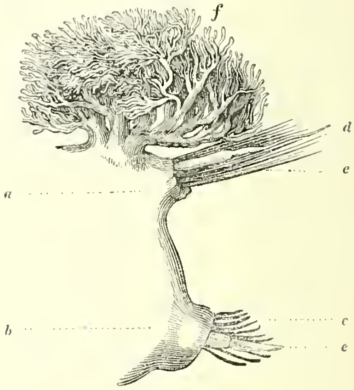


Fig. 64.

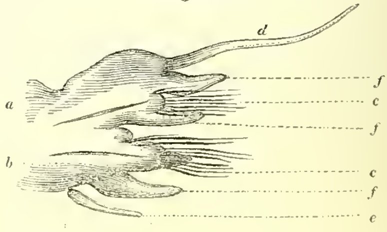


tinguished, and form, as it were, but a single organ; lastly, there are cases in which only one of the oars would seem to be developed. If one were disposed to compare the locomotive system of the annelida with that of the other articulate classes, the ventral oar should be regarded as analogous to the members which in the Crustacea, Insects, &c. are variously modified to constitute the legs, the jaws, or the antennæ: and the dorsal oar ought to be considered as representing the appendages, which, though wanting in the greater number of articulate animals, yet acquire a considerable development on the last two rings of the thoracic segment of most insects and constitute the wings. In this particular the annelida afford an example of the greatest uniformity in the development of the appendicular system in the articulate division of the animal kingdom.

Each oar is essentially composed of a fleshy tubercle more or less prominent, which supports different productions of the integument, incloses the bristles (*c*), and which is more especially designated by the name of foot. Towards the base of the setiferous tubercle there is generally a membranous appendage, sometimes filiform, sometimes lamelliform, called the *cirrus* (*d*, *e*); lastly, it is also above the margin and near the base of these organs that the branchiæ (*f*) take their origin, but in general it is only the dorsal oar that supports them. All the above parts may exist simultaneously, but it often happens that one or more are atrophied to a greater or less degree, or are altogether deficient; and this either along the entire body or on certain segments only. Thus in the terricolous annelida there are no cirri; in the hermellæ they are present on the ventral, but not on the dorsal oar; while in the cirrhatulæ the reverse obtains.

In most of the annelida errantia the setiferous tubercle of both oars is wanting on the first rings which follow the head, whilst the cirri assume a very great development, and form the appendages termed by systematic authors *tentacular cirri.* (*Fig.* 62, *d.*)

A similar modification may be frequently remarked in the composition of the appendicular system of the last ring of the body, and thence results a certain number of filiform productions called styles. Lastly, the antennæ of the annelida, which must not be confounded with the antennæ of insects and crustacea, may also be considered as representing the cirri of the dorsal oar of those rings, the union of which constitutes the head.*

The annelida pass in general a somewhat stationary life, and a great number among them remain constantly buried in the earth or enclosed in tubes formed by the mucus which is secreted by the skin, and which, while hardening, commonly agglutinates together fragments of shells and sand. The formation of these sheaths is very quick. I have seen them fabricated in the course of a few hours. Sometimes they are of extreme tenuity, occasionally they are as tough as thick leather, and there are some which possess very considerable hardness and are composed in great proportion of carbonate of lime, like the shells of mollusca. In the greater part of these animals locomotion is produced by general undulations of the body determined by contractions of a layer of muscular fibres extending from one ring to another, and fixed to the inner surface of the skin. But in other species the change of place is effected by the action of the feet, of which we have spoken; or by the contraction of the tentaculæ which surround the mouth, as in the terebellæ, and which, by shortening themselves, drag on the body of the animal in the same manner as the arms of the cephalopods: lastly, by the action of the suckers with which the extremities of the body are furnished.

The bristles (*fig.* 63 and 64, *c*,) with which the feet of the annelida are provided, do not serve merely as little levers to facilitate their movements, but are also offensive arms, and their structure is very curious. They differ considerably from the hairs of other articulate animals, which are nothing more than small tubular prolongations of the epidermic layer. By their mode of connexion with the integuments and their mode of formation they appear to approach the hair of mammalia, but their disposition is of a more complicated nature. They are inclosed in sheaths provided with muscular fibres, by the aid of which the animal can protrude and retract them again: in general, also, they are not merely simple conical filaments, but their extremity is often shaped like a harpoon, a lance, or a barbed arrow, and the annelidan uses it to inflict a wound upon its enemies.*

Sensation.—Tactile sensibility is considerable in these animals, and it seems to reside principally in the antennæ, the cirri, and the tentacula. They do not appear to possess a sense of hearing, and there are many among them which do not manifest any sign of sensibility to light; but in others, eyes (*fig.* 62, *a*,) exist, the number of which is sometimes very considerable, but the structure very simple. They are coloured points, (generally black,) and situated on the dorsal aspect of the head or on the cephalic sucker. In the setiferous annelida there are never more than two pairs, but in the hirudinidæ or leeches their number often increases to eight or ten. The anatomy of these eyes has recently been studied by Professor Müller of Berlin, and according to his researches it would seem that these organs do not contain a crystalline lens, or a transparent body analogous to the vitreous cones of

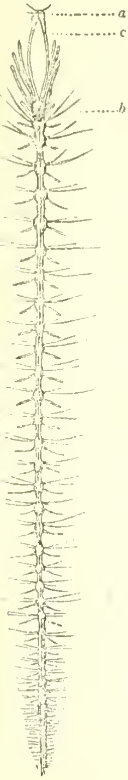
* For further details regarding the external structure of the annelida the reader may consult the excellent work of M. Savigny, intitled "Système des Annelides," principally of those found on the coasts of Egypt and Syria; the article 'Vers' of the Dictionnaire des Sciences Naturelles, tom. lvii. by M. De Blainville; and a more recent publication on the same subject inserted in the Annales des Sciences Naturelles, tom. xxviii, xxix, and xxx, and in the second volume of the 'Recherches pour servir à l'Hist. Nat. du littoral de la France, par MM. Audouin et Milne Edwards.'

* See Observations sur les Poils des Annelides considerés comme moyen de Defense, par MM. Audouin et Milne Edwards, op. cit. tom. ii. p. 31.

the crustacea and insecta, but consist simply of a terminal ganglion of the optic nerve covered by a layer of black pigment and placed immediately beneath the integument, which is thin and transparent at that part.*

Nervous system.—In like manner the nervous system of the annelida is very simple. It occupies the middle line of the ventral aspect of the body, and consists of a double series of minute ganglions of medullary matter, more or less intimately united or even blended together, and equal in number to the number of rings. (See *fig*. 65. representing the nervous system of the aphrodita aculeata). The ganglions give origin to lateral branches, and are connected together by two chords of communication, sometimes separate, sometimes united into a single trunk, so as to constitute a longitudinal chain extended through the entire length of the body. The first of these ganglions (a) is lodged in the head, or at least at the anterior extremity of the animal, in front of or above the digestive tube; the rest are placed below that canal; whence it results that the two nervous chords which form the media of communication between the cephalic ganglion and the first of the sub-œsophageal series pass along the sides of the œsophagus, and form around that canal a species of collar or ring; a character which is common to all the articulate animals.†

Fig. 65.



Organs of digestion.—The alimentary canal in the annelida extends from one end of the body to the other, and has an external communication at both extremities. The mouth is generally provided with a projectile proboscis, which is formed by the anterior portion of the digestive canal, which can be inverted and protruded like the finger of a glove, and possesses muscles for the express object of effecting these movements (see *fig*. 66, which represents the proboscis of a *phyllodoce*, and *fig*. 67, that of a *nereis*). The surface is frequently beset with small papillæ, and its extremity armed with

Fig. 66.

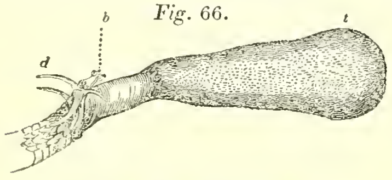


Fig. 67.

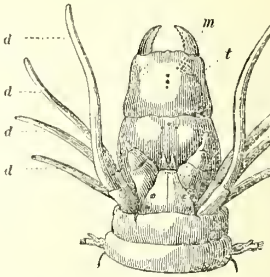

horny jaws (m), the disposition of which varies in different genera. It is to be observed that these jaws are almost always placed laterally like the mandibles of other articulate animals, and cannot act upon one another in the direction of the axis of the body, as in the vertebrata, but are not to be regarded as analogous to the mandibles and maxillæ of insects and crustacea. In their structure, the jaws of the annelida approximate rather to the solid plates with which the interior of the stomach in some crustacea is provided, and to the hooks which arm the mouth of certain gasteropodous molluscs. This conformation of the oral apparatus is met with only in the annelida errantia; in the annelida terricola there is scarcely a vestige of a proboscis, and never any teeth or jaws. In the annelida suctoria, the mouth, which is placed at the bottom of the cephalic sucker, is also occasionally protruded in the form of a small tubular proboscis, and in other species its margins are armed with little horny jaws; lastly, in the annelida tubicola, nothing of the kind is to be seen, but in general the superior border of the mouth forms a sort of projecting lip, which is provided with long tentacles, sometimes simple and filiform, sometimes pectinated and resembling tufts. In certain erratic annelida, the *Agliope*, for example, there are also found around the mouth small tentacula, which are quite distinct from the tentacular cirri, and which appear to be analogous to the appendages of which we have just made mention.

The œsophagus which succeeds the proboscis or mouth presents nothing worthy of notice, but it is in general quite distinct from the stomach. The conformation of the latter organ varies much. Sometimes the stomach is a simple enteroid tube (as in the nereida and terebellæ); sometimes it is composed of two pouches, of which the first is membranous and may be compared to a crop, while the second is muscular and is analogous to a gizzard, as, for example, in the *lumbrici*, *thalassemæ*. In other cases the stomach presents on either side a succession of enlargements which have in general the form of rounded cells, but which sometimes constitute sacs or vast and much elongated cœcums, (as in some hirudines, *figs*. 68 and 69.) Lastly,

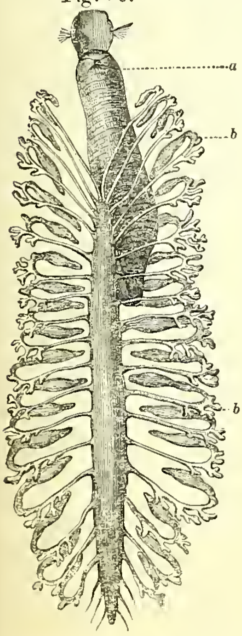
Fig. 68.

Fig. 69.

we may observe that these cœcums are replaced by blind canals, either simple or ramified; thus in the arenicola, or sand worm, we find that there communicate with the second stomach two cœcums terminated by a soft point, with thick parietes of a yellow colour; and in the aphroditæ the stomach opens on either side into a score of membranous appendages, which commence of very contracted diameter, but afterwards insensibly become dilated and divide into many branches: (see *fig.* 70, *a*, the retracted proboscis, *b b*, the appendages.) This type of structure leads to that which is manifested in the planariæ, and also approximates to what one sees in the parasitic arachnida.

Fig. 70.



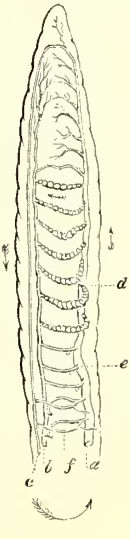
The intestine which succeeds the stomach is generally narrow, and in the majority of the annelida extends in a direct line to the anus. In some species, as the amphitrites, it presents a greater or less number of convolutions. There does not exist in these animals a gland which can be regarded as a liver, properly so called: the appendages which are grouped around the stomach in the *arenicolæ* may, indeed, be biliary vessels analogous to those of insects rather than true cœca; but in the earthworms and many other annelides the bile would seem to be secreted by a peculiar organ of a yellow colour and pulpy texture, which surrounds like a sheath a great part of the digestive canal. Lastly, in certain annelida, as, for example, the thalassemæ, there exists on either side of the œsophagus a small organ, which would seem to have a secretory office, and may very probably be a salivary gland.*

Circulation.—The blood in almost all the annelida differs from that of every other invertebrate animal by its red colour; sometimes, however, this fluid has scarcely a tinge. According to M. De Blainville the blood of the aphroditæ is yellow, and MM. Mayor and Gosse, of Geneva, assert that the circulating fluid of the genus *clepsina*, one of the hirudinidæ or leech-tribe, is even altogether white. When the blood of an annelide is examined with the microscope it is seen to contain circular globules, but of a much larger size, and in far less number than in human blood: it coagulates after rest like the blood of the higher animals, but it appears to contain a very small proportion of fibrine.

The blood circulates, as we have already stated, in peculiar vessels, which its red colour renders easily distinguishable.

The vascular system has been best studied in the earthworm: above the alimentary canal there runs along the entire length of the body a contractile vessel (*fig.* 71, *a*,) which is consequently dorsal, and in which the blood passes generally from behind forwards, sometimes in large waves, sometimes by small quantities propelled by the successive contractions of the divisions which this vessel forms through its entire extent. A portion of the circulating fluid then passes into another vessel (*c*), which originates at the anterior extremity of the one abovementioned, and which runs backwards along the ventral surface of the body below the nervous column, from which circumstance it has been called the sub-nerval vessel by Dugès. But the greater part of the blood which is contained in the dorsal vessel, instead of following this channel, passes into seven or eight pairs of large lateral branches composed each of a series of dilatations or rounded ve-

Fig. 71.



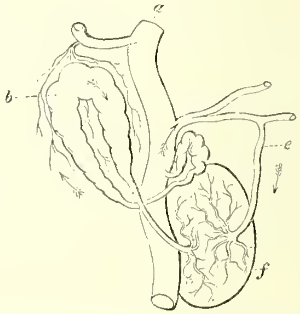
* See Willis, 'De Animâ Brutorum;' Pallas, 'Miscellanea Zoologica;' Cuvier, 'Anat. Comp.' Treviranus, op. cit. Moquin Tandon, op. cit.; Dugès, op. cit.; Home, 'Lectures on Comp. Anat.'

sicles (*d*), which are highly contractile. These 'moniliform vessels' are placed in a situation corresponding to the ovaries: they are directed downwards and open into a ventral vessel (*b*), which occupies the middle line of the inferior aspect of the animal, following the same track as the sub-nerval vessel, but situated less superficially. Its parietes are contractile, and it may be seen alternately dilating and contracting simultaneously at every part along the whole of its extent. The blood flows into this ventral vessel from before backwards, and leaves it to re-enter the dorsal vessel by passing through the branches (*e*) which ascend perpendicularly to join the latter, on either side of the alimentary canal, which they thus embrace, and to which they furnish a great number of ramifications. The blood contained in the sub-nerval vessel flows equally from before backwards, and ascends to re-enter the dorsal vessel by lateral channels (*f*), analogous to the anastomosing vessels which we have just described, but situated more superficially than those. These superficial transverse or *dorso-abdominal* vessels, as they are termed by M. Dugès, severally receive a large branch from their corresponding deep-seated *dorso-abdominal* vessel, and distribute to the skin a number of ramifications which appear to be specially destined to bring the blood into contact with the oxygen necessary for respiration.*

In the genus *naïs* the moniliform vessels, which in the earthworm perform in some degree the office of a composite heart, seem to be replaced by a single pair of wide veins, which are contractile and analogous to a divided heart, and both the superficial and deep-seated transverse vessels by which the blood ascends to the dorsal trunk seem to rise from one and the same ventral trunk; so that the circulatory apparatus is more simple in these annelida than in the earthworms. The same plan pervades the sanguiferous system in the other setiferous annelidans, in which the branchiæ are distributed throughout the entire length of the body; but when these organs are collected together at a determinate point of the anterior extremity of the body it is a little different. Thus in the terebellæ the ventral vessel is seen to bifurcate and to form two lateral branches which have the form of an arch, and which, after having passed over the sides of the œsophagus, re-unite above that tube to form a single trunk. This trunk reaches the anterior extremity and gives origin to three pairs of primary branches, which descend to the vesicular receptacles at the base of the branchiæ, and distribute the blood to these organs.

In the leech-tribe the vascular system, on the contrary, is more complicated, for the sanguiferous circle is composed of four longitudinal trunks, and the branches which bring them into communication with each other. Of the four longitudinal vessels two occupy the dorsal and ventral aspects of the mesial line, and two the sides of the body. The dorsal and ventral trunks communicate together by dorso-abdominal branches corresponding to each segment of the body. The lateral trunks also render to the dorsal trunk a series of dorso-lateral branches, and, moreover, mutually communicate by a series of abdomino-lateral branches which glide transversely beneath the nervous chords. The dorsal and ventral vessels are evidently analogous to those which we have designated by the same names in the earthworm and naïs; and the lateral vessels may be compared to the sub-nerval trunk of the earthworm, except that, instead of being single and situated in the mesial line, they form a circle in which the blood undulates sometimes in one direction, sometimes in another, but always pursuing an opposite course in the two canals. Lastly, in addition to the above 'general circulation,' there is observed in the leech-tribe something analogous to the 'lesser circulation,' (*fig.* 72):

Fig. 72.



this is effected in the branches (*b*, *e*) of the dorso-lateral vessels (*a*), which are for the purpose of bringing the blood into contact with the aerated water contained in the small membranous vesicles (*f*) situated at the sides of each segment of the animal, and opening externally upon the inferior aspect.*

Respiration.—From what has been said of the mechanism of the circulation in the annelida, it will be seen that respiration must be effected either in the vesicles above mentioned, or on the surface of the body. Such in fact is the case; the skin is in general the seat of that function; but in the greater number of instances, the integument, instead of maintaining the same texture throughout, and acting upon the air in the same manner at every point of its extent, presents at particular spots peculiar modifications, and thus gives rise to special organs of respiration called 'branchiæ.'

The branchiæ of the annelida are almost universally membranous appendages, highly vascular, fixed to a certain number of the feet of the animal, or inserted upon the back near the base of these organs.

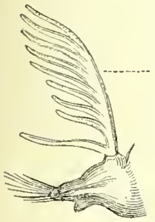
In the nereida and some other congeneric annelida, the appendages which are designated branchiæ, and which in fact seem to be in an

* See Dugès, 'Recherches sur les Annelides abranches,' Annales des Sciences Nat. t. xv.

* See Moquin Tandon, op. cit. Dugès, op. cit.

especial manner subservient to respiration, are simply a kind of papillæ or laminated cutaneous productions very little or not at all subdivided, attached either to the extremity or base of the feet and distributed in an almost uniform manner over the entire length of the body, (*fig.* 64, *f*, *f*, *f*.) In the *eunice*, and other allied genera, their position is the same, but they assume the form of an elongated filament, furnished with a series of prolongations of a similar filiform shape, disposed like the teeth of a comb, and traversed longitudinally by a canal filled with red blood, (*fig.* 73, *f*.) In the amphinomian family, as in the former groups, these branchiæ are placed on almost every segment of the body, so that these organs form along the whole extent of the back a double row; but here their structure is more complicated, for the filaments are extremely subdivided, (*fig.* 63, *f*.) In the *arenicolæ*, the form of the branchiæ is almost the same as in the amphinomes, but they are limited in their position to the middle segments of the body. In the genus terebella the branchiæ are also highly ramified vascular appendages to the integument, but their number is inconsiderable, and they are all inserted near the cephalic extremity of the back. In the serpulæ, the membrane which forms a sort of thoracic disc near the cephalic extremity of the body, ought to be regarded as an organ of respiration, and it is probable that the tentacles surrounding the mouth like a crown of plumes are subservient to the same function.* In the hirudinæ respiration is in part effected by the external skin, but there exists in these annelida a series of small membranous sacs, which communicate externally each by a minute orifice situated on the ventral aspect of the body: these sacs derive from the numerous vessels which ramify upon their parietes a considerable quantity of blood. Water penetrates into these organs and seems to subserve a true respiratory purpose. These sacs are commonly denominated 'pulmonary sacs,' and some authors think that they receive into their interior atmospheric air in a gaseous form. Their number varies from fifteen to twenty, and it may be observed, when a living leech is irritated after being recently removed from water, that a small quantity of liquid escapes from their apertures.

Fig. 73.



In the *lumbrici terrestres* there is in like manner found in each segment and on either side of the digestive tube, an enteroid vessel folded upon itself, containing a liquid and opening outwardly by a particular pore. These sacs are less vascular than in the leeches; nevertheless there is reason to believe that they fulfil an analogous office, and perform a more or less important part in respiration. Lastly, it has been proved that in the annelida there are other pores, placed on the back, which traverse directly the dermo-muscular envelope, and communicate with a cavity intermediate to the muscles and intestines, and imperfectly divided by transverse septa, into which air or water can penetrate. This structure may, indeed, belong to the respiratory apparatus, but science does not yet possess sufficient data to solve that question. An analogous disposition has been observed in the naïs.*

Generation.— The generative apparatus is only very imperfectly understood in the annelida. It appears that all these animals are hermaphrodite, but that they cannot fecundate themselves; the intercourse of two individuals being necessary for the accomplishment of the act of generation. It is in the earthworm and leech that this part of their anatomy and physiology has been most completely studied.

In the leeches the sexual apertures are placed at the inferior surface of the body towards the anterior third, and separated from one another by the intervention of five segments. The anterior aperture belongs to the male organs, and at the season of reproduction a filiform and highly contractile penis is observed to be protruded from that part, (*fig.* 74, 75, *a.*)

Fig. 74.

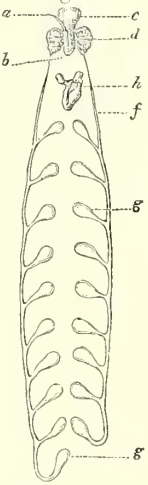


Fig. 75.

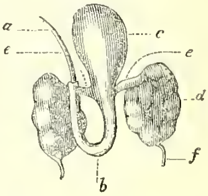


This communicates internally with a narrow cylindrical canal (*b*), which in its turn opens into a kind of whitish vesicle of a pyriform shape (*c*) commonly called the *vesicula seminalis*. On each side of this vesicle there is an oval whitish body (*d*) composed of contorted tubes filled with a whitish liquid: each of these organs is a testicle; and they severally give origin to a slender *vas deferens* (*fig.* 75, *e*) of the same colour, which opens into the vesicula seminalis. Lastly, from the posterior extremity of the testicle, another filiform duct (*f*) is continued, which passes backwards on each side of the nervous cord, and gives origin to a series of pedunculated vesicles filled with a whitish fluid similar to that which

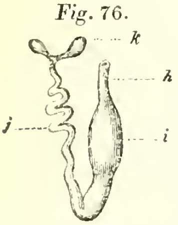
* See, for additional details, the works already cited of Savigny, De Blainville, and Audouin and Milne Edwards.

* For the structure of the pulmonary sacs, see Willis, op. cit. Thomas, 'Mémoires pour servir a l'Histoire Naturelle des Sangsues.' Home 'Lectures on Comp. Anatomy,' Moquin Tandon, op. cit. Morren de Lumbric. terrest. Dugès, op. cit.

is contained in the rest of the apparatus. These organs (*fig.* 74, *g*) are generally regarded as accessory vesicles, and they vary both in number and form in different species.

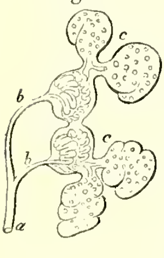
The female apparatus is of much less magnitude, but also presents a sufficiently complicated structure: it is situated between the two canals leading to the accessory vesicles of the male apparatus, and is a little posterior to the penis. The external orifice, of which we have already spoken, communicates with a short canal (*fig.* 74 and 76, *h*), of a greyish colour, which leads to a sort of pouch (*i*). This, according to some authors, is analogous to an uterus, but in the opinion of other naturalists is merely a *copulative vesicle* for the purpose of retaining the fecundating liquid which is there deposited by the male in the act of copulation. This sac is bent upon itself, and a duct (*j*) may be observed to be continued from the anterior extremity which leads to the ovaries (*k*): these are small whitish bodies two in number, and in close approximation to one another.

Fig. 76.



In the earthworm, the only parts that can be regarded as male organs are some sacs or vesicles varying in number from two to seven, and situated in a longitudinal series on either side of the ventral aspect of the body towards its anterior extremity. Each of these vesicles adheres to the parietes of the splanchnic cavity, by a small canal opening directly outwards by pores placed on the posterior and inferior part of the corresponding ring: there is farther a canal of communication, which is continued directly from one vesicle to another of the same lateral series; and at the season of copulation there is found in the interior of these organs a viscid liquid abounding with seminal microscopic animalcules. The outlets of the female apparatus occupy the sixteenth segment of the body, and are continuous internally with two narrow canals directed forwards, and situated on the internal side of the above mentioned vesicles. Having reached the ovaries, each of these canals (*fig.* 77, *a*) divides into two branches (*b*), which bend inwards and terminate by a globular enlargement (*c*). This is seen with the assistance of the microscope to be itself formed by a continuation of the canal puckered up into numerous folds, which are enveloped in a common membrane. To each of these enlargements are appended a pair of ovaries, the entire number of which is consequently eight, four on either side. The colour of these ovaries is whitish, their texture pulpy, and their interior is beset with numerous minute vesicles, which are the ova. At the period of copulation the ovaries are filled with a whitish fluid, which is probably the spermatic secretion, but it is not easy to comprehend how the male apparatus can introduce it into that part.* According to Redi, the ova, after being detached from the oviduct, pass along the whole extent of the body towards the vicinity of the anus, whence they are expelled by two orifices stated to be near the termination of the alimentary canal or to open in its interior. According to Montegre it is the fœtus and not the ovum which traverses the body to escape by the above passages, and the lumbrici according to this view are viviparous. This statement has been adopted by many authors without perhaps sufficient examination; but, according to recent observations by Dugès, it would seem not to be correct, and that what have been regarded as the young of the earthworm are in fact a species of intestinal worm.

Fig. 77.



In the naïs the male organs are less numerous than in the lumbrici, but differ very little in other respects. They consist of a single pair of vesicles opening externally by a winding canal, which terminates by a small fissure on the eleventh segment of the body. The ovaries are disposed in four principal masses, between which there winds a long oviduct, of which the extremity can be protruded outwardly like a penis.†

In some annelida, as the *clepsina carena*, the ova are developed and hatched before exclusion, so that the young are born alive; but most of the class are oviparous, and what is very remarkable, the same ovum sometimes incloses the germs of many embryos: this is the case in the earthworm, each ovum of which produces two individuals, and in the leech the ova contain severally as many as eighteen embryos. One might at first view suppose that the same circumstances obtained in the naïs; but what appears to be an ovum with multiplied germs is in reality nothing more than an aggregate of simple ova.

Reproduction.—Some annelida not only perpetuate the race by the ordinary modes of generation, but enjoy the singular faculty of producing new individuals by a transverse division of the body. A naïs or an earthworm cut in two and placed under favourable circumstances, will continue to live, and each moiety will become, in appearance at least, a perfect animal. This fact, which was first determined by Reaumur and Bonnet, has since been verified by M. Dugès, Sangiovanni, and many other observers: the anterior portion of the animal reproduces a new tail, and the posterior portion developes a head.

That faculty which the two portions of the earthworm's body possess of manifesting the vital properties independently of one another, and even after having been separated, may be explained to a certain degree by the known structure of these animals and

* See Willis, Dugès, &c.

† See Dugès, op. cit.

the general laws of physiology. With the exception indeed of the generative organs which are concentrated in a peculiar part of the body, it is easy to observe that each segment of the body is almost the exact repetition of all the rest: they all possess the same organs, and, however the total number of rings may vary, there results no change of any importance in the general structure of the animal. Now it may be laid down as a law in physiology, that a parity of organization necessitates a similitude of action; and it results that as in depriving an earthworm of a given number of segments no organ is removed of which it does not still retain the analogue, no function is completely destroyed; and consequently that if such a mutilation should weaken the vital action, it does not change its nature. This holds good for both the segments of the animal: each continues to possess all the organs essential to individual existence, and consequently if their resisting energy be sufficiently great, there can be no reason why they should not continue to live independently of one another, and become two distinct worms.* But if the anterior moiety thus becomes a perfect animal, it is probable that this may not happen to the posterior portion, but that the new individual formed by this part will always continue deprived of generative organs. For the anterior moiety retains exclusively the reproductive organs of the original individual, and there is nothing which authorizes the belief that the earthworm possesses the power from being simply mutilated, of reproducing the whole apparatus on any part of the posterior moiety. This, however, is a circumstance which it would be easy to determine.

From the sketch that we have given of the organization of the annelida, it will be seen that there exists in this branch of zoology many hiatuses. Anatomists, in fact, have hardly paid attention to any but the leech, the earthworm, and the naïs, and we possess only a vague notion of the internal structure and physiology of the erratic and tubicolar species; their comparative study would form an interesting subject of research.

ANUS, (in anatomy,) from Anus vel Annus, a round, a circle, (syn. *ostium recti, podex, culus.* Gr. πρωκτος. Fr. *anus.* Germ. *After.* Ital. *ano.*) is a term commonly applied to the lower extremity of the rectum: properly speaking, it is the inferior orifice of the alimentary tube, through which, in the higher orders of animals, the excrementitious portion of the food, as also the excretions from the digestive apparatus, are discharged; for obvious reasons it is endowed with powers to assist in expelling, as also with the faculty of retaining these for a considerable time: such opposite but important qualities would infer the existence of a somewhat complicated muscular apparatus, more or less under the influence of the will, as also a structure in other respects worthy of attention.

The presence of an anus indicates a complex system of digestive organs; hence in many of the inferior or simpler classes of the invertebrate division of animals it is absent, and in many of the superior of this division, as well as in several of the vertebrata, it presents considerable variety as to structure, function, and position. In some of the zoophytes, such as the infusory animalcules there is no central digestive cavity, and of course no distinct outlet. In them absorption takes place by imbibition through pores into cells, in a manner somewhat similar to a sponge; and most probably excretion (if any occurs) takes place through the same orifices. In others of this class, such as the acalephæ, where a rudimental cavity appears in the body of the animal, a single orifice admits the food necessary for its support, and the excrementitious portion (if any) is ejected through the same opening. In the actiniæ, also, where a distinct stomach exists, and where the retained matter obviously undergoes certain changes, the one orifice serves the two-fold purpose of admission to the food, as well as of exit to its residuum. Even in some of the echinodermata, as the asteriæ, in which the digestive apparatus is more developed, the central cavity becoming more complex, the latter is still but a cul de sac, which can be protruded at the mouth, the only orifice it presents. In other species, however, of this class, the anus appears; thus in the English echinus, where the masticating apparatus is so remarkable, this opening exists on the surface of the animal, opposite to the mouth.*

In the sipunculi the anus opens near the mouth, and in the holothuriæ near the respiratory organ.†

In the several families of the articulata, viz. insecta, crustacea, and vermes, the anus exists, and is always found at that end of the animal opposite to the mouth, and most generally on its inferior surface.

In the mollusca it is also present, but it holds situations singularly differing in the different orders and genera of this class; thus in the cephalopoda, as the cuttle-fish, the rectum opens into a sort of cloaca, which is situated before the neck, and which also receives the semen and ova, as well as the secretion from the ink-bag. In the gasteropoda, as the slug, it is generally found near the pulmonary cavity. In the patella or limpet, however, it opens on the head, and in the doris on the back, surrounded by a delicate fringe, a sort of branchial tuft. In most of the acephala, except the oyster, the rectum extends along the back of the animal, beneath the hinge, and above the respiratory organs; it then passes through the heart, and opens above the posterior muscle of the shells, into the cavity of the maulle, or between its edges, the anal opening presenting the appearance of a fleshy disc or sphincter.

Among fishes the anus varies, in the osseous and cartilaginous divisions of this class; in the former it usually presents the appearance of a round opening leading into a longitudinal groove; it is placed in front of the anal fin, and of the urinary and genital aperture, contrary to what occurs in all other vertebral animals. In the cartilaginous fish, as the ray and shark, this groove is deeper, and has the appearance of a true cloaca, through which are discharged, as in the sepiæ and in birds, not only the alvine, but also the urinal and seminal excretions.

In reptiles the anus serves as the opening of a cloaca, or common receptacle of the residuum of the food, as well as of the urine, semen, or ova; in the batrachia, as the frog, it is situated at the end of the back, and therefore above the body of the animal. In the chelonia, as the tortoise, it is under the tail. In the sauria and ophidia it is a transverse cleft, but in the salamander it is a longitudinal fissure with two prominent lips.

* Home's Lect. on Comp. Anat. vol. ii. p. 76.
† Cuvier's Comp. Anat. t. iv. p. 143.

In birds the rectum expands above the anus into the cloaca, which also receives the terminations of the ureters, the ends of the vasa deferentia, and the penis (when the latter exists); also the openings of the oviducts, and of the bursa Fabricii. In all the mammalia the rectum terminates in a distinct anal opening, which is placed at the posterior or inferior extremity of the trunk, directly under the origin of the tail, and usually in a direction opposite to the mouth, and in all it is placed behind, and not, as in fish, before the urinary and sexual orifice; in some few of the quadrumana, as the mandril, it is directed upwards. In almost all mammalia it is a distinct orifice, giving passage to the fæces only; in the beaver and sloth, however, the rectum and urethra have a common termination. The monotrematous animals also, such as the echidni and ornithorhynci, form a complete exception to this statement; in these singular and anomalous creatures a single opening gives exit to the fæcal and urinary secretions, and also subserves sexual purposes. (See INTESTINAL CANAL.)

ANUS (in human anatomy). In the present article we propose to examine not merely the structures which immediately bound this opening in man, in their normal and healthy state, as well as in their abnormal and diseased conditions, but we shall also examine the parts which enclose and surround it, and which can exert an influence, direct or indirect, on its functions; that is, we shall consider the anatomy, normal and abnormal, of the parts contained in the *Anal Region*.

The Anal Region is synonymous with the posterior portion of the perinæum; its triangular area is denoted by the following outlines: the apex, which is posterior and superior, is marked by the extremity of the os coccygis; its base, which is before and below the latter, is defined by an imaginary line extending transversely from one tuber ischii to the other, and each side is denoted by a line drawn from the last named process to the point of the coccyx: these lateral boundaries correspond to the margins of the glutæi maximi muscles, which overlap the inferior or the great sacro-sciatic ligaments; the base or the transverse line before mentioned, separates the anal from the anterior perineal or urethral region: in the adult male this line will be found to be about three inches, or nearly three inches and a quarter in length; in the female it is about half an inch longer, and more certainly so if the individual examined have borne children; great variety, however, has been found to exist in this measurement, the extremes of which may be stated at two and four inches. In children under twelve years of age this transverse diameter of the perinæum is considerably less, in consequence of the extreme narrowness of the pelvis prior to puberty.

The anal region contains the lower portion of the intestinum rectum, several muscles, and fasciæ, some nerves and vessels of importance, and an abundance of adipose substance. The quantity and consistence of the adipose substance found in this region vary considerably in different individuals at the several periods of life, and under various conditions of health; a fact most important for the surgeon to bear in mind, inasmuch as this diversity causes corresponding differences in the physical characters which this region presents under these particular circumstances. In children, and in the female, in youth and middle age, as also in the robust and healthy male, this region will be found plump, or convex around the anus, whereas in the emaciated, the sickly, or the old, it often presents the very opposite appearances; and a proportional difference may be observed in the depth of the perinæum, or in the distance between the neck of the bladder and the surface: the greatest extremes of this difference have been found between two and four inches, a circumstance which bears materially on the lateral operation of lithotomy.

So much of the *Rectum* as lies beneath the cul de sac of the peritoneum, may be considered as appertaining to the anal region, and must, therefore, be noticed at present; below the reflection of that membrane, this intestine descends obliquely forwards between the sacrum and bladder, in the male as far as the prostate gland, and in the female as far as the vagina; it is there on a level with the inferior extremity of the coccyx, and then it bends downwards and backwards, and ends in the anal opening; the perinæal portion of the Rectum, therefore, is convex forwards and concave towards the coccyx; hence in introducing into this intestine the bougie, enema pipe, or even the finger, it should be directed at first upwards, and forwards, and then upwards and backwards: in the child, however, this precaution is not necessary, as the course of this intestine is not so much curved, the name of Rectum being then more correctly applied than in the adult.

In order to examine the several parts contained in the anal region, the thighs should be fully separated, flexed, and fixed on the pelvis; the first object which attracts attention is *the Anus.*

This opening is situated in the median line, at the bottom as it were of a deep excavation, which is bounded on either side by the tuberosity of the ischium, with the superincumbent muscular and adipose substance; in the erect position it appears at a great depth from the surface, in consequence of the approximation of the nates. In the adult the anus is from one inch to an inch and a half distant from the point of the coccyx, and three inches from the arch of the pubis; it is in some measure, but not perfectly, fixed in its situation, anteriorly by an indirect attachment to the interosseous or triangular ligament of the urethra, and posteriorly by a dense fibrous tissue, which forms a sort of raphè between it and the coccyx, and to which the muscles and integuments adhere. In the natural and healthy state, the anus presents the appearance of a small rounded, or rather elliptical orifice, whose border is thrown into numerous small plaits, or rugæ, which during the extended state of the opening are effaced; these rugæ are occasionally so deep as to admit of the escape of a small quantity of fluid. As the skin approaches the margin of this opening it becomes very fine and delicate, is gathered into those several radiated folds or plaits, which sink into it, and in the same manner as at the other outlets of the body, it becomes continuous with the lining mucous membrane of the intestine, there being no exact line of demarcation, except that of an increased vascularity, to distinguish the one from the other. This plaited condition of the skin which lines this opening arises from the close contraction of the subjacent muscle, and is doubtless designed to admit of the more easy dilatability of the anus during defœcation; this opening, however, is never equal to the diameter of the rectum at a little distance above it. In the child the integument surrounding the anus is smooth and red, in the adult it is of a deep brown colour and studded with several fine hairs, which, however, are usually absent in the female. In this situation also the cutaneous follicles are very distinct and numerous, but not so prominent as in the scrotum; they secrete a mucous or sebaceous matter which gives to the skin a shining or oily appearance, and adapts it to the functions of the part: from the absence or from the vitiated condition of this secretion, painful and troublesome excoriations not unfrequently ensue. In the healthly state the margin of the anus feels firm and resisting, and together with the surrounding muscles forms a floor or support to the inferior part of the pelvis, in the centre of which floor the rectum and its contents are maintained, and on either side a mass of cellular and adipose substance.

Muscles.—The muscular apparatus connected with the lower extremity of the rectum consists of the superficial and the deep *sphincters* of the anus, also the right and left *levatores ani*, to which may be added the two *transversi perinæi*, and the two *coccygæi* muscles.

The first two, namely, the *sphincter* muscles, surround the anus, and may be regarded as a modification, or as a particular development of the general circular muscular tunic, which is continued around the whole alimentary tube from the mouth to the anus, and which in different situations exhibits a considerable increase in colour and consistence, for example, in the lips, around the fauces, the œsophagus, the pylorus, &c. The name of these muscles indicates their principal function, while the other muscles which have been alluded to proceed from certain fixed points to be inserted into the lower extremity of the rectum, and must, therefore, rather serve to retain the anus in its situation or to restore it to its natural condition, when in the exercise of its functions it has been considerably dilated, or slightly displaced by the expulsive efforts of the diaphragm and abdominal muscles. We shall first examine the descriptive anatomy of these individual muscles, and then consider their several powers or purposes in the economy of the surrounding organs. Although there are two sphincter muscles of the anus, yet this name is generally applied to the more superficial of these; we shall distinguish these muscles by the names of *sphincter ani cutaneus* vel *ellipticus*, and *sphincter ani profundus* vel *orbicularis*.

Sphincter ani cutaneus (σφιγγω, constringo,) *coccygeo-anal*, *sphincter externus*, *constrictor ani*) is the first muscle which meets the eye of the anatomist in the dissection of this region. It may be exposed by dividing the integuments from the coccyx to near the back part of the anus, and thence extending an incision on each side, and about half an inch distant from the edge of this opening to its forepart, whence it should be continued indefinitely along the median line of the perinæum; the integument should then be carefully dissected off from either side of this elliptical incision.

The muscle thus exposed is thin and flat, of an elongated and elliptical form, and cleft in the *centre* to embrace the opening of the anus; it arises posteriorly fleshy and cellular from the point of the coccyx, and from a tense fibrous or cellular tissue, called the *recto-coccygæal ligament*, which extends from the coccyx to the back part of the anus, where it divides and is lost in the cellular tissue on either side. From this origin the fibres of the sphincter collect into a rounded fasciculus, which proceeds forwards and downwards, increasing in size, and at the back of the anus divides into two bands which pass one on either side of this opening, each spreading out till it is an inch or even more in breadth; again converging in front of the anus, these bands unite into a fasciculus, which in the male is very long and passes forwards and upwards between the skin and the acceleratores urinæ muscles, to be partly *inserted* into the median line of the superficial fascia of the perinæum, and partly confounded and interlaced with the transversi perinæi, and with the muscles which cover the bulb of the urethra; through the medium of these last it is even attached to the common cellulo-tendinous central point of the perinæum, between the rectum and the bulb, whereby it is enabled to act on this part of the urinary canal. This anterior insertion is very variable in different persons; in some it stops abruptly at the bulb, while in others it continues to run forwards between the skin and the acceleratores as far as the dartos, in which it terminates. In the female this anterior fasciculus is much shorter, and ends in the sphincter or constrictor vaginæ; in the male its attachment to the muscles of the bulb is often deficient, so that in the course of the dissection, when the superficial fascia has been removed, this extremity of the muscle will be found detached and its insertion isolated. The entire of the inferior surface of this muscle is in contact with the integuments, its superior surface is related to the levatores ani, acceleratores urinæ, and transversi perinæi muscles; in front of the anus it is confounded with the two latter, and immediately behind it with the formerly named muscles; its external border is of uncertain extent, and is imbedded in adeps, while its internal edge is in close relation with the delicate inflected anal skin, being separated only by a fine cellular tissue. This muscle is composed entirely of fleshy fibres, occasionally intersected by cellular and imperfect tendinous bands; these fibres are placed in concentric arches, those of opposite sides unite at acute angles, and sometimes interlace before and behind the anus; the fasciculi are frequently separated by considerable intervals, so that they appear like different muscles; some of the internal fibres assume a circular arrangement; in the female this muscle is shorter, broader, and more rounded, particularly in front. In structure and appearance this muscle presents great diversity; in some it is red, strong, and large, in others, so pale and weak as to be difficult of perfect demonstration; it is also probable that during life great differences exist as to its power of contraction.

The *use* of this muscle is obviously to close the anus, the skin of which it throws into small rugæ; hence when the sphincter is paralysed, there is incontinence of the contents of the rectum; the most internal fibres will tend to close the opening more perfectly than the external or elliptical, which will reduce it rather to a cleft or fissure; this muscle can also raise the anus somewhat, and at the same time draw back and compress the bulb of the urethra; it will also express the secretion from the anal glands and follicles. The sphincter ani may be properly said to belong to the class of mixed muscles, both as relates to its structure and function; as to the former, its paleness, scattered fibres, connection with the commencement of the mucous surface, and absence of true tendon ally it to the muscular system of organic life; while on the other hand the parallel direction of its fasciculi, and the arrangement of many of the latter in the surrounding adeps, assimilate it to the muscles of voluntary motion. In its functions also it appears to border on the province of each division of the muscular system; thus without the efforts of the will, or even without any internal cognizance, it continues in a state of almost permanent contraction, and as unconsciously relaxes when the functions of the part impress upon its sensibility the necessity of so doing; while on the other hand the will can exert a considerable control over its powers, and can cause it to contract with considerable and continued energy, as well as throw it into a state of atony and relaxation. Although this muscle belongs to the same class with the other sphincters, the orbiculares oris and palpebrarum, yet it manifests a considerable difference in its vitality. The natural and, therefore, the usual condition of these other sphincters is relaxation; hence the mouth continues open, and partly from the same cause too, the eyelids are apart; whereas the natural condition of the sphincter ani when at rest is contraction, and hence the anal opening is always closed, although the muscle is still capable of contracting with considerably more energy when any of the contents of the rectum suddenly approach the orifice, or when any irritation exists in its vicinity.

The *Sphincter ani internus* vel *orbicularis* (*Sphincter intestinale*, Winsl.) is of much less extent than the former, and is situated more deeply; it is closely connected to the mucous membrane, or the fine lining integument, and appears a particular development of the circular fibres of the intestine, like those which surrouud the pyloric extremity of the stomach. This circular muscular ring consists of several fine and pale fasciculi of fibres, which are closely connected together, and when contracted form a thick ring around the intestine immediately within the anus; this muscle may be exposed either by detaching the lining membrane which is but loosely attached to it, or removing the rectum from the subject, everting and distending it. The mucous membrane being then detached, the muscle will be distinct; its upper border is continuous with the circular fibres of the rectum, and a distinct cellular line separates it from the cutaneous sphincter; anteriorly it is connected with the levatores ani muscles.

The action of this muscle must be to assist the former sphincter in closing the lower extremity of the rectum and supporting its contents; in the process of defæcation it assists in the expulsion of the residual portions of the fæcal matter, by the sudden or almost spasmodic action which succeeds its relaxation; moreover, it strongly opposes the entrance of any foreign body by the anus; so that from its power of resisting the ingress or egress of any substance, it may be considered as constituting a perfect pylorus.

The subcutaneous adipose tissue in perineo is very abundant in some situations; close to the anus, or between the sphincter and the skin, there is but very little; hence abscesses but seldom form there, except of very limited size, such as small furunculi, or as the result of circumscribed inflammation in some of the follicles around the opening; whereas at either side of the anus and rectum there always exists a considerable quantity of cellular and adipose matter, the former remarkable for the large size of its cells, which are intersected by irregular bands or fibres from the perinæal fascia, and which give the whole some degree of elasticity; the adipose substance is abundant, very soft, loose, sometimes reddish, and fills those large spaces which exist on either side of the rectum. In no part of the body do abscesses so frequently form as in these ischio-rectal spaces; and as such abscesses are very generally attended with consequences tedious, troublesome, and dangerous, it may be right to make a few remarks on the anatomy of these regions.

Each *Ischio-rectal space* is a deep triangular hollow, the base being situated towards the integuments, the apex towards the cavity of the pelvis; the outer side is formed by the ischium, and the inner by the rectum with its muscles; this intestine, together with the attachments of the levatores ani behind and before, separates the two spaces from each other, but the cellular membrane of one side communicates with that of the opposite, and hence in cases of diffused or extensive suppurations, the fluid is occasionally observed to pass from one side to the other; anteriorly the transversus perinæi, and posteriorly the coccygeus muscles bound this hollow. Each of these triangular recesses is lined on all sides, except towards the skin, by fasciæ, a view of which may be obtained by dissecting out of either all the contained adeps. There may then be observed near the apex, or the deepest part of the recess, a strong and tense aponeurotic line, which is the inferior folded surface of the pelvic fascia, which in this situation sends off its inferior or descending layer; this latter immediately divides into two laminæ, an internal and an external; the latter is called the obturator, the former the ischio-rectal fascia; the former is very strong and distinct, the latter very thin and cellular.

The *obturator* fascia descends a little obliquely outwards and is inserted into the falciform process of the great sacro-sciatic ligament, and into the tuberosity and ramus of the ischium. It is very dense, being composed of strong aponeurotic fibres, and it conceals and separates from the perinæum the obturator internus muscle, and the internal pudic nerves and vessels, the perinæal and hemorrhoidal branches of which pierce it as they proceed to their destination. The internal layer, or the *Ishio-rectal fascia*, is much weaker and more cellular than the last; from the before-mentioned aponeurotic line it descends obliquely inwards along the lower and outer surface of the levator ani as far as the sphincter, when it becomes thin and cellular, and is lost in the surrounding adipose tissue. Thus, by the unfolding or division of the inferior layer of the pelvic fascia into these two laminæ, the obturator and ischio-rectal fasciæ, these recesses are completely lined, and by the gradual degeneration of the last named aponeurosis into cellular and fibrous bands, which interlace in every direction, the large mass of adipose substance is enclosed and supported, whilst a general firmness and elasticity is imparted to the whole region. Towards the posterior part of each of these regions a cul de sac is enclosed between these fasciæ and overlapped by the glutæus maximus, on the surface of which the fasciæ become extended, and ultimately lost. A somewhat similar but smaller cul de sac exists anteriorly behind each transversus perinæi muscle. An inspection of the Ischio-rectal spaces will serve to explain not only the great size to which abscesses here attain, but also the difficulty in effecting a cure when they have been of long standing and of considerable magnitude; the constantly-varying form of the rectum on one side, the immoveable surface of the pelvis on the opposite, a muscle above, and the integuments below, all tend to prevent the possibility of effecting any permanent apposition between the sides of the cavity, while very generally the state of the constitution is equally unfavourable to any healthy action in the part. These several facts have impressed surgeons with the propriety of opening all such abscesses in a very early stage, otherwise a large cavity will be formed, the rectum denuded, and very frequently opened by ulceration.

Transversi perinæi muscles (*Ischio-peri-*

neal).—This pair of small muscles extends in a direction nearly parallel to the anterior border of the anal region; each *arises* from the inside of the tuber ischii, passes inwards, forwards, and downwards to join its fellow in the median line of the perinæum, where it is also partially attached to the cutaneous sphincter of the anus, and to the acceleratores urinæ muscles, or in the female to the constrictor vaginæ. These muscles are very unequal in appearance in different subjects; in some they are feeble and indistinct, in others very strong, and sometimes divided into two on one or both sides, the additional or minor muscle being superior and anterior. In the female these muscles are often found more distinct than in the male, but even here much variety exists; in many subjects they appear to be simply composed of some of the anterior and partially detached fibres of the middle portions of the levatores ani muscles. The transversi perinæi muscles form the bases of the two lateral triangular regions contained in the anterior or urethral perinæum, and one of them, the left, is necessarily divided in the lateral operation for lithotomy; they are surrounded by much adipose matter; two arteries, both branches of the internal pudic, take a course parallel to them, — viz., the superficial transverse perinæal, and the deep transverse, or the artery of the bulb. These muscles are enveloped between the layers of the perinæal fasciæ. The superficial layer, which is continuous with the Ischio-rectal, covers them in their course forwards to the urethral muscles, and the deep layer, or the triangular ligament of the urethra, which is continuous with the external or Ischiatic layer or obturator fascia, lies between them and the pelvis. These muscles, therefore, will have the effect of making tense the different perinæal aponeuroses, and thus they can support, strengthen, and compress generally the parts in the perinæum; they can also compress, and thus assist in clearing the orifice of the anus, at the same time that they draw back and raise this part, somewhat in the same manner as the levatores ani muscles. According to some anatomists these muscles are considered as dilators of the bulb of the urethra, as well as of the vagina; but it is more than doubtful whether they can exert any such action. When these muscles are divided, the base of the deep perinæal fascia, or triangular ligament of the urethra, is exposed. This will be observed to have some influence in maintaining the rectum and anus in their situation; its posterior border, being attached to the levatores ani muscles, and to the bulb of the urethra, serves to maintain a close connection between these parts, which is still further effected by the interlacement of the muscles of the anus with those which cover the bulb. (See Perinæum.)

Levatores ani (sous-pubio-coccygien).—This pair of broad, thin, flat, and nearly square muscles form a septum somewhat broader above than below, between the pelvis and perinæum, which, together with the aponeuroses covering its upper and lower surfaces, and with the coccygeal muscles and the triangular ligament of the urethra, completely intercepts all communication between these two regions except through the natural passages for the urethra, vagina, and rectum. Although these muscles are described as two, there appears no good reason for the division, for the fibres of opposite sides have a common insertion, partly into the circumference of the rectum and partly into a middle cellulo-tendinous raphé before and behind that intestine. It appears more correct to consider these muscles as one circular muscular septum extended across and within the lower opening of the pelvis, concave towards this cavity, and convex towards the perinæum. The fibres attached by their circumference to the interior of the pelvis, and converging thence towards the median line of the perinæum, are inserted into and around the rectum; in fact the muscle resembles the diaphragm in form, in the circumference being its origin or fixed attachment, and the central portion being its insertion, also in its being perforated for the transmission of certain parts; the analogy only fails in the absence of a central tendon, and in the fibres being principally inserted into the parts passing through it. The fact, however, of there being an interruption in the origin of this muscle in the middle line both before and behind, in which respect again there is a resemblance to the sternal and vertebral deficiences in the diaphragm, is the cause of its being described as consisting of a right and left muscle, which distinction, it should be observed, is only an artificial one, for during life the fibres of both sides act together, and in all respects constitute but a single muscle.

The origin of the levator ani muscle may be exposed by tearing the peritonæum from the parietes of the pelvis, together with a considerable quantity of loose cellulo-adipose membrane. The recto-vesical layer of the pelvic fascia should then be divided near to the neck and sides of the bladder, and carefully raised towards the wall of the pelvis. The muscle will then be seen to *arise* on each side by three attachments, which, however, form one continuous semicircular line extending from the pubis to the spine of the Ischium; its anterior portion is attached to the back part of the pubis, a little above its arch, and immediately below the anterior vesical ligaments by short aponeurotic fibres commencing a little distance from the symphysis, and extending outwards as far as the notch in the thyroid hole; its second or middle attachment is to a strong tendinous arch, which extends from the pubis to the spine of the Ischium, and which is formed at the separation or junction of the pelvic fascia into its superior or recto-vesical layer, and its inferior or perinæal layer; its third or posterior attachment is to the spinous process of the ischium. All the fibres pass downwards and towards the median line to their *insertion;* the inferior border of this muscle is shorter but thicker than the superior. The fibres of the first, or pubal portion, descend a little obliquely backwards on each side of the prostate gland and membranous portion of the urethra, and converging beneath the latter are inserted in common between the bulb and the fore-part of the rectum into the central point of the perinæum; these portions in their descent present a well-defined edge inwards or towards the median line. The middle, or aponeurotic portion, is broad and thin above, the vesical fascia adhering so closely to it as to render its separation difficult. As it descends it increases in thickness, expands close to the rectum, and is inserted into the coats of that intestine, intermingling with its longitudinal fibres, and with the sphincter ani; in the female it is intimately attached to the vagina also. The posterior or Ischiatic portion passes almost transversely inwards, and is inserted into the coccyx, and into the cellulo-tendinous line which extends from the latter to the rectum; some fleshy fibres are continuous from one muscle to the other. This portion of the levator ani is more aponeurotic than the preceding, and its posterior border is connected to the Ischio-coccygæus muscle. The external or inferior surface of this muscle is inclined downwards, and is more or less related to the obturator and ischio-rectal fasciæ, to the glutæus maximus and transverse perinæal muscles and vessels, and to the mass of anal fat. The internal or concave surface looks upwards, and is closely covered by the vesical fascia, below which it is in contact with the rectum, bladder, prostate gland, and urethra, or with the uterus and vagina. This muscle is disposed on the rectum in the same manner in the female as it is in the male; the fibres are also intimately connected to the vagina.

The *action* of the levator ani muscles is two-fold, and not confined to the mere elevation of the anus, as its name would imply. First, they act as a moveable floor to the abdomen and pelvis, which can antagonize the diaphragm; these two fleshy planes being opposed to each other, can, by a slight action of one or both, materially alter the perpendicular axis of the abdomen, which extends between them. This axis is at its greatest length during the state of expiration, and is most diminished when both these muscles are forcibly contracting. The levatores ani, however, have less influence in effecting this change than the diaphragm; they serve chiefly to support the lower region of the pelvis and the several viscera this cavity contains against the combined protruding forces of the diaphragm and abdominal muscles in violent exertions of the body, or in forcible efforts of respiration, or in the evacuation of the contents of the rectum and bladder; and, secondly, they not only raise, but dilate the anus, by drawing out its circumference so as to overcome the sphincters; at the same time they compress and assist in emptying the rectum, particularly the dilated pouch, which is a little above the anus; they also resist the prolapsus of the mucous coat of the intestine, and raise it after it has been to a certain extent protruded by the action of the abdominal muscles. They raise and draw forward the coccyx after it has been forced back by abdominal pressure in parturition, or in the ordinary evacuation of the bowels, and further, by raising and compressing the trigonè of the bladder, they assist in expelling its conteuts, and for the same reason they can also empty the vesiculæ seminales of their fluid. The anterior portions of these muscles are intimately connected to the membranous part of the urethra, and are variously modified in different individuals and in different animals; we consider those muscular fasciculi which have been described differently by anatomical writers under different names, compressores urethræ, &c., as parts of or appendages to these muscles: these urethral portions of the levatores ani can certainly compress the membranous part of the urethra and empty its canal; they can even interrupt or suddenly stop the stream of urine, and thus they may occasionally aid the neck of the bladder in retaining the contents of that organ.

The *Ischio-coccygæi* muscles are situated at the posterior inferior part of the pelvis; they are thin, flat, and triangular, composed of a mixture of fleshy and tendinous fibres. The apex or origin of each is attached to the spine of the Ischium, and its base is inserted into all the side of the coccyx, and a small portion of the sacrum; they are partly covered by the great sciatic ligaments. The superior and posterior border is connected to the lesser sciatic ligament, and the anterior border is in part continuous with the levator ani muscle; the anterior or pelvic surface is connected to the rectum and the surrounding adipose substance. This pair of muscles appear as a prolongation of the levatores ani, and are of use in completing the inferior boundary of the pelvis; they thus support the rectum and the pelvic viscera, and they also serve to retain the coccyx and restore it to its situation when protruded by the diaphragm and abdominal muscles in the process of parturition, and in the act of defæcation, or when drawn too much forward by the levatores ani muscles. If the several muscles in this region be now partially removed on one side, the lower extremity of the rectum will become more distinct, and will be found surrounded by a quantity of loose, fatty, cellular tissue, separating it from the surrounding muscles and bones; this contains many nervous filaments and numerous bloodvessels, particularly veins. (See Intestinal Canal.) Anteriorly in the male subject a small triangular space, the *bulbo-rectal* hollow, will now become distinct; this is situated between the anus and membranous portion of the urethra; the base of it is at the skin of the perinæum; the apex at the prostate: to the last the rectum will be seen rather intimately connected. The bulb and the membranous portion of the urethra bound this space in front, and the rectum behind. (See Perinæum and Urethra.)

Rectum.—In addition to the several muscles which have now been severally noticed, and which thus serve not only to retain and support the rectum and anus, but which even enter into the structure of the former, we have further to consider the parts more immediately composing the parietes of the lower extremity of the intestine; these are the longitudinal muscular fibres,—the mucous membrane, and the submucous cellular tissue. The longitudinal fibres of the alimentary tube exist through its whole extent, but like the circular are differently modified in different situations; thus along the œsophagus they are very fully developed, also along the arches of the stomach; in both these situations the fibres are strong and somewhat red; whereas on the parietes of the small intestines they are very indistinct and pale; on the cœcum and colon they are still pale, but very distinct, being collected into three flat fasciculi or bands. On the rectum, as on the œsophagus, they are again fully developed as to thickness and number; their colour is still rather pale. In the two superior thirds of this intestine, or as low down as the prostate gland, they predominate over the circular fibres, which are internal, whereas in the lower third the latter prevail; the former terminate, some by becoming continuous or intermingled with the fibres of the levatores ani, others with the cutaneous sphincter so low as the border of the anus, and some are inserted into the submucous tissue of the intestine; these fibres are continuous superiorly with those of the colon; they serve to continue that successive series of contractions or shortenings of the intestine, which essentially assist in the process of defæcation. As the longitudinal fibres of the rectum resemble those of the œsophagus, so the inferior circular fasciculi or the sphincters are like the muscles of the pharynx, not merely in their increased strength and colour, but also in their vital power. Over the longitudinal fibres the will has no control, whereas the inferior circular are to a certain extent under its influence. Here, then, as in the organs of deglutition, we perceive the animal and organic powers still distinct as to their elementary nature, but becoming intimately, nay inseparably associated for wise and obvious purposes.

In the act of defæcation the offices of the several muscles connected with the anus may be summed up as follows:—When the contents of the rectum, particularly if of a solid consistence, are being expelled, the whole rectum descends, and the perinæum becomes prominent in consequence of the viscera being forced against it by the contraction of the diaphragm and abdominal muscles. The presence of the fæces irritates the muscular fibres of the rectum; the longitudinal fibres shorten the intestine, while the successive actions of the circular urge down the fæcal mass; these two orders of muscular fibres are the true antagonists to the sphincters. During this stage, however, the sphincters are relaxed, and the anus becomes dilated, partly by the contents of the rectum distending it, and partly by the levatores ani muscles, which are nevertheless in a sufficiently relaxed condition to allow the protrusion of the rectum and anus, while they still support the latter to a certain extent, and thus exert a sort of check against its forcible descent; they also tend to open the orifice of the anus. During this forcible expulsion, a small portion of the mucous lining is frequently protruded. The expulsion of the last portion of fæculent matter is then effected by the subsequent strong and gradual contraction of the levatores ani compressing the rectal pouch, and raising the rectum and anus to their former position, and lastly, the sudden action of the sphincters clears and closes the orifice.

The mucous membrane lining the rectum is in every respect highly organized, it is thrown into several folds, and is larger and looser than the other coats, hence portions can be easily removed by operation, and are not unfrequently detached by gangrene. As it approaches the anus, it is very red, soft, and fungous, being highly vascular, presenting the orifices of several glands, follicles, or lacunæ. It is here very loosely connected to the muscular fibres, and is frequently found thrown into irregular folds; these are protruded somewhat during defæcation, and when morbidly enlarged or thickened, are not unfrequently the source of considerable pain and inconvenience. As the mucous membrane is not contractile, these folds are necessarily increased when the longitudinal fibres of the rectum contract and shorten the intestine; they are then protruded together with the fæcal matter. Immediately above the plaited margin of the anus the skin and mucous membrane become continuous; the termination of the cuticle appears rather abrupt, just within the internal sphincter. Some describe it as continued higher up, and gradually lost on the surface. I have not been able to exhibit it satisfactorily higher than the point indicated, nor does it appear to me that it extends through this orifice by any means to the same extent as through the other outlets of the body, the mouth, nose, urethra, or vagina. In the latter passage in particular it is very distinct, even in health; and in disease, as in cases of prolapsus uteri, its development becomes considerable; whereas in prolapsus ani, that is, a protrusion of the mucous lining of the rectum, at a little distance above the anus, I have not found the protruded mass to become covered with cuticle: I have seen cases of long standing in which the surface presented the same soft, vascular tissue as it does at first. It does not controvert this statement to find tumours about the margin of the anus (hemorrhoids or polypi) covered with a thickened or developed cuticle; for in such cases the cutaneous covering is derived from the elongation of the surrounding skin, which has increased in density from exposure to the air, and from continued irritation. The same remark will apply to cases of artificial anus, no matter in what situation: in all these the villous surface, which protrudes during the peristaltic action, retains its mucous characters, and does not become covered with cuticle. From these facts it may be inferred that cuticle is never developed in any situation in which it did not originally exist, but that circumstances favour the increase or more full development of it in those situations where it naturally occurs, even though its normal condition be extremely delicate and fine.

Nerves and vessels.—The submucous tissue in the vicinity of the anus is very loose, and the seat of nervous and vascular plexuses; in the latter the venous system predominates.

A consideration of the functions of the rectum and of its surrounding muscles, its remarkable irritability and sensibility in health, as well as its sympathies in disease, would lead us to infer what dissection proves to exist, namely, that this organ is largely supplied with nerves; numerous branches are furnished to it from the sacral plexus, which is formed by the union of the inferior spinal nerves, also from the hypogastric plexus, which is chiefly composed of filaments of the sympathetic. The *sacral plexus* of spinal nerves furnishes, in addition to many others, the hemorrhoidal, vesical, and pudic branches; the hemorrhoidal nerves are directed principally towards the inferior part of the rectum, some ascend to the colon, others descend even to the sphincter ani: they divide into numerous filaments, which are chiefly distributed to the muscular fibres of the rectum and the adjacent muscles; the vesical nerves in their course to the bladder give some filaments to the rectum, and the inferior or perinæal division of the pudic nerves also send several branches to the levator and sphincter ani muscles. The *hypogastric* plexus of nerves is composed of filaments from the sacral plexus, which interlace with some from the inferior mesenteric plexus, and with numerous branches from the sacral ganglions of the sympathetic nerves. This plexus supplies the rectum, as also the other pelvic viscera; the branches accompany the bloodvessels, and are distributed principally to the mucous and submucous tissue. The cellular tissue, also, about the coccyx, and the adjacent muscular fibres receive some filaments from the coccygeal plexus of the sympathetic. This supply of nerves from these two very different sources, the one presiding over voluntary, the other over involuntary motion, corresponds with the well-known functions of this organ, and causes its muscles to be classed by the physiologist under the head of mixed muscles, that is, partaking of the common characters of the animal or voluntary, and the organic or involuntary systems. Its supply of spinal nerves serves to explain not only the influence which the will can exert over its functions, but also the impaired or altered state of its powers in case of disease or injury of the brain or spinal cord; thus irritation of the latter may cause morbid irritability and contraction of the rectum, and, necessarily, constipation of the bowels; or, again, paralysis of the spinal cord from injury or compression may lead to perfect atony of the sphincters, and to the involuntary discharge of the contents of the rectum. The general distribution of the branches of the sacral and hypogastric plexuses to the several pelvic viscera, and to the muscles, &c. in the perinæum, associates these different organs with each other, which is so necessary to their functions, and with the urinary and generative organs, connecting more particularly the muscles of the anus with the muscular coat of the urinary bladder and with the parts about its cervix. This interlacement and subsequent general distribution of these nerves serve also to establish those several sympathies which are found to exist in acute and chronic diseases of the rectum and anus, between this intestine and the other pelvic viscera. In some the uterus and vagina partake of the irritation, in others the urinary bladder is almost incessantly irritated to expel its contents; or, on the other hand, when the sympathetic irritation engages its cervix and the parts in its vicinity, the most painful retention of urine is endured. Chronic disease of this intestine is also very generally attended with occasional attacks of pain and irritation in different portions of the alimentary canal, as also with pain in the sacrum and loins, and in various other directions, which may in most cases be explained by referring them to nervous irritation extending in the course of some of the nervous communications which are found to exist in such numbers in the pelvis.

The rectum, like the rest of the alimentary canal, is freely supplied with blood. Its arteries are named *hæmorrhoidal*, and are derived from three sources, viz., the abdominal aorta, the internal iliac, and the internal pudic arteries. The superior hæmorrhoidal is the continuation of the inferior mesenteric, a branch of the aorta; the middle hemorrhoidal is derived either from the internal iliac or from some of its branches; and the inferior or external hemorrhoidal branches from the perinæal division of the pudic. The latter are destined directly to the confines of the anus, and are lodged in the subcutaneous adeps. The two former belong properly to the rectum, and are above the levatores ani muscles. These arteries divide into several small branches, which anastomose together, and form a continued chain of inosculations along this intestine, somewhat similar to that which is continued along the whole of the alimentary tube. They form a complicated vascular net-work between and within the muscular fibres, and are largely distributed to the mucous and submucous tissues. Some branches of considerable size not unfrequently descend so low even as the sphincter, particularly at its posterior parts. These are liable to be divided in operations for the cure of fistulæ, and sometimes give rise to a hæmorrhage, troublesome and difficult to restrain. In such operations the external hæmorrhoidal arteries also are very commonly opened, and bleed smartly; they can be secured, however, with much less difficulty than the divided extremities of the superior or middle hæmorrhoidal vessels.

The whole of the rectum, particularly its lower portion, is encompassed by numerous veins, which in some persons are very large and plexiform. In the perinæum, also, many venous plexuses are found in the subcutaneous adeps. The external hæmorrhoidal arteries have their external venæ comites, which run outwardly to end in the internal pudic veins (branches of the internal iliac). Some of their branches ramify around the anus, and in some cases form a plexus, in which hæmorrhoidal tumours are frequently developed; the middle hæmorrhoidal veins are uncertain as to number, size, and situation, but the superior are very large and numerous; their branches form repeated anastomoses in the submucous tissue around the intestine, and frequently present all the appearance of erectile tissue, particularly in front, communicating below with the perinæal veins, before with a plexus of vaginal or prostatic veins, and above with the trunk of the inferior mesenteric which leads to the vena portæ. This latter communication, as also the absence of valves in the portal system, has laid the foundation of the practice of applying leeches to the anal region in chronic inflammatory affections of the liver and bowels. The same facts also have been adduced to explain the frequency of hæmorrhoids, varices, and vascular congestion about the anus and rectum in cases of diseased and hardened liver, which, under such circumstances, is supposed to obstruct the circulation by impeding the returning blood through the venæ portæ.

ABNORMAL CONDITION OF THE ANUS AND NEIGHBOURING PARTS.

Congenital malformations.—The lower extremity of the rectum and anus not unfrequently present in the new-born fœtus congenital malformations, some of which are incompatible with continued existence, while others admit of protracted suffering, with great inconvenience and imminent danger to life; while, again, some may be relieved by the interference of art. Hence it is necessary to consider these anomalous appearances with a view to discriminate those which are curable from those in which all remedial attempts are totally useless. The following congenital malformations have been noticed by surgical writers, some of which have come under our own observation.

1. The anus has appeared at first view to be natural, but on a more accurate examination no canal has been found above it; and after death it was discovered that the rectum was absent, that the left colon ended in a cul de sac, and that a dense fatty substance occupied the situation of the rest of the canal. It is plain that no operative interference could avail in such a case. In some cases of this want of rectum the anus has been absent also.*

2. The anus and rectum have appeared natural, but after death it has been found that the latter was interrupted in one part of its course, and that the intestine had ended above that in a cul de sac. This state of parts must lead to the same practical conclusion as that last mentioned. In these and in such like cases of unhappy malformation, some have suggested, as a "dernier resort," the propriety of opening the intestinal canal at some point in the abdomen, so as to evacuate its contents and establish permanently an artificial anus. The proposal was first made by Littre,† of opening the sigmoid flexure of the colon in the left iliac region. A successful case of this operation is recorded as having been performed by Duset* on a boy twenty-four hours after birth: the child was reported, at twelve years of age, to be in good health, with an artificial anus established in the left iliac fossa.†

3. No anus, but the rectum has opened into, and its contents escaped either by the urethra in the male, or by the vagina in the female. This condition is an approximation to the cloaca of birds, and of some fishes. Life may continue under such an arrangement, particularly in the female, when the intestine opens into the vagina, with great inconvenience no doubt; but in the male the prognosis cannot even be so favourable, as the urethra can scarcely suffice to give exit to the fæces after some time; and as the bladder and organs in its vicinity will be subject to constant irritation. Cases are, however, recorded of life being protracted for several months; and in one case, a boy, who lived for eight months, on examination after death it was found that a cherry-stone had blocked up the passage of communication between the rectum and urethra. In such a state of parts it has been advised to cut through the perinæum in the situation of the anus, and endeavour to open the extremity of the rectum. The bladder should be previously emptied of urine, and a sound or staff be retained in it, as a guide to the operator to protect it from injury. In the other somewhat parallel condition of these parts in the female, the exit for the alvine matters is usually more free; and several cases are on record of life being continued for several years. These cases offer more encouragement for operative interference than the former. A curved probe may be passed from the orifice in the vagina into the rectum, and then directed towards the perinæum to the situation of the anus. An incision is to be then made upon it; and when the canal of the rectum is thus opened to the surface, the channel is to be kept carefully dilated, in order to oppose the natural tendency in the parts to close.

4. The anus may be open, but the contents of the intestine retained, in consequence of a congenital contraction of the rectum at some distance above, owing either to a membranous septum extending across it, or to a circular thickening and contraction. Such cases may be overlooked, and their cause remain unknown until after death: in cases, therefore, of obstinate constipation at this early age, this part should be particularly examined. Petit ‡ describes this condition, and mentions a case in which he detected such an obstruction in the rectum, about an inch above the anus. This he divided by a pharyngotome, with success. The division may be effected by a bistoury, if situated low down; or by a trochar, if at a considerable distance from the anus.

5. No anus, but the rectum is continued pervious as far as the integuments, which in some cases are then prominent, and of a violet colour, from the meconium appearing through in the situation which the anal opening should occupy. In other cases the skin is thick and hard, and gives no indication of the situation of the rectum. In such circumstances the surgeon must divide the integuments, either by a crucial or by a transverse and longitudinal incision, and then proceed cautiously until he exposes the distended rectum. When the skin only intervenes, the prognosis as to the result of this operation may be favourable, as the sphincters are probably perfect; but when the cul-de-sac of the rectum is deep-seated, then experience affords but little encouragement to hope for success. Death is inevitable in such cases, unless relief can be afforded, and but very few cases of successful operations are on record.*

6. The anus and the continuous portion of the rectum are so contracted as scarcely to admit of any fluid discharge: we have even seen it scarcely pervious to air, so that on forcing in a grooved director, a considerable burst of flatus has escaped. This contraction may exist below, and yet the rectum be perfectly natural above. This contraction is sometimes not sufficiently noticed for several days or perhaps weeks after birth, because occasionally there is a small discharge of fæcal matter; it ultimately, however, excites attention from the great difficulty, straining, pain, and crying manifested at each evacuation. This condition of the parts sometimes admits of relief, by simple dilatation, by introducing a soft bougie, or some prepared sponge, which should be replaced after each evacuation, and secured, if possible, by adhesive plaster and a bandage. Should these means fail, an effectual cure may be obtained, as we have seen, by a division of the circumference. This may be done by introducing into the rectum a button-pointed bistoury for about an inch on a director, and dividing the wall of the intestine transversely, towards the ischium, first on one side, and then on the other, to the depth of about one quarter of an inch. The part must be carefully dressed, and the edges of each wound kept separate by lint. The success of the operation greatly depends on the care in the after treatment, particularly in renewing the dressing whenever it has been displaced.

The anus is occasionally found much contracted in new-born children who are contaminated by syphilis, and may be mistaken for a congenital malformation, especially of the kind last noticed, though not one in the strict sense of the expression; yet as it generally occurs at birth, it deserves the consideration of the practitioner in midwifery, whose attention is often first called to it by the same symptoms that attend the congenital malformation of this opening, namely, pain, difficulty, and straining at each evacuation, and a peculiarly small aperture. On examination, however, there are other appearances which will assist in explaining the real nature of the case, such as brown or dark discolouration of the surrounding parts, also considerable moisture, frequently excoriation, and even superficial ulceration in the adjacent structures. Small fissures in the anus, also, are observable, discharging tenacious matter. Similar appearances may exist about the commissures of the lips; some soft granulations or condylomata are also often present in the immediate vicinity of the anus; these frequently extend into the canal for a very little way. Other constitutional symptoms also are usually present, such as copper-coloured blotches on the skin, a tendency to cracking and excoriation of the skin about the hands and feet, and buttocks, an imperfect development of, or a tendency to a separation of the nails, general emaciation, suspicious appearances about the mouth and tongue, and a remarkable and peculiar hoarseness in crying. Many, if not most of these symptoms, aided sometimes by the history of the parents, will lead the practitioner to distinguish this contraction of the anus from the congenital malformation before described. The distinction is important, as the treatment in both is totally different; the syphilitic contraction invariably yields to gentle courses of mercury, administered in such form and dose as the circumstance of the case shall denote to be necessary. The local complaint disappears as the constitution is restored to health. Soothing, emollient applications are the best topical remedies; should there be any ulceration or excoriation about the part, the surface should be slightly stimulated daily, either by caustic or by the ordinary mercurial lotions.

Morbid conditions.—The anus is the seat of several morbid affections, some of which proceed from a specific cause; others are merely local. The *specific* diseases are syphilis and cancer; and the most common *local* derangements to which the anus is subject are, superficial ulcerations, excoriations, fissures, with or without contraction of the orifice from excessive irritability of the sphincter muscle, prolapsus ani, hæmorrhoids, fistula in ano, polypi, &c. Some of these last mentioned affections must, strictly speaking, be considered as appertaining to the rectum, under which head the reader will find them noticed. As, however, the anus is more or less engaged in these diseases, we shall make some observations on each. The anus is also subject to laceration in parturition, and from other causes.

Syphilis affects the anus at all ages; its appearances in the infant have been already noticed. In the adult it may present the primary venereal ulcer, which will have the same character here as elsewhere, only somewhat modified by the position and function of the part. The primary ulcer may be produced either by the direct application of the virus, or by extension of ulceration from the neighbouring organs, as not unfrequently occurs in the female. When the chancre is confined to the anus, which is very seldom the case, it may be difficult to discriminate between it and ulcera-

* See some observations by Petit, Mem. de l'Acad. de Chirurg. t. i. p. 378.

tions from other causes. Ulcers in this region are very generally difficult and slow to heal, owing to the irritation to which they are exposed from the passage of the fæces, and from the motion, pressure, and changes of form to which the parts are necessarily subject. Syphilis frequently appears here in the form of fissures, clefts, rhagades: these are very distinct, and different from the fissures attending the irritable anus. The syphilitic fissure is chiefly in the integuments; it seldom extends to any distance within the anus: the edges are somewhat elevated and thickened, and the surface secretes an adhesive pus, which forms crusts or scabs. Although in some instances these fissures or rhagades are attended with pain in defæcation, yet we have met many cases in which they caused very little uneasiness, and thus contrasted remarkably with the simple or the irritable fissure. Warts, condylomata, or excrescences about the anus are also frequent effects of syphilis in this region. These are generally on the cutaneous side of the anus, and very rarely, I believe, extend within it: they are not, therefore, difficult to distinguish from those vascular excrescences which are of mucous origin, and which so commonly protrude at the anus. Syphilitic warts and condylomata have generally a broad base; their surface is flattened by pressure against the opposite nates, soft and moistened with an offensive sero-purulent fluid. In these cases the surrounding skin is often excoriated, and clefts and superficial ulcers frequently exist in the vicinity of the anus.

Cancer is a disease to which the rectum is very liable, and may attack any part of the intestine, but usually exists at some inches above the anus. This opening, however, may become implicated by the extension of the disease. We occasionally see that form of cutaneous cancer called "*cancer scroti*" extend along the perinæum and involve the circumference of the anus. Its parietes may, however, be primarily affected by cancer, in which case the disease will commence by a chap or fissure, or more frequently by a tubercle, which, gradually increasing in size and in breadth, at length ulcerates and shoots out a cauliflower mass of granulations which protrude through the opening, causing great uneasiness, pain, and difficulty in defæcation: the surrounding parts in time become involved, ulceration extends, and a bleeding surface, very unhealthy, sloughy in some parts, and fungoid in others, discharging sanious and unhealthy matter, is an almost incessant source of pain and irritation, which in time wastes the health and strength of the patient. As no local application or constitutional treatment has yet been able to arrest this disease, it has been proposed to extirpate the anus and the lower end of the rectum when in this condition. Unfavourable as this operation may appear, and rarely as it has been undertaken in this country, it has been frequently performed in France, and with some success.*

* See Velpeau, Med. Oper. t. iii. p. 1033.

The anus is often affected with *warty excrescences*, which by a superficial observer might be condemned as cancerous, yet these are not of a malignant character, and may be cured by local remedies and due attention to the general health. I have seen a warty tubercular appearance about the anus, extending through it, and even involving the mucous surface for some height, and contracting the orifice so much as to cause great pain and difficulty in defæcation, and also materially impairing the general health by continual irritation; yet this state of parts is not malignant, nor is it prone to ulceration. Attention to the constitution, to the functions of the bowels, with local applications, will effect a cure. The anus is also frequently affected, and even inconvenienced by the growth of common warts; these, however, can be speedily removed either by the scissors or by caustic.

Excrescences frequently protrude through the anal opening, which are not warty or cutaneous growths, but elongations of the mucous membrane from a little distance above the anus. The anatomical disposition of these parts, before alluded to, together with a very relaxed state of the mucous membrane, accounts for the frequency of this occurrence. In some these protrusions only appear during defæcation, in others they are permanent, but much increased in volume during that act; and, indeed, in some they are so large and fill up so much of the canal, that they must be extruded before the fæces can escape. These excrescences are soft, and very vascular; they often appear without any assignable cause, though frequently they are attributed to hæmorrhoids, to constipation of the bowels, to violent straining efforts in defæcation, to fistula, or to long-continued irritation from any cause.

Prolapsus ani, or procidentia ani, although a term in somewhat common use, is rather an incorrect one, as the anus itself is too well maintained in its situation to descend, at least to any appreciable distance; the term rather implies a protrusion of a considerable portion of the relaxed mucous membrane of the rectum, or a portion of the large intestine itself, which must have become "invaginated or introsuscepted," and then protruded through the anus; in these conditions the anus is rather dilated, the mucous membrane sometimes remains protruded after defæcation, but in others it returns after this process, or it can be returned by the gentle pressure of the hand: this is not uncommon in children and in elderly persons. This disease has been ascribed to a relaxation of the sphincter; a circumstance which, however, does not seem to be proved, for in paraplegia and in paralysis of the sphincter, we do not find that the membrane protrudes, although the anus is often in these cases very dilatable; the condition referred to ought perhaps rather to be considered as one of the effects, than as the cause of the disease; moreover in some other instances the sphincter appears rather irritable, and painfully and dangerously constricts the protruded mass, which must then, in order to save the intestine from gangrene, be reduced by pressure properly applied, and by attention to posture. In the procidentia of old persons, Mr. Hey conceives that the relaxed state of the lower part of the intestine and of its surrounding cellular tissue, are in fault, and that hence the folds or excrescences about the anus remain, even when the parts have been returned; he therefore suggests the removal of these flaps from the circumference of the opening, and relates some well-marked cases in support of this practice, in which the operation had been successfully performed.

The *margin* of the anus, like that of the mouth, is subject to *fissures*, chaps, and superficial excoriations, sometimes caused by laceration induced by the passage of large and hardened fæces, but sometimes arising spontaneously, and sometimes connected with a peculiarly irritable and contractile condition of the sphincter ani. This disease must not be confounded with hæmorrhoids; on examination it is not easily seen, but little is apparent, the anus is much contracted, the orifice somewhat redder than natural, slightly tender on pressure, but exquisitely so on dilating it by introducing the finger; this must be done cautiously and slowly, a cleft will then be observed just where the skin and mucous membrane join, generally on one side extending a little way, from half an inch to an inch and a half, longitudinally up the intestine; on dilating the part still more, the surface of the fissure will be seen slightly ulcerated, and when touched it is exquisitely painful; the surrounding muscle is in a state of rigid contraction. It is doubtful whether the contraction is the cause of the fissure, or whether the latter is the cause of the irritable and contracted condition of the muscle. Both explanations may be occasionally correct; but it is most probable that the irritable state of the muscle induces the ulcerated fissure, inasmuch as this muscular contraction occasionally exists without any fissure, and is then equally painful; and fissures frequently exist, as in syphilis, without inducing any spasmodic constriction of the muscle, and accordingly are attended with little or no pain.

Contraction of the anus also frequently exists without any fissure; sometimes it is congenital, sometimes it appears in the adult; the pain and other symptoms are nearly analogous, and as severe as in the case of fissure; the examination by the finger however does not detect one part to be more painful than another, as is the case in that disease; and this is almost the only symptom distinguishing these two affections.

The term *hæmorrhoid* has been applied by writers, practitioners, and invalids to any condition of the rectum and anus in which a discharge of blood takes place. It is, however, more correctly applied to the small tumours which are frequently seen at and very close to the inner border of the anus or even occupying the very aperture, also to somewhat similar productions situated within the rectum, at the distance of one, two, or even three inches above the anus. From such tumours occupying these different positions, they have been arranged by all writers into *external* and *internal* hæmorrhoids; the latter are very important and demand the close attention of the surgeon, both as to their pathology and symptoms, as being frequently obscure and liable to be mistaken not merely for the ordinary diseases of the anus, such as fissure, blind internal fistula, &c., but also to be confounded with a varicose condition of the veins of the rectum, which is by no means an uncommon condition, or with those vascular tumours which are productions of the mucous membrane occasionally protruding at the anus, that have been already noticed, and are of a wholly different character from true hæmorrhoidal tumours, or with the protrusions of the mucous membrane itself, the effect of the relaxation of its cellular connections. As the full consideration of this important branch of pathology belongs to the article on the morbid anatomy of the rectum, we shall here confine ourselves to a few observations on external hæmorrhoids and analogous tumours.

External hæmorrhoids appear at the border of the anus as small bluish tumours, the colour however varying according to the condition of the tumours, being sometimes of a dark and deep red or black, at others pale and almost white; in size they vary from a grain of small shot to a large cherry; they are sometimes full and almost bursting, at others they are soft like a flaccid nipple, empty or withered; they are covered on the anal side by the delicate cuticle which is smooth and glossy, and on the outer side by the common integument; when small, they are moveable and can be distinctly felt to be in the subcutaneous cellular tissue; when large and tense, they appear more connected with the skin itself; an attentive examination can always distinguish between these and the several excrescences, vegetations, or condylomata, which have been already mentioned as the effects of syphilis, as also the folds or crests of integument and mucous membrane which are found so frequently prolonged from the border of the anus. These tumours remain in many persons for years free from pain, and productive of little, if of any, inconvenience; occasionally, however, and periodically in some, they enlarge, inflame, and interfere with the functions of the anus, and by sympathy engage the adjacent organs, and are relieved either by a copious discharge of blood, or by suppuration, or by the interference of art.

The liability of the veins immediately about the anus to varicose enlargement appears in some measure founded in anatomical structure. If we inject the intestinal veins in the adult with wax injection, we shall often find a little above the anus, just where the skin and mucous membrane unite, a sort of constriction on the vessels; the veins appear larger immediately above it, and again below it, and many of the branches in the venous plexus around the anus appear to be enlarged, while in the very spot or circular line alluded to, the vessels appear to be compressed. It may occur, then, that hardened fæces impacted in the rectal pouch, which is above this point, may assist in obstructing the more free flow of blood, and thus encourage the enlargement of these anal veins, and the same effect may be still further induced by the muscular pressure employed in defæcation; in support of this view we find that children are almost free from this varicose condition of these veins, unless under peculiar circumstances; and in the adult it usually occurs in those of constipated habit of bowels; it is also relieved or removed by attention to their functions. The true hæmorrhoidal tumours, external as well as internal, must be regarded as essentially different from a varicose condition of the anal veins, although they are often connected with the latter, and it must be admitted that in some cases they may owe their origin in a great measure to venous dilatation. Varices of the anal veins are simple dilatations either of a trunk or of some of the branches of these vessels; their cavity is continuous with that of the vein, and freely communicates with it, and pressure on the varix empties it of its contents; its tunics are the venous coats and the membrane of the intestine; whereas hæmorrhoidal tumours are wholly distinct from the veins, and are either simple cysts, lined by a smooth membrane, or they are composed of a spongy cellular texture, not unlike the erectile tissue. This latter is usually the condition of recently formed hæmorrhoids, whereas in those of long standing the single or divided cyst is the ordinary structure; this cyst will be found to contain a little blood, partly fluid and partly coagulated; and when the internal surface is minutely examined, one or more fine pores will be visible, the orifices of capillary vessels, through which warm water, if steadily injected by the inferior mesenteric artery, will exude on the surface. In the cellular or more recent hæmorrhoids the texture appears very vascular, soft, and spongy, as also the surface of the tumour, from which blood or serum will sometimes exude during life. These cellular hæmorrhoids in time become circumscribed, the cellular texture becomes more or less perfectly absorbed, and the cyst-like structure becomes more developed; however a very recently formed hæmorrhoid may, and sometimes does, present a distinct cyst or cavity, as may be readily conceived when we consider the process whereby these tumours come to be developed, which, as far as our observation extends, is as follows: from continued irritation from any exciting cause, such as disease of the intestine or anus, worms, or from a local plethoric condition, spontaneous, as far as we can know, the capillary circulation is increased in the loose submucous tissue in this region, a small quantity of blood, or lymph, or serum, is effused into it, perhaps from the rupture of some small vessels, or exhaled from their dilated extremities. A slight degree of inflammation attends this condition: the part affected, that is, the cellular tissue, becomes more highly organized, thickened, vascular, and spongy. After some time, this increased vascular action subsides, and in process of time the whole may nearly disappear, but in general a part of this more highly organized spongy tissue remains, it being fully supplied with nourishment; the absorbents in due course modify its appearance; the surrounding thickening is removed, as also some portion of the cellular mass, and thus the formation of the hæmorrhoidal cyst is completed. A structure like this, connected with the capillary system, must be influenced by the same causes as can affect the latter; thus irritation local or general, mechanical injury, or general or local plethora are all capable of exciting increased action in it, and of inducing all those symptoms and changes which are so well known to attend during hæmorrhoidal inflammation.

Fistula in ano is a disease of such very frequent occurrence, and so well understood and described by every surgical writer, that it is scarcely necessary to do more than allude to it in this place: strictly speaking it is not a disease of the anus, as that opening is in general totally unaffected, except as regards its functions: it should rather be regarded as a disease of the anal region. There is one form of fistula in ano, however, which is seated on the very confines of this opening; it is troublesome and distressing, attended with heat, itching, and excoriation, pain during defæcation, and constant purulent or sero-purulent discharge: without due attention it may be overlooked by the surgeon, as the orifice is so close to the anus as to be concealed by the natural rugæ, and so small as only to admit a lachrymal probe; the sinus is not more than an inch or half an inch long; its internal opening is on the very edge of the anus, the whole is immediately under the skin, and does not involve any other structure; it is not preceded by regular abscess, neither does it or the treatment necessary for its cure involve the sphincter or any other structure, except the fine integuments; it most probably originates in irritation of some of the anal sebaceous follicles, and sometimes two or three of such fistulæ may exist at the same time.

The true or deep fistula in ano has its origin in deep-seated abscess commencing close to the rectum, or in the centre of the ischio-rectal space of either side: when in the former, some mechanical irritant or some disease of the intestine may have been the cause or origin of the abscess; when in the latter, it often arises without any obvious reason, but frequently appears to have been connected with some peculiar delicate or morbid condition of the constitution. All abscesses in this situation do not necessarily end in fistula; if they have been small, superficial, opened early, and treated judiciously, they may be healed as perfectly as abscesses in any other situation; but when deap-seated, of slow growth, and long continuance, and when depending on some deep-seated mechanical irritant or on constitutional causes, then the abscess usually attains considerable size, and having opened either into the rectum or through the integuments, or in both these directions, it continues to secrete and to discharge a considerable quantity, and shews no disposition to alter its action or to heal. We have already detailed all the local peculiarities of the ischio-rectal region (the seat of this abscess) which can satisfactorily explain the difficulty or the impossibility of keeping at rest or retaining in apposition the sides of the cavity, a condition almost essential to the healing of an abscess in any situation, and hence the necessity of surgical interference. Abscess in this region frequently originates close to the rectum in consequence of irritation and ulceration in this intestine; this irritation may be caused by disease, such as cancer or stricture of the rectum, or by some foreign body becoming impacted in one of the lacunæ. Above the sphincter is the rectal pouch, and an irregularly shaped or sharp substance, such as a pin, a fish-bone, or one of the small bones of a fowl, &c. brought into this in the fœcal mass, may catch in its villous or rugous surface, the muscular powers of the intestine are excited by this irritation to increased and repeated efforts of expulsion; these only serve to impact more closely the foreign body in the parietes of the intestine; the submucous tissue, which may now contain the whole or part of this substance, becomes inflamed, suppuration follows, an abscess is formed close to the intestine; in some time the matter is discharged either through the rectum and anus, or coming to the surface of the nates it receives exit by puncture. In this case of abscess, which we suppose to have been caused by a foreign body impacted in the intestine, the matter is usually discharged by the rectum, at least at first, although this exit will not always prevent it still tending towards the cutaneous surface: in cases of fistula, however, arising from such a cause, we are most likely to meet with the *blind internal fistula*, at least in the early period; whereas, when abscess forms spontaneously in this region, and opens on the surface, the intestine is often at first and for some time wholly disengaged from the disease, even after the abscess has opened, notwithstanding which it is productive of great inconvenience and more or less of pain during defæcation; in this state, when the fistula or abscess remains discharging through the skin only, it constitutes what is termed a *blind external fistula;* by degrees the rectum becomes denuded, and ultimately ulceration opens it by one, and sometimes, but rarely, by more orifices; this opening is usually about half an inch above the edge of the anus, and between the two sphincters. I have observed it to hold this situation in a great number of cases, which I have examined both in the living and the dead; in a few instances, however, I have found it opening at a higher point. When the abscess arises from irritation in the rectum, then I have observed the internal opening to be higher, that is, in the dilated pouch of the rectum, which during life will appear to be from an inch and a half to two inches from the anus; but when the abscess has commenced spontaneously in the anal adeps, and opened on the surface first, I have then in general found the rectal opening less than an inch distant from the anal orifice, and in a groove or recess between the two sphincters. When the abscess discharges by two openings, that is, through the skin and through the rectum, a *perfect* or *complete fistula* is then said to exist.

Fistulæ occasionally appear in the anal region which have their source at a much greater distance; thus, any diseases of the uterus or vagina in the female, of the prostate or urethra in the male, which end in suppuration, may cause collections of pus which will burrow under the fasciæ and skin to the vicinity of the anus, and open near it or even into the rectum. Psoas and lumbar abscesses also may descend into the pelvis and approach the surface, either in front or at one side of the anus. In morbus coxæ also chronic abscesses which form about the nates not unfrequently open in the same situation.

Polypus is seldom a disease of the anus; it most usually grows from the rectum, and protrudes occasionally only at the anus.

(Robert Harrison.)

For the Bibliography of this article see that of Intestinal Canal.

AORTA* (human anatomy). —(*Arteria magna.* Fr. *aorte.* Germ. *Aorta, die grosse Schlagader.* Gr. αοϱτὴ.) Hippocrates applied the term αοϱται to the lower part of the bronchi. Aristotle called the great trunk of the arterial system φλεψ αοϱτὴ.

The aorta, one of the two great arteries which spring from the heart, is the trunk of the arterial system of the general circulation; it arises from the extreme right part of the base of the left ventricle of the heart, which, from this circumstance, is sometimes called the aortic ventricle. There is a ring of tendinous structure surrounding the aortic opening of the ventricle, which in the stag and some others of the ruminantia is more or less partially ossified; into this ring the muscular fibres of the heart are inserted. The middle tunic of the aorta is divided at its commencement into three semicircular flaps by an equal number of angular notches, forming thus a festooned edge which is bordered throughout its whole extent by a marginal tendinous cord. These three semicircular flaps touch the aortic opening of

* The etymology of this term is by no means clear. The following extract from Spigelius (de corp. hum. fabrica) gives a not improbable origin for it.—"Veteribus Græcis αορτην dictam fuisse vaginam cultrorum Macedonibus familiarem, quorum manubrium nonnihil incurvatum erat, ad quam sane figuram quam proxime accedere videtur arteriæ magnæ truncus, quâ parte ex corde originem suam ducit." Cloquet suggests the theme, αορτεομαι, suspendor, "parceque l'aorte considerée dans sa totalité parait comme suspendue au cœur." Aristotle, by whom the term seems to have been first employed, generally denominated it φλεψ ελαττων, in reference to the vena cava, which he considered the greater vein.—R. B. T.

the ventricle at three equidistant points by the centres of their convex edges, where the fibres of their marginal cord become intimately blended with those of the tendinous ring of the aortic opening of the ventricle; between these points are three triangular intervals, each of which is occupied by a thin tendinous expansion of considerable strength, having one of its sides continuous with the tendon which encircles the aortic opening of the ventricle, and the other two continuous with the marginal tendinous cord of the festooned commencement of the middle tunic of the aorta.

The convex margins of the sigmoid valves of the aorta are attached to the margins of the semilunar flaps, and are composed of thin expansions sent off from their marginal tendinous cord, covered by a reflexion of the lining membrane common to the heart and arteries. Hence it follows that the fibres of the middle tunic of the aorta are not continuous with the muscular fibres of the ventricle, being separated from them by the tendinous structure above described; this tendinous connexion is strengthened and supported externally by a layer of dense cellular membrane, which may be regarded as the commencement of the cellular or external tunic of the arterial system. The lining membrane of the heart, after being reflected over the sigmoid valves, extends itself into the aorta, and becomes continuous with the lining membrane of that vessel. The muscular substance of the heart rises in form of a swollen annular border around the commencement of the aorta for a little distance, and is connected to it by dense cellular membrane. The serous layer of the pericardium passes loosely from the surface of the heart over the aorta; a quantity of soft adipose substance, which is absent in the fœtus during the earlier months, begins to collect under the serous membrane in this situation, sometimes before, sometimes after birth, and, increasing as life advances, is found in considerable quantity in old age. The foregoing description of the connexion of the aorta with the heart has been determined by my own dissections repeatedly performed, and agrees, in its leading particulars, with the account given of it by M. Beclard.*

The aorta, arising from the left ventricle of the heart opposite the left side of the body of the fourth thoracic vertebra, ascends at first obliquely forwards, and to the right behind the middle bone of the sternum, until it arrives at the right side opposite the second intercostal space, and behind the sternal articulation of the cartilage of the second rib; it then stretches backwards and to the left, opposite the junction of the upper and middle portions of the sternum, on a level with the body of the second thoracic vertebra, and curving downwards it reaches the left side of the body of the third thoracic vertebra, on which there is a slight depression for lodging it; from this point it descends through the posterior mediastinum, advancing in its course downwards from the left side to the front of the bodies of the vertebræ; it passes through the aortic opening of the diaphragm, enters the abdomen, and on the body of the fourth abdominal vertebra gives off the two primitive iliac arteries, in which it seems at first view to terminate; the aorta, however, does not end here, but is continued, although greatly reduced in size, under the name of the middle sacral artery, as far as the extremity of the os coccygis.

The aorta is usually divided by anatomists into three portions; the curved portion from the heart to the third thoracic vertebra is called the *Arch* of the aorta; the remaining portion of the vessel, to which the name of descending aorta has been sometimes given, is called *Thoracic* aorta above the diaphragm, and *Abdominal* aorta below that muscle.

The *Arch* of the aorta is divided into three portions, for the purpose of describing its numerous important relations to surrounding parts with greater accuracy; these are, first, the ascending or anterior limb; second, the transverse portion; and, thirdly, the descending or posterior limb. The commencement of the aorta is covered anteriorly and to the left by the pulmonary artery, on the right by the right auricular appendage, the tip of which overlaps it in front, and behind it rests on the sinus of the left auricle. The ascending limb of the arch lies first in front of the right pulmonary artery, as that vessel crosses behind it in its course to the right lung, and then it gets in front of the right bronchus, and the cluster of bronchial glands which fill up the angle formed by the bifurcation of the trachea; it is bounded on the right side by the superior vena cava, and on the left by the pulmonary artery; anteriorly it is separated from the sternum by the anterior margins of both lungs, which here approximate, and by the narrowest part of the anterior mediastinum, where the attached surfaces of the opposite pleuræ touch. This portion of the aorta is contained within the bag of the pericardium, the serous layer of which invests it in every part except where it lies in contact with the pulmonary artery.

The transverse portion of the arch is shorter than the ascending limb. The three great arteries of the head and upper extremities arise from its superior sides; inferiorly it rests on the left bronchial tube; in front it has the cellular membrane of the anterior mediastinum, the thymus gland, and the inferior part of the vena innominata; behind it rests on the trachea a little above its bifurcation, and on the left recurrent nerve. The posterior limb is the shortest portion of the arch; it lies immediately behind the division of the pulmonary artery, which is connected to it by a ligament, the remains of the ductus arteriosus; and it is crossed by the left par vagum; on the right side it is in contact with the œsophagus, thoracic duct, and left side of the body of the third thoracic vertebra; the rest of the circumference of the thoracic aorta is covered by the left pleura, and is in contact with the internal surface of the left lung. In the generality of adults having

* Dict. de Médecine, art. Aorte. Elemens d'Anat. Générale, par Beclard. Paris, 1823.

the chest well formed, and the heart and the arch of the aorta free from disease, the origin of the aorta is opposite the sternal articulation of the cartilage of the fourth rib of the left side in the male, and the intercostal space above it in the female; the ascending limb of the arch, which is behind the middle bone of the sternum in the greater part of its length, may be felt pulsating on the right side of the sternum in the second intercostal space; the highest part of the transverse portion of the arch is on a plane with the centre of the sternal extremities of the first pair of ribs, and about an inch below the upper margin of the sternum: the arch of the aorta terminates opposite the lower edge of the cartilage of the second rib of the left side.

The *thoracic aorta* descends in the posterior mediastinum, and advances from the left side to the front of the thoracic portion of the spine, crossing in its course the left intercostal veins, and the left vena azygos when that vein exists; in front it is covered by the left bronchus, the posterior surface of the pericardium, the lower extremity of the œsophagus, and the left stomachic cord of the par vagum; on the right side it is bounded by the œsophagus, thoracic duct, and vena azygos; on the left side it is covered by the pleura, and in contact with the internal surface of the left lung, and at its lower extremity the left splanchnic nerve comes into contact with it, and most frequently accompanies it through the diaphragm.

The *abdominal aorta*, which enters the abdomen between the crura of the diaphragm, descends along the front of the abdominal vertebræ and the left lumbar veins; it is covered in front by the solar plexus of nerves, the stomach, pancreas, transverse portion of the duodenum, the splenic and left renal veins, the small intestine, and the root of the mesentery; on the right side it is bounded by the abdominal vena cava, and the commencement of the thoracic duct, and on the left it is covered by the peritoneum going to form the left layer of the mesentery. The termination of the aorta in the common iliacs and the middle sacral arteries is a little below the level of the umbilicus.

A remarkable deviation from the cylindrical form, which is one of the general characteristics of the arterial system, is observable in two parts of the arch of the aorta; the first of these occurs at the commencement of this vessel in form of three dilatations corresponding to the semilunar flaps already described; they were first pointed out by Valsalva, and have received the name of the lesser sinuses of the aorta; they exist at all periods of life, and increase in size with years; the other deviation from the cylindrical form is a dilatation on the right side of the ascending limb of the arch at its junction with the transverse portion; this dilatation, which does not exist in the fœtus, grows larger as life advances, and appears to be produced by the impulse of the blood striking against this part of the aorta at each successive systole of the left ventricle. The aorta in the succeeding part of its course gradually grows smaller in a degree proportionate to the size of the branches it gives off.

The thickness of the aorta is proportionally less than that of its branches; it is thinner at its commencement than in the arch, in which part, according to Haller, it is thicker by an eighth on the convex than on the concave side; it gradually diminishes in thickness as it descends through the thorax and abdomen, but its power of resisting distention instead of being diminished in an equal degree was found by Wintringham to be greater at its lower part than near the heart.*

The structure of the aorta is the same as that of the rest of the arterial system in general; its external tunic, however, is slighter than that of all other arteries except those of the brain, it is weaker the nearer it is examined to the origin of the aorta; it is strengthened near the heart by the covering which the serous layer of the pericardium gives to the aorta, and by an expansion from the fibrous layer of that membrane, which is lost on the transverse portion of the arch. The cellular sheath of the aorta in which the soft fat around its origin is deposited, becomes so fine where the vessel is passing out of the pericardium as to lead some anatomists to deny its existence in this situation; it becomes more evident in the course of the descending aorta through the mediastinum, and is still more considerable around the abdominal aorta, where it is usually loaded with a considerable quantity of adipose substance.

The branches which arise immediately from the aorta may be divided into orders, according to the degree of remoteness or the relative size and importance of the parts which they supply with blood; first, the branches which convey blood to the two extremities of the trunk and the limbs attached to them; these arteries, which are of considerable size, are the *arteria innominata*, the *leftc arotid* and *left subclavian*, which, arising from the transverse portion of the arch, are distributed to the head, neck, and upper extremities, and the *primitive iliac arteries* which arise from the lower part of the abdominal aorta supplying the pelvis and the lower extremities. 2nd order.—Branches somewhat smaller going to the thoracic and abdominal viscera and the parietes of the chest and abdomen; the coronary arteries which supply the heart arise from the aorta immediately after its origin; the bronchial arteries which supply the substance of the lungs, and the intercostal arteries supplying the parietes of the chest arise from the thoracic aorta; the cœliac, superior and inferior mesenteric, which supply the digestive organs; the renal arteries which supply the kidnies; the spermatic going to the organs of generation, the inferior phrenic supplying the diaphragm, and the lumbar arteries going to the parietes of the abdomen and lumbar region of the spine, are the vessels of this order which arise from the abdominal portion of the aorta. 3rd order.—Branches of much smaller size are sent from the aorta to se-

condary parts which lie in its vicinity, as the thymus, the pericardium, the œsophagus, the renal capsules, ureters, &c. 4th order.—Small arterial twigs lost in the neighbouring cellular substance, lymphatic glands, and in the coats of the aorta itself.

Development. — The aorta appears to be formed in the fœtus prior to the heart and subsequently to the system of the vena porta, with which, according to Baer, Rathke, and Meckel, it is connected by a small dilatation described by Dr. Allen Thomson* as a curved tube, which is the rudiment of the heart. (See Ovum.) Whilst the heart has but a single ventricle, the aorta and the pulmonary artery form a common trunk, which afterwards becomes divided by the dedelopment of the contiguous portions of the circumference of both vessels; during the remaining periods of intra-uterine life, and for a short time after birth, the pulmonary artery communicates with the aorta by the ductus arteriosus, which appears as a continuation of the trunk of the pulmonary artery opening into the concavity of the arch of the aorta at its termination. The ductus arteriosus becomes impervious soon after birth, and having undergone a process of complete obliteration, is finally concerted into a ligamentous cord. The size of the arch of the aorta is less in proportion in the fœtus than in the adult, whilst the thoracic aorta is larger, being increased in size below the ductus arteriosus. The arch lies closer to the spine in the fœtus in consequence of the trachea and bronchi behind it being so much less developed than in the adult, and the thymus which is between it and the sternum being so much larger during fœtal life. In old age the curvature of the arch of the aorta is much greater in consequence of the great sinus having increased considerably in size.

Anomalies.—The aorta presents occasional varieties or anomalies in the mode of its origin, its course, termination, and the number and situation of its branches. It is an interesting fact, that almost every irregularity hitherto observed in the course and branching of the aorta in the human subject, represents the disposition which that vessel constantly exhibits in some of the inferior animals. The anomaly of the aorta arising from both ventricles, and causing that condition called cyanosis, will be more properly considered in the article Heart. The following anomalies of the course of the aorta have been recorded by anatomists:—

1st. The aorta sometimes divides immediately after its origin into a right and left trunk, which, after having each given off the arteries of one side of the head and one upper extremity, join to form the descending aorta. Malacarne† has described a remarkable case of this anomaly; the aorta was of an oval form at its origin, its greater diameter being to its lesser in the proportion of three to two, it had five sigmoid valves in its interior, it divided immediately after its origin into a right and left trunk, from each of which arose a subclavian, an external and an internal carotid: after the two trunks had run for a space of four inches distinct, they joined to form the descending aorta. Hommel, a Norwegian anatomist,* relates a case in which the transverse portion of the arch of the aorta divided into two trunks, one of which passed before and the other behind the trachea, after which they joined to form the descending aorta, having encircled the trachea with a sort of ring: this anomalous division of the arch of the aorta is the more remarkable as it approaches the condition of the vessel which is constant in all known reptiles. 2d. The arch of the aorta is sometimes absent, in consequence of the vessel dividing, immediately after its origin, into two great trunks, one of which gives off the arteries of the head and upper extremities, whilst the other becomes the descending aorta.† This distribution is similar to that in the horse, rhinoceros, and other pachydermata, in the ruminantia, and some of the rodentia. 3rd. Varieties in the course of the arch sometimes, although rarely, occur, as, for instance, when the arch of the aorta, instead of crossing to the left in the usual manner, curves over the right bronchus, and gets to the right side of the spine, whence it either immediately crosses behind the trachea and œsophagus to the left, or continues its course along the right side of the spine to the lower part of the thorax; in cases of complete transposition of the viscera, where the heart is in the right side of the chest, the arch of the aorta is also reversed, in which case its thoracic portion descends along the right side of the spine.‡ Instances are recorded in which the descending aorta, a little below its arch, was very much contracted in its area or even completely obliterated for a certain distance, below which it resumed its full size: the circulation in these cases was carried on by the anastomosing of large collateral branches arising above and below the constricted or obliterated part.§

Anomalies of the branches of the aorta are more frequent: according to Meckel the branches arising from the arch deviate from the normal condition in one person out of every eight.|| The branches arising from the arch of the aorta present three kinds of anomaly, which, as to their frequency, occur in the following order: 1st, an increase in their number; 2d, a diminution; and 3d, an anomaly in the identity or order of the branches arising from this part without any increase or diminution of their number. In anomalies of the first

kind, the number of branches is most frequently increased to four, by the left vertebral arising from the arch between the left carotid and left subclavian, as in the phoca vitulina; next to this in frequency is the instance of the inferior thyroid arising from the arch between the innominata and left carotid, then the internal mammary, and, lastly, the most unusual is the thymic artery: it is more unusual to find the number of branches coming from the arch increased to four, in consequence of the innominata being absent, the right carotid and right subclavian arising separately; in such a distribution the right subclavian most frequently arises from the left extremity of the arch after the left subclavian; it may, however, be the first branch of the arch to the right, or it may arise between the two carotids, or, as more rarely happens, between the left carotid and left subclavian. The number of branches arising from the arch will be increased to five or upwards, when two or more of the above-mentioned anomalous branches arise from it at the same time. Of the second kind of anomaly, or that by diminution of the number of branches, the most frequent is where these are reduced to two, of which there occur the following varieties: *a*. the innominata sometimes gives off the left carotid as an additional branch, and the left subclavian arises separately, as in many quadrumana, several of the carnivora, as the lion, cat, dog, weazel, several rodentia, &c.; *b*. sometimes there are two arteriæ innominatæ, each dividing in a symmetrical manner into the subclavian and carotid of its own side, as in cheiroptera and the dolphin; *c*. sometimes when the arch gives off but two trunks, one of them divides into the two carotids, and the other into the subclavians; *d*. the right subclavian may arise distinct, and a common trunk give off the two carotids and left subclavian; the origin of a single trunk from the arch of the aorta supplying the arteries of the head and upper extremities is equivalent to a division of the aorta into an ascending and descending trunk, already noticed. The third kind of anomaly partakes of the characters of the two preceding, although the number of branches is the same as in the normal state: its varieties are, *a*, the left vertebral arising from the arch, whilst the left carotid comes from the innominata; *b*, the two carotids may arise from a common trunk between the origins of the right and left subclavians, as in the elephant; *c*, the right subclavian and right carotid may arise as distinct branches, whilst the left carotid and left subclavian come from a common trunk, forming a complete inversion of the usual order; *d*, the left carotid may arise from the innominata, whilst the right carotid comes from the part of the arch in the situation usually occupied by the origin of the left carotid. Anomalies of the branches of the descending aorta are less frequent; the following are among the more remarkable: *a*, the cœliac and diaphragmatic may arise above the diaphragm; one or both of the diaphragmatics may be given off by the cœliac; sometimes the cœliac and superior mesenteric arise by a common trunk as in the tortoise; sometimes there are two or more renal arteries on one or both sides, and sometimes the primitive iliacs are given off much higher than usual, in which case they are sometimes connected by a cross branch before they divide into the external and internal iliacs: it sometimes happens, when the iliacs are given off higher than usual, that the inferior mesenteric arises from the left of them.

The diseased conditions of the aorta are described in the articles Artery and Heart. The aorta, as Beclard remarks,* is more subject than any other artery to the ovoid dilatation in its ascending, and the lateral dilatation in its descending portion; it is also very subject to osseous or calcareous deposits, to fissures and ulcerations, to tubercles and small abscesses in its parietes, and to aneurism. Wounds of the aorta are constantly mortal. Laennec has observed a particular lesion of this vessel; it was a fissure of the internal and middle coats, from which the external tunic was extensively separated by a quantity of blood which had been effused between it and the middle tunic. The late Mr. Shekelton has described, in the Dublin Hospital Reports, a form of aneurism of the lower part of the abdominal aorta, in which the blood forced its way through the internal and middle coats, dissected the middle from the external for the space of four inches, and then burst into a lower part of the canal of the artery, forming a new channel which eventually superseded the old one, which the pressure of the tumour obliterated.

Granular excrescences are sometimes formed on the valves of the aorta, which Corvisart conjectured to be of venereal origin. The internal tunic of the aorta sometimes presents a red appearance, not peculiar, however, to this vessel, and occurring in certain forms of fever. Obliteration or constriction of the aorta is a condition rarely met with; its existence may be traced either to pressure on the vessel from without, morbid thickening of its coats, or the formation of coagula internally; this latter occurrence being most usually a consequence of the spontaneous cure of aneurism.

Aneurisms of the aorta produce various effects on surrounding parts; thus the heart, lungs, trachea, œsophagus, pulmonary artery, large veins, thoracic duct, and the various organs in the abdomen placed in their vicinity, may suffer derangement of their functions, displacement, atrophy or partial destruction, according to the degree of pressure to which they are subjected.

Aneurisms occurring in the ascending portion of the aorta, which is within the pericardium, are often attended during life by many symptoms very similar to those of disease of the heart itself, while their pressure may produce a diminution of the calibre of the pulmonary artery, obstruct the free passage of the blood through the vena cava superior, and even in-

* Dictionnaire de Médecine, art. Aorte.

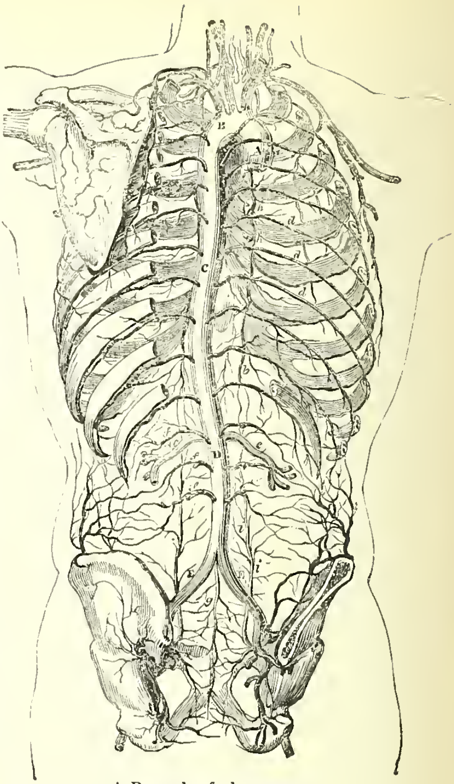
terfere with the full distension of the auricles. Aneurisms of the transverse portion of the aorta, when directed forwards, usually project at the right side of the sternum about the second intercostal space: when the sac extends upwards towards the neck, it frequently becomes a matter of extreme difficulty to distinguish an aneurism of the aorta from an aneurism of the innominata or some other large arterial trunk in the neighbourhood; cases are on record, where the pressure of such aneurisms of the aorta caused obliteration of the subclavian and common carotid. When aneurisms extend backwards, they produce a variety of effects, interfering with respiration and deglutition from their pressure on the trachea and œsophagus, sometimes producing obliteration of the thoracic duct. The pressure produced by aneurisms of the thoracic and abdominal aorta occasionally cause absorption of the bodies of the vertebræ, and give rise to an appearance not very dissimilar to that produced by caries.

Aneurisms of the arch of the aorta do not so often terminate fatally by making their way through the anterior parietes of the chest, and opening externally as by bursting internally: when they occur in that part of the arch of the aorta covered by the pericardium, they most usually burst into the sac of that membrane; cases are recorded in which aneurisms of the aorta have burst into the pulmonary artery,* or, taking a direction backwards, have opened into the trachea, œsophagus, or the substance of the lungs. Aneurisms of the thoracic portion of the aorta sometimes burst into the left pleura, sometimes into the posterior mediastinum: they have been known to point at the left side of the spine, after having caused absorption of the heads of the ribs and sides of the bodies of the vertebræ. In two cases observed by Laennec and Mr. Chandler, aneurism of the thoracic aorta burst into the spinal canal. Aneurisms of the abdominal aorta most usually burst into the cellular tissue of the lumbar regions behind the peritoneum, seldom into the sac of that membrane. An aneurism of the abdominal aorta has been observed to make its way backwards by the side of the spine, and point in such a situation as to have been at first mistaken for lumbar abscess.

Branches of the aorta. I. *Branches arising from the arch.*—From the arch of the aorta five branches are given off; two from its commencement, *the coronary arteries*, and three vessels of considerable size (*fig.* 78 *a b c*), from the upper part of its transverse portion to supply the head and the upper extremities. The coronary arteries of the heart or the *cardiac* arteries arise from the aorta close to its origin, and immediately above the free borders of the sigmoid valves; they are usually two in number, one for each ventricle.

The *right*, *anterior* or *inferior* coronary artery is often larger, seldom smaller than the

Fig. 78.



A B, arch of the aorta.

D, abdominal aorta.
E, common iliac artery.
g, middle sacral artery.

left; it arises from the anterior side of the aorta above the anterior sigmoid valve, coming out from between the roots of the aorta and pulmonary artery, it passes downwards and to the right side in the groove between the right auricle and ventricle, turns round the right edge of the heart until it reaches the groove of the septum on the inferior surface of that organ, when it changes its direction, coursing along that groove until it arrives at the apex of the heart, where it anastomoses with the left coronary artery; in its course it gives off to the right and left many tortuous branches arising nearly at right angles, the right branches are smaller and go to the right auricle, the left are larger and belong to the right ventricle, which they traverse in a longitudinal direction towards its apex. From the origin of the right coronary artery two small branches are given off, one to the commencement of the pulmonary artery and the surrounding fat, which anastomoses behind the pulmonary artery with a branch of the left coronary; the second branch anastomoses with the bronchial arteries.

The *left posterior* or *superior* coronary artery arises between the left auricle and the posterior surface of the pulmonary artery, de-

* Dr. Wells in Trans. of a Society for Improvement of Medical and Surgical Knowledge, vol. iii.

scending to the left between the left auricle and pulmonary artery, and, having reached the groove at the base of the heart, dividing into two or three branches; one anterior longitudinal descends along the anterior groove of the septum to the apex of the heart, where it anastomoses with the termination of the right coronary artery, with which it holds frequent communication by branches which it sends over the anterior surface of the right ventricle, while it sends some large branches to the left ventricle; this branch at its commencement gives small twigs to the aorta and pulmonary artery. The second branch of the left coronary artery covered by the great coronary vein passes from right to left in the groove between the left auricle and ventricle, to both of which it gives many branches, turns round the left border of the heart, changes its direction, and descends by the side of the right coronary artery to the apex; the third branch sinks into the substance of the septum and continues its course to the apex; this branch sometimes arises directly from the aorta; in this latter case, of course, there will be three coronary arteries arising from the aorta; Meckel has once seen four; the supernumerary coronary artery does not arise above any particular valve, but usually close to the origin of one of the normal branches. It is rare to find but one coronary artery in the human subject, which corresponds, according to Camper, with the normal conformation in the elephant. The three large branches arising from the transverse portion of the arch of the aorta and sent to the head and upper extremities, will be described in a separate article.

II. *Branches of the thoracic aorta.*—These may be divided into *anterior* and *lateral.* The anterior branches are, the *bronchial, œsophageal,* and *posterior mediastinal.* The lateral are the *inferior* or *aortic intercostal* arteries. The *bronchial* arteries are usually two in number, one for each lung; sometimes, however, there are two for each lung, and sometimes the right and left bronchial arise from a common trunk, which usually springs from the first aortic intercostal of the right side.

The *right* bronchial artery most usually arises from the first aortic intercostal artery of the right side, which supplies it after having arrived at the right side of the spinal column behind the œsophagus, sometimes it comes direct from the aorta; it proceeds in a tortuous course under the right bronchus, to the root of the right lung, after having given small branches to the œsophagus, the pleura, the back part of the pericardium and the bronchial glands.

The *left* bronchial artery arises immediately from the aorta and passes in front of the œsophagus to the left bronchus, to the posterior side of which it attaches itself. Both bronchial arteries are similarly distributed through the lungs, dividing with the bronchi, along each branch of which they send two or more tortuous twigs. The relation of the bronchial arteries to the other vessels of the lungs will be more particularly noticed in the article LUNG.

The *œsophageal* arteries vary in number from two to seven: they are inferior to the bronchial in size: they arise from the front of the thoracic aorta, and are distributed to the œsophagus, on which they anastomose freely with descending branches of the inferior thyroid from above, in the middle of the œsophagus with the bronchial, and below with branches of the phrenic and coronary artery of the stomach.

The *posterior mediastinal* arteries are numerous and small; they send branches to the œsophagus, thoracic aorta, thoracic duct, absorbents, and cellular membrane of the posterior mediastinum, anastomosing with the bronchial, œsophageal, and some branches of the right thoracic intercostal arteries.

Inferior or aortic intercostal arteries.—Of the eleven intercostal spaces the two superior are mostly supplied with arteries from the superior intercostal branch of the subclavian; and as the first aortic intercostal artery frequently supplies the third and fourth intercostal spaces, we often meet with but eight pairs of intercostal arteries coming immediately from the aorta (*fig.* 78, *d*). The first right aortic intercostal is usually the largest of the series in consequence of giving origin to the right bronchial; the size of the intercostal arteries diminishes in general from above downwards. All the intercostal arteries arise rather from the posterior part of the aorta, those of opposite sides arising very near each other, and sometimes springing from a common trunk. At first they descend obliquely on the vertebral column, at an acute angle to the trunk of the aorta. The right intercostal arteries are longer than the left, in consequence of the position of the thoracic aorta on the left side of the spine. Each artery is lodged at first in a groove on the side of the body of each vertebra, enters the intercostal space passing behind the ganglia of the sympathetic nerve, and immediately divides into two branches, one posterior or dorsal, the other anterior or intercostal. The posterior branch passes backwards through a space above the neck of each rib and below the tranverse process of the superior of the two vertebræ, with which the head of the rib is articulated; it gives some branches to the bodies of the vertebræ, and in passing the intervertebral hole it sends branches inwards to the spinal cord, which anastomose with the spinal arteries. The continuation of the vessel is distributed to the longissimus dorsi, sacro-lumbalis, and other muscles along the side of the spine, as well as to the integuments of the back. The anterior or proper intercostal branch is usually larger than the posterior, and traverses the intercostal space. At first it is situated between the pleura and external intercostal muscle, it shortly divides into two smaller branches, a superior and an inferior, which get between the two layers of intercostal muscles. The inferior branch, usually the smaller, runs forwards along the superior border of the inferior rib, and passes obliquely over its surface to the periosteum covering it. The superior branch, larger than the former, enters a groove in the lower edge of the superior rib, about its angle, in company with the intercostal nerve, and passes forwards between the two layers of intercostal muscles, towards the junction of the rib with its cartilage, where it descends from the rib towards the middle of the intercostal space, and there anastomoses with the anterior intercostal arteries sent off from the internal mammary. Besides supplying the intercostal muscles, pleura, and ribs, the intercostal arteries give several branches, which pierce the external layer of intercostal muscles, and carry blood to the muscles and integuments covering the thorax. The lower intercostals also send branches to the abdominal muscles, diaphragm, and quadratus lumborum, which freely anastomose with the internal mammary, epigastric, phrenic, lumbar, and circumflex iliac arteries.

Anastomoses.—The intercostal arteries have a chain of anastomoses with each other by communicating branches which cross the heads of the ribs. By this means the superior freely communicate with the subclavian by its intercostal artery. Inferiorly, their anastomosis with the phrenic, circumflex ilii, and lumbar arteries, is equally free; internally they anastomose with the arteries of the spinal cord, and in front with the internal mammary and epigastric.

III. *Branches of the abdominal aorta.*—They may be divided into *anterior* and *lateral.* The anterior branches are, the *inferior phrenic, cœliac, superior* and *inferior mesenteric.*

Phrenic arteries.—The phrenic arteries are two in number; they arise from the aorta immediately after its entrance into the abdomen, generally distinct, sometimes from a common trunk, and occasionally one or both arise from the cœliac artery, or one of its branches. Each phrenic artery passes outwards in front of the crus of the diaphragm, and along the upper edge of the renal capsule of its own side. The right artery passes behind the vena cava, and the left behind the œsophagus. They run on the abdominal surface of the diaphragm, and at the posterior edge of the cordiform tendon each vessel divides into an external and an anterior branch. The external branch supplies the fleshy substance of the ala of the diaphragm, and sends several branches towards the external attachments of that muscle which anastomose with the lower intercostal and lumbar arteries; while the anterior branch, coursing round the margin of the cordiform tendon, supplies the anterior part of the diaphragm, and anastomoses with its fellow of the opposite side, behind the ensiform cartilage, sending forwards branches to anastomose with the internal mammary.

Minute branches are given off by the phrenic arteries near their origins to the semilunar ganglia and renal capsules: a small twig from the right phrenic ascends along the vena cava through the diaphragm to anastomose with the comes nervi phrenici of the internal mammary. Another similar twig, given to the œsophagus by the left phrenic, while passing behind that tube, anastomoses with the middle œsophageal arteries.

The *cœliac artery*, called, also, *cœliac axis*, is one of the largest and shortest of the vessels given off by the abdominal aorta. It generally arises from the aorta, between the crura of the diaphragm opposite the junction of the last dorsal and first abdominal vertebra, having the renal capsules and semilunar ganglia on either side of it, with the lobulus Spigelii to the right, the cardiac orifice of the stomach to the left, the superior border of the pancreas inferiorly, and the stomach and lesser omentum in front: it is closely embraced by branches of the solar plexus.

The cœliac artery, which is often scarcely half an inch in length, immediately divides into three branches, the *gastric* or *coronaria superior ventriculi*, the *hepatic*, and the *splenic*, which constitute the tripod of Haller. Sometimes the cœliac axis gives off the *phrenic* and *superior capsular.*

Coronary artery of the stomach.—The coronary artery is the smallest of the three branches furnished by the trunk of the cœliac; it sometimes arises from the aorta itself. Passing upwards, forwards, and to the left, it arrives at the cardiac orifice of the stomach, from which it proceeds forwards and to the right, following the direction of the lesser arch of the stomach until it arrives near the pylorus, where it anastomoses with the pyloric branch of the hepatic. When the coronary artery has arrived at the cardiac orifice of the stomach, it sends one or more branches upwards along the œsophagus which supply that part with blood, and anastomose with the œsophageal arteries from the thoracic aorta: it then sends branches round the cardiac orifice, which nearly encircle that part, and ramify over the great extremity of the stomach, where they anastomose with the vasa brevia of the splenic. In its course along the lesser arch of the stomach the coronary sends many branches over both surfaces of that viscus, which anastomose with each other and with the right and left gastro-epiploic. The terminal branch of the coronary which ends at the pylorus is sometimes called superior pyloric. Sometimes the coronary artery gives off the right hepatic immediately before reaching the cardiac orifice of the stomach.

The *hepatic artery* passes forwards and to the right under the lobulus Spigelii to the neck of the gall-bladder. In this part of its course it gives a few twigs to the gastro-hepatic omentum and the inferior surface of the liver; when it reaches the pylorus, it gives two considerable branches called the *pyloric* and the *right gastro-epiploic.* The *pyloric* passes from right to left along the lesser arch of the stomach, where it meets the coronary with which it anastomoses, sending several branches over the anterior and posterior surfaces of the stomach to anastomose with the right gastro-epiploic artery. The *right gastro-epiploic* artery, much larger than the pyloric, arises after that vessel; it passes downwards behind the pylorus, and arrives at the greater arch of the stomach, along which it courses from right to left and anastomoses with the left gastro-epiploic. While passing behind the pylorus, it gives several branches to the pancreas and duodenum, one of which, somewhat larger than the rest, called pancreatico-duodenalis, lies concealed between the duodenum and head of the pancreas, and anastomoses with the branches which the pancreas receives from the superior mesenteric. As the gastro-epiploic artery courses along the greater arch of the stomach, it gives off numerous branches, some of which ascend on the anterior and posterior surfaces of the stomach, and anastomose with the coronary and pyloric; others descend in the anterior layer of the great omentum: some branches from these ascend in the posterior layer of this fold of membrane until they reach the arch of the colon, where they anastomose with the colic branches of the superior mesenteric.

After having given off these branches, the hepatic artery ascends towards the right within the capsule of Glisson, in front of the vena porta, and to the left of the ductus communis choledochus. Having reached the transverse fissure of the liver, it divides into the *right* and *left hepatic* arteries which enter the liver by divisions corresponding to those of the vena porta, the right branch having previously given off the cystic artery, which arises opposite the junction of the cystic and common hepatic ducts, attaches itself to the neck of the gall-bladder, and soon divides into two branches, one of which ramifies over the inferior surface of that reservoir, while the other sinks between the liver and the gall-bladder. For further particulars relating to the hepatic artery vide Liver.

The *splenic* is the largest of the three branches of the cœliac. Immediately after its origin it passes with numerous contortions to the left, behind the stomach and along the superior border of the pancreas to the fissure of the spleen. In this course it gives off *pancreatic* branches *(pancreaticæ magnæ et parvæ)*, which anastomose with the pancreatic branches of the right gastro-epiploic. It gives a large branch, the *left gastro-epiploic*, which sometimes arises from one of the branches in which the splenic terminates. This branch passes onwards to the left until it reaches the greater arch of the stomach, along which it descends, passes to the right until it meets the right gastro-epiploic, with which it anastomoses. In its course it gives off, like the right gastro-epiploic, superior branches, which pass over the anterior and posterior surfaces of the stomach to anastomose with the branches of the coronary and inferior branches which descend in the great omentum, where they have a similar distribution with the descending branches of the right gastro-epiploic: near the fissure of the spleen, the splenic artery divides into five or six branches, which anastomose by arches, and enter the substance of that organ. Before entering the substance of the spleen these branches give off large vessels, called *vasa brevia*, which bend to the right, and are distributed to the great extremity of the stomach, spreading over its anterior and posterior surfaces, where they anastomose with branches of the coronary and right gastro-epiploic.

The *superior mesenteric* artery, often larger than the cœliac, arises from the aorta immediately after the cœliac; sometimes from a trunk common to both vessels, as in the tortoise. This artery is at first concealed by the pancreas, it descends perpendicularly behind that gland and crossing the termination of the duodenum arrives at the root of the mesentery, between the two layers of which it descends. In the middle of this fold of the peritoneum it forms a considerable curve, the convexity of which is to the left, and directs its course towards the termination of the small intestine in the right iliac region, forming near its termination a second curve, the concavity of which is to the left. Near its origin this artery gives some branches to the duodenum and pancreas, by means of which it anastomoses with the branches of the hepatic and splenic sent to these organs: in the mesentery it sends off from its left side the arteries of the small intestines, and from its right the arteries which it supplies to the great intestine.

Arteries of the small intestines.—These arise from the left side of the superior mesenteric, varying in number from fifteen to twenty; the superior are longer and larger, those which succeed them appear to diminish progressively in length and size, they all advance between the two layers of the mesentery to the concave side of the intestine; at a certain distance from their origin they divide into secondary branches which diverge from each other at acute angles; these secondary branches subdivide into still smaller branches, which, diverging in a similar manner, form arches of anastomoses with corresponding branches of the adjoining arteries; the convexities of these arches are all turned towards the intestine, and from them numerous branches arise, which, by dividing and anastomosing like the larger trunks, form a second series of smaller arches; other branches arising from the convexities of these arches divide and anastomose to form still smaller and more numerous arches; thus we have three, sometimes four, and occasionally five series of arches, formed by the subdivisions of these arteries before they reach the intestine, and presenting in the mesentery a network with large meshes. From the convexities of the extreme arches which form the outer border of this network, thousands of small arteries pass in a straight direction to the tube of the intestine; these form two series, an anterior and a posterior, which apply themselves to the opposite surfaces of the intestine, and anastomose with each other on its convex border. The detailed description of their further distribution will come under consideration in the article Intestinal Canal.

Colic arteries. — The superior mesenteric sends off three, sometimes only two, branches from its concavity, called *right colic* arteries, distinguished as *superior* or *colica media*, *middle* or *colica dextra*, and *inferior* or *ileo-colic;* when there are but two, the superior and middle form but a single trunk; the inferior is generally distinct.

The *right superior colic* or *colica media* arises a few inches distant from the origin of the superior mesenteric; it passes forwards between the layers of the meso-colon towards the middle of the transverse colon, and divides into a right and left branch; the right follows the right part of the transverse colon, and anastomoses with the superior branch of the colica dextra; the left branch follows the left portion of the transverse colon, and communicates with the left colic branch of the inferior mesenteric artery.

The *colica dextra* or *middle right colic* artery arises close to the colica media, sometimes from a trunk common to both, and sometimes from the ileo-colic. After its origin it passes forwards, upwards, and to the right in the meso-colon towards the ascending colon, and divides into two branches; one superior ascends to anastomose with the right branch of the colica media, the other descends along the concavity of the ascending colon, and communicates with the ascending branch of the ileo-colic.

The *ileo-colic*, *cæcal*, or *inferior right colic* passes downwards, and to the right towards the cœcum, and then divides into three branches; the first ascends in the meso-colon, and anastomoses with the descending branch of the colica dextra; the second communicates in the mesentery with the termination of the superior mesenteric; and the third, arising in the angle between the two preceding, passes behind the junction of the ileum with the cœcum: at this place it gives off a branch which forms a small arch in the mesentery of the vermiform appendix, and then divides into two branches, one of which passes upwards on the colon, and the other descends on the cœcum. The colic arteries, by their anastomoses with each other, form arches, from the convexities of which, turned towards the intestine, numerous branches arise; each of these again divides into two, which with the contiguous vessels form smaller arches, and straight branches finally arise from the ultimate arches, which, passing on either side of the intestine, include it between them, and anastomose on its convex edge.

In the fœtus we have the *omphalo-mesenteric* artery arising from the superior mesenteric; this vessel, which passes along the umbilical cord to the vesicula alba, becomes obliterated towards the end of the second month of gestation.

The *inferior mesenteric* artery arises from the front of the aorta to its left side, at about an inch or an inch and a half above the origins of the primitive iliacs; it sometimes arises from the left primitive iliac, especially when the aorta has divided higher than usual; instances of the absence of this artery are very rare, but interesting as presenting an example of the normal condition in birds and reptiles, in which the inferior mesenteric artery is much reduced in size or entirely absent.

The inferior mesenteric artery runs obliquely downwards and to the left, and gets between the layers of the left iliac meso-colon, where it divides into many branches, distributed to the left portion, and sigmoid flexure of the colon and the rectum; the superior branches are distributed to the descending portion and sigmoid flexure of the colon, and are called *left colic* arteries, while the lower branches go to the rectum under the name of *superior hæmorrhoidal* arteries. The left colic arteries are three in number, the *superior*, *middle*, and *inferior*. The *superior left colic* is the largest of the three; it arises from the inferior mesenteric immediately after its origin, passes transversely to the left, and divides near the left lumbar colon into two branches, one of which ascends to the transverse meso-colon, and anastomoses with the colica media of the superior mesenteric; the other branch descends towards the left iliac meso-colon, where it anastomoses with the ascending branch of the middle left colic.

The *middle left colic* is sometimes a branch of the preceding. It divides into two branches; one ascends along the left colon, and anastomoses with the descending branch of the left superior colic; the other, inferior, smaller communicates with the ascending branch of the left inferior colic.

The *inferior left colic* goes to the sigmoid flexure of the colon, and soon divides into two branches; one superior anastomoses by an arch with the descending branch of the preceding, and the other inferior meets a branch of the hæmorrhoidal in the meso-rectum. They are distributed to the intestine in a similar manner with the branches of the right colic arteries, as already described.

When the inferior mesenteric has given off the colic arteries, it diminishes, takes a perpendicular direction, and reaches the posteror surface of the rectum lodged between the layers of the meso-rectum, here it takes the name of *superior hæmorrhoidal* artery. It soon divides into two branches, a right and left, which apply themselves to the sides of the rectum, sending branches backwards and forwards round that intestine, by which they communicate with each other, and anastomose below with the middle and inferior hæmorrhoidal arteries; some branches anastomose with the lateral sacral of the internal iliac.

The lateral branches of the abdominal aorta consist of the *capsular*, *renal* or *emulgent*, *spermatic arteries*, small twigs to the ureters and adipose substance in the vicinity of the aorta, and the four pairs of *lumbar arteries*. For an account of the capsular, emulgent, and spermatic arteries we must refer to the articles Renal Capsule, Kidney, and Testicle.

The *lumbar* arteries are four in number on each side (*fig.* 78, *f*); they arise from the lateral and posterior part of the aorta nearly at right angles, they pass outwards across the middle of the bodies of the four superior lumbar or abdominal vertebræ to the roots of their transverse processes, covered by the psoas muscle and the crura of the diaphragm. When the lumbar arteries have reached the roots of the transverse processes of the lumbar vertebræ, they divide each into two branches, one posterior and the other anterior.

The posterior or dorsal branches are smaller and pass backwards between the transverse processes of the lumbar vertebræ, opposite the intervertebral foramina, where they each send a branch inwards to the spinal cord and cauda equina; they then plunge into the substance of the great sacro-lumbar mass of muscles, in which they are lost, anastomosing frequently with each other, and with the dorsal branches of the lowest intercostal and ileo-lumbar arteries. The continuations or anterior divisions of the lumbar arteries pass outwards between the psoas and quadratus lumborum muscles, to which they give small branches, as well as to the diaphragm, kidney, renal capsule, and surrounding cellular membrane; they then continue their course forwards between the layers of the abdominal muscles, in company with branches of the lumbar nerves, and anastomose with the lower intercostals, mammary, epigastric, and circumflexa ilii.

The *middle sacral* artery arises from the back part of the abdominal aorta, immediately above the origins of the primitive iliacs, from one of which it arises in some rare cases, it descends exactly over the middle of the anterior surface of the bodies of the last abdominal vertebra, false vertebræ of the sacrum and os coccygis, lying close on the surfaces of those bones; the branches which it gives off are distributed in a lateral direction; the first is the largest and not unfrequently is the fifth lumbar artery, the size of which sometimes exceeds that of the continuation of the trunk of the middle sacral itself. This branch divides into an anterior and a posterior, the distribution of which is similar to that of the superior lumbar arteries. Two transverse branches usually arise from the middle sacral on the body of each false vertebra; these passing outwards give branches to the periosteum and the substance of the sacrum, anastomose with branches of the lateral sacral arteries, and enter the anterior sacral foramina, where they give some branches to the origins of the sacral nerves, and emerging from the posterior sacral foramina are lost in the muscles arising from the back part of the sacrum; finally, the middle sacral terminates at the extremity of the coccyx in small branches, which it sends to the rectum and surrounding fat.

The middle sacral artery is sometimes found double; in the fœtus this artery is proportionally larger than in the adult, especially in the earlier periods of gestation. In some animals, the size of the middle sacral artery is scarcely inferior to that of the aorta itself, as in the cetacea and fishes. In all animals furnished with tails, the size of this artery bears a constant relation to the size of that member.

Aneurism rarely affects any of the branches of the aorta above described; it, however, occasionally occurs in the cœliac or mesenteric arteries, or some of their branches. An interesting case of aneurism of the hepatic artery unattended by pulsation during life, and which produced jaundice by pressing on the ductus communis choledochus, is reported by Dr. William Stokes, in the Dublin Journal of Medical and Chemical Science, for July 1834. We once witnessed the dissection of a female aged forty, under the care of the late Professor Todd, in the Surgical Hospital of the House of Industry in Dublin, in whom three distinct aneurisms of large size were found in the epigastric region; one of the hepatic artery, which communicated with that vessel by a longitudinal fissure, and which had opened into the cavity of the gall-bladder; one of the trunk of the coronary artery of the stomach, and a third of the splenic artery. A remarkable feature in this case, and that of Dr. Stokes, was the absence of pulsation during life, in consequence of which the nature of the disease was not discovered until the post-mortem examination; the above circumstance may be attributed to the want of resistance in the surrounding parts, and it is one which frequently obscures the diagnosis of abdominal aneurisms.

ARACHNIDA; *αραχνη*, *aranea*; Eng. *arachnidans*; Fr. *arachnides*; Germ. *Spinne*; Ital. *Ragni*.

This class of animals was for a long time confounded with that of insects, but it has been distinguished therefrom by many modern naturalists, and more especially by Lamarck, who has applied to it the term 'arachnides,' now universally adopted.

The characters indeed which the arachnidans present are perfectly distinct, and prevent them from being confounded either with crustaceans or insects, although one cannot avoid perceiving that they have numerous relations with the animals of these two classes, and they are consequently placed in natural arrangements between the crustaceans and insects.

Zoologists have assigned the following characters as peculiar to and distinguishing this class.

Body divided into thorax and abdomen; apterous. *Legs*, eight in the adult state. *Head* continuous with the chest. *Eyes* smooth. *Sexual orifices* situated either on the thorax or base of the abdomen.

To these external characters may be added others derived from the anatomical conditions of different organs. Thus all arachnidans possess exclusively an aerial respiration, either effected by a sort of lungs, or by means of tracheal tubes, as in insects. This difference in the respiratory organs is accompanied with one not less marked in those of circulation; for example, all the pulmonary arachnidans possess vessels which carry blood, while, on the contrary, all those which have tracheæ are deprived of bloodvessels. Lastly, the latter species (or trachearies) alone undergo metamorphoses analogous, in some respects, to those of insects; while the former (or pulmonaries) suffer only changes of integument. We shall treat further on these peculiarities hereafter.

Our object here not being to treat of classification, we shall refer the reader for this subject to the works of Cuvier, Leach, Latreille, Walcknäer, Dugès, and limit ourselves at present to a tabular exposition of the principal divisions and subdivisions admitted in this class down to the genera with which it is most essential to be acquainted.

Latreille, whose method is that most generally adopted by zoologists of every country, divides the arachnidans into two great orders, as follows:—

Class.		*Orders.*
ARACHNIDA.	*Pulmonary sacs* for respiration, 6 to 12 *ocelli*.	PULMONARIA.
	Tracheæ for respiration, not more than 4 *ocelli*.	TRACHEARIA.

The same author establishes in the first order two families, which are characterized as follows:

		Families.
1*st Order.* ARACHNIDA PULMONARIA.	*Palpi* simple, pediform; *mandibulæ* armed with a moveable and perforated claw, emitting a poisonous liquid .... *Abdomen* inarticulate, terminated by spinnarets	.... *ARANEIDÆ.*
	Palpi produced, cheliform, or shaped like pincers .... *Mandibulæ* provided with a moveable digit .. *Abdomen* articulate, without spinnarets	........*PEDIPALPI.*

M. Walcknäer, who has made a special study of the family of *araneidæ* or *spinning arachnida*, and who has published many works on their methodical distribution and their habits of life, has very recently considered them with the express view of arriving at a natural arrangement of them; the result of his labour may be seen in the following

TABLE OF THE SUBDIVISION OF THE ARANEIDÆ, OR ARACHNIDA FILOSA INTO GENERA.

Family	Mandibles	Eyes	Arrangement of eyes	GENERA.	Tribe	Division	Habitat
First Family. ARANEIDÆ, Spiders.	*Mandibles* articulated horizontally; moving vertically	8 eyes.	*Eyes* aggregated ..	Mygale	*LATEBRICOLÆ*, hiding in holes and fissures......	*Venantes*, incessantly running or leaping about the vicinity of their abode to chase and catch their prey...............	*Terrestres*, living on land or in holes in the ground.
				Oletera			
				Filistata			
			Eyes segregated ..	Missulena			
				Sphodros			
	Mandibles articulated vertically, or on an inclined plane; moving laterally	6 eyes.	*Eyes* anterior	Dysdera	*TUBICOLÆ*, inclosing themselves in silken tubes..		
				Segestria			
			Eyes, anterior and lateral	Uptiotes	*CELLULICOLÆ*, sheltering themselves in small cells		
				Omosites			
				Scytode			
		8 eyes.	*Eyes*, anterior and lateral, very unequal in size	Lycosus	*CURSORES*, running swiftly to catch their prey....		
				Dolomedes			
				Storena			
				Ctenus			
				Hersilia			
				Sphasus			
				Dolophenes			
				Myrmecia	*SALTATORES*, leaping and springing with agility to seize their prey		
				Eresus			
				Platiscelum			
				Attus			
				Delena	*LATERIGRADÆ*, walking and running sideways or backwards; occasionally throwing out threads to entrap their prey	*Vagantes*, wandering abroad & incessantly spying out for prey. No fixed residence, except at the period of oviposition	
				Thomisus			
				Selenops			
				Eripus			
				Philodromus			
				Sparassus			
				Clastes			
			Eyes anterior, almost equal in size..............	Clubiona	*NIDITELÆ*, going abroad, but making a web for their nests, whence issue threads to entrap their prey	*Errantes*, prowling about the neighbourhood of their nests or near the threads which they throw out to catch their prey	
				Drassus			
				Clotho	*FILITELÆ*, going abroad, but spreading long threads of silk about the places where they prowl in order to entrap their prey		
				Emyo			
				Latrodectus			
				Pholcus			
				Artema			
				Tegenaria	*TAPITELÆ*, spinning great webs of a close texture like hammocks, and dwelling therein to catch their prey	*Sedentes*, spinning large webs to entrap their prey, lying wait in the middle or at the side	
				Lachesis			
				Agelena			
				Nyssus			
				Epeira	*ORBITELÆ*, spreading abroad webs of a regular and open texture, either orbicular or spiral, and remaining in the middle or on one side to catch their prey		
				Tetragnatta			
				Uloborus			
				Zosis			
				Lynyphia	*RETITELÆ*, spinning webs of an open meshwork and of an irregular form, and remaining in the middle or on one side to seize their prey		
				Episina			
				Theridion			
				Argyroneta	*AQUITELÆ*, spreading filaments in the water to entrap their prey	*Natantes*, swimming in water, and there spreading their filaments to entrap their prey	*Aquaticæ*, living in water

Up to the present time M. Walcknaer has not published on the second family of Arachnidans or the *Pedipalps*, and few authors have studied them. Latreille, however, has treated of them with sufficient detail in the '*Regne Animal*,' and more recently M. Ehrenberg has carefully investigated one of the principal groups. The following table will present the principal divisions adopted by these two authors.

Subdivision of the Pedipalps into Genera.

Family	Characters	Group	Subdivision		GENERA.
Second Family. PEDIPALPI, Scorpions.	*Stigmata* 4, situated near the origin of the abdomen, *mandibles* unguiculate, or terminated by a moveable claw. No thoracic *combs*..	*THELYPHONIDÆ.*	Abdomen with a caudal filament		*Phrynus.*
			Abdomen without a caudal filament		*Thelyphonus.*
	Stigmata 8, situated along the inferior lateral part of the abdomen; *mandibles* chelate, or terminated by two digits, the exterior of which is moveable. Combs on the inferior part of the thorax	*SCORPIONIDÆ*	6 Eyes	*Scorpio*, LINNÆUS	*Scorpio.*
			8 Eyes		*Buthus.*
			12 Eyes		*Androctonus.*

The second order of Araehnidans, or the Trachearies (*Trachearia*) has in general been less perfeetly studied than the first; it ineludes many anomalous species, of whieh the greater part eseape observation from their extreme minuteness. Such are, *e. g.* the Acaridæ, or mite-tribe, whieh have recently exereised the patience of our learned friend M. Dugès, Professor of the Faculty of Medieine at Montpellier.—Whilst referring the reader to his paper inserted in the Annales des Seienees (1834), we have thought it convenient to present here a Table of the seetions and genera whieh he has founded in that tribe of Arachnidans.

Table of the sub-divisions of the Tracheary Arachnidans.

Order			*Families.*		*Tribes.*	*Sections.*	*Genera.*
2d Order. ARACHNIDA TRACHEARIA	Thorax, with divisions or articulations.	*Abdomen* very distinct, large, and annulate; *Palpi* very large, pediform, or cheliform.	*PSEUDO-SCORPIONIDÆ*				Galeodes. Chelifer.
		Abdomen rudimentary, not annolate: *Palpi* small, filiform, and provided with a hooked claw at the extremity.	*PYCNOGONIDES*				Pycnogonum. Phoxichilus. Nymphan.
	Thorax, without articulations, or at most divided into two by a contraction.		*HOLETERÆ*	*Mandibles* very conspicuous, free, terminated by a didactyle nipper; *Abdomen* annulate; no metamorphosis	*Phalangidæ*		Phalangium. Siro. Trogulus.
				Mandibles and other oral organs ordinarily supported or surrounded by a lower lip in the form of a sheath. *Abdomen* not annulate; a metamorphosis in many.	*Acaridæ*	*Trombidiei.* (palpi raptores)	Raphignatus. Tetranychus. Rhyncholophus. Smaridia. Trombidium. Erythræus.
						Hydrachnei. (palpi anchorales)	Atax. Diplodontus. Arrenurus. Eylais. Lymnochares. Hydrachna.
						Gamasei. (palpi filiformes)	Dermanyssus. Gamasus. Uropoda. Pteraptus. Argas.
						Ixodei. (palpi valvulares)	Ixodes.
						Acarei. (palpi adherentes)	Hypopus. Sarcoptes. Acarus.
						Bdellei. (palpi antenniformes)	Bdella. Scirus.
						Oribatei. (palpi fusiformes)	Oribates.

Of the external covering or tegumentary system.—Although the external covering of the arachnidans varies in consistence, according to the part of the body which is examined, yet it may be said in general to be more or less soft, rarely acquiring the solidity of the integument of certain insects, and still less the hardness of that of many crustaceans.* Where it is of the greatest consistency it is elastic, of a deep brown colour, and has an aspect analogous to horn. In chemical composition, however, it is always widely different, as has been proved by the researches of M. August Odier, and some other chemists. It contains, in fact, a substance *sui generis*, called 'chitine,' which is insoluble in potassa, but, on the contrary, is soluble in warm sulphuric acid, does not turn yellow with nitric acid, and does not curl up when burnt, but leaves an ash, which, if the part experimented on is sufficiently thick, preserves the form of the organ.

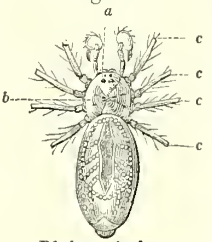
The solidity of the outer covering is generally greater on the thorax than on the abdomen. The *genera scorpio*, *phrynus*, *thelíphonus*, and *phalangium*, afford an exception to this rule, the rings of the abdomen being distinct and solid, especially on the dorsal aspect.

In the spiders properly so called, *(araneæ,)* and in the greater number of the mites *(acari)*, the skin of the abdomen is very soft, coriaceous, papiraceous, or even membranous, transparent, and susceptible sometimes of being greatly extended. It is on this account that the abdominal segment of the body shrinks and loses its form after death, and from the transparency of the integuments the same arachnidans present during lifetime the various markings and lively colours which depend on a kind of pigment situated in the interior of the body.

The head, as we have remarked in our exposition of the characters of the class, is always consolidated with the thorax; this is readily ascertained to be the fact in scorpions and spiders, and in order to express this disposition, which obtains also in many of the crustacea, the two united segments are termed 'cephalo-thorax;' the term abdomen is applied to the part properly so called, and thus the body of the arachnidans may be divided into two parts. The abdomen may be either *sessile* or *pediculate*, i. e. it may either inclose at its anterior margin the posterior part of the thorax, as in the scorpions, or it may adhere to the thorax by a very circumscribed part of that margin, as in the spiders properly so called. Anatomically speaking, the abdomen has a very simple structure: it is formed of annular segments sometimes distinct and hard, as in the scorpions; sometimes blended together and soft, as in the spiders and mites.

The other division of the body or cephalothorax is not so simple. To facilitate the study of this part it is necessary to consider the cephalic portion separately from the thoracic division. This it is easy to do, where, as in many cases, the junction of the two parts is perfectly distinct, and made obvious by the existence of a furrow along all the whole superior part of the line of union, (see the traces of it in the thorax of a pholque, *pholcus rivulatus*, *fig.* 79.) But in every case the head (*a*) is recognizable by constant characters: it supports the eyes and all the pieces belonging to the oral apparatus, while the thorax (*b*), on the contrary, gives insertion to the four pairs of legs, which on account of their extreme length are represented in the figure as truncated.

Fig. 79.



Pholcus rivulatus.

The head is often as narrow as the chest, abruptly truncated anteriorly, and terminated by a point posteriorly, so that it appears by its backward prolongation to separate the right from the left side of the thorax, and to be placed between them like a wedge, (as in the *pholcus.*) The suture is very close, and sometimes so far effaced that it is no longer possible to decide where the head terminates and the chest commences. We have already observed that the head supports the eyes on its upper part, and has the oral instruments attached to its lower surface. These consist, first, of a pair of *mandibles* or *forciples;* secondly, of a pair of *maxillæ;* thirdly, of a sternal *labium.*

The number of annuli or segments which enter into the composition of the head of an arachnidan may yet be determined at some future period: we have made some attempts to unravel this subject, but our observations are not yet sufficiently matured to permit us to decide so difficult a question.

Our researches on the thorax of articulate animals have led to more decisive results, which we shall now expound, but for the complete understanding of which we must refer the reader to the article Insecta, where a more general theory of the thorax, and a description of all the pieces that enter into its composition will be given. In the arachnidans many of these pieces are entirely wanting; and their thorax is consequently more simple than that of insects: it is even more simple than the thorax of crustaceans, to which, however, it bears a great resemblance in many points. If, for example, we take a large spider, as a *mygale avicularia*, and strip off the hairs which clothe the thorax, we shall easily perceive a plate, or plastron, intermediate to the right and left series of legs. This plastron is the sternum, or, to speak more correctly, the union of several sternums, which, were it not for this union, would manifest themselves as four distinct pieces; that is to say, corresponding in number to the pairs of legs which arise from them. This sternal plas-

* This composition being precisely analogous to that of the integuments of insects, we shall treat of it in the article relating to these animals.

tron is distinctly shewn in *fig.* 100, *e*, which represents the inferior surface of the body of the house-spider, (*tegenaria domestica*.)

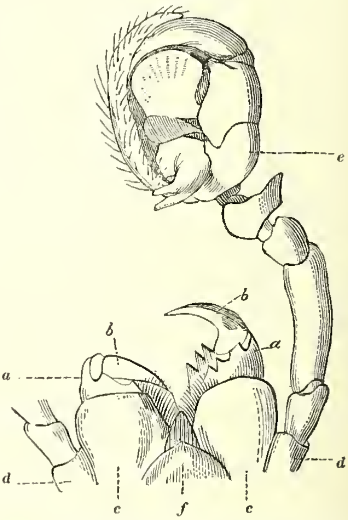
On the upper surface of the chest we find another plate much more extended than the sternum, and joined anteriorly with the head by means of a fissure or triangular V-shaped notch which receives it. This plate or dorsal shield exhibits divisions or rather lines of suture which the eye readily distinguishes. They represent arcs of circles arising from the base of the legs and all ending in the centre of the thorax, where there is a depression varying as to extent and depth according to the individual. In other arachnidans this structure is not so clearly shewn on account of the close union of the different pieces; but it is easy to detect or at least explain the unimportant modifications which obtain in these cases. In the figure, which we have taken from Savigny, of the *pholcus rivulatus*, the traces of the division may be readily followed, (*fig.* 79, *b*.) Continued comparative researches have convinced me that this dorsal plate of the thorax of the *araneidæ* is formed, not of the dorsal pieces of the thorax of insects, but only of the lateral pieces or those of the flancs. For the arachnidans being deprived of wings, the intermediate thoracic element or tergum, so largely developed on account of the presence of those organs in the thorax of insects, being no longer necessary, has completely disappeared. How has this taken place? The flancs (*pleuræ*) which in insects were divaricated and pushed to the sides by the tergum, when that obstacle was removed, have mutually approximated and become united together in the middle line, precisely at the place where the little depression exists which we have already mentioned.

We believe that we have placed these facts beyond all doubt in our 'Researches on the Thorax of Articulate Animals,' presented to the Academy of Sciences of Paris in 1820.* Now it is worthy of remark that what has happened to the arachnidans, being animals deprived of wings, is also found in the crustaceans, which are equally destitute of these organs. Only that there exists in some of the latter, as the decapods, a vast carapace which occurs independently of the flancs, and covers them. For if the carapace is raised in a crab, the flancs or pleuræ are seen beneath, extending obliquely towards one another as in the thorax of a *mygale*, with this single difference, that in the *cancer*, where the carapace covers the flancs and protects them as well as the internal soft parts, the *pleuræ* or side pieces remain divaricated and are not joined at their apices as in the *mygale*.†

Digestive system.—The arachnidans, whose habits have been made the subject of observation, feed for the most part on animal matter, not in a state of decomposition or even recently dead, but in the living state. They either boldly seize their prey, which consists of insects of greater or less size, or they attach themselves to animals much larger than themselves, and live parasitically upon their blood or some other nutritious fluid. The latter species are generally very minute: many of them, as the mites (*acari*), require our best optical instruments for their detection. The above differences in habits of life are accompanied with important modifications in the organs of nutrition, and especially in the oral apparatus, which we proceed to describe.

In the non-parasitic species, as the pulmonary and part of the tracheary arachnidans, the mouth consists essentially, first, of two *mandibulæ* or forciples (*fig.* 80, *a*) in close ap-

Fig. 80.



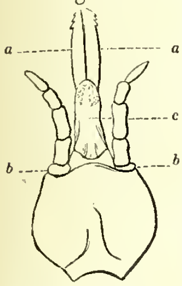
position, endowed with little lateral motion, but rather acting vertically and provided each with a hooked claw (*b*), which, near its point, is perforated, and emits a poisonous fluid, secreted by a gland, hereafter to be described. In other arachnidans of the same order the *mandibulæ* are a species of pincers, one nipper of which is alone moveable, as in the scorpions. Secondly, of two *maxillæ* (*c c*), each in the form of a more or less flattened and villous lobe, provided with a palp or jointed appendage (*d*) projecting more or less from the mouth, and terminated sometimes by pincers as in the *scorpions*, sometimes by a simple

* See the Report by Cuvier, in the Analysis of the Works of the Royal Academy of Sciences for the year 1820.

† We must again refer to the articles CRUSTACEA and INSECTA for the full comprehension of the facts which presuppose an anatomical knowledge of the external covering of the animals of these two classes. To those who already possess that information I shall observe that a single piece of the flancs of insects (*epimera*) forms the back-part of the thorax of spiders; the other piece (*episternum*) already in a rudimentary state in the crustaceans, has completely disappeared from the thorax of the arachnidans, each segment of which consequently consists only of two pieces, the *sternum* below, the *epimera* above.

claw, as in the spiders, at least the females, for in the males this palp is frequently the seat of a singular apparatus (*e*), hereafter to be described. Thirdly, of a sternal *labium (f)*, which, as its name implies, is inserted into the sternum, and does not give origin to any articulated appendage or palp. With respect to the composition of the mouth in the parasitic species, such as most of the mites, and we may take as an example an *argas*, although it is concealed under the form of a beak, sometimes with a sharp point, yet it is essentially the same. The principal difference consists in the dart-shaped mandibles (*a a*), being joined together so as to form a kind of lancet, the sides of which are sometimes denticulated, so as to cause them to adhere firmly to the flesh which they have penetrated. The *maxillæ* with their palp (*b*) and the inferior *labium* (*c*) are here more or less intimately blended together, so as to form a case or sheath. In some instances the maxillary palp remains free, as in the *argas*.

Fig. 81.



Head of a mite (Argas.)

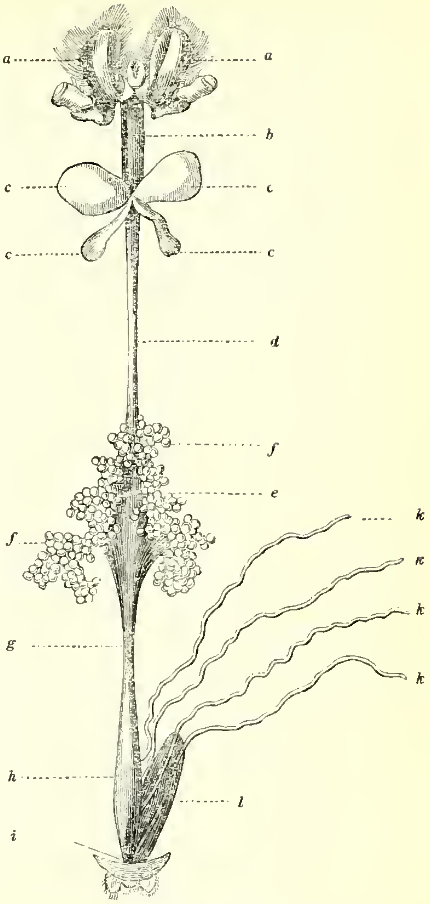
Savigny admits that in the interior of the mouth of arachnidans there exist three pharyngeal orifices, and not a single one as in crustaceans and insects. These three orifices, which are of almost imperceptible minuteness, are situated at some distance from one another, and disposed in a triangular form. He has observed this structure in spiders, scorpions, and phalangians: but he represents only two orifices in a genus allied to *galeodes*. Latreille denies the fact, and Treviranus, in his anatomical description of arachnidans, mentions only one pharyngeal orifice.

However this may be, Savigny confines the assumption of food in spiders to a true suction: "The mandibles," says he, "do not serve for bruising the food, but for seizing it, and for piercing and retaining it in firm contact with the maxillæ; these subject it to alternate pressure, and express the juices which afterwards pass into the pharynx."* This is a matter of daily observation when a spider seizes an insect.

The intestinal canal of the arachnidans is always short, and is never disposed in convolutions as in certain herbivorous insects. This disposition is in accordance with their predaceous habits, and confirms the general rule, (but which to our knowledge is not without many exceptions,) that the intestinal canal is longer in herbivorous than carnivorous animals.

In the spiders, (araneæ,) and we may take the common species (*tegenaria domestica*) as an example, the alimentary canal (*fig*. 82) communicates with the mouth between the maxillæ (*a a*) by an œsophagus, rather short and of a delicate texture (*b*). This terminates in four sacs (*c*), which M. Treviranus calls "stomach," but which, in our opinion, merit rather the name of gizzards; the digestive tube then continues, as a straight narrow canal (*d*) of moderate length, which dilates (*e*) and adheres, by its parietes, to a kind of epiploon filled with adipose granules (*f*). Posteriorly the dilated part becomes stronger in texture, insensibly contracts (*g*), then undergoes a second dilatation (*h*) before it opens into the rectum (*i*). It is near the latter part, in a kind of pouch, that the slender vessels open which M. Treviranus calls biliary vessels, and which he is, with reason, surprised to see terminating in so extraordinary a position. These vessels, in fact, which characterize so well by their presence the chilific stomach of insects, and are situated in these animals more or less anteriorly, always preceding the small intestines which have a greater or less length, terminate in the spiders in the rectum itself, and close to the anus.

Fig. 82.

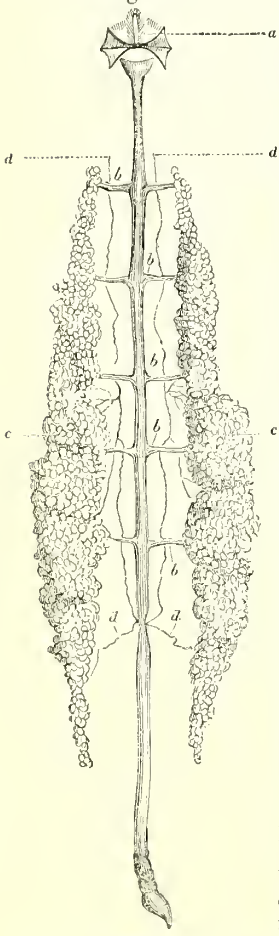


Tegenaria domestica.

* See Description of Egypt, Arachnidans, pl. 8, fig. 7, E, y, y. Savigny at first admitted but two pharyngeal openings, (Mémoir sur les Animaux sans Vertebres, p. 57); but subsequently admitted three.

Now if the observations of M. Treviranus are correct, and the four vessels which he describes are really analogous to the biliary tubes of insects, we do not hesitate to consider all the part which precedes and is intermediate to them and the four sacs, as the stomach, or chilific cavity. It would thus result, that the *tegenaria domestica* would be deprived of an intestine properly so called, and would possess no part destined to transmit along a greater or less extent the *residua* of the digestive process. And, indeed, such residua must necessarily be very inconsiderable in an animal which is sustained by juices, and these already animalized. We are, indeed, led to this conclusion by the structure presented by the hemipterous insects which are nourished, like the spiders, by suction, and which also have the intestines, properly so called, so short that the biliary vessels, which always accompany the posterior extremity of the stomach, are found close to the anus. We may form an idea of this disposition by casting an eye over the beautiful figures which our friend M. Leon Dufour has just published in his " Anatomical and Physiological Researches on the Hemiptera."

Fig. 83.



Scorpio.

In the alimentary canal of the scorpions the biliary vessels *d d* are inserted much higher up, but this is not the only peculiarity which the anatomy of these animals presents. Their digestive tube extends without any marked dilatation straight from the mouth (*a*) to the anus which opens at the extremity of the tail. It presents in this course a very singular structure: five small canals (*b*) go off at right angles from either side, above the place of communication of the biliary vessels, and terminate by ramifying in the fatty masses which make a sort of epiploon (*c*.) This truly remarkable structure is not, however, so anomalous as might be supposed, especially if we regard as cœcums these kind of lateral vessels. For the alimentary canal presents a still more ramified condition in some crustaceans,—we would cite as an example the argulus studied by Jurine;* and in another animal of the same class which M. Milne Edwards and myself† have made known under the name of *Nicothoë*, the intestinal canal sends out considerable lateral prolongations. In the leech, and especially the *Clepsina*, there exist numerous cœcums. Lastly, certain minute arachnidans (acaridæ) are remarkable for analogous lateral dilatations. It is to be observed that all these beings are sustained by animal juices, and the great part, for the better gorging of the same, are fixed either momentarily or during their whole life upon the body of their victim.

We now come to speak of the epiploon and the fatty globules which it contains. The fat, or the substance which appears as such, is extremely abundant in the bodies of insects and arachnidans. In the latter it assumes the form of granular masses or globules of various colours, and sometimes these are united together by a thin membrane. In the araneæ the fat is especially abundant in the abdomen, of which, indeed, it determines the form. The use of this fatty apparatus cannot be mistaken, and it has been placed beyond doubt by experiment, that it supplies the place of nourishment to the animal, either when the latter passes the winter in a state of torpidity, like the hibernating animals, or when in particular seasons circumstances are not favourable for catching prey.

Respiratory system.—The division which has been established in the class *Arachnida* of *Pulmonaries* and *Trachearies* indicates that there are in these animals two very different modes of respiration. In both cases the atmosphere penetrates to the interior of the body by orifices situated on different points of the body, and called *stigmata*. The *stigmata* of the *Pulmonary Arachnidans*, and especially those of scorpions, are very conspicuous; they occupy the inferior part of the abdomen, and are four in number on either side, (1, 2, 3, 4, *fig.* 84.) They are in the form of narrow fissures, surrounded as in insects with a circle of more solid substance than the rest of the integument, and to which we have given the name of peritrema.

In the spiders (araneæ) not only do they differ in form but in number and position. Treviranus counts four pairs in the thorax above the insertion of the legs, four pairs on the upper part of the abdomen, and one pair on the lower surface; the latter is the most constant and important, (*fig.* 100, *d.*)

The stigmata of the *Tracheary Arachnidans* are less easy to be distinguished, more especially on account of the small size of the species constituting a part of that group. We have here carefully figured them in an Acaroid species (*Ixodes Erinacei*), where they are situated below the sides and on the lower part of the abdomen, (*fig.* 85, *a*,) in shape like a spherical tubercle, (*fig.* 86, *a*,) perforated by

† Annales des Sciences Naturelles, first series, tom. ix. pl. 49.

Fig. 84.

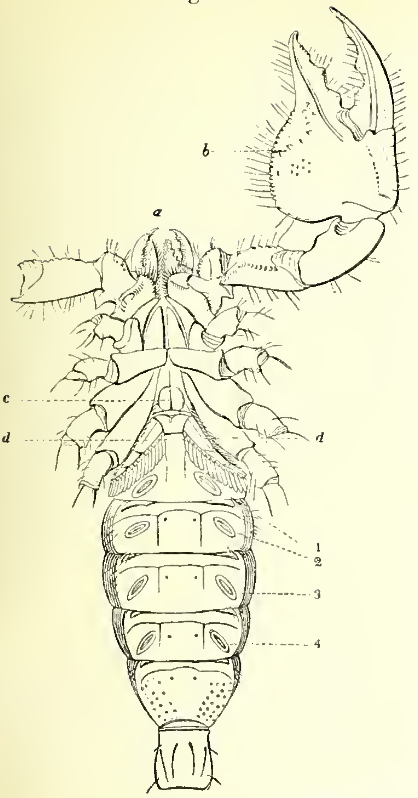

Fig. 85.

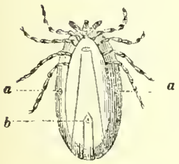

Fig 86.

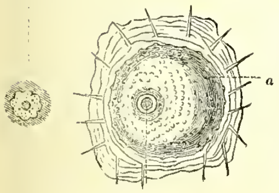

Ixodes Erinacei.

an infinite number of small holes, between which in the centre we may remark a larger circular plate (*b*.) Each little aperture is as it were stellated at the margins (*c*,) by which the air penetrates the body and gets into the tracheæ. These tracheæ are analogous in structure and position to those of insects; they are elastic, ramify after the manner of vessels in the interior of the body, and penetrate to even the minutest organs.

With regard to the internal respiratory organs of the *Pulmonary Arachnidans* they have a very different character; presenting the appearance of membranous sacs formed by lamellæ applied to one another like the leaves of a book, each of these little receptacles opens into a common cavity, the membranous margins of which adhere to the horny circle or *peritrema* of the stigma before described.

We here subjoin figures copied from those of Professor Müller of Berlin, which represent these parts in a scorpion. *Fig.* 87 shows one of

Fig. 87.

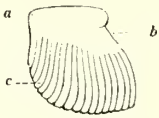

Fig. 88.

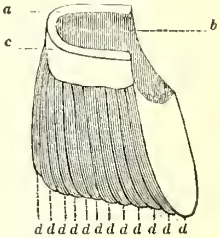
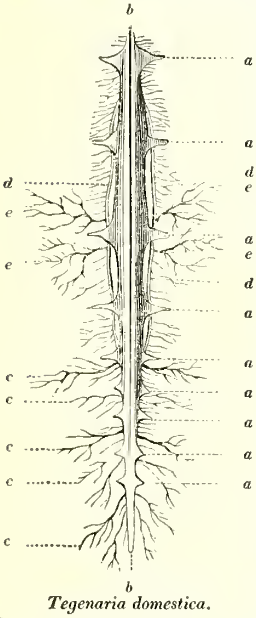


the pulmonary branchiæ entire, seen in profile: *a* is the edge by which it adheres to the circumference of the stigma; *b* the simple membrane without folds; *c* the folds or leaves. *Fig.* 88 shows a portion of the same pulmonary *branchia* laid open: *a* is the horny margin of the stigma, or peritrema, to which the simple membrane *b* adheres; *c* the common cavity into which each of the spaces opens which are formed by the laminæ.

These organs resemble closely in their structure the branchial laminæ, and hence Treviranus and Meckel compare them to branchiæ. Müller on the other hand maintains that they are lungs, because, he says, they can be distended with air. The name of pulmonary branchiæ, which we have given them, seems to reconcile the two contending opinions, although we believe that the distinction between lungs and gills is in itself of very slight importance when applied to articulate animals. It is, for example, quite impossible to establish such a distinction in certain crustaceans, as the *Oniscus*, the *Asellus*, the *Cymothoa*, which are all provided with organs of an analogous structure, although some live in water, and others in air more or less humid. Moreover, certain crabs, as the terrestrial species called *Cancer Uca*, *Ruricola*, &c., of Linnæus, possess branchiæ which are much better adapted for respiration in air than in water. The *Cancer Mænas*, so common on our coasts, is almost in the same case, since it passes a great part of its life out of the sea, and it is well known that lobsters and shrimps can live a long time out of water, provided that the air in which they are kept is humid. M. Milne Edwards and myself have demonstrated, by decisive experiments, the conditions in which the branchiæ in these animals act as lungs.

Circulating system.—The function of circulation, which is always so intimately connected with that of respiration, presents, as might be supposed, two different conditions in the *arachnidans*. Those which breathe by means of tracheæ have not an apparent circulation; and in this respect they resemble insects:—we attribute to them simply a dorsal vessel without any ramifications. Those, on the contrary, which possess branchial lungs, have an apparatus for circulation pretty well developed. It consists of an elongated vessel placed immediately beneath the integument along the middle line of the dorsal aspect of the back, on which account it has received the name of dorsal vessel (*fig*. 89). It is kept in its situation by small ligaments or muscles, (*a a*), which in insects are called *alæ cordis*. The texture of the dorsal vessel is membranous, and pretty firm; it contains a colourless fluid. This heart is in communication with numerous vessels, but hitherto it has not been discovered which of these terminate in, or which arise from the organ, or, in other words, it is not known by what route the blood arrives at, or proceeds from the heart. We believe that we are able to dissipate the doubts which still exist as to this subject, but before we state our opinions we shall speak of the anatomical disposition of the apparatus. Treviranus has described it vaguely in the scorpions, but has well elucidated its structure in the spiders (*araneæ*), more particularly in *Clubione atrox* and *Tegenaria domestica*, *Fig*. 89. In both these species numerous vessels are observed to arise from the heart, especially from its posterior part (*c c*.) These proceed to ramify indefinitely, distributing themselves over every organ; and we have no doubt with respect to their true arterial nature. But in addition to these vessels there exist two others of larger size (*d d*,) which communicate in one direction with the heart, in another, by very fine ramifications, with the pulmonary branchiæ. In *Clabione atrox* these two vessels do not give out any branches in their course.



Tegenaria domestica.

No doubt remains in our mind but that these vessels maintain a direct communication between the heart and respiratory organs. The subjoined figure (*fig*. 89) will facilitate the understanding of these facts. It represents the heart and its appendages in the house-spider, (*Tegenaria domestica*,) and shows the two canals which communicate with the heart and receive the small vessels (*e e e e*) that come from the pulmonary branchiæ. Treviranus, to whom we owe these observations, has not, however, attempted to explain the manner in which the circulation takes place in the arachnidans, and indeed this is to be determined by physiological experiment and not by the dissection of the organs merely. The experiments which I have made, in conjunction with my friend M. Milne Edwards, on the circulation of the crustaceans, enable me to give a satisfactory and doubtless true explanation of that of the arachnidans. The organs which exist in these animals, and we admit the precision of the anatomical facts detailed by Treviranus, are essentially the same as in the crustaceans. We find a heart, of the nature of which no one can entertain a doubt: then there are arteries proceeding from the heart and ramifying over every part of the body; lastly, the heart receives on each side vessels which bring it into communication with the respiratory organs. These latter vessels are the analogues of the branchio-cardiac vessels of crustaceans. With respect to veins, of which the latter animals are destitute, they are equally wanting in the arachnidans, and are doubtless replaced by cavities of an irregular form which exist between all the organs of the body. Treviranus, indeed, has remarked in the abdomen of *Tegenaria domestica* two small intervals which are discoverable through the integument, and in which he says the blood may be observed to be collected. These reservoirs are perhaps the analogues of the venous sinuses of the *Crustacea*.

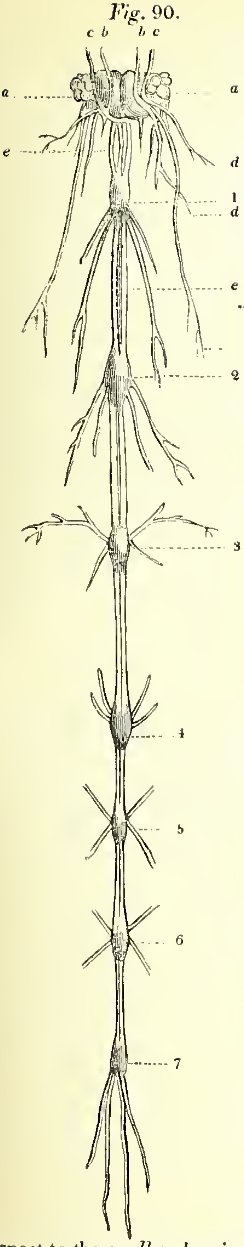
The nature of the vessels being thus determined, it becomes easy to conceive how the circulation takes place in the arachnidans—the blood, leaving the heart, is distributed through all the arteries to the different organs for their nutrition: this being effected, and the nutrient fluid being thereby converted into venous blood, it begins to circulate through the sinuses before mentioned, and arrives by an insensible course at the pulmonary branchiæ. There it is changed by contact with air into arterial blood, and returns to the heart by means of the *branchio-cardiac* vessels (*e d*) to be finally again propelled through the arteries (*c*.)

Thus the ascertained anatomical facts, few as they are, permit us already to appreciate the mode of circulation in the arachnidans; and we repeat that it is in every respect analogous to the circulation in the crustaceans.

Nervous system.—The nervous system is gangliated, as in all the articulate animals: but it presents considerable differences of disposition in the different arachnidans: the scorpions in this respect vary much from the spiders.

In the *Scorpionidæ* we find the following structure (*fig*. 90):—the *first* ganglion, which is commonly called the brain (*a*), and which supplies the nerves to the parts of the mouth (*b*,*c*) is intimately blended with the nervous mass giving origin to the nerves of the legs (*d*). The succeeding ganglia are distinct from one another, and are seven in number: the *first three* (1 2 3) are situated in the abdomen proper; they have this peculiarity, that they are united together and with the ganglion, which may be termed *cerebro-thoracic*, by *three* instead of two chords of communication (*e*), which is the number found in all other articulate animals; the *four* remaining ganglions (4 5 6 7) occupy the entire length of the post-abdomen, or that contracted portion of the body which is incor-

Fig. 90.

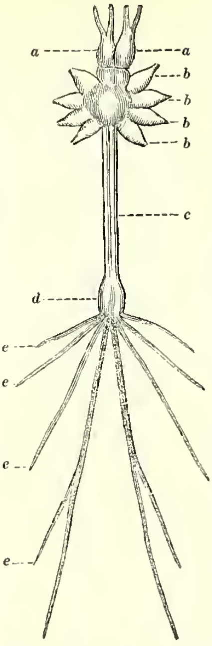


rectly termed the *tail.*

In the *Aranidæ* the ganglions are fewer than in the *Scorpionidæ:* the *first* pair, or that which constitutes the brain, (*fig.* 91, *a,*) is quite distinct from the thoracic; these are *four* in number (*bb*) but have undergone a remarkable degree of centralization, being intimately connected together so as indeed to form a mass in which all traces of junction are lost, except at the sides, which have remained free and in the form of smallconoid bodies directed outwardly so as to resemble, in the aggregate, the figure of a star. From the apex of each of these small cones the nerve is given off to each leg. In the abdomen there does not exist any ganglion, but only a double longitudinal nervous cord (*c*), which swells out at its termination. From this swelling (*d*) a great number of nerves (*ee*) pass off, which are distributed to all the organs contained in the abdominal cavity.

Organs of sense.—We have nothing particular to observe with respect to the *smell* or *hearing* of the arachnidans, for we are ignorant of the existence of these senses in the class, or at least of the parts of the body in which they are seated. With regard to *taste,* the choice which the arachnidans make of their food sufficiently indicates that it exists in variable degree; the organ is situated probably at the entrance of the pharynx. With regard to *touch,* the delicacy of that sense is in the ratio of the tenuity of the integument; but the extremities of the legs, and more especially of the maxillary palps seem to be expressly destined to bring the individual

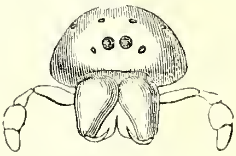
Fig. 91.



into relation with surrounding objects. The sense of *sight* is the only one respecting which no doubt can exist; particularly in the species which are the most perfect of the class, such as the spiders, scorpions, &c. The eyes belong to that kind which are termed *simple,* in opposition to those denominated *compound,* and which are found exclusively in insects and crustaceans.

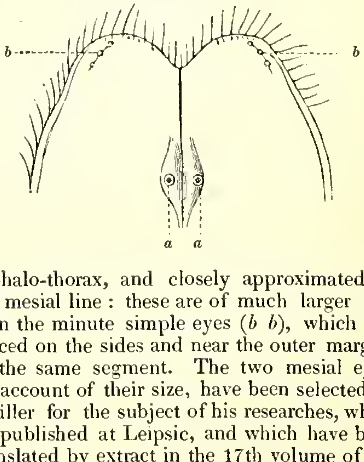
These simple eyes (*ocelli*) in arachnidans are *two, four, six,* or *eight* in number; they are situated on the anterior part of the body either superiorly or laterally. With respect to size they differ not only in different species, but in the same individual, as in the *Platyscelum,* (*fig.* 92,) and especially in the *Attus.*

Fig 92.



In the Scorpions (*fig.* 93) there are *two* eyes (*a a*) situated on the dorsal aspect of the

Fig. 93.

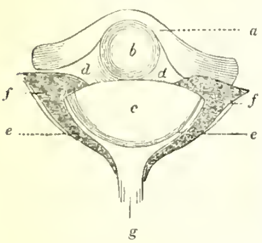


cephalo-thorax, and closely approximated to the mesial line: these are of much larger size than the minute simple eyes (*b b*), which are placed on the sides and near the outer margins of the same segment. The two mesial eyes, on account of their size, have been selected by Müller for the subject of his researches, which he published at Leipsic, and which have been translated by extract in the 17th volume of the first series of the "Annales des Sciences Naturelles." The following are the principal results of the labours of this accomplished naturalist.

He finds that each of these simple eyes is composed, 1st, of a *cornea;* 2dly, of a *crystalline lens;* 3dly, of a *vitreous body;* 4thly, of a kind of *chamber;* 5thly, of a *choroid;* 6thly, of a *retina.*

The cornea, as is shewn in *fig.* 94, which represents a vertical section of the eye, is smooth and convex externally (*a*,) its superficies presenting none of those divisions which characterize the cornea of the compound eyes of insects. The internal surface is deeply concave, and in the hollow hemisphere thus formed is lodged the anterior part of the crystalline lens. This body (*b*) is of a spherical figure, of a hard and transparent texture, resembling in these respects the crystalline lens of Fishes. Posteriorly it rests upon but does not penetrate the vitreous humour. The vitreous humour (*c*) is composed of a granular, soft material, is larger than the chrystalline, plano-convex anteriorly, wholly convex behind. As the crystalline lens rests upon without sinking into the vitreous humour, there remains a circular channel or space filled with an aqueous humour, to which the term chamber may be appropriately given, and which may be compared to the posterior chamber of the eye of some of the vertebrata.

Fig. 94.

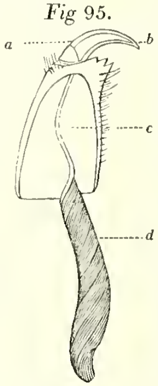


The retina (*e*) is applied to the back part of the vitreous humour, and is in some degree an expansion of the optic nerve (*g*). It is lined by a choroid, or membrane saturated with a coloured matter, or kind of pigmentum (*f*), which is afterwards reflected over the anterior margin of the plano-convex surface of the vitreous humour so as to form there a sort of pupil, the aperture of which exceeds the diameter of the crystalline, but is less than that of the vitreous humour. Such is the somewhat complicated structure of one of the large eyes of a scorpion, by the knowledge of which physiologists are now enabled better to understand the mode in which vision is effected in the arachnidans.

Organs of secretion.—We designate thus the organs that emit outwardly a matter which is sometimes liquid, and sometimes becomes concrete by contact with the atmosphere. The position of these organs varies; in one case they occupy the anterior part of the body, in another they are observed at the opposite extremity. The nature and properties of the matter secreted is not less variable; in some instances it is an irritating or poisonous liquid which the animal introduces by means of a more or less sharp pointed hook into the interior of the body to which it may be applied; in other instances, again, it is a substance which is at first in a liquid state, but soon becomes solid in its passage through a sort of sieve, or, if I may be permitted the comparison, a cullender pierced with excessively minute holes. We shall treat separately of these two kinds of apparatus.

Of the apparatus for secreting the irritating or poisonous liquid.—Every one knows how quickly a fly that has been bitten by a spider expires: the effect is instantaneous. It is by means of the mandibulæ or forciples that the spider has inflicted the wound. These mandibulæ are each armed with a moveable and extremely sharp claw, (*fig.* 95, *a*,) near to the point of which is a minute orifice (*b*), from which there escapes a drop of poisonous liquid, which spreads itself over the whole wound the instant that it is inflicted. This orifice, which from its minuteness is very difficult to be perceived even with a high magnifying power, communicates with a fine or narrow excretory canal (*c*), situated in the interior of the mandible and given off from the true secreting organ. This gland is lodged in the interspace of the muscles of the thorax; it is in the form of an elongated and slightly curved vesicle, the parietes of which have a singular structure. Treviranus describes it as consisting of filaments adhering together and united by a membrane so as to resemble a spirally disposed band. This structure presents, he thinks, some analogy to that of the trachea of insects. Lyonnet, in his posthumous work, has described this part somewhat differently: he considers each little band as being composed of two substances, one fleshy, which contracts upon drying, the other squamous, which is disposed like a watch-spring, or rather like Archimedes' screw, and which always remains in the same state. He supposes that these fibres, upon contracting, force the poisonous liquid into the excretory canal. Such a construction is not, however, necessary, since it may be readily conceived that that vesicle, being placed in the midst of very powerful muscles, it is sufficient that they contract in order to its compression and the consequent propulsion of the fluid contained in its interior, which probably the parietes have secreted.

Fig 95.



This apparatus appears to us to correspond, by its position, to that which is termed, in insects, the salivary apparatus, and in silk-worms the silk-glands: it is even possible that the poisonous fluid itself, mingling with the animal juices which the spider introduces by suction into its stomach, serves to facilitate digestion.

Spiders are not the only animals of their class that are provided with this kind of organs. Scorpions have also a poison-apparatus, but in a very different position. It is not placed in the mandibles, but at the posterior part of the body, in the last segment of the tail-like abdomen. Every one is familiar with that pyriform dilatation which the scorpions carry at the end of the tail; it is terminated by a little sharp hook generally curved backwards. Near its termination there may be observed, as in the mandibulous hook of spiders, a very minute orifice, or, according to some authors, two distinct fissures. It is from this part that a limpid fluid, having strongly-marked poisonous qualities, exudes; and, corresponding to the foramen within, there is the neck of a little bladder which is the true secretory organ. Little is known respecting its structure: according to the observations of Treviranus it is surrounded by a horny substance and provided with a muscle, which most probably has for its function the compression of the vesicle and the consequent expulsion of the poison.

Apparatus for secreting the fluid which concretes in the air.—This apparatus is peculiar to certain arachnidans: it does not exist in the scorpions nor in many other genera; but when present it is always situated at the posterior part of the body. The threads by which the spiders suspend themselves, and of which they spin their webs, are emitted from the extremity of the abdomen. There we find, in the vicinity of the anal aperture, several small appendages, which it is important not to confound with one another, (*fig.* 96.) Of these there are two which are small articulated hairy and filiform processes (*b b*;)* the others are *spinnarets*, or the organs by which the silky threads are emitted. Of the latter, four may generally be counted, (*c d.*) Their structure is very remarkable; it has been described by many anatomists, and among others by Lyonnet in his posthumous Memoirs. This patient anatomist has discovered that the surface of each of the spinnarets is pierced by an infinite number of minute holes, from each of which there escapes as many little drops of a liquid, which, becoming dry the moment it is in contact with the air, forms so many delicate threads. Immediately after the filaments have passed out of the pores of the spinnaret, they unite first together, and then with those of the neighbouring spinnarets to form a common thread; so that the thread of the spider, as it is employed in the manufacture of the web, or such as the creature suspends itself by when hanging from one's finger, is composed of an immense number of minute filaments, perhaps many thousands, of such extreme tenuity that the eye cannot detect them, until they are all twisted together into the working thread. Lyonnet has made a still more curious observation: he detected in *Tegenaria civilis* (Walck.) a different anatomical structure of the four spinnarets. The pair which is above and a little longer than the other, presents on its surface a multitude of small perforations, (*fig.* 97,) the edges of which do not project, and which, therefore, resemble a sieve. This structure has also been well described by Leuwenhoeck, Roesel, Treviranus, &c. The other pair, shorter and lower than the preceding, differs still further by having projecting or mamillary tubes independent of the perforations which also exist and are analogous to those above described. The tubes are hollow, and perforated at the extremity (*fig.* 98, *a*). Lyonnet supposes that agglutinating threads issue from these tubes, while those which are emitted from the perforations do not possess that property. We may observe, indeed, upon throwing a little dust on a spider's web, such as the circular one of *aranea diadema*, that it adheres to the threads which are spirally disposed, but not to those that radiate from the centre to the circumference; the latter are also stronger than the others.

Fig. 96.

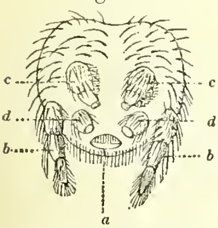


Fig. 97.

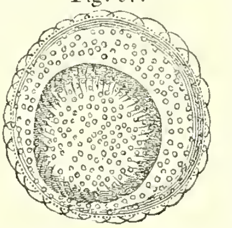

Fig. 98.

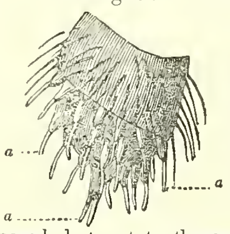

Fig. 99.

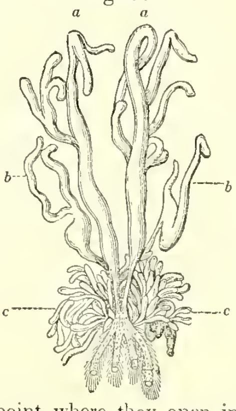


Internally there exists in the abdomen of spiders a special secretory apparatus, which consists of intestiniform canals, united together, and variable in number and extent according to the species. In *Clubione atrox*, they consist, according to Treviranus, of four vessels, two large (*fig.* 99, *a a*) and two small (*b b*); near their base, and not far from the point where they open into the spinnarets, a number of small supplementary canals (*c c*) may be observed. (*Fig.* 96 represents the spinnarets in the same species.)

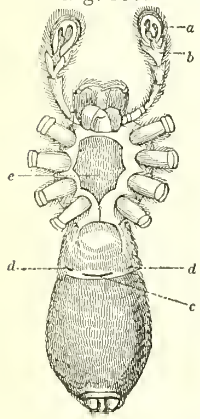
Generative system.—In the arachnidans the sexes are placed, as in insects, in different individuals. It is not always an easy matter to distinguish outwardly the male from the female;

* Mr. Blackwall, who has published some interesting observations on the structure and functions of spiders in the third report of the British Association (1833), and more at length in a recent volume of the Linnæan Transactions, considers these processes to be also spinnarets. They are provided with tubes, which, arranged along the under side of the terminal joint, present the appearance of fine hairs projecting from it at right angles; if examined, when in operation, by a powerful magnifier, the function of these tubes may be ascertained without difficulty, as the fine lines of silk proceeding from them will be distinctly perceived. Mr. B.'s observations were made on *Agelena labyrinthica* (Walck.)—Ed.

but in some cases there exists a well-marked character. The greater part of the araneæ of the male sex have, at the extremity of their maxillary palp, a swelling containing a complicated structure, which is not found in the female. Until lately this protuberance was considered, notwithstanding its anomalous position, as the penis of the male; and even now this opinion is maintained by many naturalists. All observers indeed, both ancient and modern, agree in stating that copulation takes place by means of this part. They have repeatedly observed the fact, and have described the process with all the details that can inspire confidence in their observations. Nevertheless it appears to us certain, if the anatomical facts we are about to disclose are accurate, that there is some mistake on their part, and that what they have taken for the act of copulation was in reality only a prelude to it. It is indeed true th t the male spiders are distinguished from the females by the swelling at the extremity of the maxillary palp, and that that swelling presents a very complicated structure. Treviranus, Savigny, and, earlier than these, Lyonnet, have given detailed figures of it, which may be consulted with advantage: our description will be after that of Treviranus, and from observations made on the common spider, *Tegenaria domestica*.

The male of this species, when arrived at the adult state, presents a considerable dilatation at the extremity of its maxillary palp (*fig.* 100, *a*). On carefully observing this swelling, it is perceived to arise from the penultimate joint (*b*), which is enlarged and spiny. The swelling itself, or what has been termed penis, (*fig.* 100 and *fig.* 101, *a*,) is a concave body from which a membranous, vesicular, and glandiform body (*c*) protrudes, terminated by several horny pieces (*d*), which are curved and project but slightly in this species, but acquire, in others, a considerable development, and protrude in the form of long hooks having a much greater complication of structure.

Fig. 100.



In order that this part should be a penis, as has been supposed, and as many naturalists still believe, it ought to be perforated for the emission of the prolific liquor. Now, Treviranus is certain that it is not perforated by any foramen, and also that there does not exist in the interior of the palp any excretory duct which could have brought to this part the secretion of the testicles. Lastly, and this proof is still more conclusive, on examining carefully the under surface of the abdomen of a male, he discovered at its base, i. e. at the point where it is inserted into the thorax, between the apertures of respiration, and at the part corresponding to the vulvary opening of the female, two very small orifices, placed in a transverse fissure, which he ascertained to be the true outlets of the male apparatus. He found in the interior of the abdomen two cylindrical dilated vessels, which he determined to be the testes. (*Fig.* 102, *b*, *b*.) These two organs open into two long, slender, tortuous, excretory canals (*c*), which terminate at the two orifices of which we have spoken (*a*), but without the appearance of any superaddition of a firm or horny part that can be compared to a penis. From this description it is certain that what has been regarded as the act of copulation, has been only preliminary, and that the introduction of the extremity of the maxillary palp of the male into the vaginal apertures of the female was for the mere purpose of opening the oviducts in order that the actual coitus should be effected with facility and without doubt instantaneously; which explains why no observer has hitherto witnessed the act.*

Fig. 101.

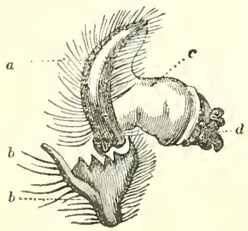


Fig. 102.

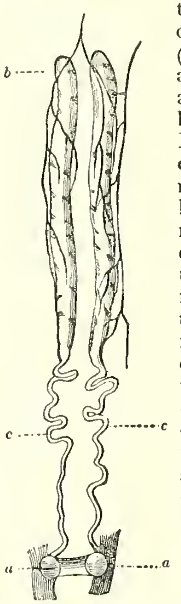


The remarkable sexual differences which obtain in the araneæ are not found in other arachnidans. Thus in the scorpions the maxillary palps have a similar organization in both sexes, being terminated by pincers, both in the male and female, (*fig.* 84, *b*.)

The external aperture of the male apparatus is placed behind the thorax, and manifests itself by the presence of a valve formed by two semicircular pieces (*fig.* 84, *c*.) The internal structure of these organs is but imperfectly known. Treviranus believes that he could distinguish the testicles which terminated at the extremity in a kind of horny penis. Leon Dufour has given a more detailed description of these organs, together with a figure which represents each testis, as being a large network of three meshes formed by cylindrical tubes.

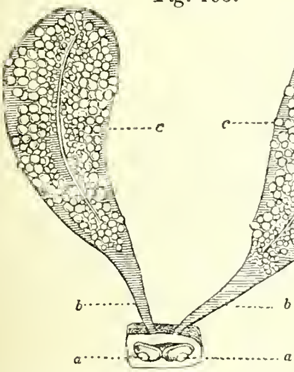
The male, like the female scorpion, presents at the inferior part of the body on either side of

* Mr. Blackwall denies the accuracy of Treviranus's opinion, and supports that of Lister and the older observers, as to the sexual function of the maxillary palp, founding his remarks on observations made on various individuals of the genera, *Epeira*, *Theridion*, and *Agelena*. We must refer for the details to the memoir before quoted from the Transactions of the Linnæan Society.—ED.

the valve certain organs of a singular structure which are called combs, *pectines*, (*fig.* 84, *d*,) on account of the disposition of a series of small appendages of which they are formed, and which are arranged on the lower surface one beside the other, like the teeth of a comb. Many speculations have been offered respecting their uses. Many naturalists believe that they render some assistance in the act of impregnation. Some suppose that they are extended during progression, and prevent the abdomen of the scorpion from trailing on the ground: others, again, regard them as hygrometrical organs, by means of which the animal judges of the humidity of the atmosphere. These are, however, all mere gratuitous hypotheses unsupported by any observation; and the fact is that we have yet to learn the use of these pectinated appendages.

Of the female generative system.—It has been long known that the orifices of the generative organs in female spiders are situated at the base of the abdomen. We observe on that part of the body two distinct cavities, (*fig.* 103, *a, a*,) which are closed by opercular pieces of

Fig. 103.



a more or less solid texture, and it is at this part that the oviducts terminate. In the *tegenaria domestica*, these oviducts (*b, b*) are continued internally in an insensible manner with the ovaries, which consist of a kind of bags (*c, c*) situated on each side of the intestinal canal, and to whose parietes the ova are attached in a racemose manner. In the *epeira diadema* the ovaries are divided by two longitudinal membranous septa, and each is again subdivided by a transverse septum. The longitudinal septum has no orifice, but the transverse one is perforated. There is, therefore, no communication between the principal chambers of each of these ovaries, but there is a passage from the anterior to the posterior division, and the ova which are in the former must pass into the latter before being extruded. This structure explains how it happens that the *epeira diadema* lays its eggs at two distinct periods. Another spider (*theridion quadripunctatum*, Walck.) presents a very analogous organization.

The female generative apparatus of scorpions has not hitherto been studied with that degree of care which it deserves; and there is a considerable difference among authors with respect to this subject; it therefore requires farther examination. Treviranus and Leon Dufour have described these organs as consisting of three elongated tubes; of these, two are lateral and mutually communicate at their apices, the third is mesial and communicates with the lateral by three branches which we observe on either side. All of them, lastly, terminate at the vaginal orifice which is concealed by a more or less rounded plate, and is situated on the middle line of the body anterior to the pectines and between the coxæ of the fourth pair of legs, at the same point where the penis is placed in the male (*fig.* 84, *c*.)

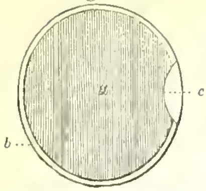
Copulation, oviposition, and development of the ova. Metamorphosis, and reproduction of the extremities.—Natural observers have hitherto given but very few details respecting the manner in which the male spider approaches the female, in accomplishing the sexual act: and we have already observed that they have been deceived in considering a preliminary step as the entire process. The preliminaries are accompanied with very curious circumstances, the account of which may be found in all the memoirs and works which treat of the animals of this class. It will be there seen with what precaution and fear the male makes his approaches to the female, who is always ready to attack and devour him, whether before or after copulation. The majority of the arachnidans deposit their eggs in great numbers. The female guards them with the utmost care, sometimes carries them about with her, and always prepares a silken nest for them which is frequently covered with a solid exterior. Some arachnidans, as the scorpions for example, are ovo-viviparous; the ova are developed in the interior of the body of the female who brings forth her young possessing the faculty of locomotion; but they rest for a certain time attached to the back of the mother, who guards and feeds them, and gives them a kind of education.

The changes which occur in the ova of spiders (araneæ) have been studied with much care. We are indebted to M. Heroldt for highly interesting observations on this subject, published in the work entitled "Exercitationes de animalium vertebris carentium in ovo formatione," folio, Marburg, 1824, from which an extract is given in the Annales des Sciences Naturelles, first series, vol. xiii. p. 250. From the importance of these researches we here present an analysis of them.

The exterior covering of the ovum is formed by a very delicate and transparent membrane, in the composition of which no pore or fibre can be distinguished on microscopical inspection.

Within this membrane there is a liquid matter in which Heroldt has distinguished several essential parts, which in relation to their functions appear to us to correspond to the *vitellus*, the *albumen*, and the *cicatricula* of the egg in birds. An idea of the disposition and size of these parts may be formed by inspecting the subjoined figure (*fig.* 104),

Fig. 104.

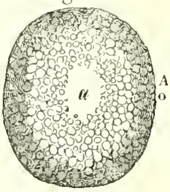


representing a vertical section of a fecundated ovum at the moment of exclusion, and before any organ has been developed. The *vitellus* or yolk (*a*) forms the greatest part of the contained liquid matter, and the egg is almost entirely filled by it: its colour is generally that of yellow ochre, and sometimes has a saffron tinge. In some species the yolk is grey, white, or reddish brown; and in each case the colour of this part determines the general tint of the egg. If the yolk be considerably magnified, it is seen to be composed of an infinite number of minute globules of various sizes, swimming in the albumen, or surrounded by it, and resembling so many small yolks.

The *albumen* (*b*) is a transparent crystalline liquid, without distinct organical parts, and consequently not presenting any globules, surrounding the vitellus as far as the cicatricula, and intermediate in bulk or quantity to these. If an ovum be opened, and the liquid which it contains be poured out upon glass, the albumen is seen to surround the globules of the vitellus and cicatricula exactly as the serum of the blood envelopes the crassamentum. In the interior of the egg the albumen is situated, like the cicatricula, externally to the yolk, and fills the interspace between the yolk and the exterior membrane of the egg. It is in this interspace that the first lineaments of the embryo appear, and here the head, thorax, members, integuments, and their appendages, and all the internal organs, without excepting the intestines, are successively developed.

The *cicatricula* or *germ* (*c*) is the smallest and most important part of the ovum. It is situated immediately beneath the exterior covering, and at the centre of the circumferenee of the egg. It is distinguished by the naked eye in the form of a little white point. If it be examined with more care, we perceive that it is of a lenticular figure, and is composed of an innumerable quantity of whitish granules. Under the microscope these granules are seen to be of a globular figure, somewhat similar in this respect to those of the yolk, but more opake, and of a smaller diameter. When segregated and diffused they present a striking analogy to the grains of pollen, but with this difference, that the pollen of vegetables is composed of vesicles filled with organic molecules, whilst each of these globules of the cicatricula must be regarded as simple. The cicatricula or germ is the centre of radiation of all the changes which take place in the ovum. All the parts which it contains seem subordinate to it, as we shall see by carefully tracing their development. A remarkable fact observed by Heroldt in the ova of some undetermined species of spiders is this, that in place of a single cicatricula, there appear to be several spread over different points of the surface of the ovum; but these small germs rapidly coalesce into one mass, which soon assumes the ordinary form of the single cicatricula. The component parts of the ovum being known, we proceed to the metamorphoses which they undergo up to the time when the young spider breaks through the shell.

Fig. 105.

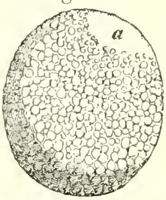


First period.—The impregnated ovum being deposited, and the temperature being favourable, development commences. The changes always begin at the margins of the cicatricula, which appear to be resolved into granules, which extend into the albumen and vitellus. The centre of the germ remains the same, the only appreciable difference is the enlargement of its circumference: (A, gives the natural size of the ovum.)

Second period.—The germ is much larger, its margins are dispersed in numerous granules; the centre is not yet affected by this tendency to molecular dispersion, but has undergone a notable modification. It changes its situation and begins to move towards the extremity of the ovum, leaving in the place which it formerly occupied a train of globules; it now, to compare small things with great, bears some resemblance to a comet, the nucleus of which is represented by the centre of the germ; the tail, which is formed by the dispersion of the globules, is transparent, and the vitellus which it covers may be as distinctly seen through it as the fixed stars through the tail of a comet.

Third period.—The nucleus of the germ (*fig.* 106, *a*), which has continued to change its place, is arrived near the extremity of the ovum, but has not quite reached it. The tract which it has traversed is marked by an infinity of granules, which are then so much disseminated that they extend almost to the opposite extremity of the ovum. It is then that the kind of comet which it represents is seen at its greatest development, and with all the characters that have been indicated. The movement of the nucleus of the cicatricula authorizes the supposition that that body has not, at least at the earlier periods, a very intimate connexion with the vitellus.

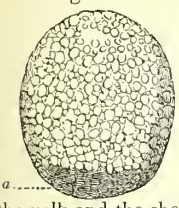
Fig. 106.



Fourth period.—The nucleus of the germ has not gone beyond the point which it had attained, but it presents a new change. The molecules are disseminated into an infinity of granules, nothing remains of the comet but the tail, which is still more extended; but we see then that the granules dispersed in the albumen have a tendency to reassemble at the point where the germ was originally situated.

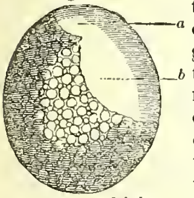
Fifth period.—The germ of the ovum, which appears to be disseminated in the albumen, has undergone a very curious transformation. Its nucleus has disappeared, all its granules are decomposed into almost imperceptible molecules, which, in destroying the limpidity of the albumen, have given it a clouded appearance, through which, however, the globules of the vitellus may be distinguished. A single point remains perfectly transparent, and this is observed at the extremity of the egg (*fig.* 107, *a*,) opposite to that which the germ occupied after its displacement. Heroldt calls this clouded albumen *colliquamentum*. Up to this period the vitellus seems not to undergo any change; all that has been hitherto observed takes place in the albumen and in the circular space between the yolk and the shell.

Fig. 107.



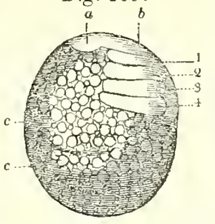
Sixth period. — The colliquamentum, or clouded albumen, which was extended over the yolk so as to conceal it, is now concentrated upon the point last occupied by the nucleus of the germ, and has assumed a pearly colour (*fig.* 108). Its consistence is pretty solid; it is opake, so that the globules of the yolk can no longer be distinguished through it, although they are elsewhere more conspicuous on account of the retreat of the clouded albumen towards this single point; from this moment the colliquamentum, which seems to have changed its nature, receives a new name, and is designated by Heroldt the *cambium*. The cambium covers more than a fourth part of the circumference of the yolk; its form is already pretty well marked, and two parts may be distinguished in it; one large (*b*), the other small (*a*), which are separated by a kind of contraction. The form of the larger division is elliptical, and it is in its substance that the thorax, the legs, and the essential internal parts of the fœtus will soon be perceived to develope themselves. The smaller division is of a rounded form, and seems, as it were, an appendage to the preceding; it is destined to give origin to the head, the organs of sense, and the appendages of those of mastication. So much being premised, we may call, with Heroldt, the larger division *cambium thoracicum*, the lesser one *cambium cephalicum*. We may also, for the better comprehension of the changes which are about to succeed each other, divide the superficies of the ovum into four regions. That which contains the cambium may be called the *pectoral* region, the opposite portion may be called the *dorsal*, and the two intermediate parts the *lateral* regions. We may observe that in other species of araneæ where the ova are spherical, the germ is at once converted into colliquamentum, and then into cambium, without a change of situation. The *Aranea diadema* offers an example of this circumstance; in other respects there is no important difference observable.

Fig. 108.



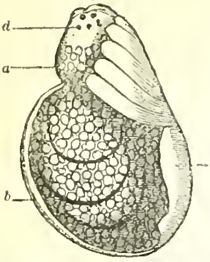
Seventh period.—The two portions of the cambium, the cephalic and thoracic, have as yet presented only the appearance of an opake and homogeneous mass, but now we may distinguish traces of rings, four in number on either side; these are the rudiments of the legs. (*Fig.* 109, 1, 2, 3, 4.) They occupy the lateral aspects of the anterior part of the ovum; they are also visible on the pectoral region, towards which they are prolonged inferiorly. The extremity of the first leg is contiguous to that of the opposite side; but the three others, though of greater length, yet do not reach so low down, but leave a triangular interspace between them, which is filled with a cloudy and somewhat transparent matter, through which the vitelline globules are visible. This triangular space, which is subsequently to be covered by the legs, seems to give origin to the trunk and to many parts contained in the abdomen. In tracing the two portions of the cambium through the changes which they have undergone, we find that the thoracic portion is represented by the legs and their intermediate space, and that the cephalic portion is anterior to this. The alterations of the latter part are not less remarkable; instead of being rounded anteriorly it is truncated, and we may perceive a ring at the sides, which is not divided on the inferior middle line of the body, and which represents the maxillary palps (*b*). One may even distinguish, as if through a cloud, the rudiments of the mandibles. It is probable that all the parts which appertain to the head, as the eyes, the mandibular hooks, and the maxillæ, have their limits well defined from this period. With respect to the head, (*a*) it is neatly separated from the chest; and this fact it is of importance to dwell on, since in all the full-grown spiders the confluence of the two parts is most intimate, and their original separation only indicated by a groove of greater or less depth. The ovum, also, now presents some other new appearances; these are a kind of furrows or arched folds (*c c*), which are seen on the vitellus behind the legs; and which deserve attention, since they indicate the formation of the common teguments of the fœtus. And we must here observe that the parts which are already developed have an intimate connection with the vitellus. Thus if an ovum be opened with all the precautions requisite for so delicate an operation, and if the matter of it be extended on a piece of glass, we see that the parts formed in the cambium preserve their general figure, and that the internal layer of the mucous and whitish matter of which it consists is in intimate communication with the vitellus. It is implanted upon the yolk just as fungi and other parasitic plants are attached to the trunk of a tree: the yolk, then, is subservient to the nutrition of the most exterior parts of the body.

Fig. 109.



Eighth period.—The exterior parts which are developed in the cambium, viz. the feet, the mandibles, and the head, are more neatly defined. The ovum (*fig.* 110) now presents a

Fig. 110.



very important peculiarity, but which was in some measure indicated in the preceding period. Its size is slightly diminished anteriorly, and the vitellus consequently is divided into two portions. The smaller and anterior part *(a)* is readily distinguishable from the dorsal part of the fœtus, and occupies the place which subsequently becomes that of the corslet; M. Heroldt consequently terms it the *thoracic region*. The other part is the *abdominal region*, which is very conspicuous, occupies more than one-half the bulk of the ovum, and seems to constitute the greatest portion of the abdomen. If the inferior surface of the abdominal region be examined, there will be seen, in addition to a spot which ornaments that part, some additional oblique and curved folds, which indicate the formation of the integuments; another and a more important change has now taken place on the middle line of the superior surface; viz. an obscure straight band *(b)* which commences at the thoracic-abdominal constriction, and reaches to the extremity of the ovum, becoming gradually narrower in that direction. This band, which does not give off lateral processes in any part of its course, is to be considered as the rudiment of the heart or dorsal vessel. The fluid which it doubtless contains in its interior is motionless. Heroldt thinks that the formation of the fluid is anterior to that of the parietes in which it is enclosed: he also believes that it is the albumen which gives origin to the circulatory apparatus, and further attributes to it the origin of all the integuments. These are, doubtless, important questions to solve, but as they are the result of speculation rather than direct observation, we have deemed it proper to omit the theories by which they are supported, and confine ourselves to a simple enunciation of the facts The eyes *(d)* are now distinguishable.

Ninth period.—The ovum presents a more sensible diminution anteriorly, and is more distinctly divisible into two parts. The anterior and narrow portion constitutes the smaller extremity, and includes the head, the thorax, and their appendages; the other portion, which is spherical and of much larger size, constitutes the greater extremity and corresponds to the abdomen. At the same time that these modifications take place the ovum becomes slightly elongated, and all the parts which can be distinguished therein have proceeded towards their perfection. The legs now present slight traces of a division into joints, and they have increased so far in length that they cover almost the whole of the lower surface of the thorax.

Tenth period.—The small extremity, which is still more elongated, is now found to be distinguished from the large one by a true constriction, dividing the ovum into the parts denominated in the perfect spider 'thorax' and 'abdomen.' The visible parts of the thorax are the mandibles, the palpi, and the legs; these latter appendages are folded upon the chest, and have grown so long as to cross the middle line of the body; they are locked in the interspaces of each other, like the fingers when the hands are clasped together. The abdomen presents nothing remarkable, except the elongated opake streak which exists along the middle of the inferior surface from the feet to the termination of the abdomen, and which was already visible at the preceding periods. (*Fig.* 110, *e.*) Heroldt imagines this streak to be an indication of the development of the internal parts of the abdomen, viz. the intestinal canal, the secreting vessels of the web, and the genital organs, &c. In proportion as the fœtus increases, the external membrane or covering of the egg is applied more exactly to its body, and seems to represent an exterior skin, of which the young spider soon divests itself, almost in the same manner as the caterpillar sheds the skin in which it is enveloped.

Eleventh period.—By the progressive increase of the fœtus the membrane of the egg becomes so much stretched, and is applied so exactly to the surface of the body of the animal that the different parts can be distinctly seen through it, like the nymph or chrysalis of certain coleopterous insects. The essential parts of the thorax are the head and the feet. The head is of a white colour, and is surmounted by eight brown streaks; the legs, which are also white, are closely applied to the chest, with their extremities alternating with each other. One may distinguish in each a hip, a thigh, a leg, and a tarsus. The articulations of the palps and mandibles are also visible through the general envelope of the egg. The inferior streak of the abdomen is much more extended, and seems to be divided into two parts, one large and elliptical in figure, the other small and rounded; the latter corresponds to the anal aperture; at this last stage of the development, the fœtus or the imprisoned young spider, as it may be called, gives no sign of motion.

Exclusion or hatching of the spider.—At length the spider bursts the egg by tearing through the exterior membrane. De-Geer* has described this phenomenon. The outer membrane or pellicle of the ovum becomes fissured along the corslet, and the spider protrudes by this aperture, first the head, the mandibles, the thorax, and abdomen, after which there remains the more difficult operation of extracting the legs and maxillary palps from that part of the outer membrane with which these parts are, as it were, enveloped. This is at length effected, though slowly, by alternately dilating and contracting the body and legs, upon which the animal is liberated, and capable of progression. In proportion as the parts are disengaged from the pellicle, it is pushed towards the extremity of the legs, and is reduced to a little white bag which is all that remains. Sometimes the pellicle is found still slightly adherent to the ab-

* Mém. sur les Insectes, t. vii. p. 195.

domen, but the spider soon entirely frees itself from it. This is the mode in which the young spiders of every species disembarrass themselves of the egg-covering, and the operation is analogous to that of moulting. This is, however, only the first birth: all the parts of the spider, the head, the jaws, the legs, the abdomen, are still enveloped by a membrane which furnishes to each a sort of sheath. The spider is embarrassed in all its movements; it changes its situation with apparent pain, and is unable to construct a web and seize its prey: it seems indeed to be stupified and indisposed to action. To this end, and in order to be fit for locomotion, it is necessary that it should free itself of this other covering; and it is only then that it can be said to see the light. This last operation, or as it may be termed the first moult, takes place after a period, varying according to the degrees of atmospheric heat and moisture. Sometimes it is observed within the first week, at others it is not effected before the end of several weeks. In every instance the moult takes place in the woolly nest or general envelope of all the eggs, and the young spider does not quit this common nest, except in fine weather, generally in the months of May and June.

Before arriving at the adult state the spider changes its skin many times, and even after that period it is still subject to moults, which occur every year in the spring, and after the exclusion of the eggs. Up to the present time it has been admitted that the Arachnidans, from the moment of their exclusion to their adult state, undergo no metamorphosis, but are subject only to the moultings of which we have just spoken. This circumstance has even been employed by zoologists as a character distinguishing the arachnidans from the class of insects, which generally undergo metamorphoses in passing through the conditions of the larva and chrysalis. The observation holds good for the greater part of the Arachnidans, but there are many of this class, which, in passing to their adult condition, undergo changes which cannot but be compared with the metamorphoses of insects. Such, for example, are many of the *acaridæ*, upon which M. Dugès has recently fixed the attention of naturalists.*

We cannot conclude the present article, without briefly noticing a very curious physiological phenomenon which has been observed in the Arachnidans, and which has long been noticed in the class Crustacea: we allude to the faculty which these animals possess of reproducing their limbs when these have been accidentally lost. This property, which belongs to the spiders, (*araneæ*,) was generally doubted, until a distinguished naturalist, M. Lepelletier, published the result of his experiments; the fact is of too much importance in science not to be dwelt upon with some detail. Spiders which have lost a limb, according to this observer,† are always found to have lost it entirely, that is, the femur, tibia, and tarsus, are all wanting. A portion of a leg is never found detached at one of its joints, nor broken off between two joints, nor the femur remaining adherent to the body by itself, or with the tibia, the rest of the leg being lost. If by accident a spider should be met with in any of these conditions, it is either dying or dead. But M. Lepelletier remarks that those which have lost one or more entire legs, are not less lively on that account.

To explain these circumstances our author commenced a series of experiments on spiders, in the year 1792, with the following results:—

The smallest wound in the thorax or abdomen of a spider is mortal, and that in a very short time, on account of the loss of the internal nutrient fluid, which cannot be staunched.

If a leg of a spider be cut off with a sharp instrument either at one of its joints, or in the interval of two, leaving a part of the limb adhering to the body, the spider appears to suffer considerably; it endeavours to tear off the rest of the leg; if it succeeds, it again acquires its powers of moving, and the hemorrhage soon ceases; in the contrary case it perishes in twenty-four hours.

The luxation of one of the joints, or the fracture of the femur or tibia in the middle are equally mortal, if the spider does not soon disembarrass itself of the leg which has received the injury.

It is necessary here to make a remark upon the anatomy of the legs of spiders and crustaceans; they have the first joint short, which connects the leg to the thorax; M. Lepelletier calls this the haunch, *coxa*. If a spider be seized by the extremity of one of its legs, and is left at liberty to make its efforts to escape, the leg will be separated from the body at the junction of the *femur* with the *coxa*; and the same thing takes place when the body of the spider is held fast, and the leg is pulled off. In both these cases the spider seems not to suffer pain; it experiences only a very little loss of the internal fluid, and does not die in consequence; it spins, seizes its prey, and oviposits in the ordinary manner.

The preceding facts are applicable to all spiders, (*araneæ*,) and M. Lepelletier has observed them repeatedly in many of the common species. The following experiments have been made only on the domestic spider, (*Tegenaria domestica*, Walck.) because it can be preserved in a lively condition, and for many years in a glass vessel.

We have successively observed a great number of individuals of this species which were mutilated of one or more legs. It was not without surprize that the author of this article observed the first spider that was experimented upon, and which wanted a leg, change its skin, and after that operation reappear with eight legs. The like occurrence was frequently observed; the new leg was two or three lines in length when it first appeared, that of the opposite side being less than an inch: each of the joints of the former continued to grow during the whole of the year.

* See his interesting Memoir in the Annales des Sciences, Nouv. Serie, tom i. and ii., 1834.

† See Bulletin de la Societé Philomathique, Paris, Avril, 1813.

The general result of these observations, and of many others of the same kind, is, 1st, that the legs of spiders can be reproduced when they have been torn off; 2d, that this reproduction can only take place when the limb has been detached as high as the moveable base; for otherwise an hemorrhage supervenes which kills the animal; 3d, that the reproduction takes place only at the time of the moult, and that the new leg is at first slender, but with all its parts or joints, each of which increases progressively, until the whole has acquired its natural relative size.*

(Victor Audouin.)

ARM. (Surgical anatomy.) (The arm, Gr. Βραχιων. Lat. *Brachium*. Fr. *Bras*. Germ. *Oberarm*. Ital. *Braccio*.) The ancients applied this term to the whole of the upper or thoracic extremity collectively, as most persons do in ordinary discourse, at the present day; but in anatomical language the term is restricted to that section of the upper limb included between the shoulder and the elbow. The arm taken in this limited sense is somewhat cylindrical, a little flattened, however, on its internal and external surfaces, particularly towards its middle; it varies much in its proportions as to length and volume: it is more rounded in fat persons, and especially in females, in whom it assumes more or less of a conoid form, tapering towards its lower part. (See *fig.* 1 and 2, p. 3.) The arm is composed of a single bone, the humerus, several muscles, bloodvessels, absorbents, and nerves connected together by cellular tissue, and inclosed in an aponeurosis, which lies immediately beneath the common integuments. Viewing the arm extended, the hand being placed in a state of supination, we observe at its superior and external part a prominence of a triangular form, the base of which is superior; this is formed by the deltoid muscle, and is bounded before and behind by two slight grooves, which unite below in a depression called deltoid fossa, situated immediately over the insertion of the deltoid muscle; this deltoid fossa is the most eligible part of the arm for the insertion of issues, as it contains a considerable quantity of cellular tissue, affording a favourable bed for the reception of peas or other bodies inserted for the purpose of exciting suppuration, while it possesses this additional advantage, that no muscular fibres extend across it, whose contractions might have the effect of deranging the surface of the ulcer or the dressings necessary to be applied to it, and thus causing an unnecessary degree of pain. From the deltoid fossa a superficial depression extends along the outer edge of the arm, and terminates in the triangular fossa in front of the bend of the elbow: along the course of this depression blisters are frequently applied by the Parisian and other continental physicians in inflammatory affections of the thoracic viscera, a mode of treatment not generally employed in such cases by the physicians of this country. Another depression extends along the inner side of the arm from the axilla to the hollow in front of the elbow, where it joins the external depression. Between these two depressions there is an oblong prominence anteriorly, formed by the biceps muscle, and a more flattened prominence intervenes posteriorly, formed by the triceps which occupies the whole of the posterior surface of the arm.

Skin and subcutaneous tissue. — The skin covering the arm is soft and delicate; sebaceous glands and hairs are not very evident on it, especially in front; it is thicker and stronger, however, on the posterior surface. The basilic vein is generally visible at the lower part of the internal brachial depression, and the pulsations of the brachial artery may be felt along the whole of its course: the cephalic vein is sometimes visible, especially in thin persons, along the course of the external brachial depression. As the skin of the arm is loosely connected to the subjacent parts, the edges of simple incised wounds in this region are easily retained in contact. The subcutaneous layer of cellular tissue or superficial fascia contains more or less adipose substance, in greater abundance in women and children than in men, and in greater quantity in the depressions than over the muscular prominences; the filaments

* Mr. Blackwall, in the paper already referred to, has related an accidental discovery of the power of some spiders to abstract respirable air from water. Several individuals have preserved an active state of existence under water for six, fourteen, or twenty-eight days, spinning their lines and exercising their functions as if in air, while others have not survived for a single hour.—Ed.

of the cutaneous nerves of the arm and the superficial veins and absorbents lie imbedded in it: thus the cephalic vein and twigs of the external cutaneous nerve appear along the outer edge of the arm, and along the inner edge are found the internal cutaneous nerve, the brachial branches of the second and third intercostal nerves, the cutaneous nerve which arises from the ulnar high in the axilla, the basilic vein, and a few lymphatic glands, which lie at from one to three inches above the internal condyle.

Aponeurosis. — Beneath the subcutaneous layer of cellular tissue lies the aponeurosis or fascia, which invests the muscles and the deep-seated vessels and nerves of the arm: this fascia commences above at the superior attachment of the deltoid muscle; externally and internally it is continuous with the fascia, which extends over the axillary space; descending along the arm it is strengthened by expansions which it receives from the tendons of the deltoid, pectoralis major, and coraco-brachialis in front; and behind it derives an accession of strength from the aponeurosis which covers the infra-spinatus and teres minor, and from the tendons of the latissimus dorsi and teres major. At the lower part of the arm the fascia is attached to the condyles of the humerus; laterally and posteriorly it is attached to the olecranon, on either side of which it is continuous with the fascia on the posterior surface of the fore-arm. In front of the elbow this fascia receives a fasciculus of fibres from the tendon of the biceps, and becomes continuous with the fascia covering the anterior surface of the fore-arm. The fascia of the arm varies in strength in different parts; it is very indistinct over the deltoid, thin but very fibrous on the posterior surface of the arm where it covers the triceps; it is much stronger over the biceps, and the thickest portion of it is found along the inner edge of the arm, where it covers the brachial artery and its accompanying veins and nerves. A strong aponeurotic septum passes in from the fascia of the arm to each of the lateral ridges of the humerus; these septa are called intermuscular ligaments, and, together with the humerus, divide the space included within the general fascia into an anterior and a posterior sheath; the external intermuscular ligament extends from the insertion of the deltoid to the external condyle; the internal extends from the insertion of the coraco-brachialis to the internal condyle. Both intermuscular ligaments are narrowest above, and grow broader as they approach the condyles: their surfaces give attachment to fibres of the triceps posteriorly and to the brachiæus anticus, supinator radii longus, and extensor carpi radialis anteriorly. The posterior sheath, formed as above described, is chiefly occupied by the triceps muscle, beneath which, in the spiral groove on the posterior surface of the humerus, lie the musculo-spiral or radial nerve and the superior profunda artery: this nerve and the anterior or musculo-spiral branch of the superior profunda artery perforate the external intermuscular ligament and enter the anterior sheath of the arm to get between the brachiæus anticus and supinator radii longus, while the posterior branch of the profunda descends within the posterior sheath to the back part of the external condyle; the ulnar nerve and the inferior profunda artery enter this posterior sheath together at its internal side, about the middle of the arm, and descend within it to the back of the internal condyle. A considerable branch of the brachial artery, the ramus anastomoticus, perforates the internal intermuscular ligament above the internal condyle, and enters the lower part of the posterior brachial sheath. The anterior sheath of the arm contains the biceps, coraco-brachialis, brachiæus anticus, and the origins of the long supinator and long radial extensor muscles; the external cutaneous nerve traverses this sheath, perforating the coraco-brachialis above, and descending obliquely outwards between the brachiæus anticus and the biceps it gets to the outer side of the latter, between the tendon of which and the supinator radii longus it pursues its course to the fore-arm; the radial nerve and the branch of the superior profunda artery accompanying it are to be found in the lower and external part of the anterior sheath, which they enter as above described: these lie deep between the brachiæus anticus and supinator longus. Along the internal side of this anterior sheath, through its whole extent, run the brachial artery, and its two venæ comites included in a sheath proper to them, and accompanied by the median nerve, which has very important relations to these vessels: this nerve is external to the artery above, crosses it in the middle of the arm, and lies internal to it below. Superiorly the ulnar nerve lies to the inner side of the brachial artery, from which it separates to enter the posterior sheath, as already noticed; the internal cutaneous nerve, the cutaneous twig of the ulnar nerve, and the basilic vein for a short part of its course before it enters the brachial vein, also lie within this sheath; and deeply situated in its lower part is the ramus anastomoticus magnus of the brachial artery.

Developement. — In the progressive developement of the upper extremity in the fœtus, the arm is formed subsequently to the hand and fore-arm, and at an earlier period than the shoulder. In men the deltoid is fuller, and the biceps in front and the triceps behind are more prominent than in women: the greater fulness of these two latter muscles, with the smaller quantity of subcutaneous fat, give to the male arm a greater diameter from before backwards than in the transverse direction; while the more slender character of the muscles and the greater abundance of subcutaneous fat laterally cause the arm of the female to assume a more rounded form. In the course of the brachial artery two trunks are often found to exist, in consequence of a high branching of that vessel, which sometimes occurs even at the lower border of the axilla: the supernumerary branch in such cases is most frequently the radial: in some instances it is the ulnar and less frequently the interosseous or median artery of the fore-arm. When this irregularity occurs, the brachial artery usually preserves its ordinary relations to the surrounding parts, while the supernumerary trunk lies to its internal side and takes a more superficial course, sometimes getting above the fascia of the arm, as we have witnessed in a few rare cases. It occasionally happens that the brachial artery divides at its commencement into two trunks, which again unite at its lower part. It is obvious that the surgeon, in performing operations on this artery, should constantly bear in mind that it is subject to the above-mentioned irregularities, and that he should cautiously guard against committing the error of including the wrong vessel in his ligature.

The internal side of the arm in the middle of its length is the most eligible place for making compression on the brachial artery; here this vessel is superficial, so that its pulsation can be felt at once, whilst it has nothing interposed between it and the bone but the tendinous insertion of the coraco-brachialis muscle. It happens, however, that the median nerve lies immediately over the artery in this situation, a circumstance which causes compression of the latter to be attended with considerable pain, and productive of injury to the nerve if maintained for too great a length of time.

As the trunk of the brachial artery and several large nerves traverse this part of the arm, it is obvious that wounds in this region are liable to be attended with more serious consequences than those of any other part of the arm. A wound in the posterior region of the arm may be attended with considerable hæmorrhage, if it should happen to penetrate so deep as to divide the profunda artery, or it may cause paralysis of the extensor muscles of the hand and fingers by dividing the radial nerve.

When the humerus is fractured, the consequent derangement of the fragments varies according to the part at which the bone happens to be broken; when fracture occurs immediately above the insertions of the pectoralis major and latissimus dorsi, the lower fragment is brought inward towards the axilla by the action of these muscles, and drawn upwards by the action of the deltoid, biceps, coraco-brachialis, and long head of the triceps, whilst the extremity of the upper fragment is rather turned outwards by the supra-spinatus. In cases where the humerus is fractured immediately above the insertion of the deltoid and below the attachments of the latissimus dorsi and pectoralis major, the deltoid will draw the lower fragment upwards and outwards, whilst the upper fragment will be drawn inwards towards the axilla by the pectoralis major and latissimus dorsi. If the bone be broken immediately below the insertion of the deltoid, little or no displacement of the fragments may ensue, as the opposing forces exercised on the superior fragment by the deltoid on the external side, and the pectoralis major and latissimus dorsi on the internal, pretty nearly counterbalance each other; it more generally happens, however, that the upper fragment is turned outwards by the preponderating action of the deltoid upon it, whilst the lower fragment is drawn upwards by the action of the biceps, coraco-brachialis, and triceps. Fractures of that portion of the humerus which is covered by the brachiæus anticus in front and the triceps behind, are often unattended by any very obvious displacement, in consequence of these muscles being inserted into both fragments; fractures near the elbow are occasionally followed by deformities presenting some of the characters of dislocations of the elbow, of which more notice will be taken in the article Elbow.

General inflammatory enlargement of the arm is rare; it sometimes appears as a concomitant affection with inflammation of the veins of the arm consequent on the operation of phlebotomy, in which case it not unfrequently happens that abscesses form along the course of the sheath of the brachial artery; red streaks along the course of the lymphatics and enlargement of the lymphatic glands are sometimes present in consequence of disease or inflammation affecting the hand or fore-arm.

Amputation of the arm below the insertion of the deltoid may be performed either by the circular incision or the double flap; when the latter method is practised, the flaps should be formed on the external and internal sides, by which the more important vessels and nerves will be included in the internal flap.

When circumstances require the performance of amputation above the insertion of the deltoid, the circular operation should never be practised, for the following reason;—in order to obtain a sufficiency of covering for the bone, the pectoralis major, latissimus dorsi, and teres major would all be detached from their insertions, a consequence of which would be that the contractions of these muscles in opposite directions, by drawing asunder the edges of the wound, would not only render complete apposition difficult in the first instance, but moreover their continued action would have the effect of converting the wound into an ulcer, which it would be extremely difficult if not impossible to heal; therefore, whenever we have to amputate so high up, it is the more judicious mode of proceeding to make a flap including so much of the deltoid muscle as will form a sufficient covering for the stump. The importance of attending to the foregoing circumstances was first pointed out by Louis, the learned secretary to the French Academy of Surgery.*

The arteries which require to be tied after amputation of the arm below the insertion of the deltoid are the brachial and inferior profunda on the internal side; on the external side there are often two branches of the superior profunda requiring a ligature, one of which accompanies the musculo-spiral nerve, and the other runs in the substance of the triceps.

When it becomes necessary to tie the brachial artery on account of a wound or aneurism, the varieties of its relation to the median nerve should be carefully borne in mind; at the upper part of the arm this artery has the median nerve external to it, and the ulnar nerve to its inner side; in the middle of the

* Mémoires de l'Academie de Chirurgie, tom. v.

arm the median nerve crosses the artery in general superficial to it, but sometimes underneath it, while in the lower part of the arm this nerve is invariably on its inner side.

When called upon to expose the brachial artery for the purpose of tying it, the surgeon should recollect that the course of the artery may be readily determined by a line drawn from the coracoid process to a point midway between the condyles of the humerus on the anterior surface of the elbow; hence his incision for the purpose of exposing the brachial artery should be always made along the course of this line and perpendicular to the axis of the os humeri. (See Brachial Artery.)

For Bibliography, see Anatomy (Introduction.)

(John Hart.)

ARM, MUSCLES OF THE.—The muscles which clothe the os humeri are part of the *deltoid*, the *biceps*, *coraco-brachialis*, *brachiæus anticus*, the origin of the *supinator longus* in front, and the *triceps* behind.

The deltoid belongs to the shoulder, and will be described with the other muscles of that part. (See Scapular Region.)

1. *Coraco-brachialis (coraco-humeral).*—The coraco-brachialis arises from the point of the coracoid process, in common with the short head of the biceps, tendinous in front and fleshy behind; it separates from the biceps at its middle third, passes inwards, and is inserted tendinous into the internal surface of the humerus a little above its middle between the triceps and brachiæus anticus.

This muscle has in front of it the deltoid and pectoralis major, which cover and conceal from view its upper part; behind it the tendon of the subscapularis, the tendons of the latissimus dorsi and teres major, the axillary artery, the median and the external cutaneous nerves. The latter nerve perforates the muscle about its middle, and passes through its substance to reach the outer side of the arm; hence the epithet *perforatus* has been applied to this muscle. The coraco-brachialis can carry the arm forwards and inwards; when the humerus is fixed, it can act upon the scapula, and by depressing its coracoid angle, elevate the inferior angle and separate it from the ribs.

2. *Biceps flexor cubiti (scapulo-coraco-radial).*—This is a long muscle swollen in the centre, divided above into two portions called heads, one internal short, the other external long. The internal or short head arises from the coracoid process of the scapula in common with the coraco-brachialis. The long head is attached by a long slender flattened tendon to the upper part of the margin of the glenoid cavity, and is united by a dense cellular tissue to the glenoid ligament. This tendon passes over the head of the humerus, and enters the groove between the two tuberosities in which it is bound down by the fibres of the capsular ligament of the shoulder-joint; a prolongation of the synovial membrane also lines the groove, and forms a synovial sheath for the tendon; the tendon terminates in a fleshy belly which unites with the short head to form the large belly of the biceps; the muscle terminates below in a tendon, which, passing over the brachiæus anticus and the front of the elbow-joint, sinks into a triangular hollow between the pronator teres and supinator longus to be inserted into the back part of the tubercle of the radius; but before it sinks into this triangular space, it sends off from its internal side an aponeurosis (the *semilunar fascia* of the biceps), which is inserted into the internal coudyle, and the fascia which covers the muscle at the inner side of the bend of the elbow.

The biceps is covered by the deltoid, the pectoralis major, the fascia of the arm and integuments in front; behind it lies on the humerus, coraco-brachialis, brachiæus anticus, and the external cutaneous nerve; internal to it lie the coraco-brachialis and brachial artery. It bends the elbow and makes tense the fascia of the fore-arm; it is also a very powerful supinator of the hand by virtue of its insertion into the radius. If the fore-arm be extended and fixed, it will depress the scapula on the humerus.

3. *Brachiæus anticus (B. internus, humerocubital).*—When the biceps has been raised from its situation, we observe the brachiæus anticus deeply situated on the front of the arm; it arises by two fleshy tongues, one on each side of the insertion of the deltoid; from the whole of the anterior surface of the humerus, and the internal intermuscular ligament which separates it from the triceps, its fleshy fibres pass downwards in front of the elbow, and end in a broad tendon which is inserted into a triangular roughness on the anterior surface of the coronoid process of the ulna. This muscle is covered in front by the biceps, supinator longus, the fascia of the arm and integuments, the musculo-cutaneous and median nerves, the brachial artery, and the pronator teres; behind it covers the front of the lower part of the humerus and the elbow-joint. This muscle is the most powerful flexor of the fore-arm upon the arm. As Bichat remarks, flexion of the fore-arm takes place *directly* if the brachiæus combines its action with that of the biceps; if either acts alone, the flexion is in the direction inwards or outwards; inwards when the biceps acts alone, outwards when the brachiæus.

4. *Triceps extensor cubiti (brachiæus posticus, tri-scapulo-humero-olecranien.)*—The triceps muscle of the arm is situated on the posterior surface of the humerus, and, as its name implies, has its origin by three heads. The long head arises by a short, flat, thick tendon from a rough portion of the inferior costa of the scapula, immediately below the glenoid cavity, and passing downwards in front of the insertion of the teres minor, and behind the teres major it forms a large belly, which covers the posterior surface of the os humeri. The second or short head arises from the outer and back part of the os humeri, beginning by a pointed origin immediately below the insertion of the teres minor; it continues to arise from the external ridge of the humerus as low down as the external condyle; from the surface of the bone behind this ridge, and from the back part of the external intermuscular ligament. The third head, which is the shortest, called

brachiæus externus, arises by an acute point from the internal ridge of the os humeri, beginning immediately below the insertion of the teres major; it also arises from the internal ridge as far down as the internal condyle, from the surface of the humerus behind this ridge, and from the posterior surface of the internal intermuscular ligament. The three heads unite above the middle of the os humeri, and cover the whole of the back part of that bone; they form a thick broad tendon, which is inserted into the rough surface on the superior part of the olecranon process of the ulna, adhering closely to the ligamentous fibres covering the posterior surface of the synovial membrane of the elbow-joint; the lowest fibres of the second and third heads of this muscle, which arise from the back of the condyles, run nearly horizontally into the tendon.

The triceps is covered posteriorly by the teres minor, deltoid, fascia of the arm and integuments; in front it is in contact with the posterior surface of the humerus, the intermuscular ligaments, and the back part of the capsule of the elbow-joint. This muscle extends the elbow; when the long head contracts, it draws the scapula towards the humerus, and, if the scapula be fixed, it draws the humerus backwards.

(J. Hart.)

ARTERY, (normal anatomy): αρτηρια, απο του τον αερα τηρειν, ab aere servando. Fr. *artere.* Germ. *Pulsader, Schlagader.* Ital. *arteria.* The arteries are the vessels which carry the blood from the heart, and distribute that fluid throughout the body. The trachea was originally called artery from the circumstance of its containing the air which it transmits to the lungs. The term artery was exclusively applied to the trachea by Hippocrates and his cotemporaries, by whom the vessels now called arteries were described as pulsating veins. Aristotle restricted the term artery to the trachea, and described the aorta as the lesser vein. We find these vessels called arteries in the writings of Aretæus, Pliny, and Herophilus, probably on account of the adoption of the opinion of Erasistratus, who taught that they contained a vapour or spirit. The vessels now known as arteries, however, were more distinctly so designated by Galen, who affirmed that they were full of blood, and described the arteries and veins as forming each a tree, whose roots implanted in the lungs, and whose branches distributed through the body, were united by a common trunk in the heart.

There are two great arterial trunks—the aorta, which arises from the left ventricle of the heart, and the pulmonary artery, which arises from the right ventricle of that organ. Each of these vessels has an origin, a trunk, and branches, which divide and subdivide in an arborescent form, until they are reduced in size to the most delicate degree of minuteness, terminating in the capillary vessels, which can be traced entering into all structures except cartilage, hairs, and epidermoid parts. Striking as the contrast is between the size of the primitive arterial trunks and that of the almost invisible capillary vessels, comparatively few divisions intervene between the two extremes of the arterial system, their number hardly exceeding twenty, as Haller ascertained by counting the divisions of the arteries of the mesentery between the place of their origins from the aorta, and their termination in the capillaries of the intestines.*

That the arteries in general are circular tubes is evident from an inspection of their orifices when cut across, even in the dead body. The walls of the larger arteries, when empty, collapse, so as to present, on a transverse section, an aperture more or less elliptical: when distended, however, either by the blood during life, or by injection in the dead body, these also are circular; so that the circular form may be considered as universal in all parts of the animal system except at the origins of the aorta and pulmonary artery, where the circumference of each of these vessels is distended into three sacculated pouches of equal size, called the lesser sinuses; and in the ascending portion of the arch of the aorta, which has a dilatation on its right side, increasing with years, called the greater sinus.

The arteries in general become smaller in their course in proportion to the number of branches arising from them. To this, however, there are exceptions, of which the aorta presents a remarkable example, being of as great a capacity near the origins of the primitive iliac arteries as it is in its thoracic portion, and the vertebral arteries are as large where they enter the foramen magnum of the occipital bone as where they arise from the trunks of the subclavians, notwithstanding that they have given off many branches in the intermediate part of their course.

Wherever an artery runs for some distance without giving off branches, it appears to suffer no perceptible diminution in its size, as has been ascertained by the experiments referred to by Baron Haller,† and repeated by Mr. Hunter,‡ in which the common carotids were found as capacious near the place of their division into the external and internal carotids as at their origins; and the same remark being considered as equally applicable to all other arteries similarly circumstanced, it has been stated in general terms that the arteries and their branches are cylindrical, and that the whole of the arterial system is a series of cylindrical tubes.

Although the cylindrical form is pretty general throughout the arterial system, it is by no means accurately preserved. Several arteries increase in size in the progress of their course; of this we have examples in the umbilical arteries, which expand as they approach the placenta, and the spermatic arteries, especially in the bull and wild boar, which enlarge considerably as they proceed to their destination. Moreover, Haller§ and Martinus have shown

* Haller, Elementa Physiologiæ, t. i. sect. 1. § 17.

† Elementa Physiologiæ, t. i. s. 1, § 3.

‡ Treatise on the Blood, &c., p. 168 et seq. 4to edit. Lond. 1794.

§ Elementa, t. i. s. 3, § 3.

by experiments, that in every instance where an artery divides in the human body, it undergoes a dilatation immediately before such division; and this fact derives confirmation from the experiments of Mr. Hunter on the carotid arteries: it is much more unusual for an artery to diminish in size in its course unless it has furnished branches. Santorini* states, however, that he observed the carotid artery of an ostrich (Struthio camelus) to have become narrower in a portion of its course of six inches in length, for which space no branch had been given off.

The arteries become smaller and more numerous by repeated divisions: the combined area of the branches of each artery, however, exceeds the area of the trunk from which they are given off, in every instance, in consequence of which the capacity of the arterial system, as a whole, is increased in proportion to the number of its divisions. It is from this circumstance that the arteries have been said to represent a cone, the apex of which is at the heart, and the base in the capillaries.

When an artery divides into several branches of unequal size, the largest usually continues its course in the direction of the original trunk.

The branches of the arteries are for the most part given off at acute angles; some few, as the superior aortic intercostals, go off at obtuse angles, and the lumbar arteries arise from the aorta at right angles.

The arteries appear in general to take the shortest course to the parts they supply; hence the tendency they have to run in straight lines.

In many situations the arteries are remarkable for having a tortuous course, as is particularly evident in the arteries of the stomach, intestines, bladder, uterus, lips, iris, &c., where this disposition appears to be a provision to obviate any interruption to the circulation which might result from the great or sudden changes of volume, form, or situation to which those organs are subject in the performance of their functions: in other instances the arteries appear to be contorted for the purpose of breaking the impulse of the systole of the ventricle on the blood, and thereby moderating the force with which that fluid is propelled into vessels partaking of the delicacy of structure of certain organs to which they are distributed, as the arteries of the brain, spleen, testicle, &c.

The smaller arteries, running among loose structures, are rendered tortuous during each systole of the ventricle of the heart, a phenomenon which we have frequently witnessed where such vessels were exposed for a few inches of their course during surgical operations.

Anastomoses.—The several parts of the arterial system communicate freely with each other; and these communications, known by the name of anastomoses,† are more frequent between the arteries in proportion to the remoteness of these vessels from the heart. Three kinds of anastomosis have been distinguished by anatomists: first, two vessels of nearly equal size approach and join so as to form an arch in such a manner as to render it impossible to determine the exact point of their union: this arch gives off smaller vessels. Of this kind is the anastomosis which takes place between the arteries of the intestines and the arteries in the neighbourhood of joints. Secondly, two arteries are sometimes connected by a transverse branch, as the two anterior cerebral in the arterial circle at the base of the brain. We find this kind of communication, also, between the two umbilical arteries as they approach the placenta. Thirdly, two arteries join at an acute angle, so as to form a single trunk: thus the two vertebral arteries form the basilar, the two anterior arteries of the spinal cord unite in a single trunk; and in the fœtus the ductus arteriosus joins the thoracic aorta in a similar manner. Besides these more obvious communications between vessels of a larger size, the anastomoses of the capillaries are so frequent as to give to those vessels, when successfully injected, the appearance of a fine net-work.

It is by means of the anastomoses that the circulation is carried on in a limb after the trunk of its chief artery has been obliterated by disease, injury, or a surgical operation; and the well-known efficiency of the anastomosis of arteries in re-establishing the circulation in parts from which the direct supply of blood through the principal artery has been cut off, has led to the performance of some of the most brilliant operations by which modern surgery has been raised to the exalted rank it holds at the present day.

The larger trunks of arteries are inclosed within the cavities of the body, or run their course on the sides of the limbs least exposed to external injuries, being in general deeply situated in the intervals between the muscles, so as to be protected against wounds or other external injuries, to which they are therefore less exposed than if they had been more superficially situated.

The arteries and their branches are every where surrounded by a layer of cellular tissue, called the arterial sheath, connected more or less intimately with the neighbouring structures, but having so loose an attachment to the arteries as to allow them to glide freely on its inner surface in all their motions, by which means they frequently escape being injured when penetrating wounds traverse parts contiguous to them; and it is owing to the looseness of the attachment of the arteries to their sheath that they retract so remarkably within it when cut across. The sheath is generally strongest around the arteries most exposed to external injury: thus it is particularly strong where it surrounds the arteries of the limbs; it is less distinct on the arteries within the thorax and abdomen, many of which receive coverings from the serous membranes; and it is so extremely delicate around the arteries of the encephalon as to have its existence in this situation questioned by some anatomists.

Structure of arteries.—The arteries are of a pale buff colour when empty. The absolute thickness of their parietes is greatest in the larger trunks, but more considerable in proportion to their calibre in the smaller branches.

* Observationes Anatom. c. 7. n. 6.

† From *ανα, per, στομα, os.*

The parietes of arteries are divisible into three tunics, known by the names of external, middle, and internal.

The *external tunic*, called the *cellular* coat, (*tunica cellulosa propria* of Haller,) is of a whitish colour, thin, dense, and firm: it is formed of condensed cellular tissue, containing fibres closely interwoven and crossing each other at obtuse angles to the length of the vessels. The structure of this tunic is loose on its external surface, and connected by delicate laminæ with the arterial sheath: its internal surface is very closely attached to the external surface of the middle tunic.

The middle tunic of the arteries (the *tunica musculosa* of Haller) is dense, firm, of a reddish yellow colour, and composed of fibres, which, on a superficial view, seem to run transversely: when this tunic is submitted to a closer examination, we find that none of its fibres are sufficiently long to form perfect rings encircling the whole of the circumference of the vessels; they are all short and straight, with a slight degree of obliquity in their direction, and their extremities are lost among the neighbouring fibres. The middle tunic may be divided into several layers by the knife of the anatomist, and these are found to increase in density from the external to the internal surface. There are no longitudinal fibres in this structure.

As Haller has remarked, the middle tunic of the arteries is not continuous with the muscular substance of the heart. For the description of the manner in which the middle tunic of the arteries is connected with the heart, and of the fibrous structure interposed between the muscular texture of that organ and the middle tunic of the arteries, we refer to the article Aorta. The continuity of the middle tunic through all parts of the arterial system is uninterrupted. Although the absolute thickness of this tunic is greatest in the aorta and larger trunks, its thickness in proportion to the area of the vessels manifestly increases as these diminish in size; wherever an artery is curved, it is thicker on the convex than on the concave side, and in all the angles formed by the divisions of arteries its thickness is more considerable than in other situations. The colour of the middle tunic is yellower in the larger trunks and more of a reddish tint in the smaller branches. The middle tunic of the arteries has a degree of firmness sufficient to preserve the circular form of the artery even in its empty state, and after the other tunics have been removed. This tunic possesses a slight degree of strength and elasticity in the longitudinal direction; in the circular direction it exhibits both these properties in a more marked degree. The strength and elasticity of this tunic diminish progressively from the larger to the smaller arteries. There is so close a resemblance between the substance of this tunic and the yellow elastic fibrous tissue of the ligamenta subflava connecting the crura of the vertebræ, as well in its yellow colour and the firmness of its fibres, as in its elastic property, that many anatomists regard both these structures as being nearly if not perfectly identical. Mr. Hunter instituted a variety of experiments to prove that this tunic possessed a power of contraction similar to that of muscular structure in addition to its elasticity; but, notwithstanding the results of the researches of this great anatomist and physiologist, by which he showed, in the clearest manner, that the arteries were endowed with a power of contraction totally distinct from their property of elasticity, he never demonstrated, in a positive and unequivocal manner, the presence of muscular fibres in it, nor has any other anatomist, who, since his time, may have investigated the subject of the structure of this tunic, been more successful in discovering in it any decided trace of muscular fibres. Beclard* considers it to be a peculiar elastic tissue having an intermediate character between muscular and ligamentous fibre.

From carefully examining this structure, it appears to differ both from the yellow elastic fibrous tissue and from the muscular tissue; possessed of the elasticity of the former, but differing from it in being composed of fibres of a softer consistence and more easily torn; from the latter it differs not only in the colour and consistence of its fibres, but moreover in the slow and gradual mode of its contraction under the influence of mechanical or chemical stimuli; unlike the muscular fibre, it retains its power of resistance as perfectly in the dead as in the living body.

Bichat† asserted that there was a total absence of cellular tissue in the structure of the middle tunic of arteries. Meckel, who ranks higher as an authority for matters of fact in anatomy, has admitted this assertion as if it were an established fact: neither of these authors, however, has advanced a single valid argument or brought forward a well-founded proof in support of the correctness of this statement; wherefore we feel the less reluctance in registering our dissent from such high authorities on this point, which we found on the consideration of the following circumstances:—

First, there is no analogous instance of an organized structure receiving bloodvessels and nerves into which cellular tissue does not also enter as a component part.

Secondly, we have the authority of the accurate and learned Haller, in testimony of the fact of the fibres of the middle tunic of the arteries having cellular tissue interposed between them, being, as he expresses himself, "cellulositate paucissimâ separatæ." Beclard entertains a similar opinion founded on the circumstance that when a portion of an artery is stripped of its external tunic, granulations will shoot up from the exposed surface of the middle tunic.

Thirdly, we have frequently observed that, when a portion of an artery stripped of its external tunic, is divided longitudinally and macerated in water for several days, the middle tunic increases in thickness, and its fibres become more distinct and are more easily separated from each other; by continuing the

* Anatomie Générale, p. 325.

† Anatomie Générale, tom. iii.

maceration, the intervals between the fibres become greater, and as the putrefactive process sets in and advances, the whole substance of the middle tunic takes on the form of a spongy mass, and ultimately the fibres cease to be any longer discernible, having been reduced to the state of a soft pulp, while the cellular structure is rendered more evident. The following appears to us to be the rationale of the phenomena above described: the increase in thickness which the middle tunic at first undergoes is owing to the cellular tissue interposed between the fibres imbibing the water in which it has been immersed, in virtue of its hygrometric property; and the spongy appearance observable after the maceration has been continued for a length of time, is the result of the cellular tissue having the property of resisting decomposition by putrefaction much longer than the fibrous tissue.

The internal tunic (*intima* of Haller) is the thinnest of the three; it is continuous with the lining membrane of the heart, in extending from which into the arteries it forms a duplicature, contributing to the composition of the semilunar valves: in the larger arteries, when empty, it sometimes forms longitudinal folds; in some arteries, such as the poplitæal, and the brachial at the bend of the elbow, it presents transverse folds or wrinkles; it also forms transverse wrinkles in arteries which have retracted after amputation: its internal surface, which is in contact with the blood in the living body, is smooth, polished, and bedewed with a fine exhalation; its external surface adheres to the internal surface of the middle tunics in the larger trunks of the arteries; this tunic may be divided into two layers, the internal of which is thin and transparent, while the external is whitish and opaque, having its structure blended with that of the middle tunic; it is the *tunica cellulosa interior* of Haller, and is the seat of the calcareous, steatomatous, and atheromatous deposits, which so frequently occur as morbid appearances in the coats of the arteries. We do not perceive fibres nor any other signs of organization in the inner layer of this tunic in its healthy state; it is almost completely inelastic and very brittle; it tears with equal facility in every direction; compared with other structures it bears the closest resemblance to the arachnoid membrane of the brain; the smooth and highly polished condition of the free surface of this tunic is an admirable provision, whereby the effect of friction in diminishing the velocity of the passage of the blood through the arteries is reduced to the smallest possible amount.

The following mechanical contrivance observable in the interior of the arteries would appear to be a provision for facilitating the distribution of the blood through the divisions of the arterial system. As the branches of the arteries mostly arise from the trunks at acute angles, the portion of the circumference of their orifices on the side next the heart is smooth and depressed, forming a sort of channel sloping gently from the trunk into the branch, while the opposite side, or that more remote from the heart, is bordered by a ridge of a semilunar valve-like form, composed of a duplicature of the lining membrane in which there is included a portion of the middle tunic; the more acute the angle at which the branch arises, the greater is the prominence of this ridge; it is altogether absent where branches arise at right angles, as in the case of the emulgent arteries, and where branches arise at obtuse angles to the trunk, it is found at their orifices on the side next the heart.

The aorta and pulmonary artery are each provided with three valves at their origins from the ventricles; these valves, called sigmoid or semilunar from their semicircular form, are attached by their inferior borders, which are convex, to the margins of the semicircular flaps or festoons, into which the edge of the commencement of the middle tunic of the artery is divided; the superior edges of each of these valves, which are free and floating, form two concave lines, separated by a projection in the centre, in which is contained a small cartilaginous body, called tubercle, *globulus Arantii* or *corpus sesamoideum*. The portions of the walls of the artery corresponding to the valves are dilated in the form of pouches, more marked in the aorta than in the pulmonary artery; these are the sinuses of Valsalva. The semilunar valves are composed of a duplicature of the lining membrane of the artery, including within it a thin but strong fibrous expansion, continuous with the fibrous structure, which connects the middle tunic of the artery with the tendinous ring encircling the arterial opening of the ventricle; the free border of each valve contains a small fibrous cord, as described by Beclard, having the globulus Arantii attached to it in its centre.

An increase or diminution in the number of the sigmoid valves is of rare occurrence, more frequently presented in the pulmonary artery than in the aorta, and oftener consists in the number of valves being increased to four than diminished to two.*

The mechanism of these valves is such as to prevent the blood flowing in a direction contrary to its regular course; for when that fluid is propelled towards the ventricle, they are separated from the parietes of the artery, and being distended by the column of blood pressing against their superior surfaces, they are laid across the area of the vessel, which they completely fill up by their edges being thus brought into perfect contact and the globuli Arantii meeting in the centre. There are no valves in the arteries in any other situation.

The arteries, like other organized structures, are furnished with proper nutritious arteries and veins called *vasa vasorum*. The aorta and pulmonary artery at their commencement receive some branches from the coronary vessels of the heart; in all other situations the vasa vasorum are supplied by the neighbouring bloodvessels; the vasa vasorum are very evident in the external tunic of the arteries, they can be traced until they penetrate the substance of the middle tunic, but not farther;

* Meckel, Handbuch der menschlichen Anatomie. Band. i.

they are more numerous and larger in young than in adult and old subjects.

Absorbents are not visible on the coats of any arteries except the larger trunks; however, the removal of coagula formed in the interior of all arteries after the application of ligatures may be regarded as proving the existence of absorbents in every part of the arterial system.

The arteries are plentifully supplied with nerves, of which the aortic system receives more in proportion than the pulmonary artery, and the smaller arteries more than the larger trunks. The trunk of the aorta, the pulmonary artery, and the arteries of the head, neck, thorax, abdomen, and those of the genital organs, receive their supply from the nerves of organic life. These form a very intricate plexus on their surface. The arteries of the extremities receive their supply of nerves from those of animal life in their neighbourhood. Two sets of nerves have been described as being furnished to the arteries; one set, consisting of softer nerves, of a flattened form, are said to be lost in the cellular or external tunic, *nervi molles;* the other set, more firm and round, penetrate the middle tunic, in which they form a thin membraniform expansion, containing distinct fibres. Meckel* justly considers the internal nerves as subdivisions of the larger flattened external branches. No nerves have yet been discovered on the umbilical arteries, and the arteries of the brain are supposed to be without any. The nerves of the arteries become less apparent in old age.

The specific gravity of the arteries exceeds that of distilled water in the proportion of 106 to 100. They are proportionally lighter and less dense than the veins; while the veins possess more power of resistance, and are not so easily ruptured as the arteries.

Physical properties.—Of the physical properties of the arteries the most remarkable are the firmness of their parietes, their power of resistance, and their elasticity. It is owing to the firmness, which principally resides in their middle tunic, that they preserve their circular form in the empty state.

Their power of resistance has been made the subject of experiment by Wintringham,† and, more recently, by Beclard,‡ from which the following results have been obtained.

Their power of resisting rupture is very great, and is generally in proportion to their thickness, being greater in the aorta than in the pulmonary artery. As the arteries diminish in size, their absolute resistance diminishes; however, as their relative thickness and softness increase, their extensibility and relative resistance undergo a proportionate augmentation. The resistance of all arteries of equal volume is not the same: for instance, that of the iliac artery is greater than that of the carotid. It is in the external tunic that the power of resistance in the longitudinal direction resides; the resistance in the circular direction is much greater, and is owing to the middle and external tunics conjointly; the internal tunic has very little power of resistance in either direction. The middle and internal tunics are as remarkable for their fragility as the external is for its toughness and great power of resistance; hence it is, that when a ligature is tightened on an artery, the two former are divided, while the latter remains unbroken, as proved by the experiments of Dr. Jones.*

The successful employment of torsion of the arteries as a means of suppressing hæmorrhage is in like manner owing to the greater power of resistance possessed by the external tunic as compared with the other two. The process by which arteries are obliterated by torsion is thus explained by M. Amussat,† to whom belongs the merit of having been the first to propose and practise it. The divided extremity of an artery is seized between the blades of a forceps, and drawn out beyond the surface of the wound: the vessel is then taken hold of with a second pair of forceps a few lines higher, and held firmly while the operator commences to twist the forceps with which he holds the extremity of the vessel in the direction of its axis, making from five to nine or ten turns, according to the size of the vessel operated upon. On examining an artery which has undergone this process, it will be found that the middle and internal tunics of the twisted portion have been broken in several places by the external tunic, which, remaining unbroken, is formed by the twisting process into a sort of spiral ligature, so tightly applied round the inner tunics as to set at defiance every attempt to unravel it by twisting the vessel in the opposite direction.

The arteries are highly elastic; they admit of considerable distension in the longitudinal direction, and quickly contract to their original length on the cessation of the distending force. In the transverse direction they yield less, and after distension resume their previous state with greater force. When a fluid is injected with some force into the arteries in the dead body, they become distended and elongated; and if, when they are in this state, the force with which the injection was propelled be removed, they will contract to their previous state, or nearly so, expelling a portion of the fluid which had been thrown into them. During life the arteries are in a state of elastic tension, so that, when divided, their cut extremities retract within their sheath.

The arteries are endowed with the power of contracting in a gradual manner, which they exhibit under the following circumstances:—when the passage of the blood is stopped in the principal artery of a limb, the vessel gradually contracts, its cavity is reduced in size, and ultimately becomes obliterated by degenerating into a filamentous band of cellular tissue; while the collateral branches, taking up its function of conveying blood to the distant parts, are proportionally enlarged, rendered more tortuous, and increased in length. In process of time the number of enlarged collateral branches diminishes, and one or more vessels of increased size become as it were promoted to

the station which the principal trunk had held in the circulation while in its normal condition. Several distinguished anatomists and physiologists have considered the property of elasticity of the arteries sufficient to account for all the phenomena of the circulation of the blood through these vessels. This opinion has been principally insisted on by Haller, Bichat, Nysten, and, at the present day, by Magendie; elasticity, however, can only account for contractions taking place in consequence of previous distension, and is equally evident after death as during life: but observation and experiments have shewn that, in the living body, the arteries possess an additional power of contraction, by which their calibre may be diminished in various degrees; in some instances even almost to obliteration. And this power of contraction has been considered by many anatomists to indicate the existence of a property of irritability in the arteries, similar to, if not identical with muscularity. The existence of irritability in the arteries was denied by Haller in consequence of his not having succeeded in rendering it evident by the application of chemical or mechanical stimuli. Bichat, Nysten, and Magendie, embraced a similar opinion, on the strength of the following facts:—mechanical or chemical stimuli, even the galvanic fluid, applied to the surfaces of the arteries, produce no motions; when the fibres of the middle tunic are dissected off in successive layers in living animals, they are not observed to display that quivering motion visible among the fibres of muscles similarly treated. When cut longitudinally, the inner surface of the arteries does not become everted like that of canals, such as the intestines, which have a decidedly muscular tunic: they do not contract when separated from the heart. The finger introduced into a living artery is not constricted; stimuli applied to the nerves of particular arteries, or to the nervous system generally, do not produce contractions; strong acids applied to arteries produce a corrugation or crisping of their structure, not a contraction, like that of muscular structure.

The contrary opinion as to the existence of irritability in the arteries has been maintained by some of the most distinguished and accurate anatomists and physiologists, among whom are Hunter, Sœmmerring, and Verschuir. It may be stated in a general manner, as an objection to the arguments of Bichat, founded on the circumstance of the arteries not having contracted when stimuli were applied to them in some experiments which he performed, that other irritable parts, even the muscles themselves, do not at all times contract on the application of stimuli. In fact, most of the experiments detailed by Bichat, as proving the absence of irritability in arteries, have been performed by Hunter, Verschuir, and Hastings, and with results directly contrary to those obtained by that very distinguished anatomist. Verschuir* found that the arteries contracted when stimulated by the mineral acids, by electricity, and the application of the point of a scalpel. Dr. Thomson* also saw them contract on the application of ammonia, and when punctured with the point of a fine needle in the living body. Irritating the nerves by the galvanic fluid or by caustic alkalies has been followed by contraction of the arteries.† Mr. Hunter‡ found that the exposure of arteries to the air was followed by their contraction to such an extent as to produce their obliteration. An instance of this we have twice witnessed in the brachial artery when exposed during the progress of an operation for traumatic aneurism at the bend of the elbow. The contraction of divided arteries is well known to be an efficient means of arresting hæmorrhage, in opposition to the force with which the blood is propelled through them by the heart's action.

In conclusion, we may observe that the arteries are proved to be both elastic and irritable; that elasticity predominates in the large trunks, and irritability in the smaller branches; that their irritability, like that of muscles, is under the influence of the nervous system, and obeys the immediate application of chemical and mechanical stimuli, the effects of which must, however, be very much modified by the influence of the elasticity with which they are endowed. (See CIRCULATION.)

In men the arteries are said to have their tunics thicker, and to possess greater density and a higher specific gravity than in women. The arteries are larger, more numerous, and their coats are softer in young persons: they become more fragile, and their elasticity diminishes, in advanced life.

In the progressive development of parts the arteries appear before the heart; but in the chick, during its evolution, the veins of the yolk precede them in their development, as ascertained by the researches of Malpighi,§ Haller,‖ Wolff,¶ Pander,** and Rolando.††

ARTERY, PATHOLOGICAL CONDITIONS OF.—Notwithstanding the brilliant success that has attended the labours of British surgeons in the department of their profession having reference to the arteries, a success that has deprived hæmorrhage of its terrors, and aneurism of half its danger, the pathology of the arterial system is still far from being perfectly understood. Doubtless, the appearances of disease in its more advanced and destructive forms have been accurately described as they have been carefully observed, but that invaluable information which enables a practitioner to detect its early and silent approach, to trace its progress by connecting each symptom with the morbid change that is going forward, and to predict with accuracy the time and the manner of its termination, is as yet but very imperfect. Many circumstances have unavoidably contributed to this. It is quite possible that arteries may be in an unhealthy condition without presenting any indication of disease during life, which is, therefore, in the subsequent examination overlooked. It is more than questionable whether arteritis occasions pain, for it has been observed in situations in which the patient never complained, and as persons do not die from inflammation of the arteries, the intensity of the disease has time to subside, and its effects only remain for observation in alterations in the coats of the vessels, or in an aneurism. Many able and intelligent practitioners who have met with aneurisms without number, have yet not seen an example of acute arteritis, and are disposed to consider the red colour of the internal membrane of the vessel observed in cases presumed to be so by others as a staining by the blood after death. These facts prove the imperfection of our knowledge of the pathology of the arterial system; and years of patient investigation must still be passed both by the bed-side and in the dissecting-room before the dreams of hypothesis give place to the certainty of scientific demonstration.

In prosecuting this inquiry, that source of information so valuable in the elucidation of other subjects in physiology, the experimenting on animals, is wholly closed; the artery of the animal bearing no analogy whatever to that of man, either in susceptibility of disease or in the powers of reparation after injury. It appears, from Dr. Jones's* experiments, that the artery of a dog, if wounded only to a moderate extent, is capable of re-uniting and of healing so completely that after a certain time the cicatrization cannot be discovered, either on its internal or external surface; whilst it is nearly certain that in man the wound of an artery can only be healed by the complete obliteration of the vessel at the spot where it has been injured. It is difficult if not impossible to bleed an animal to death by opening a moderately sized artery, whilst few surgeons would be willing to entrust a wound of a branch of the temporal in man to the resources of nature alone. The facts, too, that aneurism is a disease unknown among inferior animals,—that it cannot, by any ingenuity of contrivance, be artificially produced, and that the earthy depositions so commonly met with in the arteries of aged persons are peculiar to the human species, would tend to shew that some difference of structure existed, some peculiarity favourable to the production of dis-

* Jones on Hæmorrhage, pp. 107 to 111 incl.

ease in the artery of the latter. Indeed, in examining and comparing the artery of a sheep or a dog with that of man, some very obvious differences are apparent: the former is firmer if not actually thicker in its coats; it maintains its circular form more completely, and seems to possess the quality of elasticity in a greater degree of perfection. These circumstances, however, are insufficient to account for that comparative freedom from disease; and probably the greater susceptibility of man may be traced to the indulgence of certain habits and propensities from which the animal is debarred, and which, in many other instances as well as in this, seem to be the predisposing causes of disease in the human race.

The surgical pathology of the arteries presents itself in two different though equally interesting points of view, one having reference to the effects of a wound or other injury to a healthy vessel, embracing a consideration of the process by which such injury is remedied or repaired by the efforts of nature alone or by the assistance of art, and the circumstances that influence its success or failure; the other referring to the appearances and consequences of disease, either as it commences idiopathically within the vessel itself, or is propagated from adjacent parts or structures to it. A lesion of the structure of an artery is of but slight importance provided its function is unimpaired, that is, as long as the blood it was destined to circulate passes through it or is conveyed by some other channel in the natural course of the circulation: even the aorta has been obliterated without any serious inconvenience to the individual in whom it occurred. But when the lesion is of such a nature as to interfere with this function, when the blood is allowed to escape either externally as from an open wound, or internally as in the different species of aneurism, results of a most formidable nature ensue, greatly modified, however, in their character and consequences by a number of circumstances highly deserving of attention.

Wounds and injuries of arteries. — It cannot have escaped observation that the nature of the wound or rather of the substance that occasioned it exerts a striking influence on the phenomena both of hæmorrhage and of the process by which it is restrained. Lacerated wounds seldom bleed, although the torn artery may be left hanging out an inch or more beyond the adjacent surface. Gun-shot wounds, also, if the artery is completely divided, are not often followed by hæmorrhage, although some instances to the contrary occasionally happen; but if the vessel is only notched or partially cut, the bleeding is as profuse as from any other cause. If an artery is wounded by a cutting instrument or by puncture, however, the blood is poured out most freely; yet even here there are varieties, according to the size and importance of the vessel, the extent and direction of the accompanying wound, and the circumstance of the division of the artery being partial or complete. In like manner the subsequent progress of the case will exhibit considerable variety, and demonstrate the fallacious views of those who, grounding their opinions on experiment, would limit the process of recovery to one operation, and regard the efforts of nature as alike in all, whereas, as has been remarked by Mr. Guthrie, this process essentially depends on the size and variation of structure of the artery; it is not the same in large as in small arteries; and it is not even quite the same in the upper and lower ends of the same artery.

When a limb has been torn off by a cannon-shot, by the fall of a tree on it, or by any similar violence, the arteries do not bleed: very frequently the main trunk is seen hanging an inch or more from the wound, pulsating, or at least receiving an impulse from the sound portion of the vessel, though (as far as I have observed) not containing blood within it. It hangs white, bloodless, and flaccid in the wound, not very unlike a piece of narrow wetted tape, and is smaller at its extremity than at any other part. This narrow point, which, according to Mr. Guthrie, is formed by the contraction of the artery, is also in his opinion the only barrier to the escape of the blood; for in a case of this description he cut off the end of the artery at less than an eighth of an inch from the extremity, when it bled with the usual vigour. The extraordinary opportunities this gentleman has enjoyed, and the accuracy of observation which his writings evince, entitle his opinions to be received with great deference, although in a physiological point of view it is difficult to conceive how an artery subjected to such a lacerating force should not have its vital properties so much impaired as to prevent its contracting at all, more particularly at the spot where it was torn across, and where, therefore, the greatest injury was sustained. At the same time there is no other mode of explaining the case. All that portion of the artery that is pendulous from the wound appears to be smaller in diameter than in its healthy state; there is cellular tissue at its torn extremity, but it is not injected with blood, and the coagulum, if any, within the vessel, is so small as to be incapable by its mechanical resistance of preventing the escape of the blood. As there are scarcely any two accidents attended by exactly the same degree of injury, it is probable that nature in such cases possesses different resources. In one case where the leg had been torn off by the falling of a tree, and left attached merely by a portion of the skin over the gastrocnemius muscle, the posterior tibial artery hung nearly three inches from the wound. As the man had been carried a distance of eleven miles, and seemed much exhausted, it was not deemed right to attempt more at the moment than merely to relieve him of the annoyance of the pendulous portion of the limb by cutting through the skin. This was performed incautiously, for no inconvenience was apprehended; about an inch of the extremity of the artery was removed, and it bled just as in Mr. Guthrie's case. In another instance where the arm was shattered by a steam-engine with such violence that some of the muscles torn from their attachments remained upon the wheel, the artery, divided in the subsequent amputation more than two inches above the wound, did not pour out one drop of blood. In others, still, the cellular sheath of the artery has been seen injected with blood in a state of coagulation, the pressure of which on its orifice seemed to be sufficient to prevent bleeding.

We are told that the observation made by Amussat,* that in gun-shot wounds where all the parts were lacerated, the extremities of even the larger vessels did not bleed, suggested to him the application of the phenomenon to practical surgery, and led to the practice of the *torsion* of arteries. This operation consists in laying bare a portion of the divided artery, and carefully detaching it from the surrounding cellular membrane until its own cellular tunic is distinctly to be seen; it is then seized with a forceps, not unlike the common artery-forceps of Bell, and twisted on its axis until the extremity engaged between the blades is completely detached by the torsion. This forms something like a knot or knuckle at the end of the vessel, which mechanically blocks it up; a coagulum is formed within, and the remainder of the process is said nearly to resemble that which succeeds the application of a ligature. Not having practised torsion on a vessel of any considerable size in the human subject, nor had an opportunity of examining after death a case thus treated, I am unable to comprehend, with sufficient precision, the exact process that is established. In experimenting on the femoral arteries of dogs, I have always found that the immediate obstacle to the flow of blood was a coagulum situated at the orifice, and apparently entangled in the lacerated cellular coat; but for the reasons already mentioned, little confidence can be placed in such investigations.

Hitherto we have been considering those wounds of arteries, which, however important in other respects, are not attended by hæmorrhage, and although ignorant of the operations of nature in effecting this result, it is of the less consequence, inasmuch as it is not likely we shall attempt to imitate them, or entrust a large-sized vessel to torsion alone. The wounds of arteries, accompanied by loss of blood, present themselves under very different circumstances; there is always anxiety, agitation, and dismay on the part of the sufferer, and it may be that promptness and decision in the practitioner shall be required to preserve life. In any of these awful situations, coolness and self-possession can alone ensure a freedom from embarrassment, and these qualities cannot be expected in any individual who has neglected to make himself acquainted with the nature of the mischief that has occurred, and the means by which it may be remedied.

The phenomena attendant on arterial hæmorrhage occasioned by incised and punctured wounds exhibit remarkable varieties, according to the size, and of course to the structure of the vessel; to the circumstance of its having been fairly divided, or only notched, or punctured; to the wound being so large and patulous as freely to permit the escape of all the blood externally, or so small or oblique that the fluid, though withdrawn from the circulation, is still retained within the limb. There is still another condition of wounded artery in which the blood that escapes from it is poured into an adjacent vein, and continues to circulate, though not in its proper vessel. However, these latter cases are usually considered and described as forms of aneurism, and will, therefore, not be noticed until there is an opportunity of comparing the different species of that disease one with another.

When a large artery is divided in an open wound, it may happen that the patient dies almost instantaneously, not from the absolute quantity of blood lost, but from its being withdrawn too suddenly from the circulation, just as syncope is often produced by the rapid abstraction of blood in the common operation of phlebotomy. However, this is not uniformly the case, and experience has proved that vessels of such size and importance as the carotid and femoral arteries may be divided, and yet sufficient time allowed for the successful interposition of art. Mr. Guthrie states, that when the femoral artery is cut across in the upper part of the thigh, the patient does not always bleed to death, although frequently lost; while if the division takes place in the middle or lower half of the thigh, the bleeding will probably cease of itself. When, however, an artery of still smaller size is divided, the powers of nature are almost always competent to restrain the hæmorrhage, and consequently it is from an examination of vessels of this class under such circumstances that a knowledge can be obtained of the nature and extent of these powers.

When a vessel of moderate size is divided, the blood is poured forth in jerks from its open mouth in a large and full stream; soon, however, this stream is seen to become diminished in size, and most probably it ceases to flow per saltum. If the patient faints, the bleeding perhaps ceases altogether, nor will it be renewed unless accident or indiscretion gives to the blood an impetus sufficient to overcome the obstacle that opposes its exit, whatever that may be. When the artery is divided, its middle coat retracts immediately that its natural state of tension is removed, withdrawing with it the lining membrane, but leaving the cellular, to which it is but loosely attached, hanging out beyond it. It contracts, too, in diameter, as is evidenced by the diminished stream of blood. The power by which this contraction and retraction are performed is a vital property inherent in the artery itself; it has been called muscularity, and endless arguments have thus been raised about a name, as if no tissue in the body but muscle could be capable of contraction. But it operates in a manner very different from the rapid and decided contraction of muscle; it is slow, gradual, and continued, and, therefore, is longer in bringing the large vessel into a state favourable for the suppression of hæmor-

* Dictionaire de Chirurgie de Rust, tom. ii.

rhage than the small one. The next step is the entanglement of blood in the cellular coat of the vessel and its consequent coagulation when it comes to press in the most advantageous direction on its open mouth, and the hæmorrhage is stopped.

Thus the *immediate* agent of nature, in the suppression of hæmorrhage, is pressure effected by the clot of blood, whilst the vessel is placed by its own properties in the condition most favorable to the operation; and it is curious to observe how universally the principle has been acted on, though probably first suggested by accident or empiricism. The burning iron of the older surgeons produced the pressure of an eschar; agaric and sponge entangled the blood and retained a coagulum on the spot; even the more modern invention of the ligature is in the first instance only pressure, but with the manifest advantages of being applied directly and immediately, of being firm and not likely to slip, and independent of rest, position, and bandage, which are indispensable when other modes of compression are had recourse to.

But the *permanent* suppression of arterial hæmorrhage can only be effected by the actual obliteration of the vessel at the spot where it had been opened or divided, a process that is the result of inflammation of the lining membrane, and of the coagulating lymph thereby poured out, or of the artery ceasing to transmit blood through it, and thus becoming as it were useless in the economy. Both these influences are exemplified in the permanent cure of a wounded artery, for in an incredibly short space of time after the external coagulum has been formed, lymph is effused from the wound in the vessel: and internally, between this lymph and the nearest collateral branch, another coagulum of blood is formed, to which a considerable degree of importance has been attached, though probably without sufficient reason. It cannot be very instrumental in controlling hæmorrhage, because it does not occupy the entire capacity of the artery: its shape is conical, the base lying on the lymph poured out from the wound, from which it gradually tapers to the next branch, and it seems to be formed of a small quantity of the blood, which, being pushed into that branch, remains there, is placed out of the current of the circulation, and must coagulate. The transmission of blood to the limb below is now to be effected through the medium of the anastomosing vessels, which for this purpose become proportionably enlarged. This quality possessed by arteries of increasing their own diameters, or in other words of accommodating themselves to their contents, is curious and interesting, and although not admitting of explanation, cannot for a moment be doubted. No fact has been more satisfactorily proved by dissection, and like the contractility of the artery already noticed, the effects of this power exhibit themselves gradually and slowly. The circulation of the limb seems scarcely to be interrupted, for in a few minutes the arteries below appear, as has been observed by Dupuytren, like soft cords under the finger, evidently filled with blood, but totally devoid of pulsation. It is a long time before this latter proof of a restored activity in the circulation comes to be perceptible, and perhaps is never again equal to what it had been before the occurrence of the accident. The external wound, of course, heals like any other of a similar nature, and it is rare that the limb experiences any inconvenience subsequently. The internal coagulum is soon absorbed, and in process of time the vessel, from the point of division to the next branch above and below, degenerates into an impervious ligamentous cord.

Such is the progress of events when the efforts of Nature are sufficient to arrest the bleeding; but after all it is a fortunate case that ends thus, and experience teaches that there is little wisdom in leaving a moderately sized artery to her resources alone. What more frequently happens is this: the artery retracts and contracts it is true, and a coagulum forms, which, as the patient becomes faint or weak, is allowed to become consolidated, and for that time is sufficient to save him. But he recovers, or perhaps he uses some stimulus or some excitement, and the renewed circulation gradually loosens the clot, and a fresh gush of blood takes place. This recurs frequently, and an hæmorrhagic disposition is formed; the patient becomes pale and exsanguineous, anxious, and in coutinual agitation, and without the intervention of art has but a slender chance of surviving. In these cases, art adopts the principle of the natural cure, only regulating its force, and ensuring its continued operation for the requisite period. The first object to be attained is the application of a sufficient degree of pressure to control the bleeding: the second to maintain that pressure for a length of time to ensure the obliteration of the vessel. This is not the place to discuss the various methods that have been adopted for the accomplishment of these ends; suffice it that the superiority of the ligature has been so far proved by experience, that few surgeons of the present day would feel satisfied in entrusting a large or important vessel to a less powerful or enduring compression. But the ligature is in itself not unfrequently a cause of great and frightful mischief, and, therefore, it will be necessary to examine into all the circumstances connected with this part of the subject.

In practice, a ligature is applied around an artery under two different circumstances; one, in the case of the wounded and bleeding artery, it is placed on the open orifice of the vessel; the other, in the treatment of aneurism, the artery is taken up and tied at a part where it is supposed to be sound and uninjured. When, in either of these cases, an artery is tied, the first effect is obviously to bring its opposite sides into apposition, and to arrest the flow of blood through it. At the same time that the internal and fibrous coats being shorter and less tough yield under its pressure and are divided completely, leaving the cellular coat entire, still sustaining the ligature in its place. The consequences of this division of the internal coats are very similar to those already explained as following the complete section of the artery;

there is the same effusion of lymph, the formation of internal coagulum of the same conical shape and to the same extent, the diversion of the circulation through the collateral branches, and if the case proceeds favorably, the ultimate obliteration of the tube between the place occupied by the ligature and the next anastomosing branch. But the ligature is still to be attended to. The portion of the cellular coat included within its noose sloughs and dies, and is to be detached from the remainder by the absorption of the adjacent sound part. This process takes place at different periods of time according to the size of the vessel; it separates from the subclavian about the twenty-second day after the operation, from the femoral about the sixteenth, and from the brachial so early as the twelfth or fourteenth. Unfortunately matters do not always proceed thus favorably, and the separation of the ligature is the commencement of a series of evils to the patient and of embarrassment to the surgeon, that can scarcely be paralleled in the practice of surgery. It has been found, however, by experience, that a ligature placed on an artery that has been fairly divided, is more rarely followed by those ill consequences that frequently ensue when its continuous tube is tied, and as this latter operation is so intimately connected with the subject of aneurism, and as it will be necessary to become acquainted with the phenomena of inflammation in these structures, in order to understand those of secondary or consecutive hæmorrhage, this part of the subject cannot at present be so favorably discussed.

Morbid states of arteries. Aneurism.—Aneurism (ανευρισμος, vel ανευρυσμος,) is a term of such extensive application as to preclude the possibility of an accurate definition. It has been employed by Corvisart and others to designate certain affections of the heart, but is now most generally used to express a disease produced by a dilatation of an artery, or by solution of continuity in one or all of its coats. It is also applied to any distended condition of a part of the vascular system, such as occurs when an unnatural communication is formed between an artery and vein, constituting the diseases of aneurismal varix and varicose aneurism. The name of aneurism by anastomosis has also been given to those bloody tumours, which, at first appearing only as marks or stains occasioned by a congeries of vessels, increase either with the growth of the individual, or according as the vascular system may be accidentally excited, until finally they produce results of a most formidable description.

Aneurisms have been classed, first, as to the condition of the coats of the artery, a dilatation of them being considered as the *true* aneurism, whilst a rupture or ulceration of them constitutes the *false*: and, secondly, as to the condition of the effused blood, which, if it is contained within a sac or bag, constitutes the *circumscribed* form of the disease, or if it has been poured out throughout the circumjacent cellular tissue, forms the *diffused* aneurism. The nature of aneurism, however, will be better understood by considering it to consist of such a lesion of an artery as will permit the passage of a portion of the blood out of the usual course of the circulation, though not out of the vicinity of the injured or diseased vessel, and according to the different circumstances under which this can occur, the disease will be found to arrange itself under the following distinct species. In the first four of these the effused blood is either partially or entirely withdrawn from the circulation, and becomes coagulated in its new situation: in the others it passes from the usual course of the circulation, but is not withdrawn entirely from it, and consequently does not coagulate.

1. Where by rupture or ulceration of the internal and middle coats of the vessel, the blood is propelled against the external cellular coat, which becomes thus distended into a pouch containing within it the extravasated blood, in a more or less perfect state of coagulation, which pouch is termed the aneurismal sac. This is *circumscribed false aneurism*.

2. The *true aneurism* is when all the coats of an artery, in one particular part of its circumference, are so far deprived of their elastic properties as to yield, become distended, and form a pouch, in which the contained blood is similarly circumstanced.

3. It is not difficult to conceive that the sac of a true aneurism, as just described, will not long endure its state of unnatural distension before its internal and fibrous coats either ulcerate or rupture, and then an aneurismal sac is formed, consisting in one part of all the coats of the dilated vessel, and in the other of the cellular tunic alone. This is obviously a mixed form of aneurism.

4. When there is a wound, rupture, or ulceration of all the coats of an artery, in such wise as to permit the escape of the blood into the adjacent cellular tissue, a *diffused aneurism* is formed. This, for reasons that need not explanation, will be most frequently observed to succeed to wounds or punctures of vessels, but it may also be the consequence of an accidental rupture of the sac of a circumscribed aneurism allowing the blood to pass through it, and spread itself (as it generally does) in every direction throughout the loose cellular tissue of the entire limb.

5. A direct and immediate communication may be established between an artery and a vein lying close upon it, as by the passage of a lancet transfixing one vessel and entering the other. This is the aneurismal varix, obviously occurring with greater frequency as the result of a wound, but nevertheless occasionally seen as the product of disease.

6. A small circumscribed aneurismal sac has been found situated between an artery and vein so transfixed, communicating with both, and permitting a transmission of blood from one vessel into the other. This variety has been named the *varicose aneurism*.

7. A portion of blood may be contained within a new and diseased formation of cellular structure, the precise nature of which is not understood. The trunks of the arteries in

the neighbourhood are neither distended nor ruptured, and the blood within it passes through the general circulation, and of course does not coagulate. It is difficult to class this disease with aneurism in any form, yet is it termed *the aneurism by anastomosis.*

No part of the natural history of any disease can be more interesting than that which has reference to its causes, whether predisposing and remote, or immediately exciting. Certainly, when an aneurism has been formed, a knowledge of the circumstances that occasioned it will not be very useful in contributing to its removal, although it may often assist in forming a prognosis as to the result of an operation: yet if it can be made available in the prevention of the disease, it must prove of no inconsiderable value. It is admitted that aneurism frequently appears suddenly as the result of a blow, a strain, or some violent exertion, the patient being conscious of something having torn or given way within him. With still greater frequency it occurs without any such consciousness on the part of the sufferer, and persons have borne this formidable disease about them for months, and even for years, not only without being themselves aware of its existence, but, if situated internally, without its being recognized by their professional attendants;* and it often happens that a patient complains of the crookening of the fingers or the numbness of the foot, unmindful of the tumour under the clavicle or in the popliteal space. Without denying that an artery, in a perfectly healthy condition, can become the seat of aneurism, because there are too many facts apparently in support of such an opinion, it may be remarked that if such was generally or even frequently the case, the disease ought to be much more common amongst the labouring poor, and also that it should prevail amongst some particular trades. These considerations lead to a belief, that previous to the occurrence of spontaneous aneurism, the artery has undergone some change predisposing to it, although it may not be so easy to point out the nature of that change, or the causes that lead to its production.

It is observed that aneurism is of far less frequent occurrence in woman than in man; a comparison between the numbers of internal cases proving this fact in a remarkable manner, and in cases of external aneurism still more so. It is very rare to meet with a popliteal aneurism in a female. Certainly, the more laborious habits and constant exposure to accident in the one sex may in some respects serve to account for this circumstance, but to those who know that in many places women are obliged to undergo at least as much hardship and fatigue, the explanation will be far from satisfactory. Again, it has been stated that certain pursuits of life predispose to aneurism, inasmuch as it prevails amongst coachmen and postilions, but there never has been even a plausible reason offered to explain this greater liability of particular callings. It cannot be the bent positions of the limbs of such persons, because many other classes, studious persons for instance, maintain similar postures for a longer time and with greater frequency, yet is not aneurism common amongst them. Neither will the sudden stretching of the limb by pressing the foot against the stirrup or footboard in managing the horses throw any light upon the subject, for it is found by experiment that no force will rupture a healthy artery short of what would also tear asunder the ligaments of the adjacent joints. Allowing, therefore, the accuracy and truth of these observations, their explanation is still to be sought for.

Some have supposed that old age, and the deposit of earthy material which is formed in the arteries at that period, are predisposing causes of aneurism; yet, if this was the case, the disease should be very prevalent indeed among those advanced in life, whereas it is in reality almost as rare as in infancy or early youth. Of fifteen cases of large aneurism operated on, only two had exceeded the age of forty years, the average of all being but thirty-one and a half; and if a larger number of cases (inclusive of the internal forms of the disease) were collected and compared, it would probably be shewn to be considerably less. With respect to the earthy deposit alluded to, it is found between the fibrous and internal coats closely adhering to the latter, from which it can scarcely be separated: it is disposed in thin laminæ or plates of different sizes, the largest being seldom greater than a spangle, and these earthy spots are distinct and separate, not running into or connected with each other, and never encircling the vessel with an uninterrupted bony ring. They are supposed to render an artery friable and brittle, and therefore to predispose to aneurism, and have been considered by some to be the products of arterial inflammation. Unfortunately the origin and progress of this earthy degeneration have not yet been satisfactorily traced. Scarpa* seems to regard it as arising from the same cause that produces the steatomatous deposit, and states that it cannot be said to be proper to old age, as it is sometimes met with in patients who are not much advanced in life. I have seen these earthy depositions in the aorta of a female not twenty-five years of age, which was also highly inflamed and covered with spots of soft steatomatous deposit, but still that is far from proof of its being the product of active inflammation, or of its rendering the artery weak or disposed to aneurism.

Of any number of subjects above the age of sixty brought into a dissecting-room, three-fourths will be found with this earthy degeneration in some of the arteries, yet the infrequency of aneurism amongst old patients has been already remarked. Again, this deposit has been seen in the sac of a true aneurism, a circumstance that would shew it did not greatly interfere with the distensibility of the arterial tunics or render them more friable,

* A very curious case of this description is related in the Dublin Hospital Reports, vol. v. p. 167.

* On Aneurism, page 90.

and, lastly, a large and important vessel in this condition has been tied without its being crushed or broken down short, and being followed by consecutive hæmorrhage. From these observations some reasonable doubt may be entertained of these deposits being the result of inflammation, more particularly as, at the period of life alluded to, there is an evident disposition to the formation of earthy deposits in many structures and organs as well as in the arteries.

When a large aneurism runs its course with great rapidity, an opportunity is frequently afforded of observing a condition of the vessel most favourable to the production of the disease, and which therefore may be considered as one of its direct or immediate causes. The vessel in this case, on being slit up, exhibits its internal lining membrane less smooth and polished than in its natural state; its colour is changed to a deep roseate carmine, and it separates from the subjacent fibrous coat with comparative facility. This latter structure is also changed in colour, but not to so bright a red as the other. Between these coats, but more closely attached to the internal, (for they peel off with it,) are numerous specks of a soft steatomatous material of a white or pale grey colour, presenting, on a superficial inspection, somewhat of the appearance of the calcareous deposit already spoken of. An artery in this condition has lost more or less of its elastic properties; it is distended, and its calibre increased equally around. As the arteries are always full, the impulse of every new wave of blood driven on the greater quantity contained within the distended vessel increases its apparent pulsation, for it is in the diastole or expanded condition of the artery that the pulse is felt. This loss of elasticity must obviously weaken the vessel, and cause it to be less resisting: a fact that can be proved by experiment after death, when an artery so circumstanced will be found to yield and tear under a distending force that would have little effect on it if in health, and will explain how an apparently trifling exertion may produce aneurism in one man, whilst numbers of others exposed to similar or even greater violence escape safe and unharmed.

If arteritis can be justly considered as an immediate cause of aneurism, it follows that any thing tending to produce this condition of the vessel will predispose to the disease. An investigation of the natural history of this affection would, therefore, prove equally useful and interesting, but as yet a sufficient number of facts have not been collected from which any useful practical induction can be drawn. The experience of an individual cannot be sufficient to establish a fixed and general position, but may be valuable if it induces others to a similar line of investigation, in order to its being verified or contradicted; and from a minute attention to the previous history of several cases, I have frequently been able to connect intemperance, particularly in the use of spirituous liquors and repeated or ill-conducted courses of mercury, with the production of arteritis. How far these can explain the comparative infrequency of the disease in females and its prevalence amongst men subject to exposure, and too often of reckless and dissolute habits, must be determined by future observation; but, in corroboration of the latter part of this opinion, it may be remarked, that few old persons are subjected to a course of mercury that do not perish shortly after by the bursting of a bloodvessel,—of apoplexy, or hæmoptoe most frequently.

When arteritis has proceeded to the extent of producing these steatomatous deposits, if aneurism is not inevitable, it is certainly very likely to ensue. In some instances the loss of elasticity is so great as to cause all the coats of the vessel to yield and become distended into the sac of a true aneurism: in others, (and far more frequently) the process of ulceration commences, the lining membrane covering one of these spots first becoming soft, then exhibiting a distinct ulcer which proceeds from within, eroding the middle coat either through its entire thickness to the cellular, which is then easily distended into the aneurismal sac; or so far as that it shall be likely to give way and tear under a trifling shock, even under the impulse of the circulation. In the pathological collection of the medical school of Park-street, Dublin, there are preparations exhibiting these forms of aneurism and the different stages of dilatation, of softening, and of ulceration in the most satisfactory manner.

Circumscribed false aneurism. — When a person experiences a sensation as if something had given way or been torn within his limb, or even without such previous warning, perceives a small hard, pulsating tumour situated somewhere immediately on the course of a large or leading artery, it is to be suspected that an aneurism has formed. And this suspicion is confirmed, if the tumour becomes larger or smaller, according to the diastole or systole of the artery, or is diminished by pressure, or almost disappears if the patient should happen to faint. If pressure be applied on the trunk of the artery between the tumour and the heart, its pulsation ceases, its size is sensibly diminished, and it becomes soft and flaccid; if on the farther or distal side of the tumour, its size is increased, and its throbbing rendered far more evident. The pulsation is said to become more faint in proportion to the growth of the tumour, and this, though generally true, is not so universally, for this symptom will presently be found to be influenced by a number of circumstances, such as the blood within the sac being fluid or coagulated, the situation and depth of the tumour within the limb, and the coverings of fascia it may possess. In most instances there is a peculiar whizzing sound, plainly perceptible on applying the ear or a stethoscope to the tumour, termed by the French the "bruit de soufflet;" but its presence or absence is by no means pathognomonic, for it may be artificially produced by pressure on the trunk of any large artery.

On examining a circumscribed aneurism

after death or the removal of the limb, the artery should, if possible, be always slit up on the side opposite to that from which the tumour springs. The appearances of inflammation will probably depend on whether the aneurism be recent or of long standing, and obviously on whether it has been the result of accident or disease. Also, if it be recent, the aperture leading into the sac is generally well defined, circular, and circumscribed, its edges remarkably thin and fine: if, on the contrary, it is old, the aperture is large, smooth, and so even as to present an appearance as if the lining membrane had been prolonged from the artery into the sac. On cutting into the sac some fluid blood is usually found, and always a quantity in a state of coagulation. Besides, there is always more or less of fibrine, the remains of former coagula deposited in irregular laminæ, and varying in colour from a pale red or grey. The most external layers are closely fastened to the internal wall of the sac by means of large depositions of flaky lymph, from which, however, they can be separated by careful washing or maceration. This lymph thickens the walls of the sac, and imparts to them considerable firmness and resistance. The sac, itself, is most generally of an oval form, but to this there are some exceptions, amongst which the occasional occurrence of a *dissecting* aneurism is the most curious. This happens when the internal and middle coats having ulcerated or given way, the blood insinuates itself between the fibrous and cellular coats, detaching them from each other to a considerable extent, whence the disease has derived its name.* Such is an outline of the appearances on dissection, but they will avail little in explaining the nature of aneurism, unless combined and compared with the phenomena of the disease during life.

And, in the first instance, it must be recollected that the tumour is pulsatile, a quality that proves the entrance of a quantity of fluid blood, and its return back again into the artery by the resistance or reaction of the sac. It was this circumstance that principally led Fernelius to believe and to teach that aneurism consisted in a dilatation of all the coats of the artery, inasmuch as he could not understand how pulsation occurred if the tumour did not possess an elastic covering, and moreover imagined that if the blood was driven into a sac otherwise constituted, it must of necessity remain there and become coagulated. It is, however, unnecessary now to discuss the question as to whether the sac of an aneurism possesses elasticity or not, when it is daily observed that any tumour (an enlarged gland for instance) situated on an artery, and receiving an impulse from the heart, may communicate the sensation of pulsation, provided the skin and other elastic tissues covering it are sound. Nay, farther, it may be remarked that the pulsation of an artery, even with its elastic coat uninjured, is much more apparent than real, and when felt ab externo, is greatly influenced by the skin and its other coverings. It is a fact too well known to every operating surgeon to be for a moment controverted, that an artery when exposed exhibits nothing like the force of pulsation that it did before the skin was divided; sometimes it is difficult to ascertain it satisfactorily at all. The late Professor Todd has strongly pointed out this circumstance in his case of axillary aneurism, published in the third volume of the Dublin Hospital Reports, where he says, " For some time I could not be convinced that the feebly pulsating vessel, to which the point of my finger was applied, was really an artery of such magnitude as the subclavian ;" and similar observations could be adduced, if necessary, from other sources.

It is of little consequence, then, whether the aneurismal sac possesses an elastic covering proper to itself or not, the resistance of the external structures being sufficient to explain the phenomenon of pulsation, and the importance of the integrity of these structures in the progress and termination of the case is extremely interesting. If even a small quantity of blood was thrown at each pulsation of the heart into a yielding, unresisting bag, it must of necessity remain there, and in a very short space of time the accumulation would be enormous; but if there is a re-acting force capable of returning a portion of this blood and restoring it to the circulation, the accumulation and consequent growth of the tumour will be measured by the quantity of blood thus left behind. The volume of blood sent into an aneurismal sac must be proportioned to the aperture through which it has to pass, while the actual quantity lost must depend not so much on this as on the non-resistance of it and its coverings, and their incapability of returning the fluid back into the circulation. Hence the growth of external aneurisms is in general rapid or slow according as they have existed a greater or less length of time; for in old aneurisms the aperture into the sac is generally large, and the elasticity of the external coverings is weakened by over-distension.

The pathology of aneurism arranges itself under two distinct orders, one having relation to the open and bleeding artery, the other consequent on the hæmorrhage being internal. This latter circumstance is interesting to the surgeon, because the presence of the blood in the limb, the position it occupies, and the pressure exercised by it on the adjacent structures and organs, very often form the most prominent and important features of the disease, and nearly as frequently cause the destruction of the patient as the bursting and bleeding of the tumour. But the consideration of this part of the subject does not immediately belong to the pathology of the arterial system, to which these remarks are more particularly directed. To return, then, to the open or ruptured artery. The condition of the vessel is scarcely different from that of one wounded by a knife. It is a bleeding artery, and the same principle that is applicable to hæmorrhage under any other

* See Dissections of Aneurism, by John Shekelton, Dub. Hosp. Rep. vol. iii.

circumstances is also available here, for if a wound of this species of vessel cannot heal whilst its calibre remains open, neither can an aneurism be cured until the artery from which it springs is completely obliterated at the spot where the aperture into the sac exists. The complete closure of the vessel is to be accomplished by placing its opposite walls in contact and under the influence of such pressure as will occasion inflammation and the effusion of coagulating lymph,—a pressure that can be applied either *ab externo* by means of compress and bandage, or from within, by placing the blood in the sac in a condition that will admit of its perfect and complete coagulation.

Pressure on the tumour, if it could be exactly applied and firmly maintained, ought to succeed, and, in truth, has often been successful, particularly when the disease is consequent on a wound; but there are so many difficulties to be surmounted and dangers to be encountered in its use, that few entertain much confidence in it, and perhaps it never would be resorted to but from a dread of consecutive hæmorrhage after a ligature. A bandage, if applied with sufficient firmness to operate with rapidity, occasions such excruciating pain that it can scarcely be endured; and if loosely, it is liable to slip; and if even it does finally work a cure, the progress of the case is so protracted that many patients become wearied with the trial. Again, the large trunks of arteries throughout the extremities are generally accompanied by nerves and veins in such close apposition with them, that a compress can scarcely be applied to one without interfering with the other; and instances have occurred of dreadful mischief having been occasioned by interruption of the venous circulation in such cases, even in the course of one night. Finally, pressure has very frequently caused the rupture of the sac, and the aneurism, from being circumscribed, has suddenly become diffused; and if there was no other source of apprehension but the possibility of this latter occurrence, it should make a surgeon pause before he adopted so hazardous a mode of treatment.

Pressure from within is effected by removing the impulse of the heart from the blood within the sac for a sufficient time to permit of the sac becoming perfectly filled with blood, and for that blood to become coagulated. This object will be accomplished by interrupting the flow of blood under the impulse of the heart through the leading trunk of the vessel for a given time: in cases of small aneurisms forty-eight hours being sufficient, but the larger and older requiring a longer period. A ligature placed around the vessel between the tumour and the heart effects this purpose; but it does more than is requisite, for it divides its internal and middle coats, occasions the effusion of lymph and the obliteration of the artery there, and involves the risk of consecutive hæmorrhage afterwards on its final separation. To avoid these inconveniences, the *presse artere* of Deschamps and a number of other contrivances for arresting the flow of blood through an artery, and admitting of easy removal after the object has been accomplished, have been proposed and tried, but success has not been so great as to warrant their general adoption, and the operation by ligature is still very generally preferred. It may be applied either at the cardiac side of the tumour, when it acts in the manner above stated, or between the aneurism and the capillary circulation, in which case the principle of its operation is somewhat different.

In the former instance, when a ligature is applied to the trunk of an artery, the supply of blood to the limb below it is interrupted for a few moments; the aneurism loses its pulsation, and sinks and diminishes in size more or less according as its contents had been fluid or coagulated. Soon the blood begins to flow through the collateral branches, and enters the aneurismal sac also, but it passes into it slowly and without impetus, and no part of it is again forced back into the circulation. It coagulates and comes to press upon and close the ruptured vessel, which is soon obliterated by lymph, and in process of time becomes degenerated into little more than a ligamentous cord. A beautiful illustration of this entire process was seen in Mr. Crampton's case* of ligature of the common iliac artery. The patient had two aneurisms, one of very large size at the groin, the other in the popliteal space of the same limb, firmer, and of much smaller dimension. A ligature of catgut was placed round the common iliac, which either rotted or by some accident became detached on the sixth day: the pulsation returned in the larger tumour, which soon afterwards burst, and the patient perished. The sac of the popliteal aneurism being so much smaller had time to become perfectly filled with blood, which was there coagulated and firm. The ligature had accomplished all that was necessary for it, and the cure would have been complete even although the ligature had loosened—whilst the opposite was the fact with reference to the larger tumour.

Sometimes, soon after the ligature has been applied, pulsation reappears in the tumour. This must always be considered as an untoward circumstance, but does not necessarily involve the failure of the operation; for it may take place under two different conditions of the parts. 1. In aneurisms of very long standing, in situations where there is a free and extensive collateral circulation, probably increased by the pressure of the tumour. In these the pulsation does not return for some time after the vessel has been tied, and is never so strong as before the operation. It may continue for several days, but gradually diminishes in force, and at last ceases. The progress of the case then resembles that of the ordinary forms of the disease, except that in this the cure is much more protracted. Apparently, such was Sir A. Cooper's first successful case † of ligature of the common carotid artery, as also the case of carotid aneurism published in the fifth volume of the Dublin Hospital Reports.‡ It is not un-

likely that Mr. Turner's case of aneurism in the fore-arm, in which he secured both radial and ulnar arteries, was of a similar description also. 2. Where by an irregular distribution there exist two trunks in the limb, both conveying blood to the aneurismal tumour. Sir C. Bell had a case of popliteal aneurism in the Middlesex Hospital, in which, just below the origin of the profunda, the femoral artery divided into two branches of nearly equal size, which ran parallel to each other until they arrived at the spot where the artery perforates the tendon of the triceps muscle, and there they united again. Only one of these was tied, and although the pulsation in the tumour ceased for a moment, yet it soon returned, and never disappeared until the patient's death, which happened a few days afterwards, from erysipelas. A preparation of a similar distribution is preserved in the Museum of the Royal College of Surgeons in Dublin;* and it is quite clear that where such exists in an aneurismatic limb, the securing of one of the trunks could produce no benefit.

It has been already stated that one of the effects of the ligature on an artery is the eventual obliteration of the entire calibre of the vessel between it and the nearest collateral branch at each side, and, therefore, it might be supposed that if it be tied immediately close beyond an aneurismal sac in such wise that no branch shall intervene between the cord and it, the whole of the canal to the next branch, including the spot where the rupture had taken place, ought to become obliterated, and the aneurism thus be cured. This is the principle that led to the performance of the operation of tying the artery at the distal side of the aneurism. It was (I believe) originally proposed by Delpech, and put in practice by Desault, but the termination of the case gave little encouragement for future trials, and it fell into disuse until of late years, when it has again been tried in England, and still subsequently by Mott, in New York, but not with a success to justify its general adoption. There is but one artery in the body (the common carotid) so circumstanced as to answer the design of the operation; and even in this, if the smallest and most trifling branch happened to intervene between the aneurism and the ligature, it must defeat the principle of the operation altogether, and perhaps tend to aggravate the disease.

True aneurism.—Two different pathological conditions of an artery have been regarded as constituting this disease; one in which the entire circumference of the vessel is distended, forming a tumour of an oval shape, pulsating strongly during life, and not containing coagulated blood: the other is where all the coats of an artery at one particular spot are dilated in such wise as to form a sac springing from the side of the vessel, and containing blood withdrawn from the circulation, and in a state of coagulation. Perhaps it would be more correct to regard the former of these as a state of vessel predisposing to the formation of a false aneurism, whilst the latter, presenting during life the same phenomena, and curable on the same principles that have been already laid down, must be considered as offering truly a specimen of the disease.

When in consequence of arteritis, or from any other cause, the elasticity of the arterial structure becomes impaired or weakened, a dilatation of the vessel at the spot so debilitated ought to be the result; and this probably takes place in all arteries previous to the formation of idiopathic aneurism. But the circumstances that determine an artery to become dilated rather than to ulcerate are very obscure, for the same morbid appearances in the vessel are observed to precede both. In the eleventh number of the Dublin Journal of Medical Science there is an account of two cases of internal aneurism, one formed by ulceration of the internal and middle coats of the artery, which burst into the œsophagus; the other, evidently by dilatation, which destroyed the patient by pressure on the trachea: and in both the aorta exhibited the same appearances of inflammation and steatomatous deposit beneath the lining membrane. The preparations are preserved in the collection of the school in Park-street, and as showing this pathological fact are extremely satisfactory. Again, it is not easy to say what dilatations should be considered aneurismal or not. The aorta, in a great proportion of subjects above the age of forty, is dilated; yet such dilatation is not regarded as an aneurism. Other arteries present a similar appearance occasionally; and a case occurred not very long since in the Meath Hospital, in which all the arteries of the inferior extremities in an aged man were dilated to more than twice their natural calibre. These vessels were found after death filled with coagulated blood, yet as the fluid seemed to circulate through them during life, and the patient never experienced any inconvenience, it is difficult to admit them as specimens of true aneurism. On the other hand, nearly at the same time, a man died in another hospital who for years had a small aneurism of the femoral artery, with every observable symptom of the disease except that the growth of the tumour was unusually slow; and on dissection this appeared to have been a species of true aneurism, caused by an equal dilatation of the entire circumference of the vessel, and did not contain coagulated blood. It would seem, then, impossible to pronounce during life on the real nature of an aneurismal tumour, nor is it always easy to demonstrate it after death.

In most instances of aneurism, particularly those of long standing, the edges of the aperture into the sac are smooth and even, and the lining membrane seems to be prolonged into it. The internal wall of the sac is so thickened, and all the parts so matted together and confused by depositions of lymph and fibrine, that the appearances altogether become so deceptive as almost to countenance the old opinion as to the pathology of the disease. Professor Scarpa, who principally opposed the doctrine of aneu-

* There is a similar preparation in the Museum of St. Bartholomew's Hospital.—Ed.

rism by dilatation, was obliged to support his opinions more by argument than by facts demonstrable by dissection; and although later investigations, particularly those of Mr. Hodgson and Mr. Guthrie, have satisfactorily proved the occasional existence of both true and false aneurism, yet it must be a favourable case and patient examination that will enable the morbid anatomist to exhibit its nature and structure without possibility of error. When cases of inflamed or diseased artery are seen, complicated with aneurism, and the same depositions are observed in the artery and in the sac, it proves beyond doubt the identity of structure in both. Thus, if an aorta be found studded over with specks of a soft steatomatous deposit situated between its internal and middle coats, and if on one side of it an aneurism is placed, in the sac of which, throughout its entire extent, the same appearances and the same deposit are observed, it follows that the same structures must exist in both, and that one is a prolongation of the other. One of the cases already noticed as being a true aneurism, that destroyed the patient by pressure on the trachea, exhibited such evidence of its nature: and a similar one, but still more satisfactory, occurred in the person of a gentleman, who died some years since. This patient had laboured under some anomalous cerebral symptoms, and on inspecting the brain a small aneurismal tumour was seen at the bifurcation of the basilar artery, in the sac of which were found the same kind of earthy depositions that pervaded all the arteries of the body—the same so generally observed in the arteries of aged persons. These examples are sufficient to prove that aneurism by dilatation may exist, and perhaps its occurrence in the aorta and larger vessels is more frequent than has been supposed.

During the past spring two opportunities occurred of examining into the nature and condition of aneurism, both in its early stage and long after it had been apparently cured by operation. They were, probably, both examples of what has been termed true aneurism, although unquestionably all the coats of the artery were not engaged: and as the morbid appearances have not been hitherto described, it may be useful to take notice of them here.

A man was admitted into the Meath Hospital, with popliteal aneurism in each ham: one of these had existed for several weeks; the other was of very recent occurrence. The limb in which the older and larger one was situated was first made the subject of operation, the femoral artery was tied, but the patient died on the sixteenth day afterwards, of venous inflammation, the ligature on the vessel still remaining firm and undetached. On examining the aneurismal tumour externally it appeared of an oval shape, and to have been formed by the gradual expansion of all the coats of the vessel. On being cut into, however, it was found that the lining membrane was wanting throughout the entire extent of the sac, the edge of it terminating sharply and abruptly, above and below, at the junctions of the tumour with the more healthy parts of the vessel, and being as accurately defined as if made by a careful dissection. The fibrous coat was evidently continued into the tumour, which seemed to be formed of an expansion of it and the cellular. It was, moreover, otherwise diseased, being thickened, greatly softened and thrown into irregalar rugæ or folds, the interstices between which were filled with coagula of lymph or fibrine. As the sac of this aneurism was in a state of suppuration, the deficiency of the lining membrane was attributed to that circumstance until the other aneurism came to be examined when the same appearances were observed. The second tumour was not so large as a walnut and evidently formed by the gradual expansion of the fibrous coat, for the abrupt terminations of the lining membrane at the healthy extremities of the artery were still more exactly defined.

The other case is even more interesting, because it exhibits a cure of aneurism after operation in a manner that has not been described, the principle of which it is not easy to understand. A man was operated on by Mr. Collis, in the Meath Hospital for popliteal aneurism on the 22d of January, 1831. The ligature came away on the seventeenth day, the tumour diminished; in short, every thing went on well and the patient left the hospital perfectly cured. So far as the aneurism was concerned, he remained healthy and free from inconvenience until his death, which happened in March 1835, from fever, and such an opportunity for pathological inquiry was not neglected. The tumour which had been originally of the size of a turkey's egg, was found to have diminished to little more than that of a walnut: externally it felt hard and as if completely solidified: on being cut into, however, neither artery nor sac was obliterated, the latter being occupied by a coagulum of a deep red colour, through the centre of which was a canal of a sufficient size to allow the blood from the portion of the artery above the tumour to flow freely into that below it. It seemed as if the current of blood through the sac had never been interrupted, the only effect of the former ligature having been the removal of the impulse of the heart from it. This aneurism *appeared* to have been a true one, so far as the fibrous and cellular coats were concerned, but the fact could not be so satisfactorily demonstrated as to admit of no dispute; however, the absence of the lining membrane and its sharp and abrupt terminations at the healthy portions of the vessel were sufficiently obvious.

If it be difficult to demonstrate the nature and constitution of the small and recent aneurism, it becomes impossible when the tumour has attained to a considerable size. It seems probable, however, that the arterial structures will not long endure this state of unnatural distension, and they either ulcerate or tear in their internal and middle coats. A mixed aneurism will thus be formed, having its sac at first composed of all the structures of the artery, and subsequently in the largest portion of its circumference, of the cellular coat alone. The long continuance and gradual increase of some aneurisms, as contrasted with their sudden and rapid growth afterwards, have been explained on this supposition.

Diffused aneurism.—An aneurism is termed diffused when the blood, removed from the circulation, is not confined within a pouch or sac, and therefore passes in every direction throughout the cellular tissue of the limb. This may be occasioned by the rupture or ulceration of an aneurismal sac, but far more frequently by some violence applied to the artery itself in such a manner as to open its cellular as well as its other coats. Thus a spicula of a fractured bone, or a pointed sequestrum, in coming from a necrosed limb, may produce the disease; but the most common examples that fall under a surgeon's observation are furnished by awkward or ignorant persons in their attempts to perform the operation of phlebotomy. In the latter case there is an external wound communicating with the injured vessel, and then it also presents a familiar illustration of traumatic aneurism.

When the blood is thus diffused throughout the cellular tissue, there is always the greatest danger; not so much from the loss of a large quantity to the circulation as from the rapidity with which a limb so circumstanced runs into a gangrene,—a rapidity so great that the mortification either is not or seems not to be preceded by inflammation, and its occurrence is often the first notice a surgeon receives of the extent and nature of the accident. When the injured artery lies deep and is covered by a dense and resisting fascia (as in the instance of the posterior tibial artery being ruptured by a blow), it may bleed for some time without affording any indication beyond the pain and tension complained of by the patient, and a slight tumefaction of the limb. When, however, the fascia has yielded or sloughed and permitted a more extended diffusion of the blood, the part becomes swollen, glassy, and œdematous, pale if the blood did not occupy the cellular tissue underneath, but of a livid colour, like that of a bruise, if it does. The joints in the neighbourhood are kept flexed, and any attempt at motion gives intolerable pain. In a very short space of time circumscribed spots of gangrene appear, which, on separating, permit masses of very dark coagula to protrude, accompanied by an oozing, or perhaps, a flow of arterial blood, under which a patient will very soon sink. And it may be, the real nature of the case has not been suspected until this blood has made its appearance. Doubtless, if a diffused aneurism has been occasioned by a wound, the rush of blood at the moment, its colour, and the difficulty of controlling the hæmorrhage will point out what has happened; or if there had been a circumscribed aneurism that on a sudden lost its defined character while the limb began to enlarge above and below it, there would be good grounds for suspicion; but in any other case it is so difficult to separate the pain and tension and the other symptoms from those which might naturally supervene on a severe injury, that the appearance of a tendency to gangrene is too often the first circumstance to create alarm. There are many symptoms in which the diffused aneurism differs from the circumscribed, that render the diagnosis of the former particularly difficult. It has been already stated that the "bruit de soufflet" is, even when present, not a pathognomonic symptom, and if the vessel lies deep it is not to be heard at all. Pulsation of the tumour, the most satisfactory symptom of an aneurism, is generally absent, and when otherwise, is very weak, fluctuating, and indistinct. To those who reflect that the effused blood is thrown out amongst inelastic and unresisting structures, that no portion of it is returned to the circulation, but that it lies a coagulated mass amongst the surrounding cellular tissue, the absence of these symptoms will not require explanation.

Traumatic aneurism.—But if, as very frequently happens, the accident that caused the aneurism has also created an external wound communicating with the injured vessel, and permitting the escape of a portion of the blood through it, although still a diffused aneurism, the leading circumstances of the case are essentially altered. This is the form of disease termed by the French traumatic aneurism, the name having reference not so much to the fact of its having been produced by violence, as to the co-existence with it of a solution of continuity in the skin and other structures external to the vessel. Thus, although an aneurism may be caused by the prick of a lancet in the bend of the arm, or by a bayonet-wound in the thigh, yet if the external wound is healed, or, being unhealed, if it is so oblique or devious that the blood flowing from the artery does not escape from the limb, it may not be called traumatic, whilst a common popliteal aneurism that had arisen spontaneously, if it is accidentally opened, assumes the character just designated. The chief peculiarity of this case, then, is the external wound, and if it be conceded that it is the resistance of the unyielding structures that presses the coagulum against the vessel, and thus accomplishes the cure of those forms of aneurism already described, it will be seen that a material part of the process must be deficient, and, therefore, that the principles applicable to the former cannot be made available here.

In order to the proper understanding of this part of the subject, it will be necessary to take a familiar case for illustration. A person in attempting to open a vein in the arm strikes his lancet into the artery, and is, perhaps, unconscious of the extent of the mischief he has occasioned. The arm is tied up, but it swells and becomes intolerably painful. When the bandage is removed, the wound is found not to have united, and a coagulum is probably seen plugging it up, which loosens occasionally and allows the escape of a considerable quantity of red and florid blood. In the meantime the diffusion throughout the limb is extending in every direction, and the hæmorrhages from the external aperture are more frequent. If this case is treated by ligature at a distance from the situation of the aneurism, although the patient may appear relieved at the moment, that relief is but delusive. The blood may coagulate, but being unsupported by any external resistance, it cannot make sufficient pressure on the orifice of the bleeding vessel. Fresh blood is carried round by the collateral circulation, and as it constantly oozes from the punctured artery, it disturbs the coagulum in the neighbourhood, and bursts out into new and repeated hæmorrhages until the surgeon is obliged to end where he ought to have begun, by cutting down (if he has still the opportunity) directly on the injured part of the vessel, and tying it above and below the aperture. The great difference between the traumatic aneurism and the other forms of the disease is, that in it the hæmorrhage is external as well as internal, and that the coagulum within the limb being unsupported may press outwards through the wound more freely than inwards upon the vessel. The coagulum, therefore, is not available in the cure, and the treatment must have reference to the wounded artery alone. If the radial artery was opened and bleeding freely from the external orifice, few surgeons would think of taking up the brachial high in the arm, knowing that the inosculating branches would still supply abundance of blood to the wound, and although the pathology of traumatic aneurism is somewhat different, inasmuch as a portion of the blood lost still remains within the limb, yet the principle of treatment is unchanged.

It may be objected that in very many instances of traumatic aneurism success has attended the application of a ligature on a distant part of the artery; but every one of these cases will require to be accurately examined before the treatment here laid down can be impeached. The definition of traumatic aneurism must be borne in mind, and that it implies not only the existence of a wound, but of one through which coagulated blood may protrude and fluid blood may trickle. The only case in which such practice could succeed is, where, after the ligature had been tied, a sufficient degree of pressure *ab externo* could be maintained to lay the opposite sides of the wounded artery together, and produce sufficient inflammation to procure its complete obliteration,—in short that it shall effect that which the resistance of the skin and fascia and other superincumbent structures would have accomplished in a limb less injured. Such pressure as this must occasion intolerable suffering; and experience has proved, in numerous instances, how little reliance can be placed on it.

Secondary hæmorrhage.—Hitherto the application of a ligature has been noticed only as a curative process, its advantages have been discussed, and the manner in which it may be supposed to operate explained; but it has been also stated that "the ligature is in itself not infrequently a cause of great and fearful mischief," and as the consideration of the different cases that might require the operation has been just concluded, perhaps this may be a fit opportunity for examining into the nature of these unfavourable cases. Secondary or consecutive hæmorrhage occurs, as its name implies, at some period subsequent to the application of the ligature, and the blood flows from the place where the vessel has been tied. In many instances the patient has a kind of presentiment of that which is about to happen, and becomes restless, uneasy, and agitated; in other instances there is not the slightest warning, and the first notification of the mischief is the appearance of the dressings soaked in blood. In general it has been stated that it is on the separation of the ligature that this bleeding takes place, but this is not the fact, for commonly it happens whilst the cord is fixed and firm, and three or four days before its fall ought to be expected. The longer the ligature remains, provided no nerve or fascia had been included with the vessel, the safer the patient is, and it must be rare to meet with secondary hæmorrhage after the cord has become detached and been quietly withdrawn. It is remarkable that the blood comes from the inferior portion of the artery; it wells up abundantly from the bottom of the wound, and never flows with a gush or per saltum; it is easily restrained by pressure on the bleeding orifice; and if such pressure is accurately applied, and can be maintained during a very few days, the cure is permanent, and the patient would be safe but for a number of collateral circumstances, which, however important in the management of the case, form, properly speaking, no portion of the pathology of arteries.

Various causes have been assigned as producing secondary hæmorrhage, the chief of which is the too extensive detachment of the vessel from its surrounding connexions during the operation, an opinion that I cannot think is borne out by observation. If it is supposed that this dissection of an artery is injurious by depriving it of its vascularity, and diminishing its supply of nutrient blood, the result should be analogous if not exactly like that which takes place when the vessel is deprived of its cellular coat from any other cause, that is, a slough should form on it, on the separation of which the hæmorrhage should occur violently and with a gush. An illustration of this is familiarly observed in the phagedenic ulceration of buboes in the groin, where the artery for a time appears to resist the destructive process, and lies denuded like a white cord at the bottom of the sore; but one or more black spots form upon it, which are really specks of mortification, on the detachment of which the bleeding commences with awful violence. Perhaps consecutive hæmorrhage does occasionally occur from the burrowing of an abscess along the coats of an artery, an example of which is on record in Mott's case of ligature of the innominata, in which the bleeding occurred ten days after its removal, was so violent from the first as to be with much difficulty restrained, and destroyed the patient on the day but one afterwards. But it may be observed that the phenomena attendant on these cases are different from those already described as characteristic of the common forms of the accident—that they usually occur at a later period, even long after the separation of the ligature might have inspired confidence in the result, and they are evidently more hopeless, for neither pressure nor ligature can here be of the slightest avail. Farther, to appeal to experience, the best and surest foundation of every scientific principle, is it not a matter of daily observation that this much-dreaded insulation of the artery can have but little effect on the ultimate termination of the case, as operations performed in this respect in the most bungling and clumsy manner occasionally end well, whilst the utmost caution in not exposing more of the artery than will barely permit the passage of the ligature cannot ensure the patient from secondary hæmorrhage?

When the bleeding is occasioned by any defect in the operation, such as tying the cord too loosely, including adjacent structures, &c. it usually appears so early as from the third to the fifth day after the operation, and there is another form of early consecutive hæmorrhage that occurs in consequence of the artery itself being inflamed or otherwise diseased at the time of the operation. An example of this is too often met, when, as a means of controlling consecutive hæmorrhage, a fresh ligature has been tied on the trunk somewhere higher up or nearer to the heart. It has been remarked by Dupuytren, that an artery under such circumstances is in a most unfavourable condition for an operation; it is surrounded by cellular tissue in a state of inflammation, in which it participates; its coats are rendered so brittle that they break down immediately under the ligature, and the hæmorrhage returns in a few hours.* It is worthy of remark that in this case also the bleeding comes from the orifice of the vessel below the ligature; indeed, in all cases of divided artery, whether by a cutting instrument or by a cord, the remedial process seems to be different in the two fragments, being far more perfect in the upper. On this point the statements of Mr. Guthrie are most valuable because founded on extensive observation, and he remarks in the case of an artery, the bleeding from which had ceased of itself, that if it recurs it is more likely to proceed from the lower than the upper portion. This latter fact is the more important as it bears upon another supposed cause of secondary hæmorrhage, namely, the state of tension in which an artery inclosed in a ligature is necessarily placed.

Many years ago it occurred to Mr. Abernethy that, "as large arteries do not ulcerate when they are tied upon the surface of a stump after amputation, it would be right to tie them in cases of aneurism as nearly as possible in the same manner and under the same circumstances." It is familiarly known that he recommended for this purpose the application of two ligatures with the division of the artery between them; and he argues that the divided portions would be like the large vessels on the surface of the stump in possession of all their surrounding connexions, whilst they are left in a *lax state* in consequence of their division. But the cases after all are not analogous, because in the stump there is no inferior portion of vessel from which it has been seen the chief cause of apprehension arises—it has been cut away, and only the superior remains, from which it is rare to meet with hæmorrhage under ordinary circumstances. In Mr. Abernethy's operation it is only the upper division of the vessel that bears analogy with the artery of the stump, and the insufficiency of the removal of the tension in preventing hæmorrhage from the inferior is proved, first, by the fact that consecutive hæmorrhage occurs in cases that have been thus treated proportionally as often as in others; and, secondly, by Mr. Guthrie's observation that in the case of a wound there is no tension: the artery has been fairly divided, and its surrounding connexions are undisturbed; yet the bleeding, having ceased spontaneously, or, in other words, having been controlled by the power of nature alone, may recur, and when it does the blood flows from the lower orifice.

Others have believed that the accidental position of a collateral branch near to the ligature might be a cause of consecutive hæmorrhage by interfering with the formation of the internal coagulum. I have already stated that the importance attached to this coagulum was greater than it deserved; and it will be only necessary here to add, that I have tied the common carotid artery within an eighth of an inch of its origin from the innominata without the slightest ill consequence from that circumstance.

It has been pretty generally believed that in those cases which have ended favourably, a mild, healthy, and mitigated process of inflammation had been established which terminated in the effusion of lymph and the obliteration of the vessel, whilst in the unfavourable the inflammation was more violent and ran into ulceration. Nothing is more familiar than to hear of the ulceration of an artery in connexion with and as the cause of secondary hæmorrhage, yet the existence of such ulceration is very questionable. Arteries are not prone to ulcerate. It has been shewn that in the midst of phagedenic destruction, the artery escapes for a length of time, and when it is attacked, it is rather by mortification: and the appearance of arteries traversing in safety the cavities of tubercular abscesses in the lungs, where they have lain for weeks or months bathed in purulent matter, should make us hesitate in speaking so boldly of ulceration in these structures. The fact, as observed on dissection, appears to be quite otherwise, and the hæmorrhage to be occasioned not by a hyper-activity of inflammation tending to ulceration, but by an absence or failure of the process altogether.

As persons, the subjects of consecutive hæmorrhage, seldom die (at least in this country)

* Leçons Orales, tom. iv. p. 573.

of actual loss of blood, it is not easy to procure a dissection which can satisfactorily shew the condition of the vessel at the moment it begins to bleed, and no subsequent examination can be relied on, because the pressure or other means used to stop the bleeding may in the course of a very few days alter the appearances completely. I have availed myself of every opportunity that occurred, and state the results, not with the presumptive hope of being able to establish any general principle, but to excite others to inform themselves on every case favourable to the further prosecution of the inquiry, and, perhaps, in some respects to justify the opinions I have formed. It is worthy of remark, that secondary hæmorrhage occurs much more frequently in the arteries of the lower than of the superior extremities or of the neck, and all the specimens I have examined were of the femoral that had been tied from half an inch to an inch and half below the profunda. In all, the portion of the artery above the ligature gave indications of inflammation extending nearly as high as the common iliac; the lining membrane more or less vascular; the portion of the vessel between the ligature and profunda of its natural size or slightly diminished; its cavity occupied by the remains of a coagulum. Above that point the calibre of the trunk was evidently increased, and the texture of its coats less resisting. The inferior portion resembled a vessel simply cut across, its calibre diminished, its internal coat discoloured, its divided edge smooth and even, not rough, jagged, or irregular, as would probably be the case if it had been the seat of ulceration.

When a ligature is tied tightly round an artery, every thing included within its noose is killed, but this is only a very small ring of the cellular coat, the internal and middle being as completely divided as if it had been done with a knife. When the absorbents have detached the connection of this ring with the remainder of the cellular coat, there is nothing (so far as the vessel is concerned) to retain it farther, nor is it of use in preventing hæmorrhage: it might be withdrawn, only that being entangled in lymph or granulations from the adjacent parts, such a proceeding would disturb the divided vessel before the curative process was complete. This process is in some instances, perhaps, never attempted in the inferior portion, although such a deviation from the usual course is probably not frequent; when it does happen, the cure is more tedious and longer of accomplishment, and when interterrupted prematurely, of course it is from this portion that the blood is poured out.

Whatever the process is by which the extremities of the two segments are closed, it is certainly not the same in both. This fact I was enabled to verify in one of the cases already alluded to,—namely, that of the man who died on the sixteenth day after the operation for popliteal aneurism, and whilst the ligature still remained undetached from the artery. The vessel was carefully removed from the body, and on being slit up, the lining membrane of the portion at the cardiac side of the ligature was of a pale yellow colour and nearly of its natural appearance, with the exception of one or two broad spots of a very light pink colour. A large coagulum extended upwards from the seat of the ligature, the base of which was attached to the lymph situated there. The ligature was still firm, but on attempting to tear it away, the lower portion of the vessel easily separated from it, leaving it still fixed firmly on the upper section: a circumstance which explained a fact I had frequently witnessed, that of secondary hæmorrhage occurring before the final separation of the cord. Below the spot where it had been tied the vessel appeared to be of a deep pink colour approaching to carmine, the seat of which colouring matter was in the cellular tissue between the fibrous and internal coats. This cellular substance seemed to be hypertrophied and largely congested with blood, whilst it caused the lining membrane to be thrown into transverse rugæ or folds. On pulling off this membrane, it was pale, transparent, and colourless—devoid of any proper vascularity: and on looking along the slit-side of the vessel the fibrous coat and the internal membrane were seen like white lines with the congested cellular tissue between them. *There was not a particle of coagulum either of blood or lymph in any portion of the vessels below the ligature.*

It may be objected that in this very dissection, the appearances would warrant a belief that a more active form of inflammation was present in the distal portion of the vessel, because of the deeper tint of colour and the superior thickness of the cellular tissue there observed. Such, however, was not the impression of those who witnessed the dissection. There was no result of inflammation visible after seventeen days, neither adhesion, nor suppuration, nor ulceration: there was merely a congested condition of the part—a condition not found in other structures or situations to lead to any of the usual products of inflammation.

An artery, the coats of which have been divided by a ligature, is subject to the same conditions as if it had been severed with a knife: its cavity must be obliterated from the wounded spot to the next collateral branch above and below. Now, the constitutional causes that can delay or impede this obliteration, if any, are not sufficiently known; but it is obvious that any local interference may (as in a case of open hæmorrhage) prove singularly perilous. During the first few days, whilst the continuity of the cellular coat is still unbroken, there is no cause for apprehension; but afterwards, any irregularity of diet, any excitement of the circulation, any unwary motion, any injudicious meddling with the ligature; in short, any one circumstance that can interfere with or disturb the operations of nature within the part before they are perfect and complete, will have a much more intimate connexion with the production of secondary hæmorrhage than any of the causes hitherto advanced. Hence it is, that the bleeding occurs some two or three days earlier than the period at which the ligature naturally separates and comes from the wound.

When the bleeding has commenced, it is a case of hæmorrhage from an open wound, and must be managed on similar principles, that is, pressure to a sufficient extent must be applied directly on the orifice of the vessel. I have never seen a second ligature applied on the mouth of the vessel, either in consequence of the difficulty of finding the artery in a wound swollen and matted up with lymph and granulations, or from an apprehension of the existence of such a diseased condition of its coats as would cause it again to break down under the cord. But I have frequently witnessed the effective operation of direct pressure, particularly in three cases, which occurred within the last few months, two of which were patients in the Meath Hospital, and all of whom recovered. In the application of this pressure, however, much caution is required. It should not be greater than is absolutely necessary to command the hæmorrhage; it ought to be maintained by means of some mechanical contrivance, and be independent of all bandages which are liable to stretch, to loosen, or to slip, and it should be removed the very moment this can be done with safety. If the bleeding has been perfectly restrained during three or four days, it is probable it never will return. The sequelæ of secondary hæmorrhage ought always to have been regarded as more important and more perilous than the bleeding itself. I have invariably found the wound to become the seat of unhealthy suppuration: very frequently abscesses form in different parts of the limb, and occasionally gangrene supervenes. It is sometimes difficult to connect any of these occurrences with a lesion of any structure within the limb; but too frequently the mischief can be evidently traced to the pressure being directed on the vein, and being either too forcible or too long continued.

Having thus, however imperfectly, sketched the pathology of the arterial system in connexion with the use of the ligature, it will be necessary to revert to other forms of disease, which have hitherto been postponed, in order to permit the introduction of the subject of secondary hæmorrhage, and that the practical arrangement of aneurism and its consequences, both fortunate and otherwise, might be as uninterrupted as possible.

Aneurismal varix.—In the year 1761, Dr. William Hunter* directed the attention of the profession to a disease that had not been before observed, one not indeed very formidable in its consequences, but exceedingly curious as to its exciting cause and subsequent progress. When an artery and vein lying in close contact are transfixed by a cutting instrument in such a manner that the aperture in one shall exactly correspond with that of the other; and when subsequent inflammation has so glued and fastened these apertures together, that, whilst a mutual transmission of blood between the vessels is freely permitted, not a drop will be allowed to escape in any other direction, a disease is formed, to which the discoverer gave the name of *aneurismal varix*. All and each of these several conditions are absolutely indispensable, and there are so many chances of their not being fulfilled in a case of wounded artery, that the infrequency of the disease may be easily explained. It does, however, occasionally occur, and for obvious reasons will most generally be found in the arm as a consequence of phlebotomy.

Soon after the infliction of the injury that has been the cause of the disease, a small tumefaction is observed in the vein; its appearance is irregular and knotted, but it is soft, yielding, and disappears on pressure. On laying the finger on it, a peculiar thrilling sensation is perceptible, and on applying the ear, a whizzing noise is heard, very much resembling that occasioned by a fly inclosed in a small paper bag. These phenomena disappear on either current of blood being interrupted by pressure on the artery above or on the vein below: at the same time that the tumour subsides a little, (though it soon regains its original size) and the peculiar noise is no longer heard. If the disease is allowed to advance uninterruptedly, the calibre of the artery above the point of communication becomes enlarged, but it is diminished below: the vein also enlarges chiefly in the direction of the current of its blood, rarely in the opposite, and then but very slowly. Another interesting circumstance is, that the peculiar thrill is heard and felt all over the dilated portion of the vein, at a distance from, as well as in the immediate neighbourhood of, the point of communication between the two vessels. It seldom produces any inconvenience that cannot be remedied by the use of a moderately tight bandage, and if thus managed in time never requires a severer treatment.

From the circumstance of pressure, either on the artery or vein, diminishing the size of the tumour and removing the thrilling sensation it imparted, it may be fairly inferred that both these phenomena are produced by the meeting of the two currents of blood, and their mutual resistance to the escape of either from its proper vessel. And further, it is obvious that if the disease should by any chance prove troublesome or alarming to the patient, its growth might be checked and its progress altogether stopped by permanently obliterating the canal of either the artery above or the vein below: but no operation that a surgeon would be justified in undertaking can remove the tumour, inasmuch as the blood still will continue to flow into and through the enlarged vein. The dangers of secondary hæmorrhage after an artery is tied, or of venous inflammation if the other vessel is tampered with, ought to inculcate the greatest caution, and it may be easily understood why in such cases Dr. Hunter thought it advisable not to interfere.

* Medical Observations and Inquiries, vol. i. and ii.

This disease must, in the great majority of instances, be the result of accident, and its probable situation has been already pointed out, but it is also possible that it may appear as an idiopathic affection without any previous violence. Some years since a young female applied at the Meath Hospital as an out-patient, in whom aneurismal varices existed between every artery and vein in the body that lay in a state of approximation to each other. In the neck, in several parts of the arms, the thighs, &c. the peculiar thrill and sound were remarkably distinct and plain. She did not seem to experience much uneasiness, nor could any probable exciting cause be assigned for such a singular form of disease. She had previously suffered from syphilis and been subjected to irregular mercurial treatment, but it would be scarcely fair to assume as the cause of a solitary specimen of disease in one individual, influences that operate so very differently on others.

Varicose aneurism.—When a vein and artery communicate with each other in a manner similar to that already described, excepting that an aneurismal sac formed of condensed cellular tissue and containing some coagulated blood is interposed between their orifices, the disease is termed a varicose aneurism. As this disease is generally the result of some accident in bleeding, as it occupies the same situation at the bend of the arm, and as the sac in that case never attains to any considerable size, it is difficult and frequently impossible to distinguish during life between the two affections: nor is the diagnosis of much importance, for as the pathological changes in the artery and vein, and the phenomena produced by them, are exactly the same, so will be the rationale of the treatment.

Some few years since, a patient was admitted into the Charitable Infirmary with a popliteal aneurism of the size of a child's head, and with all the veins of the limb, particularly of the thigh, enormously distended so as to appear like ropes twisted and knotted under the integuments. In every one of these veins the peculiar thrill and sound of aneurismal varix could be distinctly perceived. The account he gave of himself was this: he had a pulsating tumour in the ham for fourteen years previously, which gradually increased to its present size, until the veins began to swell, when the large tumour became stationary. He experienced but little inconvenience, and said he was able to walk eleven or twelve miles a day. He was frequently permitted to leave the hospital, and exhibited himself to several professional men for money. As he refused to submit to any treatment, and indeed no operation held out a prospect of much benefit, he was soon discharged. This man (I believe) still lives, and as he resides in a distant part of the country, perhaps the true pathological nature of a case so very interesting may never be ascertained. Could it have been that this was originally a case of popliteal aneurism that had burst into the popliteal vein? The position of this vein, and its very intimate connexion with the artery, cause it to appear to be a part of the sac of every popliteal aneurism, and it is not difficult to conceive that the tumour might have given way in this particular situation, and a communication been thus established between the artery and vein through the medium of the aneurismal sac.

It may not be unimportant to observe, that rare as these latter forms of disease are acknowledged to be, they are still more so in reality than is generally imagined. It often happens that a congeries of knotted and contorted veins forms a tumour strongly resembling the aneurismal varix in its external characters, and imparting similar sensations of thrill and sound. If one of these happens to occupy a situation favourable to the production of aneurismal varix, it might easily occasion a mistake, and perhaps it would be very difficult to point out a satisfactory diagnostic. I have seen two of these tumours dissected, which during the lives of the patients were supposed to have been aneurismal varices, in neither of which could the slightest communication with any neighbouring artery be discovered.

Aneurism by anastomosis.—The disease which was so named by John Bell, and by him first placed in the class of aneurismal tumours, has no title to such a position, unless that it forms a reservoir of blood, and occasionally exhibits the phenomenon of pulsation. But it materially differs in that the blood contained within it is fluid, is not withdrawn from the circulation, and therefore does not coagulate. The circumstances, however, of these tumours being increased or diminished in size by those influences which excite or depress the activity of the circulation, and of the leading trunks of the vessels supplying them having, however erroneously, been made the subjects of operation for their cure, serve to connect them in some respects with the pathology of arteries, and justify a passing notice of the subject here. This kind of tumour has also been called the nævus maternus or mother mark, because it so often appears from birth or at a very early age, and its shape, colour, size, or situation is explained by the mother on the supposition of some substance having been thrown at her, or from other causes of affright. It may, however, appear for the first time in more advanced life, in the form of a speck or pimple, which gradually enlarges until it constitutes a disease of a most important and sometimes dangerous nature.

The external characters of aneurism by anastomosis are somewhat varied, and have admitted of its classification under three forms apparently distinct from each other: 1. Where the mark or stain is merely cutaneous, does not increase in size, and is never pulsatile. These marks may be of different colours, sometimes red, sometimes of a brassy yellow, or perhaps brown; and as they occasion no inconvenience beyond the unsightliness of their size and situation, they can scarcely be considered as diseases. Indeed, if the common mole be admitted under this class of nævi, in many instances it seems to constitute a beauty rather than a defect. 2. Where the disease is situated in both the skin and sub-cutaneous cellular tissue. It appears as a patch, slightly elevated, of a red or purple colour, being generally of a brighter hue on the face or breast, and darker on those parts usually kept covered. The colour of the nævus also seems to depend on the quality of the blood with which it is altogether or principally supplied, as sometimes tumours are met with which might be termed venous aneurisms of this description, consisting evidently of veins indurated, knotted, and contorted on each other, increasing gradually, and never pulsatile; these frequently occur in different parts of the body of the same individual, and are always attended more or less with pain. The arterial nævus is, however, most intimately connected with the present subject. It sometimes presents an appearance as if irregularly granulated; more frequently is it smooth and velvety. The deep stain possesses a sharp and circumscribed edge, yet a net-work of minute vessels may be seen like an areola around it, conveying blood to nourish the tumour, and therefore forming an important part of the diseased structure. The tumour is increased in size and intensity of colour by every thing that accelerates the circulation—by exercise, intemperance, paroxysms of passion, and even by an elevation of temperature, and hence the supposed marks of currants and other fruits are said to grow red and ripen at the proper season. Its feel is doughy, and communicates a sensation as if it contained a jelly. It sinks, and is diminished by pressure on its surface, but immediately the pressure is removed it recovers its former level. It may be stationary for years, but the contrary is generally observed; its growth, however, is always irregular, being more rapid at one period than another. 3. The distinguishing characteristic of the third form of nævus is its pulsatility. It beats synchronously with the heart and arteries. When wounded, blood of a bright red colour flows from it, often in such abundance as to occasion syncope or even more dangerous consequences. As it grows larger, the skin gradually becomes thin; it bursts and bleeds; masses of coagula lie upon its surface, putrefying and occasioning the most unsightly appearance and most offensive odour. This is a condition that cannot endure long, the patient soon becomes irritable and weak, and falls a victim to that irregular, ill-formed hectic which is seen in every disease accompanied by extensive hæmorrhages. It is manifest that the distinctions between these latter forms of nævi are merely artificial; the second can be made to pulsate and to increase by heat or intemperance, the third can often be restrained by cold, by abstinence, and other means that debilitate the circulation.

The external appearances, however, yield no information as to the condition of the parts within, or the nature of this newly-formed structure; and on this subject anatomical investigation affords but little satisfactory knowledge. When a nævus is extirpated, it seems to consist of a mass of cellular tissue, collapsed and flaccid, which cannot be unravelled, and seems to bear no proportion in size to that of the tumour before removal. If it be cut away close to its defined edge, and without the extirpation of the zone of small vessels already described, the bleeding is frightful, and in very young children may be fatal, evidently shewing that these vessels are not endowed with contractility, and are a diseased and a new formation. If a nævus is injected, it only affords a swollen and unshapely mass of whatever material had been used, and throws no light whatever on the real pathology of the disease. Here, then, in the absence of demonstration, theory and conjecture are permitted, and all that is known, or supposed to be known, is only the fruit of speculation.

Bell supposed the tumour to consist of a congeries of cells, into each of which an artery and vein opened; that these cells increased both in number and in size with the growth of the patient, until they became immense reservoirs of blood; and, finally, that they became so distended as to burst and destroy life, as any other aneurism would, by a profuse discharge of blood. But still this explanation is defective, as showing nothing of the nature of the cells themselves, or why blood poured out into them should not coagulate as it would in any other cellular structure. It remained for Dupuytren to offer an ingenious and extremely probable hypothesis relative to these points, and he conceived the aneurism by anastomosis to be a "tissu erectile," analogous to that naturally found in many parts of the body.*

In the penis of man, and in the clitoris and mamella of woman, there is a particular structure, capable of receiving, retaining in a fluid state, and afterwards returning a given quantity of blood. These organs are provided with strong fibrous sheaths, that prevent their distension beyond a certain size, and are furnished with a number of nerves that preside over the circulation through them, and determine their conditions of erection and collapse. The abnormal "tissu erectile" consists of a cellulated structure, in itself of the same or a similar structure, but not being invested by a fibrous sheath or capsule, its growth is unrestrained, and the size to which it may attain has no limit; and as it has not a similar distribution of nerves, there is nothing to occasion either unwonted distension or collapse, and it is left solely under the influence of those causes that act upon the circulation. (See

* The late Mr. Shekelton of Dublin injected one of these tumours with wax from a large artery in its vicinity, and corroded away the animal matter by immersing it in a weak acid solution, by which it was shewn to consist of a congeries of vessels arranged in a retiform manner, dilated at some points and contracted at others. An able and interesting paper was read on this subject, and on the tortuosity of arteries generally, to the medical section of the British Association, which lately met at Dublin. The great attainments of its author (Mr. Adams) in pathological science lead us to look, not without some degree of impatience, for the full publication of the paper, of which but an imperfect report has appeared in the Dublin Medical Journal for September 1835.—Ed.

ERECTILE TISSUE.) Thus an aneurism by anastomosis is made to increase by heat, by passion, or by excess of any description, and by the removal of these, or by the application of opposite influences, its growth may be checked, or its pulsation stopped. But when once formed, it remains for ever, unless removed by spontaneous ulceration, by adhesive inflammation of the cells, or by operation; for although, if the general circulation be depressed, that in the tumour will be less active also, yet the structure is there still unaltered and ready to receive the blood and to exhibit all its wonted phenomena whenever the requisite stimulus is applied.

(W. H. Porter.)

ARTICULATA (*articulus*, a joint,) a primary division of the animal kingdom founded by Cuvier,* and characterized by him as follows: "Body jointed externally, corresponding to the divisions of the nervous system internally: a very small brain placed above the œsophagus gives off two filaments which extend along the abdomen and unite together from distance to distance by means of ganglions, which resemble as many small brains, from which nerves are given off. The muscular system is disposed on the inside of the rings or segments of the body so as to separate and approximate these segments; when there are articulated members, the muscles of these parts are also placed within the hard parts. The divisibility of the body, and the power which the fragments possess of retaining a kind of independent

* This division was virtually established by Cuvier in his earliest work, the "Tableau Elémentaire de l'Histoire Naturelle des Animaux," although it was not defined with that clearness, nor its characters so fully developed as in the Règne Animal. In the "Tableau Elémentaire" the second section of 'white-blooded animals,' including the *Insecta* and part of the *Vermes* of Linnæus, corresponds precisely with Lamarck's division of invertebrate animals, which he first denominated 'Articulosa.' (Hist. Nat. des Animaux sans Vertebr. tom. i. p. 454.)

vitality corresponds to the distribution of the nervous system into as many centres as there are corporeal segments."* With respect to the agreement between the number of segments of the body and the ganglions of the nervous system, it must be observed that in the higher crustaceans, arachnidans, and insects, the ganglions, though originally as numerous as the segments, subsequently become concentrated by progressive development into masses which are fewer in number, and that also in some of the lowest annelidans, as the leech-tribe, the external segments are more numerous than the internal ganglions.

In many of the molluscous class two nervous cords proceed backwards from the supraœsophageal ganglion or brain, and are afterwards brought into communication by ganglionic masses on the ventral aspect of the body; but in the Articulata the uniting ganglions are always confined to the mesial line of the body, are perfectly symmetrical in their arrangement, and are accompanied by a symmetrical or bilateral form of the whole body. It is this *homogangliate* disposition of the nervous system which essentially distinguishes the Articulate from the Molluscous and other divisions of the Animal Kingdom, and it is an infallible guide to the true affinities of the classes possessing it. The *Cirripeda* present a striking example of this fact: these animals, on account of their inarticulate body enveloped in a fleshy mantle and protected by a multivalve shell, were for a long time classed with the mollusca: but the views of those naturalists who considered that they had closer relations to the *Articulata*, although that opinion was founded on a knowledge of their nervous system only, has since been corroborated by every additional fact which has been discovered respecting them. Latreille, in his "Familles Naturelles du Règne Animal," first placed the cirripeds in the Articulate series, but being guided by their adult organization, and supposing that they were deficient in visual organs, and underwent no metamorphosis, he joined them with the annelidans, to form a division of Articulate animals, "*Elminthoida*," distinct from the "*Condylopeda*," which include the insects, arachnidans, and crustaceans, or the Articulata *with jointed feet*. The later researches of Mr. I. V. Thompson and Dr. Burmeister† have proved that in the immature state the Cirripeds undergo repeated metamorphoses or moults; that they move freely in the water by means of setiferous articulated members, and during this period guide their wanderings by the aid of distinctly developed, though simple eyes.

Besides the cirripeds the higher organized infusoria and intestinal worms have been proposed by some naturalists to be added to the articulate division of Animals: but as they are neither articulated nor possess articulate members, and as their nervous cords are simple and not brought into communication by a regular series of ganglions, we prefer to leave the Rotifera and Cœlelmintha with the Entozoa and Echinodermata, as a separate and higher subdivision of Cuvier's Radiata, and thus preserve the Articulata as a distinct and well defined subkingdom, characterized by a dispersion of the nervous system in a series of ganglions, symmetrically arranged and brought into communication by a double nervous cord; by an articulate or jointed structure of the body or its appendages, by the lateral position and horizontal movements of the jaws, when these are present, and by the presence of distinct respiratory organs. The subdivisions of this subkingdom are not founded on the modifications of any single system, but principally rest on the conditions of the sanguiferous and respiratory organs, in connexion with exterior form, modes of locomotion and generation.

I. The *Cirripeds, (cirripedia, cirripeda, cirrhopoda)*; oceanic animals called barnacles and acorn shells: they are characterized by their fixed condition, being either sessile, or attached to foreign bodies by means of a peduncle; their generation is, consequently, hermaphrodite, without the intercourse of separate individuals, but the male and female organs are distinctly developed in each animal. The blood is colourless and is propelled by a dorsal vasiform heart, but the venous system is diffused. The branchiæ are internal. The cirripeds undergo metamorphoses, but are ultimately inclosed in an inarticulate defensive covering of shelly pieces varying in number, form, and size.

II. The *Annelidans, (Annelida, red-blooded worms,)* are always locomotive; and, consequently, although hermaphrodites, they enjoy the intercourse of the sexes, and reciprocally fecundate each other. Their blood, which is generally red, like that of the vertebrate animals, circulates in a closed system of arteries and veins, which sometimes has appended to it several well-marked propulsive cavities or hearts; they respire by means of organs sometimes developed externally, sometimes remaining on the surface of the integument, or lodged in its interior. Their body, which is of an elongated form, and covered with a soft skin, is always divided into numerous transverse segments, of which the first, called the head, scarcely differs from the others, except by the presence of the mouth and of the principal organs of the senses. Many possess branchiæ, arranged the whole length of the body, or situated at the middle; others, which for the most part inhabit tubes, have the branchiæ collected at the anterior part of the body; in others, again, the respiratory organs are in the form of internal air sacs. The annelidans never possess articulated limbs, but many have, instead thereof, stiff bristles, or hooks, frequently inclosed in tubular prolongations of the integument.

The other *articulate classes*, viz., *insects, arachnidans*, and *crustaceans*, differ from the preceding classes in the possession of articulated limbs, terminated by claws; and in

* See his celebrated memoir, "Sur un nouveau rapprochement à etablir entre les classes qui composent le règne animal." "*Annales du Muséum d'Histoire Naturelle*, 4to, tom. xix. p. 73.

† Beiträge zur Naturgeschichte der Rankenfuesser, 4to. Berlin, 1834.

connexion with the superior powers of locomotion afforded by these appendages, the sexes are separate, and the organs of vision are well developed, and often highly complicated. With the exception of some genera, as the myriapoda, in which the body is divided into a number of nearly equal segments, and of the *arachnida* and many *crustacea*, in which the head and thorax are blended together, the body of the condylopes of Latreille is divided into three principal parts, viz., the *head*, which bears the antennæ, the eyes, and the mouth; the *thorax*, which supports the feet and the wings, when the latter are present; and the *abdomen*, which contains the principal viscera.

These segments present different degrees of hardness in the different classes of condylopes, being most flexible in the arachnidans, firmer in the insects, and calcareous in most of the crustaceans. The origin of the *insections* or articulations of the body which form so marked an external character of these animals, is as follows:—

The integument is composed of two layers or pellicles, viz., the epidermis and the corium, and is originally of equable consistence, and presents an uninterrupted continuity, save by some slight transverse superficial wrinkles. The epidermis subsequently becomes solidified, in arachnidans and insects, by the superaddition of a peculiar substance termed *chitine*, and in crustaceans by a calcareous deposition, so as to be divided into bands or rings. As the external development proceeds, these epidermic pieces are detached posteriorly from the inferior pellicle, or corium; and the intervals of the segments remaining membranous, and preserving their flexibility, yield readily to the various movements and inflections of the body.

The IIId class of articulate animals or *Insects (Insecta)*, are either myriapod or hexapod. Most of the latter are furnished with wings, which they acquire at a certain age, after undergoing metamorphoses varying in kind and degree. In every state they respire by tracheæ, or elastic vessels which receive the air by stigmata, situated along the sides of the body. A dorsal vessel propels the circulating fluid, which is afterwards diffused throughout the cellular tissue of the body. They have conglomerate or compound eyes, and antennæ.

IV. The *Arachnidans (Arachnida*, Spiders, Scorpions, &c.), are octopod and apterous; they have no antennæ, and have simple eyes. Their circulation is effected by a dorsal vasiform heart which transmits arterial branches, and receives the returning blood from veins. Their organs of respiration vary, some possessing true pulmonary sacs which open upon the sides of the abdomen, others receiving the air by tracheæ, like insects. In both cases, however, the air is respired by lateral orifices or true stigmata.

V. The *Crustaceans (Crustacea)* have never less than ten feet; they have two compound eyes, and also antennæ, which are generally four in number; their blood, which is white, is circulated by means of a muscular ventricle situated on the back. They respire by means of gills, and have no stigmata, or spiracles on the surface of the skin.

In the Articulate sub-kingdom, as in the vertebrate, there may be traced one general plan of structure pervading all the classes, but with such variations in it as are, in each case, demanded by the particular exigencies of the individual to which it is applied; but these variations are of such a nature, that a gradation of complexity or perfection may be followed through all the organic systems. With regard to locomotion, we commence with a class (the Cirripeds) as fixed and immoveable as the polypes and sponges of the Acrite sub-kingdom; and afterwards trace a series of forms adapted first to slow and tortuous reptation; next to swifter progression, as creeping, running, or leaping; and, lastly, to a rapid flight through aerial space.

Generation, in like manner, is effected, in the lowest class, without the intercourse of separate individuals; afterwards by the reciprocal impregnation of co-equal hermaphrodites, and, lastly, as in the vertebrate division, by individuals of distinct sexes.

The perfection of the nervous system results from the approximation of many separate ganglions into fewer masses of nervous matter. The organs of the senses also augment in number and complexity.

The Articulata present, in the organs of the vital functions, as strongly marked differences as are met with in the vertebrate animals. With respect to the sanguiferous system, a gradation may be traced from a circulation in closed vessels to a diffused condition of the nutritious fluid; and a corresponding passage from the articulata which respire by means of circumscribed branchiæ, to those in which indefinitely ramified tracheæ carry the air to all the parts of the body. The amount of respiration thus produced occasions the same effects here, as in the Vertebrate sub-kingdom, and the Insects thus constitute, as it were, the Birds of the Articulate division of animals.

(Richard Owen.)

ARTICULATION *(in anatomy)*, synonymous with *joint*. (Gr. αρθρον. Lat. *articulus*, *arthrosis*, *junctura*. Fr. *articulation*. Germ. *Articulation*, *Gelenk*. Ital. *articolo)*.

The power of motion, to an extent however limited, seems to be inseparable from our idea of an animal, and in looking through the animal series we find none which do not appear to be endowed with this power whether for the purpose of progression, or simply of altering the position or condition of some part of their bodies with respect to the others. The organic structure which is the immediate agent in this motive power (the muscular fibre), is one and the same throughout the whole chain of animals, variously modified according to the degree and force of the motions necessary for the particular individual. The mechanism by which this structure acts upon the different parts of the body varies considerably, and increases in complexity as the forms of the animals themselves become more complex. In the lowest grade of animals the structure is so soft and pliant that nothing more is required to produce motion than this contractile tissue, which acts in obedience to certain stimuli. But when hard parts are superadded to the structure of the animal, we then find a peculiar mechanism to allow of the motion of these hard parts on each other without the risk of injury. It is obvious that such motion could not take place were these hard parts united in one piece. Hence we find that they are subdivided into segments, and these segments are joined to each other through the medium of some structure more flexible than that of the segments themselves, or by an apparatus of such a construction as to admit of the motion of one segment upon the other. It is to these joinings of different segments of an animal body that the term *articulations* or joints has been applied.

An articulation may, therefore, be defined to be the union of any two segments of an animal body through the intervention of a structure or structures different from both.

The most perfect and elaborate forms of articulations are those which are seen in animals that possess a fully developed internal bony skeleton, and in none may they be studied with more advantage than in man. We propose to treat of the forms and structure of the articulations in man, and at the same time to inquire what modes of mechanism are employed for analogous purposes in the lower classes. In the human subject and in the vertebrated animals generally, we shall, indeed, have particular occasion to admire the articulations, as mirabiles commissuras, et ad stabilitatem aptas, et ad artus finiendos accommodatas, et ad motum et ad omnem corporis actionem.*

It will be observed that the definition here given of articulation is of the most comprehensive nature. In most instances, in man, two parts articulated together are joined by their solid portions, which are never in immediate apposition with each other, but have some elastic structure interposed which may or may not form a bond of union; and it is obvious that the fact of the intervening substance being, or not being also a bond of union will greatly influence the extent of motion of which the joint is capable. Before inquiring into the variety of forms of joints, we shall first examine briefly the various structures which enter into their composition, and which essentially contribute to the perfection of their mechanism.

These parts may be enumerated as follows, and we propose to observe the same order in treating of them: — 1. Bone. 2. Cartilage. 3. Fibro-cartilage. 4. Ligament. 5. Synovial membrane.

1. *Bone.* — The osseous or an analogous structure constitutes the fundamental portion of an articulation in all the vertebrated animals, in the mollusca, and in some of the articulated classes. In the human subject and all vertebrated animals we find that certain parts of the bones have surfaces marked upon them in correspondence with similar surfaces on others with which they are connected, or that, as in the long bones, the extremities are expanded or enlarged, and present surfaces which are adapted to similar surfaces on contiguous bones. In this way are formed the articular portions of the bones, and we observe that these portions present considerable varieties in their characters according to the nature of the articulation which they contribute to form. In fact, in examining these articular portions of the bones we cannot fail to notice the diversity of their form, so that some are adapted to each other in such a manner as evidently to favour motion, and others are so framed as to limit and restrict it. The articular surfaces in dry bones are generally characterised by a peculiar smoothness, indicative of the existence on them of a cartilaginous incrustation in the recent condition. The expansion of the extremities of the long bones on which the articular surfaces are formed is to be attributed to the accumulation there of a considerable quantity of the reticular texture, covered by a thin lamina of compact tissue, whereby a large surface is obtained without the inconvenient increase of weight which would necessarily result did that portion of the bone contain compact tissue to any extent. In the neighbourhood of the articular portions of the bones we find certain eminences, depressions, or roughnesses, which indicate the points of attachment of those bonds of union by which the joints are secured and strengthened. In general it may be observed that the long bones are articulated with each other by joints which possess a considerable extent of motion; the flat bones, again, have articulations very limited in their mobility, and this is likewise the case with the irregular bones.

2. *Cartilage.*—Pure cartilage enters into the composition of almost all joints, but more particularly of those which are very moveable, and indeed the chief purpose for which it is employed in the economy of adult animals is as an important and valuable element in these moveable joints. *Articular* cartilage, therefore, constitutes a primary subdivision of this texture by systematic writers. Its hardness, its elasticity, and the limited degree of organization which it possesses, peculiarly adapt it for the purposes to which it is applied in the mechanism of the articulations.

Although cartilage is chiefly employed in those joints which possess considerable mobility, it nevertheless also exists in joints which are limited in their motions, and as it possesses peculiar characters according as it belongs to one or other of these classes of articulations, we may very conveniently subdivide it into— *a*, cartilage of moveable articulations, or articular cartilage properly so called, or diarthrodial cartilage; *b*, cartilage of articulations very limited in their motions, or cartilage of sutures, or synarthrodial cartilage. Under these heads we propose to treat of articular cartilage.

* Cicer. de Nat. Deor. l. ii. c. 35.

a. Diarthrodial cartilage. — The general characters of this class of articular cartilage may be best examined on the articulating extremities of the long bones. Here we observe it moulded exactly to the forms of those surfaces, insomuch that, after a little maceration, the cartilage may, by careful dissection, be removed from the bone, to which it adheres with great firmness, and will be found to exhibit an exact mould of the articular extremity; hence these cartilages have been called "*cartilages of incrustation.*" This cartilage is perfectly distinct at the early periods of life from the temporary cartilage which forms the nidus of the future bone, and cannot be regarded as a portion of that cartilage left unossified; this may easily be seen by examining a vertical section of a femur or tibia at this period; and the peculiar arrangement of the fibres of the articular cartilage, hereafter to be noticed, constitutes an additional proof that it is completely distinct from that which is afterwards transformed into bone.

The physical properties and general characters of this form of cartilage do not differ from those of the others; it possesses the same pearly whiteness—the same apparent homogeneousness of structure—the same elasticity—the same absence of vessels carrying red blood. It is not covered by a perichondrium; the surface towards the joint is peculiarly smooth and glistening, and is generally supposed to owe these properties to its being lined by a layer of the synovial sac of the joint; this point, however, has been controverted, as we shall notice in a subsequent part of the article. The first and the most complete investigation of the true anatomical construction of articular cartilage was that announced by Dr. William Hunter so long ago as 1743.* His paper still deserves the most attentive perusal, not only for the actual information it affords on its professed subject, but as a specimen of the careful and original method of observation pursued by its distinguished author. To examine the structure of articular cartilages, it is necessary to subject them to boiling or a long-continued maceration.†

"When an articulating cartilage is well prepared," says Dr. Hunter, "it feels soft, yields to the touch, but restores itself to its former equality of surface when the pressure is taken off. This surface, when viewed through a glass, appears like a piece of velvet. If we endeavour to peel the cartilage off in lamellæ, we find it impracticable, but if we use a certain degree of force, it separates from the bone in small parcels, and we never find the edge of the remaining part oblique, but always perpendicular to the subjacent surface of the bone. If we view this edge through a glass, it appears like the edge of velvet, a mass of short and nearly parallel fibres rising from the bone, and terminating at the external surface of the cartilage: and the bone itself is planned out into small circular dimples where the little bundles of the cartilaginous fibres were fixed. Thus we may compare the texture of a cartilage to the pile of velvet, its fibres rising up from the bone, as the silky threads of that rise from the woven cloth or basis. In both substances the short threads sink, and bend in waves upon being compressed, but by the power of elasticity recover their perpendicular bearing as soon as they are no longer subjected to a compressing force. If another comparison was necessary, we might instance the flower of any corymbiferous plant, where the *flosculi* and *stamina* represent the little bundles of cartilaginous fibres, and the calyx, upon which they are planted, bears analogy to the bone."*

The total absence of vessels capable of carrying red blood in articular cartilage is proved by the failure of even the minutest injections to pass into the cartilage, and a further confirmation of this opinion is derived from the fact that madder taken into the system of a young animal does not stain them. The attempts of anatomists to trace lymphatics and nerves into this structure have been equally unavailing.

The design of articular cartilages, as means to break the violence of shocks, is well illustrated by comparing the different arrangement of the cartilaginous incrustation on convex articular surfaces from that on concave. In the former, we observe the layer of cartilage to be very thin at the circumference of the articular surface, its thickest portion being in the centre, while the opposite arrangement obtains on concave surfaces: there the thinnest portion of the cartilage is in the centre, and the layer increases in thickness as it approaches the circumference.

"The articulating cartilages are most happily contrived to all purposes of motion in those parts. By their uniform surface they move upon one another with ease: by their soft, smooth, and slippery surface mutual abrasion is prevented: by their flexibility, the contiguous surfaces are constantly adapted to each other, and the friction diffused equally over the whole: by their elasticity, the violence of any shock, which may happen in running, jumping, &c. is broken and gradually spent; which must have been extremely pernicious, if the hard surfaces of bones had been immediately contiguous. As the course of the cartilaginous fibres appears calculated chiefly for this last advantage, to illustrate it, we need only reflect on the soft undulatory motion of coaches, which mechanics want to procure by springs, or upon the difference betwixt riding a chamber-horse and a real one."†

* Of the Structure and Diseases of Articular Cartilage, Phil. Trans. vol. xlii.

† The articular cartilage on the patella may be selected as very favourable for this purpose. See the plate annexed to W. Hunter's paper.

* Loc. cit. p. 516.

† Hunter, in loco citato. Hunter's account of articular cartilage is completely confirmed by M. De Lâsone in a paper in the Mém. de l'Academie Royale des Sciences, An 1752. He describes the cartilage as "une multitude des petits filets adossés et liés les uns aux autres tous perpendiculaires au plan de l'os, en un mot parfaitement semblables par leur structure, ou par leur position à la substance emaillée des dents, laquelle n'est composée, comme on sait, que de filets osseux, posés perpendiculairement sur le corps de la dent: la comparaison est des plus exactes."

b. Synarthrodial cartilage.—The cartilages of synarthrodial articulations are destined in some degree to act as bonds of union, as well as means of separation and for the prevention of the effects of concussion. They are simply cartilaginous laminæ interposed between the osseous articular surfaces, very adherent to both, and adherent likewise by their margins to the periosteum or ligamentous expansions which may pass from one bone to another. We find instances of these cartilages in the sacro-iliac symphysis, or *synchondrosis*, as it has been called from the junction of the bones by cartilages;* also in the sutures, where there are very thin cartilaginous laminæ interposed between the osseous margins. These laminæ will be found to be triangular in their section, the thin edge or apex being internal, which, as Meckel observes, may in some degree account for the earlier obliteration of the sutures on the internal than on the external surface of the cranium. These cartilages of sutures are not strictly permanent; they disappear with age: and according to Beclard, hold the midway, as to frequency of ossification, between permanent and temporary cartilages.†

The cartilages of the ribs perform in some degree the office of articular cartilage; they are situated between two osseous surfaces; they form bonds of union, and their elasticity is eminently essential to the full performance of the movements of the thorax.

In fishes most of the moveable articulations are provided with elastic cartilages, which serve the double purpose of forming bonds of union as well as of permitting motion by their elasticity.

3. *Fibro-cartilage.*—This remarkable structure, called by the older anatomists *ligamentous cartilage* or *cartilaginiform ligament*, is made much use of in the articulations; and it is well adapted for a means of union, by reason of its great strength, which it owes to its ligamentous part, and of its elasticity, for which it is indebted to its cartilaginous portion. We find fibro-cartilage to be connected with the joints under three forms:

a. In the form of laminæ, free on both surfaces to a greater or less extent, and lined to the same extent by the synovial membrane reflected upon them.‡ These are the interarticular cartilages or *menisci* of authors. They are found in the temporo-maxillary, sterno-clavicular, and tibio-femoral articulations, sometimes in the acromio-clavicular, between the bodies of the cervical vertebræ in birds, and in general in those joints where there is constant and extensive motion, and consequently where the articular surfaces are exposed to considerable friction. The principal use of these fibro-cartilaginous laminæ must unquestionably be to guard against any bad consequences likely to arise from this continued friction; this is particularly obvious in the sterno-clavicular articulation. To increase the depth of an articular excavation is another object, as appears from the semilunar cartilages of the knee-joint; and moreover, in conjunction with the attainment of these two objects, to ensure in all the motions of the joint a perfect adaptation of the articular surfaces to one another, as will appear obvious to any one who carefully considers the construction of the temporo-maxillary or even of the knee-joint.

It will be observed, that I do not include in the class of interarticular fibro-cartilages, the lamina which is commonly known by the name of the *triangular cartilage* of the wrist joint, as is done by all the systematic writers I have looked into; for, first, it does not appear to me to be fibro-cartilaginous in its structure; it is purely cartilaginous; and, secondly, it is not interarticular, in the sense in which we here use that term, viz., as lying between two articular surfaces. This lamina seems to be merely an extension of the cartilaginous incrustation of the inferior extremity of the radius, which completes the articular surface for the reception of the first row of carpal bones. The scaphoides and lunare are provided for by the radius; but as the ulna could not be brought into the composition of the wrist-joint without interfering with the motions of the inferior radio-ulnar articulation, a structure such as the triangular cartilage, was necessary—one which would present a sufficient opposing surface to the articular portion of the os cuneiforme, and which would not impede or obstruct the necessary motions of the joint between the radius and ulna.

In the cases of the temporo-maxillary and sterno-clavicular articulations, these fibro-cartilages form, in general, complete septa between two portions of the joint: so that there are then two synovial sacs; but sometimes there is a perforation in the centre of the fibro-cartilage.

b. The second class of articular fibro-cartilages consists of those which Meckel designates *fibro-cartilages of circumference*, or *cylindrical fibro-cartilages.* They form fibro-cartilaginous brims to certain articular excavations; they are triangular in their section, attached by their basis to the osseous margin of the articular cavity, and free at their apices, lined by synovial membrane on the whole of one side, and a great part of the other. They are to be found only in two joints, namely, on the margin of the acetabulum in the hip-joint, and on the edge of the glenoid cavity in the articulation of the shoulder; in the former, this fibro-cartilage is much larger and stronger, and is evidently

* No one can have failed to notice the peculiar yellow appearance of the cartilage in the sacro-iliac articulation. Does that arise from an admixture of the yellow elastic tissue with the pure cartilage, by which the elasticity of the latter is increased?

† It is doubted by some whether these cartilaginous laminæ can be admitted into the class of articular cartilages; they being regarded as forming a nidus for the extension of the flat cranial bones, and the sutures being supposed to be useful only for this purpose, viz. to admit of the growth of these bones at their margins in a manner analogous to that of long bones at their extremities. See Soemmerring de Corp. Hum. Fab. t. i. p. 212, and Gibson on the use of sutures in the skulls of animals, Manchester Memoirs, 2d series, vol. i.

‡ This point, however, is liable to the same objections as that of the continuity of the synovial membrane over diarthrodial articular cartilages, which will be considered in a subsequent part of the article.

intended to obviate the ill consequenees which must have resulted from the violent applieation of the neck of the femur against the bony margin of the acetabulum: for, where the margin of that cavity is ligamentous, viz., at the notch on its inner side, this fibro-cartilage does not exist.

c. The most remarkable and beautiful variety of this structure belongs to the third elass. It consists of fibro-eartilaginous laminæ, generally of considerable thickness, which intervene between two bones and adhere intimately to each. Examples of it are to be found between the bodies of the vertebræ, (intervertebral substance)—between the pieces of the sacrum in early life—between the sacrum and coccyx, and between the pieces of the latter—also, between the ossa pubis at the joint called the symphysis pubis. In this class of fibro-cartilages too, we may place that which is situated between the scaphoid and lunar bones in the carpus.

It is evident that these fibro-cartilages are useful, not only as very powerful bonds of union, but also as elastic cushions placed between the bones to prevent the concussion which must necessarily result, did the unyielding bony surfaces come together with any degree of force. No where is this so beautifully exhibited as in that chain of bones which forms the spinal column in the mammiferous vertebrata, the strength and flexibility of which result from the fibro-cartilaginous discs, which, placed between the bodies of the vertebræ, are commonly called *intervertebral cartilages.*

As to the structure of articular fibro-cartilage, we can distinctly observe, without any process of dissection, that it is compounded of fibrous tissue as well as of cartilage. As these fibro-cartilages generally assume more or less of the circular form, we find that the fibrous tissue is most abundant towards the circumference, and that the cartilage is most manifest at the centre. In the intervertebral substance, the fibrous tissue is arranged in concentric laminæ, placed vertically behind one another. Each lamina is composed of a series of interlacing fibres, which have intervals between them; these intervals, as well as those between the laminæ, are filled by cartilaginous tissue; towards the centre the fibrous laminæ diminish in number, the intervals become large, and at length the fibrous tissue disappears in toto; hence the gradually diminishing density towards the centre, which characterises the intervertebral substance. In fishes, there is such a diminution of density, that the central part is fluid, but here the surfaces of the vertebræ are excavated, not plane as in the mammiferous vertebrata, and the character of the articulation is thereby materially altered. The incompressible central fluid forms a ball, round which the cup-like excavations of the vertebræ play, while the fibro-cartilage at the circumference is made available in the lateral motions of the spine.

Of the three varieties of fibro-cartilage above enumerated, the menisci possess the most cartilage in their structure, and the circumferential fibro-eartilages the greatest quantity of fibrous tissue.

It may be questioned whether that peculiar structure which intervenes between the base of the skull and the condyle of the lower jaw in the whalebone whale, (*balæna mysticetus*) belongs to the class of fibro-cartilages, although it seems to bear a nearer resemblanee to that than to any of the other structures employed in the composition of joints. The following is Sir Everard Home's description of it.* "Between the condyles of the lower jaw and the basis of the skull is interposed a thick substance, made up of a network of ligamentous fibres, the interstices of which are filled with oil, so that the parts move readily on each other. The condyles have neither a smooth surface nor a cartilaginous covering, but are firmly attached to the intermediate substance, which in this animal is a substitute for the double joint met with in the quadruped, and is certainly a substitute of the most simple kind."

4. *Ligament.*—The term *ligament*, as it is used by systematic writers on descriptive anatomy, is by no means confined to portions of the "fibrous system" of Bichat, although all the articular ligaments (properly so called) belong to that system. Weitbrecht comprehends under this term all fibrous structures in and about joints, including the fibrous sheaths of tendons, and also all membranous folds, which are in any way concerned in maintaining soft parts or viscera *in proprio situ*. I apprehend, however, that a better definition of *articular ligament* could not be given than the following, which is that of Weitbrecht, the words printed in italics being added,—"Ligamentum est particula corporis, *plerumque* albicans, *interdum flava,* ex fibris flexilibus, *interdum* elasticis, plerumque parallele concretis, in substantiam tenacem fibrosam, ruptioni fortiter resistentem, et solidam compacta, eum in finem creata ut duæ pluresve partes quæ alias divulsæ per se subsisterent, adunentur atque in situ respectivo determinentur."† Most of the articular ligaments are employed to unite the bones which compose a joint; they also will be found uniting some of the interarticular cartilages within joints, or passing from one part of a bone to another (forming the "mixed" class of ligaments of Beclard); and such is the vagueness with which names are applied in descriptive anatomy, that folds of the synovial membrane often receive this appellation without the least title to it.

Artieular ligaments are divisible as regards their forms into two species, the capsular and the funicular or faseicular.‡

Capsular ligaments are generally cylindrical in shape, or rather barrel-shaped, being wider in the centre than at the extremes. Eaeh extremity envelopes one of the bones that enters into the formation of the joint, so that the articular cavity is completely surrounded by and enclosed within the ligamentous capsule. Liga-

* Comp. Anat. vol. i. p. 83.
† Syndesmologia, § 5.
‡ Beclard, Anat. Gen.

ments of this kind are composed of fibres which are closely interwoven with each other, and they sometimes receive accessions from bundles of ligamentous fibres coming from neighbouring bony prominences (these fibres being generally called *accessory ligaments.)* Capsular ligaments are not calculated to restrict the extent or direction of motion between the bones which they surround, and we consequently find them only in that kind of joint which admits of motion in all directions, viz. the *enarthrosis* or *ball-and-socket* joint, of which the only examples in the human subject are to be met with in the hip and shoulder. The internal or articular surface of capsular ligaments is to a great extent lined by one lamina of the synovial membrane, which is reflected upon it from the articular portion of the most moveable of the bones which form the joint.

Funicular ligaments are found in the form of rounded cords or flattened bands: they exist generally on the exterior of joints, very rarely on the interior, and always externally to the sac of the synovial membrane. They pass from bone to bone, adherent sometimes to the synovial membrane of the articulation, sometimes to the intervening fibro-cartilage. In ginglymoid joints they are always placed on the sides, and are called *lateral* ligaments; sometimes they cross or decussate with each other, whence the appellation *crucial*, and sometimes a ligament of this class assumes a nearly circular course, and forms a greater or smaller portion of the circumference of a circle, the remainder of the round being completed by the bone into which the extremities of the ligament are fixed; a ring is in this way produced within which the head, or a special process of another bone, is enclosed, as is seen to be the case particularly with the head of the radius in the superior radio-ulnar articulation, and with the processus dentatus in the joint between the axis and atlas: the ligament in such instances is called *coronary*. When a ligament is concealed in the interior of a joint, although situated externally to the synovial sac, or, to speak more correctly, in the space between the articular surfaces, it is called an *internal* ligament, e. g. the ligamentum teres of the hip-joint, the mucous ligament of the knee, or the transverse ligament of the same articulation.

Elastic ligament.—Hitherto we have been examining ligamentous structure, one of whose most prominent characteristics is the want of elasticity; but we now come to a kind of ligament which forms a most valuable constituent in the mechanism of some joints, and is eminently distinguished for the great elasticity which it possesses. It differs from ordinary ligament by its yellow colour, (whence the French appellation *tissu jaune,)* as well as by its elasticity. We find it in the human subject most developed in the *ligamenta subflava* of the vertebræ. In joints, as elsewhere, this tissue is employed to restore to the position of quiescence, parts which have been previously acted upon by muscular contraction. John Hunter fully appreciated the value and utility of this structure in supplying the place of muscle, with less expense of exertion to the economy, and assigned it a place in the arrangement of his museum.* The thyro-hyoid and crico-thyroid ligaments in man are formed of this structure.

5. *Synovial membrane*.—The articular synovial membranes, (by the older anatomists called, and confounded with, the capsular ligaments,) like all others, possess in common with serous membranes the form of a sac shut in all points; they line the whole interior of the joints, and secrete from their internal surface a peculiar fluid, obviously destined for the lubrication of the articular surfaces. These membranes are remarkable for their great tenuity; they are transparent; in a state of inflammation, their vascularity, which is imperceptible during health, becomes very apparent by the general redness which the membrane assumes; and their internal or secreting surface is easily distinguished from the external, by contrasting the smooth and glistening appearance of the former with the roughness which the latter receives from the cellular tissue and ligamentous fibres which adhere to it. The internal surface of the membrane is sometimes thrown into folds with fringe-like margins, which project into its cavity or sac. These folds contain more or less of cellular tissue and a number of pellets of fat, which being supplied with vessels, the margin of the synovial fringe is sometimes tinged red. These folds are compared, and certainly with much justice, to the epiploic folds of the abdominal serous membranes, more especially to the appendices epiploicæ of the great intestine. Beclard supposes that these fringes are specially the seat of the synovial secretion, which being perspiratory likewise takes place, though less abundantly and manifestly, from the rest of the synovial surface. The best examples of these folds occur in the knee and hip-joints, in the former of which they have been absurdly called *alar ligaments*.

Some idea may be formed of the manner in which the synovial membrane is related to the other articular structures by examining the annexed figure, (*fig*. 111,) representing a vertical section of the knee-joint. The cut margin of the synovial membrane is indicated by *a*, which after lining the posterior surface of the patella and ligamentum patellæ, is reflected upon the condyles of the femur, whence it is carried in front of the crucial ligaments to line the articular surface of the head of the tibia, and from that is again reflected upwards, and is continuous with the portion lining the posterior cartilaginous surface of the patella. This description is founded on the opinion, which I believe to be correct, that the analogy between serous and synovial membranes is accurate, in so far as their possessing in common the form of shut sacs is concerned. On this subject, how-

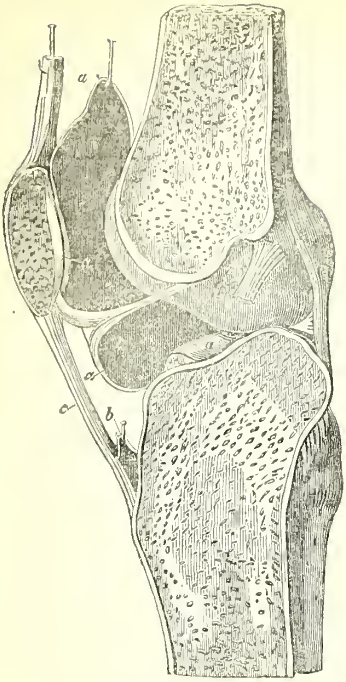
Fig. 111.



ever, anatomists are by no means likely ever to be unanimous, because of the difficulty or impossibility of tracing by the ordinary methods of dissection the synovial membrane over the articular cartilages. The continuity of this membrane over the cartilage was first distinctly announced and described by Dr. W. Hunter, in the paper to which we have already referred in the Philosophical Transactions: after him Soemmerring described it, and still later Bichat, who insisted more particularly on its analogy with serous membranes. Bichat's description has been followed by Meckel, Beclard, and most of the anatomists of modern times; but its accuracy has been called in question by Cruveilhier,* Gordon,† Magendie,‡ Blandin,§ and more recently by Gendrin|| and Velpeau.¶

The advocates for the continuity of the synovial membranes over the diarthrodial cartilages, found their opinion on the following facts:—1. Synovial membranes elsewhere, lining tendinous sheaths or bursæ mucosæ, are distinctly and obviously shut sacs. 2. We do not find cartilage to present the smooth and polished aspect exhibited by the articular surfaces, excepting where it is connected with synovial membrane, as it evidently is to at least a certain extent in the moveable articulations. 3. If by an oblique cut we raise a slice from an articular cartilage, and turn it back so as to rupture it at its base, we shall find it still retained in connexion with the rest of the cartilage by a thin pellicle, which seems to have all the characters of synovial membrane. A similar membrane may be seen by sawing a bone vertically down to the cartilage, and then breaking the cartilage by forcibly separating the segments. 4. Some observers state that they have seen the redness of inflammation affecting the synovial membranes prolonged over the cartilage,* but becoming gradually less marked towards the centre—(this, I must confess, I have never seen). 5. Bands of adhesion are also said to have been met with in some cases of chronic inflammation of the synovial membrane, passing from the articular surfaces, as well as from other parts of the interior of the joint. 6. In that peculiar disease of the synovial membrane described by Brodie, the pulpy substance has been seen on the articular cartilages, as well as on the menisci.†

On the other hand, the opponents of this opinion deny: 1, that the membrane demonstrable by slicing the cartilage in the way above described, is any thing else than a very thin lamina of cartilage; 2, they say that by even the most successful injection the fluid cannot be made to pass beyond the margin of the cartilage; 3, they assert that inflammation always stops abruptly at the circumference of the cartilage; 4, and that if a synovial membrane did exist on the free surface of the cartilage, there would take place a continual exhalation of synovia from the articular surface, contrary to what was found to be the case in an experiment tried by Cruveilhier: synovia was freely exhaled from the membrane lining the ligaments, and after having been wiped off reappeared with rapidity; but not so over the articular cartilage, the surface of which became quite dry.‡

Cruveilhier, however, relates a case which in some degree invalidates his own conclusions; it was one in which fungous granulations sprang from the articular surfaces of the femur and tibia in the knee-joint, and by their adhesion produced anchylosis of the joint: this fact Cruveilhier § very candidly expresses his inability

* I am uncertain whether the fourth case related by Sir B. Brodie in the last edition of his work on the joints, may not be regarded as affording an instance of this. In the account of the post-mortem examination it is said, " The synovial membrane was *everywhere* of a red colour, as if stained by the secretion," p. 15. Beclard, whose powers and accuracy of observation few will be disposed to question, speaks with the confidence of one who had seen this extension of the vessels over the cartilage.—Anat. Gen. p. 214.

§ He confesses, " ma conviction n'est pas cependant pleine et entière."

to explain without admitting either the existence of the synovial membrane, or the organization* of the cartilages. Velpeau,† too, although he asserts that the synovial membrane "terminates at the circumference of the cartilages," furnishes us with an argument in opposition to his own views: namely, that no appreciable line of demarcation can be detected indicating where the synovial membrane ceases. "Viewed in this way," he says, "the synovial apparatus consists of surfaces, membranes, and glandular folds, between which there exists not the least interruption, and the use of which is to isolate the interior of the joint from the tissues which surround it."

It will appear then sufficiently evident that the weight of argument preponderates in favour of the doctrine that the synovial membranes line the articular surface of the cartilages, and that maintains their analogy with the serous membranes, an analogy which receives the strongest support from the physical properties of the synovial membrane, from its obvious functions during health, and from the diseases with which it is affected; and I apprehend, that nothing tends more fully to establish identity or similarity in the nature of two membranes, than the fact of a close resemblance between their morbid conditions. We may add, what was long ago remarked by W. Hunter, that this question as to the continuity of the synovial membrane on the cartilages is very similar to that as to the continuity of the conjunctiva over the cornea of the eye; the affirmation of which latter question, Gordon considers equally an *anatomical refinement* as that of the former.

Velpeau ‡ ascribes much importance to the dense and fine cellular tissue which is subjacent to the synovial membrane and is analogous to the subserous cellular tissue elsewhere. This would appear to be the seat of the vessels which in a state of inflammation give rise to the red colour of the synovial membrane. He particularly alludes to it as affording a clue by which the formation of loose cartilaginous bodies in joints can be explained; these he supposes to originate in sanguineous effusions into this tissue, which subsequently become indurated and cartilaginous, and push the synovial membrane before them into the cavity of the joint. It will be remembered by many readers that this opinion is very similar to that of John Hunter regarding the origin of these bodies. §

Allusion has already been made to the fatty bodies which are found in connexion with most of the joints, and in general lying behind the synovial fringes formerly described. These fatty pellets were supposed by Clopton Havers* to be the agents of the synovial secretion, and, in consequence, have obtained much celebrity under the title of *Haversian glands*.† The opinion of Havers and his followers as to their glandular nature was successfully combated by Bichat, who proved that they were merely composed of adipose substance, and in no way concerned in the function of synovial secretion: for 1st, the secretion of synovia takes place where no such bodies exist, as in almost all the bursæ mucosæ, and tendinous sheaths; aud 2d, these bodies have no trace of glandular structure, nor are they provided with any thing resembling an excretory duct; whilst, on the other hand, they possess all the properties of fat.

The synovial sac is lubricated by the synovia, also called *unguen articulare*, *axungia articularis*. How is this secreted? We believe it to be a perspiratory secretion precisely similar to that of the serum from serous membranes. Its formation cannot be imputed to a combination of the serosity of the blood with the fat, nor to the transudation of the marrow through the extremities of the bones, nor, with Desault, to a sweating from all the parts which enter into the composition of the articulation, inasmuch as the chemical analysis of synovia proves that it is essentially different from any oily fluid, and does not contain a trace either of elaine and stearine.

In addition to the structures already named as entering intrinsically into the formation of joints, we find that the tendons and muscles, which lie in the immediate vicinity of or which surround the joints, contribute much to their strength and security. In joints of the hinge kind we generally see the anterior and posterior parts protected more or less by the tendons of muscles, and even by muscles themselves passing from one segment of a limb to another, and here it frequently happens that the tendon is bound down on the bones which form the member, by a fibrous expansion of great strength, lined by a synovial membrane of the same characters as the articular, but adapted in its form to the osseo-fibrous canal in which the tendon is placed, e.g. the tendons of the fingers. The protection and strength afforded by muscles is particularly evinced in the case of the shoulder-joint, where the capsular ligament is closely embraced by four muscles, whose tendons become identified with the fibrous capsule as they go to be inserted into the bone. A muscular capsule, as it were, is thus provided for this joint, by which the bones are maintained much more firmly and powerfully in apposition than were they kept together by an uncontractile ligamentous capsule alone; hence the elongation of the arm which ap-

* This is a bad word; we cannot deny the organization of cartilages, however we may deny that they are supplied with red blood. It has been said, I know not with what authenticity, that cartilages have become yellow in jaundice.

† Weitbrecht called these fatty bodies, "Adiposo-glandulosæ;" and Cowper, "mucilaginous glands." See them figured in Monro's work on the Bursæ, Tab. viii.

pears as a consequence of paralysis, and hence also the greater liability to luxation which exists in a debilitated state of the system. Articular or capsular muscles thus placed, have also the effect, as it is said, of preventing the pinching of the capsule or synovial membrane between the articular extremities of the bones in the different motions of the joint.

The joints are very generally copiously supplied with blood, and are remarkable for the arterial anastomoses which take place around them. The best examples of these are met with in each of the joints of the extremities. The parts supplied with blood are the synovial membranes, the ligaments, the fat, and the extremities of the bones; but the cartilages certainly do not receive vessels carrying red blood: I believe there is no fact in anatomy, more generally admitted or better determined than this. The vascular ramifications which proceed from these vessels may be seen, particularly in young subjects, advancing in the subsynovial cellular tissue, and forming a vascular net-work there, as far as the margin of the articular cartilage where they stop abruptly; this is what W. Hunter described under the name of *circulus articuli vasculosus*.

Of the forms and classification of the articulations.—It is not difficult, by passing in review the various motions which take place between any two segments of a limb, to form an idea, *à priori*, as to the kinds and shapes of the articulations by which these segments will be united; it is only necessary not to lose sight of the fact, that in the construction of a joint regard is had not to its mobility alone, but to its security, its durability, and the safety of the neighbouring parts. We may expect to find joints varying in the *degree* of motion, from the slightest perceptible quantity, to the freest that is compatible with the maintenance of the segments in their proper relation with each other, and also in *extent* of motion, from that which is so slight as to admit of almost no appreciable change in the position of the parts, to that which allows of the most ample variety of relation between the segments, consistent with the integrity of the articulation.

It will appear, then, that the most simple kind of articulation is that by which two parts are so united as that the slightest appreciable degree of motion only shall exist between them. This constitutes the first great division of joints —the *Synarthrosis* (συν, *cum*, and αρθρον, *articulus*)—where the parts are continuous, *i. e.* not separated from each other by an intervening synovial cavity. Some anatomists consider all synarthrodial joints to be immoveable; which, although not far from the truth, cannot be said to be strictly accurate. Had immobility been the object to be obtained, I imagine that that might have been more effectually accomplished by the fusion of the extremities of the segments together, as in anchylosis.

In the second class of joints, motion is enjoyed freely and fully: this class is designated by the term *Diarthrosis* (δια, *per*, and αρθρον): the segments are interrupted completely in their continuity; the extremities of the bones can only be said to be contiguous.

Synarthrosis.—The general characters of the articulations belonging to this class are, 1. that they are very limited in their motion, insomuch as to be considered by some as immoveable; 2. that their surfaces are continuous, *i. e.* without the intervention of a synovial cavity, but with that of some structure different from bone. The following varieties may be noticed among synarthrodial articulations.

a. Suture (Germ. *Nath* or *Naht. Commissura cranii*, Vesal.).—When the margins of two bones exhibit a series of processes and indentations (dovetailing) which are received and receive reciprocally, with a very thin cartilaginous lamina interposed, this is the ordinary kind of suture, *sutura vera*, of which three kinds are distinguished: *sutura dentata*, where the processes are long and dentiform, as in the interparietal suture of the human skull; *sutura serrata*, when the indentations and processes are small and fine like the teeth of a saw, as in the suture between the two portions of the frontal bone; *sutura limbosa*, when there is along with the dentated margins a degree of bevelling of one, so that one bone rests on the other, as in the occipito-parietal suture.

When two bones are in juxta-position by plane but rough surfaces, the articulation is likewise said to be by suture, and this is the false suture, *sutura notha*, of which there are two kinds: *sutura squamosa*, where the bevelled edge of one bone overlaps and rests upon the other, as in the temporo-parietal suture, and *harmonia* (αρω, *adapto*), where there is simple apposition: this last kind of articulation is met with, as Bichat* observes, wherever the mechanism of the parts is alone sufficient to maintain them in their proper situation, as may be seen in the union of most of the bones of the face.

It is in the articulation of the bones of the skull and face of animals, as has been already noticed, that we see the best examples of sutures. In the chelonian reptiles, as the tortoise, the bodies, laminæ, and spinous processes of the vertebræ are united by suture, and the same mode of articulation unites the elements of the sternum of the land-tortoise to each other.† The bones of the head of birds and fishes are united chiefly by the harmonie and squamous sutures. In the lateral parts of the heads of fishes, and in the opercula of their gills, as between the opercular and subopercular bones, there is a species of articulation, most resembling the squamous suture, but differing from it in admitting a considerable latitude of motion by which these bones can glide on one another.‡ To descend still lower in the scale, we may observe a mode of joining very similar to suture, between the tubercular and

* Anat. Gen. t. iii. p. 63.

† See Grant's Comp. Anat. p. 83, fig. 43.

‡ Cuvier, Leçons d'Anat. Comp t.. i. p. 125.

ambulacral plates which form the shell-like covering of the echinida.*

The sutures have the peculiarity of a considerable tendency to become obliterated by age, the intervening cartilage being ossified; it rarely happens that the sutures are all manifest in a human skull past fifty years of age, and sometimes the obliteration takes place at a much earlier period. The frontal suture is by no means permanent; it is not often found at puberty. In birds and fishes this tendency to the obliteration of the sutures is particularly manifest.

b. Schindylesis (σχινδυλησις, *fissio*, σχιζω, *diffindo*).—This form of articulation is where a thin plate of bone is received into a space or cleft formed by the separation of two laminæ of another, as is seen in the insertion of the azygos process of the sphenoid bone into the fissure on the superior margin of the vomer; and in the articulation of the lacrymal bone with the ascending process of the superior maxillary.

c. Gomphosis (γομφος, *clavus*. *Clavatio*, *conclavatio*).—When a bone is inserted into a cavity in another, as a nail is driven into a board, or as a tree is inserted into the earth by its roots, the articulation is by gomphosis. The only example we have of it in the human subject or in quadrupeds is in the insertion of the teeth into the alveoli. In the weapon of offence of the saw-fish we find also an example in the manner in which the strong osseous spines are inserted like teeth into its lateral edges. Cuvier mentions a variety of gomphosis, the only modification of the above: it is where a bony process grows from the bottom of the recipient cavity, and is inserted into a cavity in the base of the received bone or hard part. This is the mode of articulation of the nails with the ungueal phalanges in animals of the cat kind; the nail is received into an osseous sheath, from the bottom of which the body of the phalanx projects and fills up the cavity of the nail. A similar pivot grows from the bottom of the alveoli, into which the long canine teeth of the walrus are inserted.

d. Amphiarthrosis (αμφι, *utrinque*, αρθρον, *articulus*, *i. e.* a mixed form of articulation. *Articulatio dubia*, Bartholin. *Synarthrosis diarthrodica*).—This is a form of articulation where two plane or mutually adapted surfaces are held together by a cartilaginous or fibro-cartilaginous lamina of considerable thickness, as well as by external ligaments. In virtue of the elasticity of the interposed cartilaginous or fibro-cartilaginous lamina, the amphiarthrosis possesses a manifest, although certainly a very limited degree of motion, and hence most systematic writers class it with the diarthrodial articulations. To me it appears much more consistent to place it among the synarthrodial joints, for, 1. its anatomical characters agree precisely with those of synarthrosis; 2. the surfaces in amphiarthrosis being continuous, it would make an exception in diarthrosis were we to place it there; and, 3. its degree of motion is greater than that of suture, only because of the greater development of the interosseous substance. These points of similarity led some anatomists to call it *Diarthrosis synarthrodica*; for the reasons above stated, as well as because it has one point of resemblance to diarthrosis in its greater latitude of motiou, I propose the appellation *Synarthrosis diarthrodica.*

The examples of this form of joint in the human body are the articulation between the bodies of the vertebræ, that between the two ossa pubis at what is called the symphysis, and that between the ilium and sacrum. We may also, I think, place here the articulation of the ribs with the sternum by means of the costal cartilages.* The bodies of the vertebræ in most of the mammalia are articulated in the same way; so are they in fishes also; but in these last there is a peculiarity already referred to, which increases the degree of motion of which the joint is susceptible.† Like the sutures, the amphiarthrosis is liable to become obliterated by age, and from the same cause, namely, the ossification of the interosseous lamina. This is very common in the costo-sternal joints, less so in the interpubic, and still more rare in the inter-vertebral and sacro-iliac.

Diarthrosis.—Evident mobility is the distinguishing characteristic of this class of joints; the articular surfaces are *contiguous*, each covered by a lamina of cartilage (*diarthrodial cartilage*), having a synovial sac, and in some cases two synovial sacs interposed, which are separated by a meniscus. The integrity of the articulation is maintained by ligaments which pass from the one bone to the other. Their mechanism is much more complicated than that of synarthrodial joints, being intended not only for security, but also to give a certain direction to the motions of which they are the centre.

Before proceeding to the enumeration of the varieties of joints that come under this head, it will not be amiss to describe briefly the various motions which may take place between any two segments of a limb, and which it is the object of these joints to admit of. It is obvious that the most simple kind of motion which can exist between two plane or contiguous surfaces, is that of *gliding*: one surface glides over the other, limited by the ligaments which extend between the bones. This motion, however, is not confined to plane surfaces, it may exist evidently between contiguous surfaces whatever their form. When two segments of a limb, placed in a direct line or nearly so, can be brought to form

* Meckel, Anat. Comp. (Fr. transl.) t. ii. p. 43.

* It may be objected to this arrangement that at the sternal extremity of each cartilage there is a synovial membrane between it and the sternal depression. All anatomists agree in denying its existence at the articulation of the first cartilage, and all admit the great difficulty of fully demonstrating its existence in the others. For my own part I do not believe that it exists in any.

† The articulation of the lower jaw in the whalebone whale, above referred to, is a joint of this kind.

an angle with each other, the motion is that of *flexion*, the restoration to the direct line is *extension*. These two motions belong to what Bichat calls *limited opposition;* the flexion and extension of the fore-arm on the arm illustrate it. Sometimes a motion of this kind takes place in four directions, indicated by two lines which cut at right angles. This is best understood by a reference to the motions which take place at the hip-joint: there it will be seen that the thigh-bone may be brought forward so as to form an angle with the trunk, *flexion*—or it may be restored, *extension;* it may be separated from the middle line of the body so as to form an angle with the lateral surface of the trunk, *abduction*—or it may be restored and made to approximate the middle line, *adduction*. Bichat terms this "*opposition vague*." It is evident that a joint, which is susceptible of these four motions, may also move in directions intermediate to them. When these motions are performed rapidly, one after the other, it appears as one continuous motion, in which the distal extremity of the bone describes a circle indicating the base of a cone whose apex is the articular extremity moving in the joint; this motion is called *circumduction*.

Rotation is simply the revolving of a bone round its axis. It is important to bear this definition in mind: through losing sight of it many anatomists have attributed rotation to a joint which really does not possess it.

The varieties of the diarthrodial joint are as follows:

a. Arthrodia (articulatio plana or *planiformis.)*—In this species the surfaces are plane or one is slightly concave, and the other slightly convex: the motion is that of gliding, limited in extent and direction only by the ligaments of the joint or by some process or processes connected with the bones. The examples in man are, the articular processes of the vertebræ, the radio-carpal, carpal, carpo-metacarpal, inferior radio-ulnar, superior tibio-fibular, tarsal and tarso-metatarsal, temporo-maxillary, acromio-clavicular and sterno-clavicular joints. This last articulation and the wrist-joint possess a greater latitude of motion than the others; the former, in consequence of the shape of its articular surfaces: each surface is convex in one diameter and concave in the other, so that the gliding that takes place in this joint is in the direction of the long and short diameters, which intersect each other at right angles. It is capable, therefore, of vague opposition in those lines, but certainly not in the intermediate directions, the nature of the surfaces being calculated to prevent this. The wrist owes its mobility to the laxity of its ligaments, which permit it to move as well in its transverse as in its antero-posterior diameters, as also in the intermediate directions; it consequently admits of vague opposition and circumduction. The articulation of the metacarpal bone of the thumb with the trapezium, is also an arthrodia very similar to the sterno-clavicular, but with a greater degree of motion. Arthrodial joints are generally provided with ligaments, placed at the extremities of the lines in the direction of which the gliding motion takes place.

b. Enarthrosis (diarthrosis orbicularis—ball-and-socket joint.)—This is a highly developed arthrodia. The convex surface assumes a globular shape, and the concavity is so much deepened as to be cup-like, hence the appellation *ball and socket*. The ball is kept in apposition with the socket by means of a capsular ligament, which is sometimes strengthened by accessory fibres at certain parts that are likely to be much pressed upon. The best example of enarthrosis is the hip-joint, and next to it the shoulder: in the latter the cavity is but imperfectly developed. All the quadrupeds have their shoulder and hip joints on this construction, and the same common plan is observed in the vertebrata generally whose extremities are developed. In birds and reptiles the bodies of the vertebræ are articulated by enarthrosis, and the solid calcareous spines on the external surface of the shells of echinida are adapted to round tubercles on which they move, thus exhibiting a very complete form of enarthrosis.*

This species of joint is capable of motion of all kinds, opposition and circumduction being the most perfect, but rotation limited. Indeed what is called rotation at the hip-joint, is effected by a gliding of the head of the femur from before backwards, and vice versa in the acetabulum; it is not a rotation of the head and neck, but of the shaft of the femur.

c. Ginglymus (γιγγλυμος, cardo, articulatio cardiniformis, articulation en charniere, en genou, hinge-joint.)—The articular surfaces in the hinge-joint are marked with elevations and depressions which exactly fit into each other, so as to restrict motion in all but one line of direction. They are always provided with strong lateral ligaments, which are the chief bonds of union of the articular surfaces.

The elbow and ankle joints in man are perfect ginglymi; the knee also belongs to this class, but is by no means a perfect specimen, for in a certain position of the bones of this joint, the ligaments are so relaxed as to allow a slight rotation to take place. The phalangeal articulations, both of the fingers and toes, are ginglymi. This form of joint is most extensively employed among the lower animals. In quadrupeds, most of the joints of the extremities come under this head. In amphibia and reptiles, too, there are many examples of the hinge-joint. The bivalve shells of conchiferous mollusca are united by a very perfect hinge, and a great number of the joints of crustacea and insects are of this form.

The true ginglymus is only susceptible of limited opposition: hence the knee-joint cannot be regarded as a perfect example; in fact, in the perfect ginglymus there is every possible provision against lateral motion.

d. Diarthrosis rotatorius (commissura trochoides.)—A pivot and a ring constitute the mechanism of this form of joint. The ring is

* Vide fig. 9 in Grant's Comp. Anat. p. 21. See also the article ECHINODERMATA.

generally formed partly of bone and partly of ligament, and sometimes moves on the pivot, sometimes the pivot moves in it. The motion is evidently confined to rotation, the axis of which is the axis of the pivot.

In the human subject the best example of this articulation is that between the atlas and odontoid process of the axis or vertebra dentata. The ring is formed by a portion of the anterior arch of the atlas, completed behind by a transverse ligament. Here the atlas rotates round the odontoid process, which is the axis of motion. Another example is the superior radio-ulnar articulation: here the ring is formed one-fourth by bone, namely the lesser sigmoid cavity of the ulna, and the remaining three-fourths by the round ligament called the coronary ligament of the radius. In this case there is rotation as perfect as in that just mentioned, but the head of the radius rolls in the ring, and the axis of motion is the axis of the head and neck of the bone. Some anatomists consider this joint a species of ginglymus, which they designate lateral.

The terms *Symphysis*, *Synchondrosis*, *Synneurosis*, *Syssarcosis*, *Meningosis*, have been employed by anatomists to designate certain kinds of articulation, chiefly in reference to the nature of the connecting media. Symphysis, although originally employed with great extent of meaning, seems to have been in later days applied exclusively to denote the articulations of the pelvis, which we have classed under Amphiarthrosis. I pass over the other terms, because they ought to be discarded from use, as only tending to encumber a vocabulary already too much crowded with difficult and unnecessary terms.

The descriptive anatomy of the several joints will be found under the heads—ANKLE, CRANIUM, ELBOW, FACE, FOOT, HAND, HIP, KNEE, PELVIS, RADIO-ULNAR, SHOULDER, SPINE, TEMPORO-MAXILLARY, TIBIO-FIBULAR, WRIST, and the morbid anatomy under the head JOINT.

(R. B. Todd.)

ASPHYXIA. (Gr. Ασφυξια. Fr. *Asphixie*. Ger. *Scheintod*, *Asphyxie*. Ital. *Asfissia*.) The word Asphyxia, according to its derivation (from α and σφυξη, pulsus,) ought to signify what is usually expressed by the term Syncope, i. e. failure of the heart's action; but it is now always used to express failure of the process of respiration.

It is hardly necessary to say, that there is no more general law of vital action, in all classes of organized beings, than its *dependence on oxygen*, i. e. on a certain chemical action taking place between the nourishing fluids of that living body (whether animal or vegetable) and the oxygen of the atmosphere. This law is, indeed, as general as the dependence of vital action on heat, and in like manner as a certain elevation of temperature (short of what acts chemically on the organized textures) is destructive to life, so a certain concentration of oxygen in the air inhaled, at least by the higher orders of animals, affects them as a poison.*

Many organized substances, as the seeds, roots, and stems of vegetables, the pupæ of insects, eggs, even perfect animals of some of the lower classes, may retain their vitality, as is commonly said, i. e. *remain susceptible of vital action*, for very various periods of time, at low temperatures, without exercising any action on the oxygen of the atmosphere; but whenever the *phenomena indicating vital action* take place in them, exposure to oxygen, and a certain alteration of the air surrounding them, very soon become necessary conditions of the continuance of vitality.

The alterations which take place in the air in contact with different living bodies are somewhat various. Water is exhaled probably in every instance. In the case of some animals, particularly fishes, there is certainly an absorption of azote; and in that of vegetables growing under the influence of light, there is a decided absorption of carbon from the carbonic acid of the atmosphere, and an evolution of pure oxygen. But it is now generally agreed, that, in all cases, the action between the atmosphere and the nourishing fluid which is *essential* to the motion and vivifying power of the latter, is that which is denoted by the disappearance of part of the oxygen from the air that comes in contact with that fluid, and the substitution of a quantity of carbonic acid.

Some time since it was the prevalent opinion, that the nature of that action was merely an

* See Broughton in Journal of Science, 1830.

excretion of carbon, which immediately on its being evolved from the nourishing fluid, entered into combination with the oxygen of the air, and was carried off; and the chief reason for this opinion was, that the volume of oxygen which disappeared in the process, was believed to be just equal, in all cases, to that of the carbonic acid that appeared. As it is known that the volume of any quantity of carbonic acid is just the same as that of the oxygen contained in that quantity of acid, if the fact had been as above stated, the coincidence could hardly have been accidental, and the inference would have been nearly inevitable, that the oxygen of the atmosphere did not enter the nourishing fluids, but merely dissolved and carried off the excreted carbon.

But the numerous experiments of Dr. Edwards * and of M. Du Long,† seem to have nearly established the proposition, that in the respiration of by far the greater number of animals, the volume of oxygen that disappears from, is somewhat greater than that of the carbonic acid that appears in, the air employed: the same result was obtained in experiments by Allen and Pepys on *birds*;‡ and if this be so, it is certain that the respiration of these animals is attended with an actual absorption of oxygen, at least to a certain extent.

This conclusion authorizes us to inquire farther, whether it is not more probable, that the whole of the oxygen which disappears from air in contact with the nourishing fluid of living beings, is absorbed into that fluid, and that the carbonic acid which appears is exhaled, ready formed, in its place. And several facts shew that this is by far the more probable supposition; and that oxygen is essential to vital action, not merely as a means of carrying off superfluous carbon, which has become noxious; but *as itself an ingredient in the nourishing fluids, necessary for the maintenance of their motion and vivifying power.*

But without entering at length into this question, which will be more fully discussed under the head of Respiration, it is obvious from what has been said, that provision must be made, in the œconomy of all living beings, for the exposure of their fluids to the air of the atmosphere, in circumstances admitting of exhalation and absorption; and it may be farther stated, that, in the different classes of animals, the amount of this mutual action for which provision has to be made, must be proportioned to the energy and activity of vital action which each animal is destined to exhibit, these qualities being very generally found to be greater, as the consumption and vitiation of the air are more rapid.§

These principles explain the intention of many different contrivances and arrangements, afterwards to be described, which are employed in different classes of animals for the performance of the function of respiration; and the variations of which may be said, in a general view, to be determined by two conditions, first by the medium in which each animal is destined to exist, and secondly, by the intensity and variety of vital actions which it is to be capable of performing.

The importance, to all living beings, of the action of oxygen on their fluids is most unequivocally shewn by the nature of the fatal changes which ensue, when that action is in any way obstructed; i. e. by the nature of the changes which take place in *death by asphyxia.* The study of these has long been held to be of the highest importance, not only as a cardinal point in physiology, but as affording the only precise information in regard to the fatal tendency of many and various diseases.

It is chiefly in animals of the highest orders, i. e. in warm-blooded animals, that these phenomena have been studied; and it is to be remembered, that in them the subject is rendered more complex by the higher endowments and greater power over all functions of the body, which the nervous system there possesses. When we trace the connection, in these animals, of the different changes that precede the fatal event, it is right to bear in mind, that the interruption of the process by which their fluids are exposed to the air is equally fatal, not only to those animals in which no action of the nervous system is concerned in that process, but also in vegetables, where no nervous system exists.

The phenomena of asphyxia in the higher animals are very nearly the same, in whatever manner the access of air to the organs of respiration is prevented. This may be done, in the case of animals that breathe by lungs, in a great variety of ways; by strangulation or suffocation, i. e. by any mechanical means prohibiting the ingress of air by the trachea and bronchi; by submersion in water or any other fluid; by confinement in vacuo or in such gases as contain no oxygen, but are not themselves poisonous, such as azote and hydrogen; by forcible compression of the thorax, preventing its dilatation; or by the admission of air into free contact with the surface of the lungs on both sides of the chest, so as to prevent their distension, as in the celebrated experiment of Dr. Hooke; or by the section, either of all the separate nerves which move the muscles concerned in the dilatation of the thorax in inspiration, or of the spinal cord in the upper part of the neck, above the origin of the phrenics, by which the whole of these nerves are simultaneously palsied, as in many experiments of Galen, Cruikshank, Le Galleis, and others.*

In the case of fishes or other animals that

* These last are the lesions of the nervous system which cause sudden death by asphyxia. Section of the par vagum, the sentient nerve of the lungs, produces death by asphyxia also, but slowly, and through the intervention of disease and disorganization of the lungs, to be afterwards noticed.

breathe by gills, where several of the methods above enumerated are inapplicable, asphyxia is produced, either by confinement in air, or in distilled water, or water impregnated with any gas that does not contain oxygen; for no animal has the power of decomposing water by its organs of respiration, to obtain oxygen, and all aquatic animals are dependent, either on the occasional respiration of atmospheric air by lungs, or on the more constant respiration of the air contained in water by gills or analogous organs.

In the case of fishes breathing by gills, as the motion of these organs is dependent on nerves arising as high as the medulla oblongata, injury of the nervous system must be as high as that part, in order to produce asphyxia; and on the other hand, in the case of birds, where the expansion of the thorax in inspiration is effected almost entirely by the motion of the ribs, asphyxia may be produced by section of the spinal cord in any part of the neck.*

We exclude here entirely the cases, often described under the name of asphyxia, in which gases positively noxious (such as carbonic acid, carburetted hydrogen, &c.) have been breathed, because accurate observation shows that these are in fact cases of poisoning, where the poison has been introduced by the lungs, and not simply cases of asphyxia.

The phenomena of asphyxia, in all the cases above-mentioned, (as occurring especially in the warm-blooded animals,) may be divided into three stages. The first is characterized by the intensity of the sensation which prompts to acts of inspiration, and the consequently violent and laborious, though ineffectual attempts to appease that sensation by the action of all the muscles of inspiration; and in some instances by other actions, voluntary or instinctive, but still under the guidance of sensibility. Lividity of the surface takes place before the end even of this stage. The next is distinguished by insensibility, rapidly increasing, and attended with irregular spasms or convulsions; and the last by cessation of all effort, and of all outward signs of life, while the heart's action and circulation are known still to go on for a short time.

In the case of a warm-blooded animal (excluding the cetacea, and animals that habitually dive) in the full possession of its vital powers, exposed to complete and sudden obstruction of the access of air to the lungs, it may be stated, that the two first of these stages are very generally over within three minutes, seldom extending to five, and that the circulation through the heart has very generally ceased within less than ten minutes from the commencement of the obstruction. The time during which the privation of air can be borne may be somewhat extended by habit; and there are instances of men trained to diving in India who have remained under water three, four, or even five minutes without loss of sensibility or subsequent injury.

* Flourens in Annales d'Histoire Naturelle, t. 13.

In cases of disease, terminating in death by asphyxia, all these stages may often be observed to be distinctly gone through, although in a very gradual and somewhat irregular manner; the dyspnœa and lividity being succeeded by delirium, often by spasms, and ultimately by coma, and the respiration coming to a stand in general a little before the action of the heart.

The most characteristic appearance which is seen after death by asphyxia, is simply the great accumulation of blood in the vessels of the lungs, in the pulmonary artery, right side of the heart, and great veins, and the comparatively empty state of the left side of the heart, the larger pulmonary veins, and the aorta. The left ventricle is not found empty after death, but seldom contains half as much blood as the right; and it is in this part of the heart that the contractions are soonest observed to cease. The accumulation of blood in the lungs and right side of the heart is greatest in cases where the asphyxia has been gradual, the access of air to the blood not having been absolutely obstructed.*

Besides this appearance of congestion of blood in the thorax, the liver, the spleen, and the whole venous system in the abdomen, are generally observed to be unusually congested in such cases, especially those parts which are *depending* after death; and even ecchymosis on the mucous membrane of the stomach, after strangulation, has been observed by Dr. Yelloly and others. This congestion of blood in the liver, and in the veins of the abdomen, is remarkably observed, and leads to important consequences, in various chronic diseases of the thorax, threatening death by asphyxia.

The blood after this, as after other kinds of sudden or violent death, is usually found fluid, and very imperfectly coagulated; and in connection with this state of the blood there are frequently livid marks resembling ecchymosis, (though not depending on extravasation of blood,) in various parts of the surface of the body, and not exclusively in depending parts. This appearance is, of course, most remarkable in the face and neck after strangulation, and is much less observed on any part of the surface after drowning.

After strangulation, if the body is soon examined, congestion of blood in the vessels of the brain and pia mater may often be remarked, but there is seldom any morbid effusion. After drowning, a frothy fluid, in consequence of the introduction of a small quantity of water, and of efforts at respiration, is generally found in the trachea and bronchi.

The successive steps by which physiologists have been led to what we may regard as a satisfactory account of the phenomena now described, and of the death by asphyxia, may be recapitulated, as curious in themselves, and as affording the clearest view of the evidence on which the doctrine, which now appears to be well founded, is supported.

* Bichat, Recherches Physiologiques, &c. (4th edit.) p. 333.

1. The first opinion on this subject, which need be noticed here, is that which was supported by the great Haller, viz. that the circulation, and with it all other functions of the body are brought to a stand, because when the movements of respiration cease, and the lungs are no longer dilated and contracted, there is a mechanical difficulty to the propulsion of the blood through the pulmonary capillaries, by which the fatal stagnation in these vessels, obvious on dissection, is produced.

This doctrine was satisfactorily refuted by Goodwyn, in his treatise on the Connection of Life with Respiration, who shewed that the air-cells of the lungs are not necessarily contracted at the time of asphyxia, and that after having once admitted air, these cells never are so much emptied of it again, or contracted on themselves, as to offer any considerable impediment to the free motion of blood in their parietes. Besides, we know that the same stagnation in the lungs takes place in the case of an animal confined in a gas which does not contain free oxygen, as in the case of drowning or strangulation, although in the former case, any impediment to the mechanical acts of respiration that can occur, must be the consequence, not the cause, of the fatal changes within the chest.*

2. The well-known theory of Goodwyn himself on this subject was, that the venous blood is not an adequate stimulus to the left side of the heart, which in the natural state circulates arterial blood only, and which fails to contract upon or propel blood which has passed unchanged through the lungs.†

This doctrine was, in its turn, refuted by Bichat, who showed by experiment that in the case of strangulation the venous blood does penetrate the lungs and left side of the heart, and is delivered from the carotid arteries if these are punctured; that the appearance of venous blood in these arteries is contemporaneous with what was described as the second stage of asphyxia, viz. the insensibility and spasms; and further, his experiments have been generally admitted as affording satisfactory evidence, that the circulation of venous blood through the brain is a sufficient cause for these symptoms, and produces them when the venous blood from the heart of one dog is sent to the brain of another.‡ He also found by experiment, that venous blood could be injected artificially into the left cavities of the heart, with the effect of exciting, not suppressing their action.§

3. Bichat ascribed the cessation of the circulation in asphyxia, however, not to the penetration of the brain by venous blood, and the consequent insensibility (which is now well known to be compatible with the maintenance of circulation for many hours, provided the blood can be arterialized,) but to the penetration of the muscular substance of the heart by venous blood, sent to it by the coronary arteries, and which he held to be equally (although less rapidly) fatal to the vital action of this organ, as of the brain or nerves.

4. Later experiments and observations have, however, shewn that this explanation likewise is, in some measure, incorrect. In fact, while the free flow of venous blood in the carotid arteries of an asphyxiated animal was urged with perfect fairness by Bichat, as a refutation of the theory of Goodwyn, it was with equal justice argued by Goodwyn,* in opposition to Bichat, that if the heart's actions ceased in asphyxia, only because its substance is penetrated by venous blood from the coronary arteries, these actions could not be restored by blowing air into the *lungs* and arterializing the blood *there*.

Bichat, indeed, foreseeing this objection, maintained that the artificial respiration never is successful in restoring the circulation, unless employed in the interval which, as was already stated, always exists between the occurrence of insensibility and the final cessation of the circulation. But subsequent and careful observations (e.g. those of Roesler, Edinburgh Journal, vol. xxiii) show that life has been restored, by this means, after warm-blooded animals have lain from twelve to seventeen minutes after their immersion in water, i. e. until a time when all observations made by laying open the chests of similar animals show that their circulation must have ceased. The records both of the Humane Society in London and of a similar institution in Paris, seem sufficiently to show that resuscitation has occasionally taken place in the human body after fifteen minutes' immersion.† And we are therefore well assured that the arterialization of the blood at the lungs may, in some instances, restore the natural state of the heart's action after the circulation has come to a stand.

Farther, although there is a laboured attempt, by Bichat,‡ to explain the accumulation of blood on the right side of the heart, and the comparative emptiness of the left side, in asphyxia, consistently with his own explanation of the failure of the circulation; yet it seems obvious, that if that explanation were correct, the left side of the heart, receiving the venous blood and contracting on it until it loses its power from the penetration of its own fibres, should be found after death distended with that blood; and that the accumulation of blood taking place in the lungs and right side of the heart, indicates that the *capillaries of the lungs* are the main seat of the cause which ultimately stops the circulation.

That this is really the fact has been more unequivocally shown, first, by the experiments by Dr. Williams, and afterwards by those of

* This point has been further elucidated by some experiments, of which an account was read, by the author of this article, to the Medical Sections of the British Association.

Dr. Kay,* which we know to have been carefully performed, and sufficiently repeated, and which appear to solve satisfactorily all the difficulties that have been stated. Bichat had not adverted to the *length of time* during which the circulation of venous blood by the left side of the heart, is carried on in asphyxia; but the experiments of both Dr. Williams and Dr. Kay prove, that this time is very short, and that before this side of the heart has lost its contractile power, *the pulmonary veins have ceased to deliver the blood* to it, in such quantity as to maintain any effective action. A short quotation from Dr. Kay's paper will show the evidenee for this proposition.

"Experiment 1. The trachea of a large rabbit was tied, the abdomen and chest opened, and at the end of the second minute from the commencement of the experiment, the external iliac artery was divided; a considerable quantity of dark blood flowed, but at the third minute it had almost ceased to escape. The heart continued contracting vigorously; very small quantities of dark blood collected slowly every twenty seconds at the extremity of the artery. In five minutes all flow of blood had entirely ceased. *The left heart contracted spontaneously for a very considerable period longer.* I repeated this experiment with similar results."† Again, one of the variations of the experiment was as follows: "Experiment 3. A rabbit was asphyxiated by tying the trachea. The chest was opened. At the end of three minutes and a half no pulse could be discovered in the aorta. The left auricle was then opened, the blood contained escaped, and for a period of from one to three minutes, blood occasionally eollected in very minute quantities, as though it gradually drained from the larger vessels of the lungs, *but never, as often as the experiment was repeated, collected in quantity.* The heart continued vigorous the usual period."

"In general," says Dr. Kay, "the phenomena of the cessation of motion in the left heart in asphyxia are these. A smaller quantity of blood is received into its cavities, and expelled for a time vigorously into the arteries. The ventricle meanwhile diminishes in size, as the quantity of blood supplied becomes less, until at length, although spontaneous contractions still occur in its fibres, no blood issues from a divided artery, *and the ventricle, by contraction, has obliterated its cavity.* After this, blood slowly accumulates in the auricle from the large vessels of the lungs; and its contractility continues for a very eonsiderable period."‡

Farther experiments by Dr. Kay show, that after the aorta of an animal has been tied, and after the muscles of its lower extremities have, in consequence, gradually lost all contractile power, that power is restored for a time by the injection of *venous* blood into the lower portion of the aorta; § and from these, and from some experiments by Dr. Edwards,* we learn, that the venous blood, though less powerful than arterial in maintaining the vital power of muscles, is by no means rapidly destructive to it.

The changes in asphyxia, in the warm-blooded animals, have, therefore, of late been generally thought to be as follows:—that the venous blood, though more or less noxious to all parts of the body which it fully penetrates, is nevertheless transmitted through the lungs in the first instance, in sufficient quantity to stimulate the left side of the heart, and is sent from thence in sufficient quantity to penetrate the brain;—that by its action there it destroys the sensibility, but that it passes more and more slowly through the pulmonary vessels, and after a few minutes is no longer delivered to the left side of the heart in such quantity as to keep up regular and efficient contractions there; and that thus, while the *animal* life is suddenly extinguished by the noxious influence of venous blood on the brain, the *organic* life is more gradually brought to a stand by its noxious influence in the lungs, and the consequent failure in the supply of blood to the left side of the heart.

This explanation is consistent with all the phenomena, and particularly with the *very rapid* restoration of the flow of blood by the admission of air to the lungs of half-asphyxiated animals, stated by Bichat himself as a difficulty in his view of the subject.

The more reeent experiments by Dr. Kay had, however, led him to question the validity, even of that part of Bichat's doctrine, which has been most generally admitted, viz. the rapidly noxious effeet of venous blood on the brain and nerves. He found, in various cases, that large quantities of blood from the veins of one rabbit could be injected (*slowly and cautiously*, so as to avoid all injury of the cerebral matter) into the carotid arteries of another, without causing more than muscular debility and lassitude; so that he considers venous blood to be only a weaker stimulus to the brain than arterial, not a direct poison to it; and thinks the *sudden insensibility* of asphyxia is to be explained by the rapid diminution of the quantity, not by the change of quality, of the blood sent to the brain from the heart.†

And when we bear in mind the faet stated in the outset of this inquiry, that the motion and vivifying power of the nutritious fluid is dependent on its exposure to oxygen, not only in the higher animals, but even in the lowest tribes, and in vegetables, where neither heart nor nervous system exists; it appears reasonable to suppose, that the chief impediment to the blood's motion, from the failure of the supply of oxygen, will be *in the lungs themselves*, where the venous blood is accumulated in the greatest quantity, and where all the minute vessels carrying it must be most completely exposed to its action.

But before we can be completely satisfied upon this subject, it will be necessary to carry the inquiry one step further, and to ascertain in what manner the change from venous to

* Edinburgh Medical and Surgical Journal, vol. xix. and xxix.

* De l'Influence, &c. p. i. ch. i. and p. iv. ch. 4.

† Treatise on Asphyxia, p. 193 et seq.

arterial blood so greatly promotes the flow of blood through the capillaries of the lungs, and how the presence of venous blood in the beginnings of the pulmonary veins can so effectually retard it, that the action of the right ventricle of the heart, though continuing vigorous for a time thereafter, fails of its wonted effect, and the blood stagnates in those capillaries.

The common expression employed on this subject is, that arterial blood is a stimulus peculiarly adapted to excite the capillaries of the lungs and pulmonary veins; and that venous blood stagnates in those capillaries for want of power to excite them. But it must be remembered that we have no distinct evidence of the existence of coats, still less of irritable coats in the minute capillaries of the lungs;* that although the circulation there has been often examined with the microscope, no contraction of the vessels has ever been observed; that the only vital power of contraction which experiments authorize us to ascribe to any arteries, is a power of permanent or tonic contraction on their contents, which, when called into action, lasts for some time, and while it lasts must obviously impede the flow of fluids through these vessels; that on these grounds Magendie and other eminent physiologists believe the only power, which arteries can exercise over their contents, to be simply a power of either relaxing, so as to give them a free passage, or contracting so as to lessen and retard their flow;† and that, conformably with these views, it was found by Wedemeyer, that when he injected stimulating liquids into the arteries of living animals, they were much longer of making their way into the veins, than mild liquids were.‡

These considerations evidently point to the conclusion, that, if the difference depend on any vital action of vessels, venous blood, which makes its way so slowly through the capillaries of the lungs, must be the stronger stimulus to them, and that arterial blood, which is transmitted so readily, must act as a sedative, to the only vital action of which these vessels are susceptible. But this conclusion is again strongly opposed by the fact, that in all other instances, in relation to muscular contraction, to the functions of the nervous system, and of secreting organs, arterial blood, and the oxygenated fluids in general, manifestly possess the stimulating power, and venous blood or carbonized fluids the sedative.

In this difficulty it is important to remember, that we have many facts to indicate the existence of powers which move the blood and other organized fluids in living animals, independently of any contractions of moving solids. It would appear that the power by which any texture is nourished, or secretion or excretion is formed from the blood, in any part of the circulation, is, to a certain degree, a cause of movement of the blood towards that part, and that any stimulus given to such act of nutrition or secretion, although applied at the extremity of the capillaries, produces an effect on the circulation which, as Sir C. Bell expresses it, is *retrograde along the branches* of the arteries. Thus, the flow of blood to the mucous membrane of the stomach and bowels during digestion, to the uterus during gestation, to the mammæ during lactation, to any part of the body during inflammation, suppuration, or the growth of a tumour, is excited by causes acting at the extremities of the arteries of these parts; although there is the same difficulty in all these cases, as in the case of the lungs, in understanding how a cause acting there, and exciting the only vital power which arteries can be shewn to possess, should increase the flow of blood through them.

It is always to be remembered, that precisely analogous phenomena are observed from the application of heat, or other stimuli, to single branches, or roots, of vegetables, where there is no evidence of the existence, either of a structure or of a contractile power, in the vessels or cells through which the fluids pass, capable of giving them a determinate direction towards the parts, which are thus stimulated; and where the movement of fluids that can be seen, (in the case of those plants that have milky juices,) is not only unattended with any visible contraction of solids, but is of a kind, (as the recent observations of Schultze, Amici, Raspail, and others indicate,) which no contractions of solids appear capable of producing.

It is farther to be observed, that when venous blood becomes arterial, it acquires an increase of fibrin,* and that its tendency to coagulation is decidedly increased,† which implies such an increase of an attraction of aggregation in the particles of the fibrin, as may be held to be strictly vital. And on the other hand, when arterial blood becomes venous, according to the microscopical observations of Kaltenbrunner, its globules seem to separate somewhat from one another, and its whole bulk appears somewhat increased.‡

Lastly, it is to be remembered, that when a vessel is opened in a living animal, and the blood exposed to the air, the consequence is, a movement of *derivation* of the blood, in all directions, towards the aperture; which is certainly altogether independent of the heart's action, and which the elaborate investigations of Haller led him (and apparently with good reason) to think inexplicable likewise by any contraction of vessels.§

The consideration of all these facts may lead us strongly to suspect, that the stimulus to the circulation which is given by the arterialization of the blood, and which we have found to act chiefly in the capillaries of the lungs, is of the nature of an *attraction* of the venous blood towards the part where it is to

undergo this change, and towards the arterial blood in advance of it in the vessels; not of the nature of an increased *contraction* of the vessels themsleves; and that it is in consequence of the failure of this *auxiliary power* in the circulation, that the stagnation of the blood in the lungs in asphyxia, and the extinction of the organic life, are effected.

What has been said of the manner in which death is produced in asphyxia, enables us to understand in what circumstances it can happen, that life may be retained, even by a warm-blooded animal, for an unusual length of time, without respiration. As the stop to the circulation is the immediate cause of death, it is obvious that an animal which can exist for a time, in a lowered state of vitality, with little or no circulation, will during that time require no exposure of its blood to air, to maintain that grade of vitality; and farther that in such an animal, as the brain will not suffer from the afflux of venous blood, and as the lungs will not be hurtfully congested, these organs will retain a condition much better adapted for the recovery of their functions, than they will in those cases where asphyxia is produced at a time when the circulation is vigorous.

Hence we can easily understand, that persons who are in a state of syncope, (from a temporary cause,) in whom the circulation is nearly at a stand before the access of air to their lungs is obstructed, may survive a longer suspension of the acts of respiration than persons in health. This has been stated, by Des Granges and Foderé, as the explanation of some cases in which it appears certain, that recovery has taken place after fifteen minutes or more of submersion in water.*

The case of hybernating animals was, until lately, considered to be of this nature, i. e. it was supposed that circulation is gradually suspended in those animals, simultaneously with respiration, and therefore that such animals, although consuming little or no air, did not suffer the noxious influence of venous blood on their solids, and remained susceptible even of sensation. But the experiments of Dr. Marshall Hall † appear to have established that in warm-blooded hybernating animals in the complete state of torpor, when respiration is quite at a stand for many hours, circulation, although slow and feeble, still goes on regularly; so that we must suppose the essential peculiarity of these animals, during the state of lowered vitality, to which they are reduced by cold, to be this, that the venous blood has little of the noxious effect, in any part of the system, which it has, on them as on other animals, during the state of activity; it has neither the same difficulty of making its way through the lungs, nor the same destructive influence on the brain.‡

The nearest approach to this mode of vitality in the human body, is in the case of the new-born child, which has never felt the influence of perfectly arterial blood, and which has been known to live, although its natural respiration was not established for nearly an hour after birth.

The study of the fatal changes in asphyxia is also of peculiar importance as illustrating the manner in which the circulation, and the organic functions maintained by it, are connected with the nervous system. It will be observed, that as the vitality of hybernating animals, during the state of torpor, is independent of respiration, so it is also, in a great measure at least, independent of the larger masses of the nervous system; and Dr. M. Hall found, by experiment in a hedgehog in this state, that the circulation went on regularly for *ten hours* after the gradual but complete destruction of the brain and spinal cord.

Indeed, the maintenance of the circulation after the head of an animal has been cut off, by the artificial respiration, i. e. by inflating its lungs in a manner resembling its natural breathing, (which has been so often practised by Fontana, Cruikshanks, Bichat, Brodie, Le Gallois, Wilson Philip, and others,) is in itself a clear proof that the circulation, and other functions of *organic* life* in animals, are necessarily and immediately dependent on the *animal* life, only inasmuch as the natural respiration of animals, and the arterialization of their blood, are dependent on sensation. And accordingly we know, that in that stage of animal existence, where the supply of sufficiently arterialized blood is provided for without the intervention of sensation, i. e. in the fœtus in utero, the whole organic life is altogether independent of the animal, and goes on perfectly, not only before sensation is felt, but even in cases where the essential organs of sensation and of voluntary motion, the brain and spinal cord, do not exist. It is not until the moment of birth, when the arterialization of the blood is put in dependence on sensation,—that the brain and spinal cord become essential for the maintenance of organic life; or that we possess any proof of influence being exercised by the nervous system, over that part of the animal œconomy.

It seems probable, that if we possessed the means of making the artificial respiration exactly similar to the natural, and neither injuring the structure of the lungs, nor introducing more air into them than is useful, in practising it, the circulation, and perhaps all the functions of organic life, might be maintained, after the head of an animal is cut off, until nearly the time when it must fail for want of nourishment; but it must also be remembered, that in the adult animal, as the experiments of Le

* Foderé, Med. Legale, § 613.

† Phil. Transactions, 1832.

‡ Dr. M. Hall considers the essential peculiarity of these animals to be, that the left side of the *heart* in them, is irritable by venous blood; but as it appears from the facts above stated, that the stop to the circulation in asphyxia is at the *lungs*, the chief peculiarity of these animals must lie there also.

* By organic life, we mean those vital acts which take place without the intervention or consciousness of the mind; by animal life, those in which some mental act is an essential constituent.

Gallois, Dr. Wilson Philip, Flourens, and others have shewn, injuries of the brain and spinal cord, (particularly injuries *suddenly* inflicted on any *large* portions of these organs,) may directly influence, or even wholly suppress, vital actions belonging to the head of organic life, for the performance of which we have no evidence of their furnishing any necessary condition.

As the function of respiration thus appears to be the only link by which the organic life is immediately and necessarily connected with animal life, it is naturally to be expected that the extinction of animal life should affect the organic functions just in the same way as the suspension of respiration does, and therefore that in the case of death beginning at the brain, as Bichat expressed it, (*i. e.* of death consequent on the extinction of sensation and voluntary motion,) the circulation and other organic functions should be brought to a stand just in the same manner as in death by asphyxia. And in what is strictly called death by coma, this is really the case; the sensations being gradually more and more impaired, the sense of anxiety in the chest, which prompts to the acts of respiration, is ultimately extinguished; but even after the last breath has been drawn, the pulsations of the heart still continue, and the blood then gradually stagnates in the lungs, the circulation comes to a stand, and the blood is found after death congested on the right side of the heart, just as in the case of asphyxia already described.

That this is truly the mode of fatal termination in cases where death takes place strictly in the way of coma, was first unequivocally proved by Sir B. Brodie,* who found, by experiment, that animals poisoned by opium or other narcotics, and in which the acts of respiration had ceased, in consequence of the impression made on the brain and the gradually increasing insensibility, might be recovered by the artificial respiration, just as asphyxiated animals may be. Indeed the same expedient had been previously employed with success (although not suggested by an equally accurate view of its mode of action) by Mr. Whately.†

The reason why the same expedient cannot be expected to avail in cases of *disease* terminating by coma is simply that in these cases the cause of the coma is not temporary, like the effect of a narcotic poison, but permanent. It seems possible that it may yet be found successful in some cases of insensibility with convulsion, in children, unconnected with organic lesion.

In so far, therefore, as the extinction of the organic life is concerned, the death by coma, or beginning at the brain, resolves itself into the death by asphyxia, or beginning at the lungs, the difference lying merely in the mode in which the arterialization of the blood is arrested.

But although this is strictly true as to cases of violent death, produced experimentally in such a way that a single cause only is allowed to operate; and although we occasionally meet with cases of equal simplicity in disease, and ought always to keep in view the principles which these simple cases illustrate in the treatment of disease, yet it ought not to be supposed that either the death by asphyxia, that by coma, or that by syncope, often present themselves to the observation of the medical practitioner in the same simplicity as to the experimental physiologist. We can state from frequent observation, that it is only in a certain number of cases of disease, strictly belonging to the head, such as apoplexy or hydrocephalus, that death takes place exactly in the way of coma, as above described, or that the function of circulation can be observed to survive that of respiration; and on the other hand there are many instances of disease of the lungs, particularly of phthisis, in which the ultimate extinction of life is rather in the way of syncope than of asphyxia. The simple principle, that the circulation, though not dependent on any action of the nervous system, is liable to be influenced in various ways by causes acting on the nervous system, enables us to understand that death may often take place, in the course of diseases, in a way different from that which the seat of the disease may lead us to anticipate.

Nevertheless it may often be of real and practical importance, with the view of acquiring clear and precise ideas of the modes of fatal termination which are to be expected in the course of diseases, and particularly of such diseases as fever—where the symptoms immediately preceding death, and the causes evidently inducing death, are remarkably various in different individual cases,—to study attentively the phenomena, and causes, of the fatal termination, in the simpler cases of violent death, such as those which have been here considered.

(W. P. Alison.)

AVES, birds; (Gr. Ορνιθες; Fr. *Oiseaux*; Germ. *Vögeln*; Ital. *Uccelli*:) a class of oviparous vertebrate animals, with warm blood, a double circulation, and a covering of feathers.

Birds are organized for flight, and as this, the most vigorous kind of locomotion, demands the greatest energy in the contractility of the muscular fibre, so the respiratory function finds its highest development in the present class. Not only the ramifications of the pulmonary artery, but many of the capillaries of the systemic circulation, from the singular extension of the air-cells through the body, are submitted to the influence of the atmosphere, and hence birds may be said to enjoy a double respiration.

Although the heart resembles in some particulars that of the *Reptilia*, the four cavities are as distinct as in the *Mammalia*, but they are relatively stronger, their valvular mechanism is more perfect, and the contractions of this organ are more forcible and frequent in Birds in accordance with their more extended respiration and their more energetic muscular actions.

As Birds exceed Mammals in the activity of those functions on which the waste and renovation of the general system more immediately depend, so they possess a higher standard of animal heat: their ordinary temperature is 103° and 104°, and according to Camper is occasionally as high as 107° Fahr.

The modification of the tegumentary covering characteristic of the present class is to be regarded rather as dependent upon, than occasioning, this high degree of internal temperature, which requires for its due maintenance against the agency of external cold an adequate protection of the surface of the body by means of non-conducting down and imbricated feathers; and this warm clothing is more especially required to meet the sudden variations of temperature to which the bird is exposed during its rapid and extensive flights.

The generative product is always excluded from the oviduct in an undeveloped state, inclosed, in a liquid form, within a calcareous case or shell. The female organs are, therefore, developed only on the left side of the body. The ovum is subsequently perfected by means of *incubation*, for which action the bird is especially adapted by its high degree of animal heat.

Birds form the best characterized, most distinct, and natural class in the whole animal kingdom, perhaps even in organic nature They present a constancy in their mode of generation and in their tegumentary covering, which is not met with in any other of the vertebrate classes. No species of Bird ever deviates, like the Cetacea among Mammals, the Serpents among Reptiles, and the Eels among Fishes, from the tetrapodous type of formation which so peculiarly characterizes the vertebrate division of animals.

The anterior extremities are invariably constructed according to that plan which best adapts them for the actions of flight; and although, in some few instances, the development of the wings proceeds not so far as to enable them to act upon the surrounding atmosphere with sufficient power to overcome the counteracting force of gravity; yet, in these cases they assist, by *analogous motions*, the posterior extremities; either, as in the Ostrich, by beating the air while the body is carried swiftly forward by the action of the powerful legs; or, as in the Penguin, by striking the water after the manner of fins, and by the resistance of the denser medium carrying the body through the water in a manner analogous to that by which the birds of flight are borne through the air. In a few exceptions only are the wings reduced to mere weapons of offence, as in the Cassowary and in the singular Apteryx of New Zealand, in which they are represented by a single spur. In no instance do the anterior extremities take any share in stationary support or in prehension.

Birds are therefore biped, and the operations of taking the food, cleansing the plumage, &c. are almost exclusively performed by means of the mouth, which consists of two unlabiate and edentate mandibles, sheathed with horn. To facilitate the prehensile and other actions thus transferred to the head, the neck is elongated, and the body generally inclined forwards and downwards from the hip-joints. The thighs are accordingly extended forwards at an acute angle from the pelvis towards the centre of the trunk, and the toes are lengthened and spread out to form an adequate base of support. The actions of perching, walking, running, scratching, burrowing, wading, and swimming, require for their perfect performance different modifications of the posterior extremities. The mandibles, again, present as many varieties of form, each corresponding to the nature of the food, and in some degree indicative of the organization necessary for its due assimilation. Ornithologists have, therefore, founded their divisions of the class chiefly on the modifications of the bill and feet. Since, however, Birds in general are associated together by characters so peculiar, definite, and unvarying, it becomes in consequence more difficult to separate them into subordinate groups, and these are necessarily more arbitrary and artificial than are those of the other vertebrate classes.

A *binary* division of the class may be founded on the condition of the newly-hatched young, which in some orders are able to run about and provide food for themselves the moment they quit the shell *(Aves præcoces)*; while in others the young are excluded feeble, naked, and blind, and dependent on their parents for support *(Aves altrices)*.

Scopoli, in his 'Introduction to Natural History,' published in 1777, proposed a dichotomous systematic distribution of Birds, founded on the form of the scales covering the tarsus. The species which have these scales small and polygonal are the *Retepedes* of this author; those which have the legs covered anteriorly with unequal semicircular plates are the *Scutipedes*.

Nitzsch,* the celebrated professor of natural history at Halle, has synthetically grouped together the feathered tribes under *three* grand orders, according to the great divisions of the terraqueous globe which form the principal theatres of their actions.† The first *order* consists of the birds of the air *par excellence*, *Aves aereæ* (Luft-vögeln); the second order embraces the birds of the earth, *Aves terrestres* (Erd-vögeln); the third great division includes the birds which frequent the waters, *Aves aquaticæ* (Wasser-vögeln). The Eagle and the Sparrow may be named as examples of the first; the Ostrich and the common fowl of the second; the Heron and the Gull of the third of these extensive divisions.

A more definite arrangement of Birds, in which a similar principle may be traced, has been proposed by a distinguished naturalist of our own country, Mr. Vigors. He divides the class *Aves* into *five* orders. The *first* includes the birds which soar in the upper regions of the air, which build their nests and rear their young on the highest rocks and loftiest trees, and which may be regarded as the typical species of Nitzsch's *Aerial Birds*; this order is termed *Raptores*, from the rapacious habits and animal food of the species so grouped together.

The *second* order affects the lower regions of the air; the birds composing it are peculiarly arboreal in their habits, and are therefore termed Perchers or *Insessores*.

The *third* order corresponds to Nitzsch's *Aves terrestres*, and is denominated *Rasores*, from the general habit which these granivorous species present of scratching up the soil to obtain their food.

By dividing the aquatic birds of Nitzsch into those which frequent the fresh waters, and are limited to wading into rivers, lakes, &c. in search of their food, and those which possess the power of swimming in the great ocean, we obtain the two remaining orders of the quinary arrangement of Mr. Vigors, viz. the *Grallatores*, or Waders, and the *Natatores*, or Swimmers. The merit of this system is not, however, confined to the defining of the different groups in as clear and readily appreciable a manner as the subject will admit; but it also aims at displaying the natural affinities by which the several orders and families are connected with and pass into one another. In the ornithological systems of other naturalists, who have made this branch of zoology their particular study, we find the greatest discrepancy both as to the number and value of the primary divisions of the class.

Sandewall has *four* orders or cohorts.
Vieillot, like Vigors, has *five* orders.
Linnæus, Cuvier, Carus, and Dumeril have *six* orders.
Illiger has *seven*.
Scopoli, Latham, Meyer, Wolf and Blainville have *nine*.
Temminck (1820) has *sixteen*.
Schœffer has *seventeen*.
Brisson has *twenty-eight*, and
Lacepede has *thirty-eight* orders.

Where so many masters of the science differ, it is difficult for one less profoundly versed in ornithology to select the most unexceptionable system of arrangement, and as Kirby* observes, 'the choice perplexes.' We have here adopted the arrangement proposed by that distinguished naturalist as being the one which facilitates the expression of the leading anatomical differences which obtain in the class of Birds, and which may therefore be considered as the most natural.

Orders.

I. Raptores, Vig. *Syn. Accipitres*, Linn. Cuv. Birds of Prey or Raveners.†
II. Insessores, Vig. *Passeres*, Linn. Cuv. Perchers.
III. Scansores, Illig. Cuv. Climbers.
IV. Rasores, Illig. *Gallinæ*, Cuv. Scratchers.
V. Cursores, Illig. *Brevipennes*, Cuv. Coursers.
VI. Grallatores, Illig. *Grallæ*, Linn. Cuv. Waders.
VII. Natatores, Illig. *Palmipedes*, Cuv.; *Anseres*, Linn. Swimmers.

The following are the characters of these orders.

Class Aves *(Birds.)*

Animal vertebrated, oviparous, biped.
Anterior extremities organized for flight.
Integument plumose.
Blood, red, warm.
Respiration and *circulation* double.
Lungs fixed, perforated.
Negative characters, no auricles, lips, teeth, epiglottis, diaphragm, fornix, corpus callosum, scrotum.

Order I. *RAPTORES.*

Body, very muscular.
Beak, strong, curved, sharp-edged and sharp-pointed, often armed with a lateral tooth; upper mandible the longest. *(Fig 112.)*

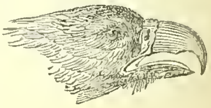

Fig. 112.

* See *Schoepfs*, in *Meckel's Archiv für Physiologie*, B. 12, p. 73.
† Blumenbach more vaguely proposes a Binary arrangement of Birds on the same principle; he divides the class into *Land-Birds* and *Water-Birds*. In *Lawrence's Blumenbach, Comp. Anat.* p. xxxiii.

* Bridgewater Treatise, vol. ii. p. 444.
† This word is proposed by Mr. Kirby as the English for *Raptores*; it is the substantive of *ravenous*, from the verb *to raven*.

Fig. 113.

Legs, robust, short, with three toes before, and one behind; all armed with long, strong, crooked talons. *Fig.* 113.

All the Birds of Prey feed on the flesh of living or recently killed animals. They have a prompt, powerful, and rapid flight. They are monogamous; the female exceeds the male in size. They nidificate in lofty situations and rarely lay more than four eggs: the young are excluded in a blind and feeble state.

The Birds of Prey are either diurnal or nocturnal.

The *Diurnal Raptores* have their eyes directed laterally, and are divided into the following families—*Falconidæ*, Eagles and Hawks; *Vulturidæ*, Vultures; and *Gypogeranidæ*, which includes the Secretary vulture. In the first two divisions the characters of the order are most strongly marked; in the third the legs deviate from the ordinal character and are remarkably elongated, adapting it to an inferior kind of prey, viz. noxious reptiles, serpents, &c.

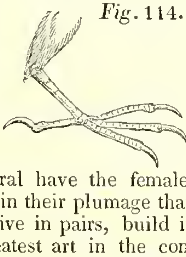
The *Nocturnal Raptores* have the eyes directed forwards, and include the *Strigidæ* or owl-tribe.

Order II. *INSESSORES.*

Legs slender, short, with three toes before and one behind, the two external toes united by a very short membrane.*

The *Perchers* form by far the most numerous order of birds, but are the least easily recognizable by distinctive characters common to the whole group. Their feet, being more especially adapted to the delicate labours of nidification, have neither the webbed structure of those of the *Swimmers*, nor the robust strength and destructive talons which characterise the feet of the *Bird of Rapine*, nor yet the extended toes which enable the *Wader* to walk safely over marshy soils and tread lightly on the floating leaves of aquatic plants; but the toes are slender, flexible, and moderately elongated with long, pointed and slightly curved claws. (*Fig.* 114.)

Fig. 114.

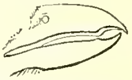


The perchers in general have the females smaller and less brilliant in their plumage than the males; they always live in pairs, build in trees, and display the greatest art in the construction of their nests. The young are excluded in a blind and naked state, and wholly dependent for subsistence during a certain period on parental care. The brain arrives in this order at its greatest proportional size; the organ of voice here attains its utmost complexity, and all the characteristics of the bird, as power of flight, melody of voice, and beauty of plumage are enjoyed in the highest perfection by one or other of the groups of this extensive and varied order.

The beak of the *Inscssores* varies in form according to the nature of their food, which may be small or young birds, carrion, insects, fruit, seeds, vegetable juices, or of a mixed kind. The modifications of the rostrum have therefore afforded convenient characters for the tribes or subdivisions of the order; these are termed, 1, *Dentirostres;* 2, *Conirostres;* 3, *Tenuirostres;* 4, *Fissirostres.*

The *Dentirostres*, (*fig.* 115) characterized by their insect food, and the notch near the extremity of the upper mandible, include the families termed *Laniadæ* or Shrikes; *Merulidæ*, Thrushes; *Sylviadæ*, Warblers; *Pipridæ*, Tits; and *Muscicapidæ*, Fly-catchers.

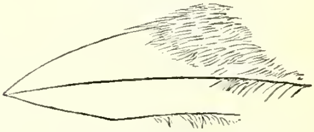
Fig. 115.



Rostrum of a Shrike

The *Conirostres* (*fig.* 116) include the two orders of M. Temminck, termed *Omnivores* and *Granivores;* and are characterized by a strong and conical beak, the margin of which is generally entire; the greater part are omnivorous, the rest granivorous; these latter are the *Hard-billed Birds* of Ray. The families of the tribe are the following: *Sturnidæ*, Starlings; *Corvidæ*, Crows; *Buceridæ*, Hornbills; *Loxiadæ*, Cross-bills; *Fringillidæ*, Finches, Larks.

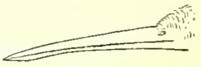
Fig. 116.



Rostrum of a Crow.

The *Tenuirostres* (*fig.* 117) or suctorial birds form, Mr. Vigors observes, "the most interesting group, perhaps, of the animal world. Deriving their subsistence for the most part from the nectar of flowers,* we never fail to associate them in idea with that more beautiful and perfect part of the vegetable creation, with which in their delicacy and fragility of form, their variety and brilliancy of hues, not less than by their extracting their nourishment from vegetable juices, they appear to have so many relations. As the tribe is confined exclusively to the torrid zone and southern hemisphere, the naturalists of our northern latitudes have little opportunity of observing their manners or of inspecting their internal construction."†

Fig. 117.



Rostrum of the Orthorhynchus, or Straight-billed Humming Bird.

* The genus *Ceyx*, Lacép. (*Alcedo tridactyla*, *Pall.*) affords an exception, the inner toe being deficient; and the two other anterior ones being united as in the other Syndactyles, it appears as if there was but one toe in front opposed to one behind.

* In the Humming-Birds which we have dissected, we have found the remains of minute insects in the gizzard.

† We have selected the skeleton of the Humming-bird, one of this tribe, as a striking illustration of the

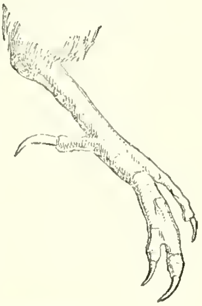
This distinguished ornithologist proposes to divide the *Tenuirostres* into the following families: *Cinnyridæ*, Sugar-eaters; *Trochilidæ*, Humming-birds;—in which families the beak and feet are more remarkable for their tenuity and length: and *Promeropidæ*, Hoopoes; *Meliphagidæ*, Honey-suckers; *Nectariniadæ*, Nectar-birds;—in which the slenderness of the beak and feet is less remarkable.

Fig. 118.

Rostrum of the Caprimulgus.

The *Fissirostres*, (*fig.* 118), like the *Tenuirostres*, are distinguished by a habit of feeding on the wing, but as their food, instead of vegetable juices, consists of living insects, the form of the beak is modified accordingly, and is remarkable for its shortness and the wideness of its gape, especially in the typical families. In these the mode of catching the prey is conformable to their distinguishing characters; they receive it in full flight into the cavity of their mouths, which remain open for that purpose, and where a viscous exudation within and a strong fence of *vibrissæ* on the exterior, assist in securing the victim. The longer-billed *Fissirostres*, on the other hand, seize their food by their bills. The following are the families of the Fissirostral tribe: *Hirundinidæ*, Swallows; *Caprimulgidæ*, Goat-suckers; these are characterized by the short, wide, and weak bill. *Todidæ*, Todies; *Halcyonidæ*, King-fishers; *Meropidæ*, Bee-eaters; these latter families are characterized by their stronger and longer bill, and further differ from the preceding in having the external toe nearly as long as the middle one to which it is united as far as the penultimate joint; they are therefore termed *Syndactyles* by Cuvier. *Fig.* 119 represents the foot of the King-fisher.

Fig. 119.



Order III. *SCANSORES.*

Feet with two toes before and one behind. (*Fig.* 120.) The disposition of the toes which results from the external one being turned back like the thumb, gives the *Scansores* great facility in climbing the branches of trees, but proportionally impedes their progression along level ground.* Their nests are less skilfully constructed than those of the Insessores, and are generally made in the hollows of old trees; one family, indeed, is remarkable for depositing its eggs in the nests of other birds. Their powers of flight are moderate;* their food consists of insects and fruit. The scansorial families are the *Psittacidæ*, Parrots; *Picidæ*, Woodpeckers, Wry-necks; *Cuculidæ*, Cuckoos; *Rhamphastidæ*, Toucans.

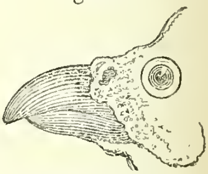
Fig. 120.

Foot of the Woodpecker.

Order IV. *RASORES.*

Upper mandible, vaulted; *nostrils*, pierced in a membranous space at their base, covered by a cartilaginous scale. *Legs*, strong, muscular; three toes before united at their base by a short membrane, and one behind, higher than the rest, furnished with short, blunt, and robust nails, for the purpose of scratching up the food. *Tail-feathers* 14—18.

Fig. 121.



Beak of the Guinea-fowl.

The food of the Scratchers, or gallinaceous birds, being vegetable substances, as grains and seeds, they have a large crop and extremely muscular gizzard. They mostly deposit and hatch their eggs on the ground in a rudely constructed nest of straw. Each male has ordinarily many females, he takes no part in nidification or in rearing the young; and these are generally numerous and able to run about and provide for themselves the moment they quit the shell.

The families of the *Rasores* are the *Columbidæ*, or Dove-tribe; *Craeidæ*, Curassow-birds; *Phasianidæ*, Pheasant, common Fowl; *Tetraonidæ*, Grouse, Partridge.

Order V. *CURSORES.*

Wings very short, not used for flying; *legs* robust; *Sternum* without a keel.

This order includes the *Brevipennes*, which constitute a tribe of Waders (Grallæ) in the Cuvierian system; and form in the system of Mr. Vigors, a family of Rasores under the term *Struthionidæ*. They differ remarkably from one another, both in the form of the beak and feet, and each known species forms the type of either a separate genus or family.

adaptation of the vertebrate skeleton to powers of flight.

* There are peculiar exceptions to the general character in this as in most other orders of birds. Among the *Cuculidæ*, the 'Traveller's Friend,' of South America,' and among the *Psittacidæ*, the 'ground parrots' of New South Wales, are remarkable for their preference of the ground, for progression along which their elongated naked tarsus, and slender toes, of which one of the hind ones can be brought forward to the front row, favourably adapt them.

* The *Trichoglossi* of New Holland afford as remarkable an exception in respect of powers of flight; for instead of the usual short rounded wings of the parrot tribe, they have them elongated and pointed like those of a hawk, and dart through the forests with inconceivable rapidity.

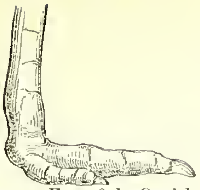


Fig. 122.

Foot of the Ostrich.

The *Coursers* with a *depressed* beak have the longest and strongest legs, and run with remarkable velocity; these include

The Ostrich (*Struthio Camelus*) which has only *two* toes. (*Fig.* 122.)

The Rhea (*Rhea Americana.*), the Cassowary (*Casuarius galeatus.*), the Emeu (*Dromaius ater.*), which have three toes, all turned forward.

Of these four giants of the class the first inhabits the continent of Africa, the second South America, the third Java, and the fourth Australia.

The *Coursers*, with a *compressed* beak, are represented by a single and now extinct genus, the Dodo, (*Didus ineptus*, Linn.)

This bird is known from a description given by one of the early Dutch navigators, and preserved in Clusius (*Exoticorum libri decem descr.* 1605, pp. 99 and 100); by an oil-painting of the same period, copied by Edwards (*Gleanings*, plate 294); from a description and figure in Herbert's *Some Years Travels in Africa, Asia, &c.* 1677; and from the *Historia Naturalis et Medica*, of Jacob Bontius, 1658.

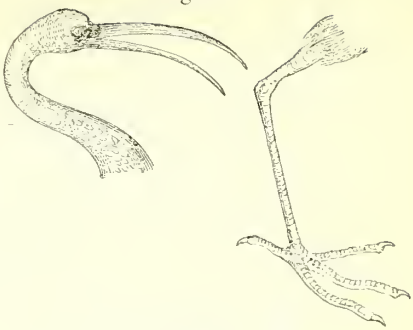
A foot of the Dodo is preserved in the British Museum, and a head in the Ashmolean collection at Oxford. The beak resembles that of the Penguin or Albatross rather than that of a Vulture, to which it has been compared. The foot would resemble that of the Aptenodytes, if it were webbed, which however it is not nor has been. It is very similar to, but proportionally stronger than, the foot of the Curassow. We have examined carefully the foot in the British Museum, and also the head of the Dodo at the Ashmolean Museum, and derived a conviction that they are the remains of a bird *sui generis*.

A third form of beak among the *Brevipennes* or *Cursores* is presented by the *Apteryx Australis*; a bird inhabiting and apparently peculiar to the island of New Zealand. The mandibles are elongated and slender, the upper one is marked on either side by a longitudinal furrow. The toes are, as in the Dodo, four in number; but the fourth, or posterior one, is smaller, being reduced almost to a spur, and the three anterior ones have the lateral skin, notched as in the *Phaleropes*. The wings are shorter than in any other known bird, are quite concealed by the feathers, and terminate in a sharp spine or claw. The feathers are narrow like those of the Cassowary.

Ordo VI. *GRALLATORES.*

Legs with the tibia, and especially the metatarsus very long, stretched out behind in flight; the distal end of the tibia unfeathered; *toes* elongated, straight. *Wings* long. *Body* slender; neck and beak long.

Fig. 123.



Head and leg of the Ibis.

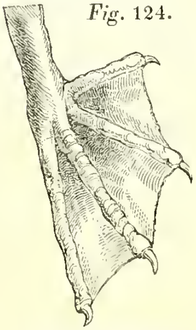
The Waders,—or *Grallæ*, as they were termed by Linnæus from being raised on their long legs, as on stilts,—frequent for the most part the banks of lakes and rivers, marshes, and the shores of estuaries, and derive their food, some exclusively from the waters, feeding on small fishes, aquatic mollusks, worms, small reptiles, and insects, as well as their spawn, while others are of more terrestrial habits and food. Of the latter kind are the *Gruidæ*, or Stork tribe, which are chiefly vegetable feeders, and resemble the land birds in their bill and feet; the former being more obtuse than in the typical waders, and the latter shorter. Then follow the *Ardeidæ*, or Heron tribe; the *Scolopacidæ*, Snipe, Woodcock; the *Rallidæ*, Rail, Coot; and the *Charadriadæ*, Plover, Sanderling, &c.

The Waders are remarkable for their power of preserving a motionless position upon one leg for a considerable length of time; the mechanism by which this is effected will be afterwards described. During flight they stretch out their long legs behind to counterbalance their long neck, and the tail is always extremely short, its function as a rudder being transferred to the legs. They mostly make or choose their nests on the ground, and the young are enabled to run about as soon as hatched, excepting in those Waders which live in pairs.

Ordo VII. *NATATORES.*

Body closely covered with feathers, and coated with a thick down next the skin. *Legs* short, placed behind the point of equilibrium. *Toes* united by a membrane or web, which is sometimes divided.

Fig. 124.



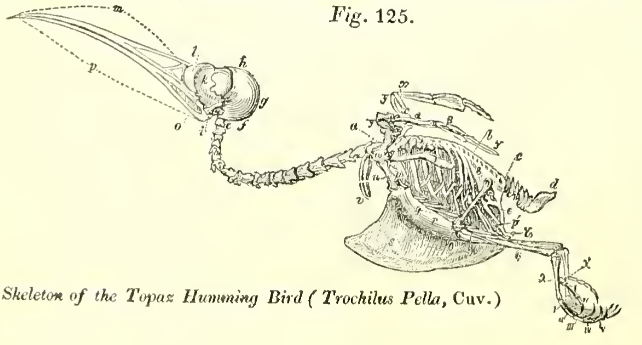
Foot of the Pelican.

The Swimmers, or *Palmipedes*, are of all the orders of birds the most easily recognizable by the structure and position of their oar-like feet: this peculiarity which occasions an awkward gait on land, is extremely favourable to those birds 'whose business is in the great waters.' Their body is boat-shaped, and generally elongated, as is also their neck. Their dense plumage is oiled and lubricated by the secretion of the coccygeal glands, which are remarkably developed for that purpose. In general the males have many females, and in harmony with this speciality the young are hatched in a condition which renders the cooperation of both parents for their support unnecessary, being able to take to the water and swim about in search of food the instant that they are liberated from the egg-coverings. The families of Swimmers are the *Anatidæ*, Swan, Goose, Duck; *Colymbidæ*, Divers; *Alcadæ*, Auks; *Pelecanidæ*, Pelican, Cormorant, Gannet; *Laridæ*, Gulls.

1. *Osteology.*—The skeleton of Birds is remarkable for the rapidity of its development and the light and elegant mechanism displayed in the adaptation of its several parts. The osseous substance is compact, and exhibits more of the laminated and less of the fibrous texture than in the other vertebrate classes. This is more especially the case in those parts of the skeleton which are permeated by the air. The bones which present this singular modification have a greater proportion of the phosphate of lime in their composition than is found in the osseous system of the mammalia, and they are whiter than the bones of any other animal. In the bones where the medulla is not displaced or dessicated by the extension of the air-cells into their interior, the colour is of a duller white. In the Silk or Negro-fowl of the Cape de Verd Islands (*Gallus Morio*, Temminck) the periosteal covering of the bones is of a dark brown, and in some parts almost black colour; but this ought to be regarded as a peculiarity of the cellular rather than of the osseous texture, which does not differ in colour from that of other birds; indeed the thin aponeurosis covering the lateral tendons of the gizzard of the Silk-fowl is observed to have the same dark hue as the membrane which invests the bones.

Although in the disposition of the parts of the osseous system of birds the plan which pervades the vertebrate type of structure is nowhere absolutely violated, yet the variations from that plan required by the peculiar exigencies of the class are of the most striking and interesting kind. We shall successively consider the relations of these modifications to the powers and habits of the bird as they present themselves in the vertebral axis, in the bones of the head and thorax, and in those of the anterior and posterior extremities.

Fig. 125.



Skeleton of the Topaz Humming Bird (Trochilus Pella, Cuv.)

The vertebral axis or spine is divisible into a *cervical* (*fig.* 125, *a*), *dorsal* (*b*), *sacral* (*c*), and *caudal* (*d*) region; the vertebræ immediately succeeding those which bear ribs have a lateral anchylosis with the *iliac* bones, and therefore there is no part of the spine which possesses the characters of the *lumbar* vertebræ of mammalia and reptiles.

The vertebræ are the first parts of the osseous system which make their appearance in the development of the embryo, and they are of all parts of the skeleton the most constant in their existence and general characters.

The *dorsal* or costal vertebræ in birds rarely form more than a fourth part of the entire vertebral column, and in some of the long-necked *Grallatores*, as the Stork, form only an eighth part of the spine; they have not been observed to be fewer than six nor more than eleven in number throughout the class: the latter obtains in the Swans (*Cygnus canorus et olor*) and Sheldrake; the most common numbers are seven or eight.

The dorsal vertebræ are short, as compared with the cervical: they appear broad when viewed superiorly, in consequence of the great development of the transverse processes; but their bodies are much compressed in the lateral direction, so as to be reduced almost to the form of vertical laminæ towards the sacral region. This is especially observable in the Penguins (*Aptenodytes, Catarrhactes*); but in the Ostrich the bodies of the dorsal vertebræ retain their breadth throughout.

The bodies are not united by intervertebral substances, but by capsular ligaments and synovial membranes; the anterior articular cartilaginous surface is convex in the vertical direction, and concave in the transverse; the posterior surface is the reverse. The Penguins, however, present a remarkable exception to this rule. The posterior surface of the third dorsal vertebra is uniformly concave, to which the opposed end of the fourth vertebra presents a corresponding convexity: the ball and socket joint is continued between the several vertebræ to the last dorsal, which is anchylosed to the sacrum. This is an interesting affinity to the *Reptilia*, in addition to numerous others displayed in the construction of these singular birds. In most birds the bodies of some of the middle dorsal vertebræ are anchylosed together; and in general those which are nearest the sacrum. In the Flamingo we have observed this anchylosis extending from the second to the fifth dorsal vertebra. In the Sparrow-hawk the second, third, fourth, and fifth dorsal vertebræ are consolidated into one piece, while the sixth enjoys considerable lateral motion both upon the fifth and seventh, which last is anchylosed to the sacrum; so that the body can be rapidly and extensively inflected towards either side during the pursuit of prey. This structure and its uses were first pointed out by Mr. H. Earle.

The bodies of the anterior dorsal vertebræ send down processes from their inferior or ventral surfaces for the advantageous origin of the *recti antici majores* muscles of the neck. These processes differ from the inferior spines of the tail in not being perforated for the passage of an artery. This part of the spine is further strengthened by the extension of osseous splints from the transverse processes, which unite those of contiguous vertebræ together, and also by the anchylosis of the spinous processes. But where a similar necessity for the fixation of the trunk does not exist, as in the Struthious birds and Penguins, which cannot fly, all the dorsal vertebræ are moveable upon each other. When it is considered that the head, posterior extremities, and viscera are suspended in flight from this central portion of the trunk, and that it has almost exclusively to sustain the shock of the violent contractions of the principal muscles of the wings, the necessity for the mechanism consolidating the dorsal vertebræ will be readily appreciated.

Immobility and strength are still more obviously required in that part of the spine by which the weight of a horizontal body is to be transferred to a single pair of extremities articulated to the trunk behind the centre of gravity. The anchylosis of the bodies of the vertebræ, which already begins to appear in the last dorsal, is, therefore, continued through all the sacral vertebræ as far as the caudal region; and this consolidated mass (*b* to *c*) is united laterally to the iliac bones. Hence it is always difficult to determine the number of vertebræ of which it is composed. We have made sections of the sacrums of many different birds with a view to determine this fact, and have generally found the number greater than that which is indicated in the tables of Cuvier. Thus the Stork has twelve, instead of eleven sacral vertebræ; the Coot thirteen, instead of seven; the Kingfisher eleven, instead of eight: while the Ostrich, on the other hand, has but seventeen, instead of twenty bones of the sacrum. The bodies of the sacral vertebræ are broad, but shallow, and towards the tail the floor of the vertebral canal is formed by a mere lamina of bone: the canal is remarkably dilated in this part of the spine for the enlargement of the cord which gives off the nerves to the posterior extremity. It is a curious fact that the roots of these nerves pass out of the osseous canal by separate orifices, the ganglion on the posterior root and the union of the two being external to the spine. The aspect of all these orifices is lateral, in the intervals of the transverse processes of the different vertebræ, which are not united together as in the mammalia. The first four or five sacral vertebræ give off two sets of transverse processes, one ventral, the other dorsal; the ventral ones are wanting in the succeeding four, and then suddenly reappear to abut against the symphysis of the ilium and ischium, and are so continued double to the end. The spinous processes which are principally developed from the anterior sacral vertebræ, give off from their extremities lateral expansions, which anchylose with the iliac bones, and form an osseous roof, arching over and concealing the transverse processes.

The *coccygeal* vertebræ of birds, though never prolonged into a conspicuous caudal appendage, are in general moveable upon each other, and are frequently nine in number. With the exception of the last, they are broad and short and perforated for the lodgement of the spinal marrow. With the exception of the last also they have spines on both the dorsal and ventral aspects; and the anterior vertebræ have also transverse processes. The last caudal vertebra (*d*, *fig.* 125) is so singularly shaped, that were it found alone in a fossil state it would hardly be recognized as a bone of the spine. It has no medullary canal and no processes; but is compressed laterally and terminates above and often also below in a sharp edge; its posterior extremity is obtuse. It supports the coccygeal oil-gland, and affords a firm basis to the tail feathers, which, from their use in guiding the motions of the bird through the air, Linnæus termed the *rectrices*.*

In the Toucan the three last caudal vertebræ are anchylosed together; the six anterior ones are articulated by ball and socket joints, the ball and the socket being most distinct in the two last of these joints; that between the sixth and seventh vertebræ is provided with a capsule and synovial fluid, the others have a yielding ligamentous mode of connexion. The spinous processes of these vertebræ, both superior and inferior, are of moderate size, but smallest in the sixth, where the greatest degree of motion takes place; the transverse processes on the contrary are large and broad so as almost to preclude lateral motion. We have given a more particular description of these vertebræ because of the singular movements observable in the tail of the Toucan; it can be inflected dorsad till the superior spines of the vertebræ are brought in contact with the sacrum; and in the performance of this motion the lateral muscles, which at first tend rather to oppose the elevators, become, at a certain point of inflection dorsad of the centre of motion, elevators themselves, and thus combining with the elevators jerk the tail upon the back; it is thus that the tail turns as if on a hinge operated upon by a spring.

As the prehensile functions of the hand are transferred to the beak, so those of the arm are performed by the neck of the bird; this portion of the spine is therefore composed of numerous, elongated, and freely moveable vertebræ, and is never so short or so rigid but that it can be made to apply the beak to the coccygeal oil-gland, and to every part of the body for the purpose of oiling and cleansing the plumage. In birds that seek their food in

* In the tail-less variety of the common Fowl the coccygeal vertebræ have degenerated into a single unshapely knotty process.

water it is in general remarkably elongated, whether they support themselves on the surface by means of short and strong natatory feet, as in the Swan, or wade into rivers and marshes on elevated stilts, as in the Crane, &c.

The articular surfaces of the bodies of the *cervical* vertebræ, like those of the dorsal series above mentioned, are concave in one direction and convex in the other, so as to lock into each other, and in such a manner that the superior vertebræ move more freely forwards, the middle ones backwards, while the inferior ones again bend forwards; producing the ordinary sigmoid curve observable in the neck of the bird.

This mechanism is most readily seen in the long-necked waders which live on fish and seize their prey by darting the bill with sudden velocity into the water. In the common Heron, for example, *(Ardea cinerea)* the head can be bent forward on the atlas or first vertebra, the first upon the second in the same direction, and so on to the sixth, between which and the fifth the forward inflection is the greatest; while in the opposite direction these vertebræ can only be brought into a straight line. From the sixth cervical vertebra to the thirteenth the neck can only be bent backwards; while in the opposite direction it is also arrested at a straight line. From the fourteenth to the eighteenth the articular surfaces again allow of the forward inflection, but also limit the opposite motion to the straight line.

Two transverse processes are ordinarily continued from the anterior part of the bodies of the cervical vertebræ: the inter-space of these is filled up externally to the vertebral artery by a rudimentary styliform rib, which is separated in the young bird, but afterwards anchylosed, and directed backwards parallel to the body of the vertebræ. These processes give attachment to numerous muscles of the neck, and being, with the transverse processes, more strongly developed in the rapacious birds, give a greater breadth to the cervical region in that order.

The superior spinous processes are but feebly developed; they are most distinct on the vertebræ at the two extremities of the cervical portion of the spine. Inferior spinous processes are also found on the vertebræ at the commencement and termination of the neck, but are wanting in a great proportion of the intermediate cervical vertebræ.

The atlas is a simple ring. In general it is articulated with the occipital tubercle by a single concave facet on the body; but in the Penguin and Ostrich there are two other facets, continuous with the middle one, but corresponding with the anterior articulating processes of the rest of the vertebræ and applied to the condyloid portions of the occipital bone, while the middle facet is articulated to the basilar portion as in other birds. The body of the dentata is joined to the atlas by a single synovial capsule, its odontoid process is tied down by a strong transverse ligament stretched above it, and by a longitudinal one extending from its extremity to the posterior part of the occipital condyle. In the articulations of the bodies of the remaining cervical vertebræ a moveable inter-articular cartilage is found inclosed between reduplications of the synovial membrane, as in the joint of the lower jaw in mammalia. The articulations of the oblique processes have no peculiarities worthy of notice.

A remarkable difference is found in the diameter of the spinal canal contained in the cervical vertebræ. If, *e. g.* the sixth cervical vertebra of a Stork be sawed down vertically, the antero-posterior diameter is greatest in the middle, least at the ends; but if it be sawed lengthwise horizontally, the transverse diameter is the reverse, being narrowest at the centre and widest at the ends. In the Ostrich, the Swan, and many other birds the spinal canal is widened in every direction at the extremities of the vertebræ; and on the dorsal or posterior aspect of the spine, the canal remains open for some extent in the intervals of the vertebræ, the cord being there protected only by membrane and the elastic ligaments which connect the roots of the spinous processes together. The final purpose of this structure has been ably illustrated by Mr. Earle in the Philosophical Transactions, (1822, p. 276.) where he shews that it is adapted to prevent a compression of the spinal cord during the varied and extensive inflections of the neck.

The vertebræ of the different regions of the spine bear a different proportion to each other in respect to number among birds, from what we observe in the mammalia and reptilia. The cervical portion in this class is generally composed of a much greater number of vertebræ than any of the other divisions of the spine; in this respect the fossil reptilian genus called *Plesiosaurus* alone resembles the bird. This singular animal was an inhabitant of the waters, and it is interesting to observe that the peculiarity which distinguishes it, viz. the great length of neck, is chiefly characteristic of the *Aves aquaticæ* of Nitzsch. In the *Grallatores* the length of the neck is determined by the height of the legs: in the *Natatores* it is necessary for the purpose of obtaining their food while swimming the waters. The dorsal vertebræ are usually less numerous than in mammalia. The caudal vertebræ are subject to few variations; they never project in the form of a tail, but are most numerous in those birds which make the greatest use of the tail-feathers, as in the Swallows, to direct their rapid flight, and in the Woodpeckers, where they serve as a prop or climbing pole.

The following table, which, with some corrections, is extracted from Cuvier's Leçons d'Anatomie Comparée, exhibits the variety that exists with respect to the number of vertebræ in different species of birds.

Table of the number of vertebræ in birds.

Order. RAPTORES	*Vertebræ.*			
Species.	Cervical.	Dorsal.	Sacral.	Caudal.

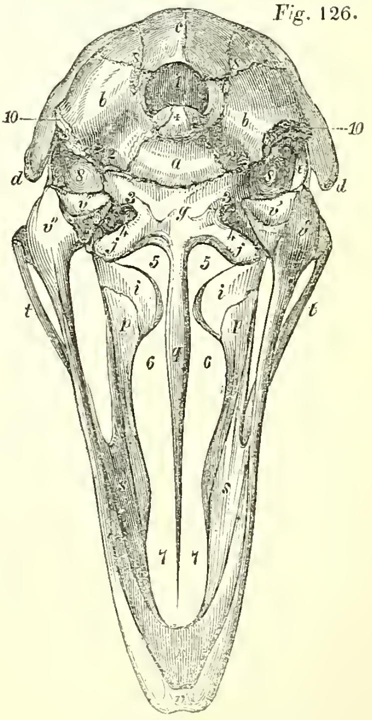
Grebe	14	10	13	7

The skull in all the Vertebrated Classes is composed of a considerable number of osseous pieces, which, in the Mammalia, unite in definite numbers and proportions, so as to form the bones termed *occipital*, *temporal*, *sphenoidal*, &c. In the cold-blooded Vertebrata the component parts of these bones generally remain separated throughout life, giving an appearance of great complexity to the skull, and occasioning much difficulty in tracing their correspondence with the cranial bones of the higher classes. Equal difficulty is experienced in determining the component parts of the head in Birds, but from a very different cause. In the cold-blooded Crocodile, and Fish, this difficulty is caused by the tardiness of ossification, which prevents the coalition of the several elements of the cranial bones into their determinate groups; while, in Birds, the

Fig. 126.



Skull of a young Ostrich.

energetic respiratory and circulating functions occasion so rapid an evolution of the osseous system, that the bones of the cranium become at an early period anchylosed into one piece, with a total obliteration of the original harmoniæ; it is necessary, therefore, to examine the skull of the Bird at an early period of existence, and to compare it with the fœtal condition of the skull of the Mammal, when it will be found to be ossified from analogous centres, which, in their expansion and subsequent union, obey the same laws of, as it were, elective attraction.

The *occipital bone* is originally composed of four pieces: the *basilar*, below, (*a*, *fig.* 126,) the two *condyloid*, laterally, (*b*, *b*,) and the expanded *spinous* process, or supra-occipital piece above (*c*). These fulfil the usual functions of the occipital bone, protecting the cerebellum and medulla oblongata, and forming the medium of connection between the cranial and cervical vertebræ.

The head is articulated to the spine by means of a single hemispherical tubercle (*a*, *fig.* 126,) which plays in a corresponding cavity of the atlas. In most birds the tubercle is formed exclusively by the basilar piece of the occipital bone, but in the Ostrich and Penguin the condyloid portions also contribute to its formation, which is an approximation to the structure of the occipital condyle in the Chelonian reptiles. In all birds, however, the articulation is such as to allow of a much greater extent and freedom of motion to the head than exists in the Mammalia.

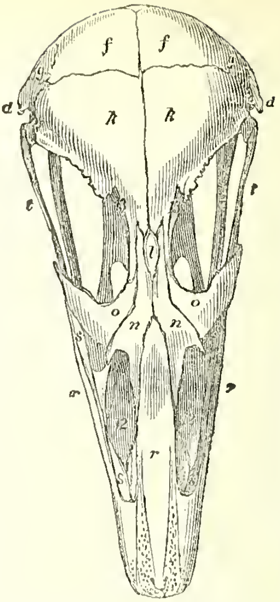
The *temporal bone* consists of the *petrous* portion, the *squamous* portion, (*d*, *d*, *fig.* 126, 127) and the *tympanic* bone, or os quadratum (*e*.) The petrous bone includes the complex parts of the internal ear, and is soon anchylosed to the condyloid portions of the occipital bone, which fulfil the functions of the mastoid processes. The squamous, or, as it may be termed, the zygomatic portion of the temporal bone (*d*) remains for a longer time separate; it forms the lateral boundary of the cranial cavity, as in quadrupeds, and the tympanic element is moveably articulated to its inferior part.

The *parietal bones* (*f*, *f*, *fig.* 127) retain their separated condition till after the union of the occipital pieces, they then unite and protect the posterior part of the cerebral hemispheres.

The *sphenoid bone* is composed of a *basilar* portion, (*g*, *fig.* 126,) two *orbital* plates, (*h*, *fig.* 127,) forming the floor and part of the septum of the orbits, and which rapidly anchylose with the preceding; two *cranial* portions, or alæ majores, (*g*, *fig.* 127, 128,) which remain longer separate, and form the posterior part of the orbits, and two *pterygoid* portions ('interarticular' or 'omoid' bones), (*i*, *i*, *fig.* 126,) which, in birds, abut against the tympanic or quadrate bones. The great alæ of the sphenoid join the parietal, and separate the temporal from the frontal bones.

The *frontal bone* (*k*, *fig.* 127) continues for a longer period than the parietal to be separated into two lateral halves by the continuation of the sagittal suture through its whole length.

Fig. 127.



Skull of a young Ostrich.

The ant-orbital processes (13, *fig.* 127) are elongated and pointed, extending forwards to join the lachrymal bones, (*o*, *o*, *fig.* 127,) considerably beyond the origins of the nasal bones, and are separated from each other by these and by a process of the ethmoid bone. The post-orbital processes are most developed in the Parrots and Maccaws, in the latter of which they join the lachrymal bones, and complete the bony circumference of the orbits, (*fig.* 128.) In the Emeu they remain for a long time distinct bones, as in the reptiles. The frontal bone thus forms the whole of the superior, and, more or less, of the outer boundary of the orbits, and protects the anterior part of the cerebrum. It supports the horn-like prominences which are seen upon the heads of the Cassowary, Pintado, and Curassow, the bony bases of which commence by distinct ossifications.*

A small part of the *ethmoidal* bone (*l*, *fig.* 127) is seen, in the Ostrich, on the exterior of the cranium lodged between the ant-orbital processes and nasal bones (*n*, *n*.) The ethmoid separates, as usual, the orbits from the cavity of the nose, and forms a great part of the inter-orbital septum where this exists, as in the parrots, (*m*, *fig.* 128.)

In the mature bird the whole of the preceding bones, with the exception of the tympanic elements of the temporal bone, are usually found anchylosed into one piece.

The internal surface of the cranium exhibits a well-marked transverse ridge, which divides the cavity into two principal depressions. In the anterior division the hemispheres of

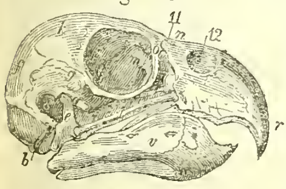
* 'A most remarkable sexual difference appears in the skull of the *crested Hens*: in these the frontal portion of the cranium is dilated into an immense cavity, on which the crest of feathers is placed. This degeneracy of the formative impulse, which is propagated to the offspring, is quite unparalleled in the whole animal kingdom: I have lately examined several heads of such hens in a fresh state, and have found that this peculiar dilatation of the cranium is filled by the hemispheres of the cerebrum, and is separated from the posterior part which holds the cerebellum, as in the common hen, by an intermediate contracted portion.'—*Lawrence's Blumenbach's Comp. Anat.* p. 61.

the cerebrum are lodged, the rest of the brain is contained in the posterior division. The relative proportion of these divisions varies in the different orders; in the *Insessores* and *Accipitres* the anterior superior depression is the largest; in the *Rasores*, the posterior inferior depression equals, and in some species, exceeds the former in size. The orbits form two slight projections in the anterior fossa of the cranium, which is partially divided longitudinally by a ridge corresponding to the interspace of the cerebral hemispheres. This is developed in the Gallinaceous birds into a thin falciform osseous crest, which is especially remarkable in the Partridge, Turkey, and Capercailzie. It is also well developed in the Parrot tribe. The *sella turcica* in all birds is a deep round cell, lodging the pituitary gland, as in the Mammalia.

The foramen magnum (1, *fig.* 126) is formed, as usual, by the union of the four pieces of the occipital bone: its size is considerable, having relation to the mobility of the cranium upon the spine. The foramen lacerum posterius (2, 2, *fig.* 126) is situated immediately below the membrana tympani (8, 8, *fig.* 126.) There is no fissure analogous to the foramen lacerum medius. The carotid foramina (3, 3, *fig.* 126) are transversely oblong, and situated on the body of the sphenoid; the same bone, in the Ostrich, is perforated immediately anterior to the carotid canal by the Eustachian tube, (4, 4.) The posterior palatine foramina are wide spaces, (5, 5,) separated from each other by the vomer (*q*, *fig.* 126). Anterior to these, in the base of the skull, are seen the still wider posterior apertures of the nostrils (6, 6). In the inside of the cranium the internal auditory foramina are distinctly seen. The foramen lacerum anterius is divided into several distinct foramina. The optic foramina, on the contrary, are closely approximated, and frequently blended into one. The olfactory nerves escape each by a single foramen, and are continued to the nose either along a deep groove on the upper part of the orbital septum, or, as in the Toucan, pass through a complete osseous canal.

The bones of the face correspond in number and relative position with those of the Mammalia, but differ considerably in their forms and proportions; they bear most resemblance to the facial bones of the Rodentia. They are always moveably connected with the bones of the cranium, and retain much longer than these their separate condition.

Fig. 128.



Skull of a Parrot.

The *nasal bones* (*n*, *n*, *fig.* 127, 128) are a large and elongated pair, extending from the inner side of the ant-orbital processes of the frontal to the outer side of the ascending processes of the intermaxillary bones, expanding as they advance forwards, and giving off from their outer sides a process which curves downwards to join the superior maxillary bone, to which it has erroneously been considered to belong. The nasal bones soon anchylose with the frontal, ethmoidal, inter-maxillary, and superior maxillary bones.

The *lachrymal* or *ungueal bones* (*o*, *o*, *fig.* 127, 128, *l*, *fig.* 125) are also of considerable proportionate size. They are more exposed than in mammalia, and are usually moveably articulated by their mesial or anterior edge to a varying number of the bones of the skull. These are commonly the frontal, nasal, and malar bones; but in the ostrich the lachrymal articulate with the palatine bones; in the Parrot they extend backwards beneath the orbit to the post-orbitals, and thus complete the bony circumference of that cavity, while in the Owls they do not at all articulate with the frontal bone. They are smallest in the *Rasores* and *Natatores*, and attain their greatest development in the diurnal *Raptores*. In these the separated supra-orbital bones give additional protection to the eye, over which they form, in conjunction with the lachrymal, the projecting arch so characteristic of the physiognomy of the bird of prey.

The *palatine bones* (*p*, *p*, *fig.* 126,) are of great proportional size: each is of an elongated, slender, depressed figure, becoming narrower anteriorly, forming the posterior part of the palatine arch, and completing with the vomer the boundary of the posterior nostrils. In the *Raptores* the palatine bones are united together only by a small part of their anterior extremities. In the Owls the posterior extremities are widely separated from each other. In the *Insessores* they are not united together in any part of their extent, except in the Grossbeak, (*Loxia Coccothraustes*,) at the anterior extremity. In this bird and in the Parrots, the palatine bones have not a horizontal but a vertical position, contrary to what they are in most other birds. They are least developed in the *Rasores*.

The *vomer* (*q*, *fig.* 126) is rapidly anchylosed in the Ostrich with the sphenoid, appearing as a long, moderately compressed, pointed process, extending forward from the spine of the sphenoid in the interval of the palatine bones, and dividing the posterior aperture of the nose into two lateral halves. In most other birds it remains distinct from the spine of the sphenoid, as it is also in the ostrich at a very early period.

The *intermaxillary bone* (*m*, *fig.* 125, *r*, *r*, *fig.* 126, 127, 128) determines the form, and constitutes the greater part, of the upper mandible. It consequently presents considerable variety in its figure and proportions, and also in its mode of articulation, in different birds; but in every species it is of considerable size. When completely ossified, which it is at a very early period, the intermaxillary bone consists of three processes which diverge from, or unite to form, the extremity of the upper mandible: the superior mesial process or nasal plate is lamellate, depressed or flattened horizontally, extends backwards between and above the lower ends of the nasal bones, and becoming wedged, as it were, between their upper ends, is articulated in general by an anchylosis to them and the ethmoid bone. This union, however, always allows of a certain elastic or yielding motion to pressure from below. In the Parrots, where the upper mandible is an important instrument in their climbing habits, the nasal plate of the intermaxillary bone is joined to the cranium by a ligamentous substance (11, *fig.* 128). The two lateral or mandibular processes (*r*, *r*, *fig.* 127) of the intermaxillary bones diverge and extend backwards, external and superior to the superior maxillary bones; and, in the Ostrich, they articulate with the anterior extremities of the malar or zygomatic bones. Throughout their whole course the mandibular processes are in close contact with, and soon become anchylosed to the superior maxillary bones. The ossification of the intermaxillary bone obeys the ordinary law of centripetal development. The lateral moieties are still separate in the chick at the conclusion of incubation; and in the duckling they do not anchylose until six weeks after that period. The union commences at the anterior extremity, while at the opposite or cranial end of the nasal process, traces of the original separation may frequently be observed in the full-grown bird; these are very conspicuous in the Gulls, (*Laridæ*).

The *superior maxillary bones* (*s*, *s*, *fig.* 126, 127) are very seldom united together in birds. They are comparatively of small size. Each may be said to commence mesiad of the origin of the mandibular processes of the intermaxillary bone; it then expands as it proceeds backwards, and, opposite the anterior end of the palatine bone, divides into two processes. The mesial or palatine process extends along the outside of the palatine bone, and soon becomes anchylosed to it; the external or malar process is articulated obliquely to the under part of the anterior moiety of the zygomatic bone. At the origin of this process a small projection meets the descending process of the nasal bone. In most Gallinaceous birds, the body, or part anterior to the palatine and zygomatic processes, is wanting; but in the common fowl it extends towards the mesial line, and unites with the vomer, so as to divide the palatal fissure into an anterior and posterior cavity. In the Ostrich, where the body of the upper maxillary extends forwards to the symphysis of the intermaxillary bone, a process is also given off at the origins of the palatine and zygomatic bones, which passes inwards to the vomer, and completes, in the adult, the boundary of the anterior palatal fissure.

The movement of the bony framework of the upper mandible resulting from the union of the intermaxillary, superior maxillary, and palatal bones, is immediately effected by the elongated *malar* or *zygomatic bone*, (*o*, *fig.* 125, *t*, *t*, *fig.* 126, 127, 128,) which transfers to the zygomatic process of the superior maxillary the movements of the tympanic bone, being so placed as to form the medium of communication between these parts. It extends in a straight line from one to the other, this being the form best adapted to resist the pressure upon its two extremities. With the superior maxillary bone it is soon anchylosed, but with the tympanic bone it is in most Birds articulated by a moveable ball and socket-joint, the articular surfaces being connected by a fibro-cartilaginous substance; in the *Caprimulgi*, however, it is anchylosed at both extremities. The malar bone is commonly of a compressed or vertically flattened form, but sometimes, as in the Ostrich, it is cylindrical. It is originally composed of two pieces placed in a parallel line, one above the other; the superior being pointed at both extremities, and much smaller than the other.

The *tympanic*, pedicellate, or quadrate bone (*i*, *fig.* 125, *e*, *fig.* 126, 128,) is never anchylosed with the other elements of the temporal bone, but is freely moveable as in most of the cold-blooded ovipara; and it is interesting to observe that in the rodent quadrupeds, which exhibit many other affinities to birds, the tympanic element remains for a long period a detached bone, but is situated altogether posterior to the maxillary articulation. In birds, where the base of the cranium is remarkably shortened in the antero-posterior diameter, the tympanic bone is, as it were, thrust forward and wedged in between the inferior maxillary bone and the zygomatic process of the temporal, thus intercepting, and articulating with, both the lower jaw and cheek-bones. The *membrana tympani* continues, however, to be attached by about half its circumference to the posterior part of the os quadratum, and for the remainder of its extent to the occipital and sphenoidal bones.

The upper end of the tympanic bone is articulated by two distinct transverse condyles with the zygomatic portion of the temporal bone; below these it is contracted, and then expands as it descends, giving off a strong process from the middle of its anterior surface, which projects into the orbit, then a smaller process from its posterior surface extending backwards, and lastly, sending off at its lower extremity an external process for the malar bone, and an internal one for the pterygoid, between which processes are two oblique oblong convexities for the articulation of the lower jaw.

Having an immediate connection with the motions of the whole beak, it necessarily presents varieties of form in different birds, without, however, losing the characteristic figure which has been described. By whatever cause the tympanic bone is carried forwards, whether by the action of the *pterygoid muscles* inserted into its orbitar process, or by the pressure of the lower jaw upon its inferior surface, that motion is communicated to the pterygoid and malar bones, which transfer it, the one to the palatine, the other to the superior maxillary bones, and thus the upper mandible is elevated at the same time that the lower one is depressed. The elasticity of the union of the nasal process of the intermaxillary bone with the cranium restores the upper jaw on the cessation of the pressure from below, to the position from which the movement of the tympanic bones had displaced it.

These movements are freely allowed in most birds from the nature of the articulation of the tympanic bone; but in the Struthious birds they are more restrained, from the connection of the bone with the descending zygomatic process of the temporal bone; the extent of this attachment is greatest in the Emeu, where it almost produces a complete fixation of the tympanic bone.

The *inferior maxillary bone (p, fig.* 125, *v, figs.* 126, 128,) is originally composed of twelve distinct pieces, each lateral moiety being made up of six. The anterior *symphyseal* or dental portion of each ramus first unites with its fellow at the symphysis; the two portions which form the *condyle (v, fig.* 126) next anchylose; the *angular (v, fig.* 126), *supra-angular* and *opercular*, or *splenial* pieces are consolidated at a later period. The anterior extremities of the angular and supra-angular pieces are wedged into corresponding grooves of the symphyseal element; and the opercular portion is extended like a splint along the inner side of the gomphosis, by which the preceding portions are united.

The traces of the original separation of these bones long remain in the semi-aquatic and aquatic birds (*Grallatores* and *Natatores*), which, as the lowest of the class, manifest their affinity in this respect to the cold-blooded Ovipara, where this complex structure of the lower jaw continues throughout life.

As the lower jaw, thus constituted, forms with the upper jaw the principal organ of prehension in birds, it presents many variations of form and magnitude, which immediately relate to, and are consequently indicative of their mode of life, food, &c. These general modifications will be treated of in relation to the digestive function, but some of the less conspicuous characters of the lower jaw may be more appropriately considered in this place.

The rami are in general completely anchylosed at the symphysis, the extent of the united portions varying considerably in different birds, but occupying in most cases only a small proportion of the jaw. In the Pelicans the rami are united by the mere extremities, appearing as if bent upon each other at the symphysis, and supporting the dilatable sac which fills up the intermediate space, like the hoop of the fisherman's landing-net. The symphysis is also of very small extent in most other Palmipeds. It is small in the *Rasores* and *Cursores*. In the Storks and Cranes it extends along a third part of the entire jaw. In the Flamingo, where the anterior part of the jaw is bent down at an obtuse angle, nearly half of the rami are united. In the Skimmers (*Rhyncops*), Hornbills, and Toucans, two-thirds. In the Curlew the two rami are in apposition for two-thirds of their anterior extent, but are not anchylosed, and form, in this respect, the only known exception to the rule.

In diurnal Birds of Prey, in many of the Parrot-tribe, in the Herons and Swans, each ramus of the lower jaw forms an entire bony plate. In the rest of the class a membranous unossified space is left at the place of union of the symphyseal with the angular, supra-angular, and splenial elements. This deficiency is of a longitudinal form, and is always situated behind the middle of the ramus. In the Bustards, Woodcocks, Curlews, Gulls, Skimmers, Guillemots, Petrels, and Penguins, there is a second foramen, of a rounder figure, posterior to the preceding, and resulting from a defective union of the angular, supra-angular, and condyloid pieces. In the Cassowary this space is subdivided into several small foramina. In the Emeu (*Dromaius*) and Ostrich (*Struthio*) there is a single small foramen at the corresponding part.

At the posterior part of each ramus the following processes are developed in various degrees in different birds. The suprangular piece ascends in a greater or less degree in the form of a thin lamina with a gently rounded outline, representing the *coronoid process.* From the inner side of the condyloid piece there extends a more marked process, which may be called the *internal angular;* and from the posterior part of the ramus a third process is continued, which may be termed the *posterior angular process.*

The coronoid process is most developed in the Parrots, Gulls, Herons, and Cross-bills (*Loxia*), in some of which, as the *Loxia coccothraustes, cardinalis,* and *pulverulentus,* the lower jaw presents the following peculiarity. A large sesamoid bone of a triangular form, but rounded and transverse, with the base directed outwards and the apex inwards, is situated at the posterior and internal aspect of the articular ligament of the lower jaw. It completes the maxillary articulation posteriorly, and corresponds by its anterior articular surface to the posterior part of the outer condyle. The articular surface of the lower jaw of the Parrots is a simple narrow longitudinal furrow, open at the two extremities. That of the Toucans is almost equally simple, but of a rounder figure. In most other birds the articular surface is divided into two distinct portions, of which the internal is an oblique concavity, the external also oblique, but terminating in a convex eminence behind.

In the Rasorial birds the coronoid process is feebly developed, but the internal and angular processes are of large size. The latter is very remarkable in the great Cock of the woods, (*Tetrao urogallus,*) where it extends upwards and backwards in a curved form for the extent of an inch, affording attachment to the powerful muscles required to produce the wide expansion of the mandibles necessary to seize the large fir-cones which constitute its food. In the lamellirostral Palmipedes not only are the internal, and the posterior angular processes of large size, but there are also two eminences for muscular attachment on the outer side of each ramus anterior to the articular surface. In the Gulls an oblique ridge is continued from a single eminence similarly situated.

The articular capsule of the lower jaw is strengthened by ligamentous fibres arising from the lower extremity of the tympanic bone, and passing backwards to be inserted into the outer side of the internal angular process. This ligament assumes a fibro-cartilaginous structure at its anterior part: it is attenuated internally, and is situated between the two bones in the outer part of the capsular ligament. At the posterior part of the joint a strong fibrous band extends from the end of the mastoid process to the internal angular process of the lower jaw, so as to restrain the forward movement of the jaw.

The skull presents fewer varieties of form in birds than in any other class of vertebrate animals. With the exception of a few species, in which the beak assumes what may almost be termed a monstrous development, it has the form of a pretty regular five-sided pyramid, of which the occiput forms the base, and the anterior extremity of the beak the apex.

The posterior facet or base of the pyramid is formed by the upper and larger portion of the occiput, together with part of the temporal bones. It is the smallest facet of the head, and is larger in the transverse than the vertical diameter. It presents the vertical prominence corresponding to the narrow cerebellum, which is separated by a venous foramen and furrow (8, *fig.* 126) from a broad muscular depression on either side; below these are the large occipital foramen, (1, *fig.* 126); the hemispheric tubercle, which unites the head to the atlas; and on either side of this tubercle a smaller muscular depression, separated by a transverse ridge from the larger one above, and perforated by the pneumogastric and hypoglossal nerves; these depressions are bounded laterally by the mastoid processes. (10, 10, *fig.* 126.)

The inferior facet or base of the skull joins the posterior and lateral facets almost at a right angle. It is bounded anteriorly and at the sides by the lower jaw, which, on account of the compressed form and divarication of the rami, scarcely intercepts any part of the view of this very complicated surface. The occipital condyle, with the muscular depressions on either side and the mastoid processes, may be considered in some, and more especially in the Struthious birds, as forming part of the base of the skull. Anterior to the basilar portion of the occiput comes the body of the sphenoid, which in the *Struthionidæ* sends outwards and forwards two rounded processes *(j j, fig.* 126) to abut against the flattened pterygoid bones. Between the origins of these, and anchylosed to the spine of the sphenoid, the vomer extends forwards to a distance varying in different birds. The tympanic bones are seen on either side of the body of the sphenoid, and external to these the zygomatic processes of the temporal; the space circumscribed by these bones, with the mastoid processes behind, forms the expanded external passage of the ear, which is closed in the recent state by the large convex *membrana tympani*, (8, 8, *fig.* 126.) Anterior to the tympanic bones the pterygoid processes *(i i, fig.* 126) extend forwards and inwards to join the palatine bones; which are then continued forwards to the superior maxillary, leaving between them the large posterior nasal fissure divided longitudinally by the vomer. These fissures are commonly continuous with the anterior palatal fissure, (7, 7, *fig.* 126,) but in the full grown Struthious and some Gallinaceous birds, the palatine and maxillary bones unite with the vomer and separate the two fissures, thus increasing the bony floor of the nasal cavities. External to the rami of the lower jaw, the malar or zygomatic bones may in general be seen converging from the tympanic to the superior maxillary bones, the elongated triangular space between these bones and the pterygoid and palatine leads directly from below into the large orbits.

The two lateral facets present posteriorly the tympanic or auditory cavity, (8, *fig.* 128,) anterior to which is the tympanic bone, with the malar and inferior maxillary bones extending forwards from its lower extremity. Above the tympanic bone is the zygomatic process of the temporal, *(d, fig.* 128,) arching over it in the Struthious and Psittaceous birds, as if to effect its normal connection with the malar bone. Between the zygomatic and post-orbital processes is the crotaphyte depression, (*g*, *fig.* 128,) always well-marked, but bounded by ridges more or less developed in different birds. At the lower part of this depression may be perceived the large foramen common to the superior and inferior maxillary divisions of the trifacial nerve. Then come the spacious rounded orbits, bounded above by the supra-orbital lamella, behind by the sphenoid and frontal expansions, which form, at the same time, the anterior walls of the cranium; separated from each other, but always more or less incompletely, by the thin sphenoidal and ethmoidal plates, the deficiencies of which are supplied in the recent state by aponeurotic membranes, and defended anteriorly by the largely developed lachrymal bones and the ethmoidal alæ, between which there are always present apertures varying in size. The pterygoid and palatine bones, with the styliform malar bone, form a very incomplete floor of the orbit.

Anterior to the orbits the sides of the skull become gradually narrower to the end of the beak; between the lachrymal and the superior maxillary bones a large triangular or rounded space is left, (11, *fig.* 128,) which conducts to the nasal cavity. A second vacancy occurs, anterior to this, bounded by the nasal, superior maxillary, and intermaxillary bones, forming the osseous boundary of the wide external nostrils. (12, *figs.* 127, 128.)

The superior surface of the cranium is generally convex in relation to and indicative of the development of the brain; it is rounded posteriorly, where it is generally widest. Here on each side is seen the temporal depression: the interorbital space in the Gulls, Petrels, Albatrosses, Penguins, and other sea-birds, presents also two depressions, scarcely less marked, of a semilunar form, the convexities meeting in the mesial line, and lodging a gland, whose secretion is carried into the nose to lubricate the pituitary membrane. Slight traces of these glandular depressions may be seen at 13, *fig.* 127, in the Ostrich. In other birds the interorbital space is moderately concave or flattened. Anterior to this part the cranium in the Parrot presents the moveable junction of the upper mandible, but in other birds a continued osseous surface converges more or less gradually to the end of the beak, only interrupted by the anterior orifices of the nasal cavity.

The skull in the *Raptores*, especially in the nocturnal division, is short, broad, and high, in proportion to its length, and the cranium is large compared with the face. The posterior facet is convex, and remarkably extended upwards and laterally, and is continued insensibly at an obtuse angle with the upper surface. The occipital foramen is almost horizontal. The temporal fossæ are not very deep, and do not meet above at the middle line. The cerebral convexities are not strongly marked; the frontal region is flat. A longitudinal furrow extends along the whole upper surface of the cranium, and is especially remarkable in the Owls. The cranium and face are separated by a sudden contraction. The orbits are very complete, on account of the development and complete junction of the frontal, ethmoidal, ungueal, and palatine boundaries.

The cranium of the *Warblers* presents a more regular sphericity, but the interorbital space is very concave. The anterior parietes of the orbits are large and very complete from the size of the lachrymal bone and of the transverse lamina of the ethmoid; the internal and posterior bony parietes are, on the other hand, remarkably defective; the optic foramina are indeed commonly blended into one, and continuous with the larger fissures above.

The distinctive characters of the skull of the *Scansores* are the most remarkable, especially in the Parrots and Toucans. In the former the upper surface of the cranium is flattened or slightly convex, and greatly extended in breadth between the orbits. These cavities are very complete; and the nasal inlets on the sides of the skull are much limited in size by the extent of ossification. However, the breadth of the posterior part of the base of the cranium and the large size of the pterygoid bones occasion a very considerable interval between these and the body of the sphenoid.

In the Toucans the cranium slightly increases in breadth to the anterior part where it is joined to the enormous bill. Its superior surface presents an equable convexity. The temporal fossæ, like those of the parrots, are small, and wholly confined to the lateral aspects of the cranium. The posterior surface, which is absolutely concave in the Maccaws, from the backward extension of the mastoid processes, is slightly convex in the Toucans, where it is separated from the upper surface by a regularly arched ridge. The cerebellic prominence extends over the occipital foramen, the plane of which inclines forwards and downwards from the horizontal line at an angle of 45°. The circumference of the orbit is uninclosed by bone at the posterior part, the postorbital processes of the frontal not being developed as in the parrots. The zygomatic process of the temporal, with the ligament extending between it and the malar bone, forms here the posterior boundary of the orbit. The septum of the orbits is very incomplete. The ungueo-maxillary fissure and the external nasal apertures are very small, and situated on nearly the same perpendicular line, the nostrils open on the posterior part of the upper mandible, and the remainder of the lateral facet is, therefore, a smooth entire osseous surface formed by the thin parietes of the dilated cellular mandibles.

In the Hornbills the skull presents the same characters as in the Toucans, with the exception of that extraordinary species the Helmeted Hornbill (*Buceros Galeatus.*) In this bird the whole outer surface of the skull is sculptured with irregular furrows and risings, a character which it presents in no other bird, and which can only be compared to the surface of the skull in the Crocodiles. The posterior surface is concave, and separated by a strongly developed ridge from the temporal furrows, which almost meet at the vertex. The bony rim of the orbit is completed by the extension of the zygomatic process of the temporal to that of the malar bone, which, however, are not anchylosed, but joined by a ligamentous union. The bony septum of the orbits is complete, and formed by two strong plates, separated by an intermediate cellular diploë, except at the posterior part. The optic foramen is directed transversely outwards. In all the Hornbills the malar bone is moveably connected with the maxillary as well as the tympanic bones, as in other birds.

In the Wood-peckers the cranium is rounded, the temporal fossæ shallow, the internal wall or septum of the orbits incomplete, but the anterior boundary is well developed. The posterior facet of the cranium is raised. The superior surface is traversed by a wide furrow extending longitudinally forwards, generally to the right, but sometimes also to the left, as far as the lachrymal bone. It is in this furrow that the elongated cornua of the os hyoides are lodged, which relate to a peculiar mechanism hereafter to be described. In some of the larger species of Wood-pecker, as the *Picus major*, L. the cranial furrow is more symmetrical. In the Humming-birds it is double, the hyoidean furrows being separated at first by the cerebellic protuberance, and afterwards by a mesial longitudinal ridge.

The skull in the *Rasorial* birds is narrow, but slightly raised, and without ridges. In the Capercailzie (*Tetrao Urogallus*) it is almost square, flattened on the posterior and superior surfaces, and impressed with a considerable longitudinal furrow anteriorly. The orbit is very incomplete, the anterior parietes being almost entirely wanting, and the ungueo-maxillary vacancy being consequently continuous with the orbit. In the Bustards the posterior boundary of the ungueo-maxillary fissure is complete, but in other respects the cranium resembles that of the *Rasores*.

The skull is remarkable for its length in the majority of the *Waders*. In the Herons and Bitterns the occipital region is low, and inclines from below upwards and forwards; it is separated from the upper and lateral regions by a well developed, sharp, lambdoidal crest; and it is divided into two lateral moieties by a slight longitudinal ridge. The temporal fossæ are deeper and wider than in any of the preceding orders; and they now extend upwards, as in many of the carnivorous mammalia, to the sagittal line, along which an osseous crest is developed to extend the surface of attachment of the temporal muscles. The cranium is expanded, anteriorly to the above fossæ, as if to allow of a compensating space for the development of the cerebral hemispheres, the interspace of which is indicated by a deep longitudinal furrow, almost peculiar to these genera of birds. The roof of the orbits is expanded laterally, which gives great breadth to this part of the head, but the posterior orbital walls are very imperfect, and the internal walls or septum almost wholly wanting. The optic foramina are blended with each other and with the smaller foramina, which in other birds represent the *foramen lacerum orbitale*. The anterior boundary of the orbits is also very imperfectly completed, the ungueo-naso-maxillary and anterior nasal fissures are not remarkable for their extent.

Woodcocks, Snipes, Curlews, and Lapwings, resemble Herons in their defective bony orbits; but they want the extended superior parietes of those cavities, and differ much in the almost spherical form of the cranium, which is smooth and devoid of the muscular ridges characteristic of the fish-feeding *Grallæ*. In this order the intermaxillary bones present some of their most eccentric forms. They are narrow, elongated, and curved downwards in the Ibises and Curlews; bent upwards in the contrary direction in the Avosets; extended in a straight line in the Snipes; singularly widened, and hollowed out in the Boat-bill (*Cancroma*); widened, flattened, and dilated at the extremity in the Spoon-bill; thickened, rounded, and bent downwards at an obtuse angle in the Flamingo.

Among the *Natatores*, the sea-birds, as the Divers, (*Colymbus*), Grebes, (*Podiceps*), and Cormorants (*Carbo*), are characterized for the defective condition of the bony orbits, and of the anterior parietes of the cranium; the septum of the orbits is almost entirely wanting; in place of the posterior parietes there are two lacunæ leading directly into the cranial cavity, one superior, of large size, and one inferior, smaller; they are, in general, separated by a narrow osseous bar, but in the Coulterneb, (*Fratercula arctica*) this is also wanting, so that all the anterior cerebral nerves escape by a common opening. But in this species it must be observed, that the vertical lamina of the æthmoid is ossified at its posterior part. In the Petrels and Albatrosses, the internal and posterior walls of the orbits are more complete. In the *Diomedea exulans* the optic foramina are separated both from each other, and from the neighbouring outlet. The occipital region is low, and divided into a superior and an inferior facet, the latter being concave from side to side. The plane of the occipital foramen is almost vertical. The occipital or lambdoidal crista is well-marked, and the temporal fossæ nearly approximate in the middle line. In these sea-birds and in the Gulls, the lateral lacunæ in the bony parietes of the face are very considerable.

A most remarkable characteristic of the cranium of both the Brachypterous and Macropterous Sea-birds is the presence of the two deep, elongated, semilunar glandular depressions before mentioned, extending along the roof the orbits. In the aquatic birds which frequent the marshes and fresh waters, as the *Anatidæ* or *Lamellirostres*, these glandular pits are wanting, or very feebly marked, as in the Swans. They are, however, again met with of large size, though shallow, in the Curlews (*Numenius*) and Avosets (*Recurvirostra*); and are also found, though of smaller size, in the Flamingo.

Of the thorax.—In every part of the skeleton of Birds, we may observe that there is a close adherence to the oviparous modification of the vertebrate type of structure. This is manifested in the forms and connections of the several vertebræ, and of the cranial bones. It is no less conspicuous in the structure of the thorax.

The ribs are apparently in moderate number, but when their analogues are closely sought for, they are found to extend, as in the Crocodile, along the greater part of the cervical region. In fact the small styliform processes which point backwards from the lateral projections on the anterior parts of the bodies of these vertebræ remain separate after the true elements of the vertebræ have coalesced. In an Ostrich which had attained half its growth, we have found these spurious ribs still moveable. They anchylose, however, with the transverse processes in general long before the growth of the individual is completed, excepting towards the caudal extremity of the cervical region, where comparative anatomists, from this circumstance, have always found a difficulty in determining the commencement of the dorsal vertebræ. If the moveable ribs had commenced, as in Mammalia, by extending to the sternum, the determination of their number would have been easy; but they begin, sometimes by a gradual and at others by a sudden elongation,* opposite the furculum, from which point, either one, or two, as in the Humming-bird, (see *p*, *fig*. 125,) terminate by extremities imbedded in muscle, and unconnected with any corresponding portion extending from the sternum.

Meckel considers the true number of ribs in the Diurnal *Raptores* to be nine pairs, of the Nocturnal eight; in the *Insessores* seven or eight; in the *Scansores* nine, except the Cuckoo, which has seven or eight; in the

* This is remarkably the case in the Wood-Grouse (*Tetrao Urogallus*), where the penultimate and last cervical ribs, instead of gradually enlarging, diminish in size, so that the determination of the first thoracic rib is easy.

Rasores seven or eight; in the *Struthiones* the number of ribs varies; in the Ostrich (*Struthio*) we find ten pairs, of which the 3d, 4th, 5th, and 6th, are articulated with the sternum; in the Nandou (*Rhea*) there are nine pairs, of which only the 3d, 4th, 5th, and 6th, are completed by sternal portions; in the Emeu (*Dromaius*) there are nine pairs, the 3d, 4th, 5th, 6th, and 7th, being joined to the sternum; in the Cassowary (*Casuarius*) there are ten pairs, and of these the 4th, 5th, 6th, 7th, 8th, and 9th, have sternal portions. The last pair of ribs in *Struthio* and *Rhea* are extremely short, and abut against the expanded iliac bones. Among the *Grallatores* we find seven pairs of ribs in the Herons (*Ardea*), and Gigantic Stork (*Ciconia Argula*) while the Cranes (*Grus*) have nine, and the Coots and Water-Hens have ten pairs. In the *Natatores*, which vary so much in their locomotive powers and habits of life, we find a corresponding variety in the number of ribs; in the Willock (*Uria troile*) there are twelve pairs, and in the Guillemots and allied sea-birds eleven; in the Swans eleven; in the Penguins nine, of which six are articulated with the sternum.

The true ribs are not joined to the sternum by elastic cartilages, but by straight osseous portions, called sternal ribs, (*q*, *fig*. 125, *h*, *fig*. 129,) which are moveably connected at both their extremities. These are the centres upon which the respiratory motions hinge; the angle between the vertebral and sternal ribs, and between these and the sternum becoming more open in inspiration, and the contrary when the sternum is approximated to the dorsal region in expiration.

As the ribs are traced backwards, their vertebral extremities are seen to become gradually double or bifurcated from the increasing development of the part answering to the cervix and head of the rib in Mammalia. The spurious cervical ribs may be plainly seen to be articulated, like the posterior spurious ribs of the Cetacea, by the tubercle only; and, as they increase in length in the proximity of the thorax, the head of the rib is then seen to be thrown downwards to join a distinct tubercle on the side of the body of the vertebra close to its anterior margin, but without encroaching on the intervertebral space. The comparative immobility of the dorsal vertebræ allows of this mode of articulation; but it is an interesting circumstance that in the Ostrich, where the costal vertebræ preserve their mobility, the heads of the ribs, at least of those of the anterior ones, evidently pass forwards to the intervertebral space. The tubercle of the rib has thus less the character of a subordinate process than in the ribs of mammalia; it is supported on a pedicle, and is articulated by a simple synovial joint with the transverse process of the corresponding vertebra. The ribs, below the union of the two articular processes, are thick and strong, but they gradually become flattened, and increase in breadth as they descend towards the sternum. This is especially remarkable in the second, third, and fourth ribs of the Woodpecker. The dorsal ribs are not only connected together by muscles and aponeurotic membranes, but cooperate with the anchylosed dorsal vertebræ, in giving stability to the trunk by means of small osseous splints, detached from the posterior margin of each true rib, and directed backwards and upwards to the next in succession, to both of which they are united by means of oblique fibrous ligaments. In birds of powerful flight these connecting pieces are, as might be expected, most developed. In the *Raptores* they extend beyond and overlap the succeeding posterior rib, and in this order they are anchylosed.

In some of the Struthious birds, as the Ostrich and Rhea, they exist from the third to the fifth rib, while in the Emeu and Cassowary there are only rudimentary traces of them. In the Penguins these accessory processes are remarkable for their breadth, but they are never anchylosed to the ribs, and consequently are apt to be lost if care be not taken in preparing the skeleton.

The sternal ribs (*h*, *h*, *fig*. 129) are of a less flattened form than the vertebral; they increase in length as they are situated further back; their costal extremity is simply rounded, while their sternal extremity is extended transversely and divided into two smooth surfaces moveably articulated by two synovial capsules with corresponding cavities in the sides of the sternum. The first sternal rib is, however, joined by fibro-cartilaginous substance only, while one or two of the posterior pieces are anchylosed with the rib immediately preceding them, and do not reach the sternum. In the Ostrich the last rib abuts against the ilium, to which it is anchylosed.

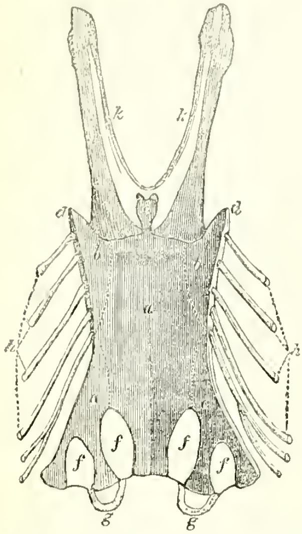
In the Peacock, Pintado, and common Fowl, the vertebral and sternal portions of the last pair of ribs are unconnected with each other; the latter thus representing the ossified tendinous intersections of the rectus abdominis muscle, as in the Crocodile. This analogy is still more striking in the Herons, Storks, and Curlews, and in many of the *Natatores*, in which the sternal portions alone exist, and are remarkably elongated.

The part of the skeleton which has undergone the most remarkable modifications in relation to the powers and functions of the anterior extremities is the *sternum*, (*r*, *s*, *fig*. 125 and 129,) which gives origin to their principal muscles. It is so developed, both in length and breadth, as to extend over the whole of the anterior or ventral aspect of the thoracic and of a great part of the abdominal cavities, reaching in some birds of great powers of flight even to the pubic bones, so as to require removal before the abdominal cavity can be examined.

In order to afford origin to the accumulated fasciculi of the pectoral muscles, which otherwise would become blended together over the middle of the sternum, an osseous crest (*s*, *fig*. 125, *a*, *fig*. 130) is extended downwards, analogous to the cranial crest which intervenes to the temporal muscles in the carnivorous mammalia; and as this crest indicates in these the powers of the jaw, so the sternal keel bespeaks the strength of the anterior extremity in the bird.

Besides the difference of form and development of the mesial crest or keel, the extended sternum presents many other varieties in the different orders and families of birds. A zoological arrangement of the class has even been founded on the modifications of this characteristic and important part of the skeleton. In every species the sternum is more or less

Fig. 129.



Sternum, coracoids, and clavicles of a Woodpecker.

quadrilateral, more or less convex outwardly, and each of its margins affords distinctive characters. The anterior margin presents two grooves (*b*, *b*, *figs.* 129, 130) extending along the greater part of either side, and affording a secure articulation to the coracoid bones; and in many birds it sends forward a process from the middle part where the two grooves meet, as in the Woodpecker and Penguin (*e*, *fig.* 129). This mesial process we shall term the *manubrial process*, since it is analogous to that which extends from the manubrium or first sternal bone of the seal, mole, &c.

The lateral margins are straight and excavated anteriorly, to a greater or less extent, for the lodgement of the sternal ribs. In some birds a process (*d*, *figs.* 129, 130) is given off at each angle of the union of the lateral with the anterior margin· as this process seems to supply the sternal portions of the anterior floating ribs, it may be termed the *costal process*.

The posterior margin is most varied in its contour, and is in general interrupted by fissures, (*f*, *f*, *figs.* 129, 130.) which are always symmetrical in their position, but vary in number and depth, so that this margin is sometimes represented by the extremities of three or five long processes.

In the *Diurnal Raptores* the sternum is a large elongated parallelogram, convex both in the direction of its length and breadth, but especially in the latter sense. The manubrial process is thick, the contour of the keel convex, and its margin extended laterally.

In the Eagles and Secretary-bird the sternum is entire, but in the Vultures and Hawks it is pierced on either side by a small round aperture situated near the posterior margin. Ossification sometimes extends along the aponeurotic membrane stretched over this aperture so as to divide it into two, as has been observed in the Buzzard; or so as to obliterate it on one side only, as seen by Meckel in the Kite.

In the *Nocturnal Raptores* the sternum is short, convex as in the preceding tribe, but weaker: there is no manubrial process. The keel is less developed, its margin less convex, and not thickened. The posterior margin is concave and presents two fissures, separated by a middle process, except in the common Barn Owl (*Strix flammea*) where it is wanting, and a large but shallow fissure is found instead.

The greater part of the ***Insessorial Birds*** are characterized by the following form of sternum. It is large, a little longer than broad, and pinched in, as it were, at the sides, just behind the costal margin. The keel is prominent and convex along its inferior margin; its anterior margin is slightly excavated, and terminates below in a slightly projecting angle. The manubrial process is compressed, prominent, and curved upwards; the costal processes are moderately developed. The posterior margin presents a single deep fissure on either side, and a single lateral process, the extremity of which is constantly dilated. The lateral margins are slightly excavated.

In the *Corvidæ* the keel is more excavated at its anterior margin; the manubrial process is stronger, and is bifurcated at the extremity; the posterior fissures are shallower; the angular processes directed outwardly and not dilated at the extremity. In the Swallows (*Hirundo*) the sternum is large and the keel greatly developed; there are two posterior fissures, but they are still shallower than in the Crows; the angular processes are not dilated at the extremities. In the Swifts (*Cypselus*) the sternum is entire, and corresponds in its proportional magnitude with the superior length and power of wing which characterizes this genus. The manubrial process is wanting, but the costal processes are moderately long and pointed.

In the Humming-birds, which sustain themselves on the wing during the greater part of the day, and hover above the plant while extracting its juices, the sternum (*r*, *s*, *fig.* 125,) is still further developed as compared with the body; it approaches to a triangular form, expanding posteriorly, where the margin is entire, and rounded. The depth of the keel exceeds that of the entire breadth of the sternum. The coracoid depressions are deep and approximated; the manubrial process is small, but evident, and directed upwards; the costal processes are also present, but of small size.

In the Creepers (*Certhia*) and Hoopoes

(*Upupa*), the sternum again becomes diminished in size, and presents the two fissures on the posterior margin; the keel is moderately developed; the manubrial process is produced anteriorly; it is of a compressed form in the Hoopoe, but thick, and bifurcate in the Creepers; there are no costal processes.

In the Wood-peckers the keel of the sternum is more feebly developed, its inferior margin is straight, and the angle formed by its union with the anterior margin truncate. The manubrial process enlarges as it advances forwards, and is bifurcate at the extremity. The costal processes are also long, and curved forwards; the posterior margin has four deep notches (*ff*, *fig.* 129).

In the Trogons, Rollers (*Coracias*), Kingfishers, Bee-eaters (*Merops*), Toucans, and Touracos, the sternum is characterized by two fissures on either side at the posterior margin.

In the Parrot tribe the sternum again singularly resembles in its integrity that of the higher *Raptores*, being in some species simply perforated on either side near the posterior margin, and in others wholly ossified. It is, however, narrower in proportion to its breadth. The keel is well developed, its inferior margin concave, its anterior one describing a sigmoid flexure; their angle of union rounded. The costal depressions occupy almost the entire lateral margins of the sternum. The manubrial process is slightly developed, trihedral, and truncate at the extremity.

In the Pigeons, which unite the *Insessorial* to the *Gallinaceous* order, the sternum is narrow, but the keel is deep, with its inferior border convex, and the anterior one curved forwards, thin and trenchant; the manubrial process is strong and bifurcated; the costal processes short. The posterior margin is cleft by two fissures on either side of the mesial plane, the lateral and superior fissures being the deepest; the mesial ones are occasionally converted into a foramen. The costal surface of the lateral margin is, as in the Gallinaceous birds, of very little extent. In the Crown Pigeon the superior fissures are so deep and wide as to convert the rest of the lateral margin into a mere flattened process, which is dilated at the extremity.

In the true *Rasores* the four posterior fissures of the sternum are so deep and wide from its defective ossification, as to give to the lateral parts of this bone, or hypo-sternal elements, the appearance of a bifurcated process extending backwards from the costal margin. The mesial fissures are here the deepest, extending as far as the anterior border of the keel. This part is short, straight, or very slightly convex inferiorly; concave at the anterior margin, which is formed by two ridges which converge to it from the anterior margin of the sternum. This margin is convex laterally, and largely excavated for the coracoid bones; the depressions are continuous with each other, and the compressed manubrial process, arching over the canal, converts it into a foramen. The costal processes are prolonged upwards and forwards; the posterior lateral processes pass backwards exterior to the ribs, supporting them in the Capercailzie, like a semi-hoop; these processes are dilated at their extremities.

In the *Grallatores* or Waders the sternum corresponds in size to the shortness of the thoracic-abdominal cavity. In the *Ardeidæ* the grooves of the anterior surface pass reciprocally beyond the middle line, increasing the surface of attachment for the expanded lower and posterior extremities of the coracoid bone. In most of the genera the posterior margin presents a single fissure on either side; these in the Storks and Herons are wider at the commencement than at the termination. In the Plovers, Woodcocks, Avosets, and Oyster-catchers, it occupies the whole breadth of the sternum. In the Curlews, Ibises, and Spoonbills, there are two fissures on either side. In the Coots and Water-hens the single fissures on either side of the keel are long and narrow, and the lateral portions of the sternum extend backwards beyond the middle, and become larger towards their extremities.

Among the *Natatores*, the Albatrosses, Petrels, Pelicans, and Cormorants present a strong wide convex sternum, similar to the Storks and Herons; the keel is moderately developed, but prolonged anteriorly; the posterior margin presents a single slight fissure on either side. In the Penguins, these fissures are of considerable extent (*f*, *f*, *fig.* 130,); but the keel of the sternum is well developed, even in the Aptenodytes; its inferior border is straight. In the Gulls and Sea-swallows the sternum is of large size, wide, and convex; it presents posteriorly two small and shallow fissures on either side, of which the lateral and superior are sometimes converted into foramina. The keel extends along the whole of the sternum, but is of moderate depth, and convex inferiorly.

In the *Anatidæ* or *Lamellirostral* tribe the sternum is thin, but of large size, very convex transversely, and much elongated. The keel is of moderate depth, and of a triangular form, its inferior margin being straight; there is only one fissure on either side posteriorly.*

In the Divers (*Colymbus*) the portion of sternum intermediate to the two fissures is prolonged beyond the lateral pieces, and the manubrial process is strongly developed, and of a rounded form; the whole bone is remarkable for its length. In the Grebes the sternum is characterized by a third mesial fissure of a chevron figure intermediate to the two ordinary fissures of the posterior margin.

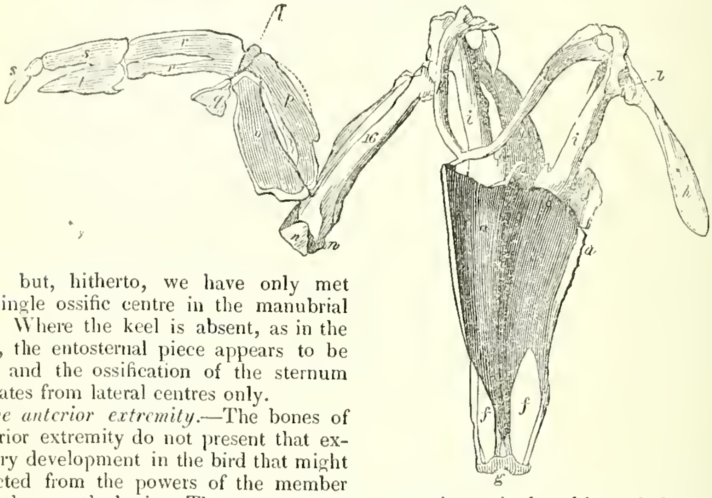
The sternum of the Cursorial Birds presents few affinities of structure to that of the rest of the class, resembling rather the expanded plastron or abdominal plate of the Tortoises. It has neither a keel, nor manubrial, nor costal processes, and may be compared to a square shield. It is most convex in the Rhea, and least so in the Ostrich;

* The modifications of the sternum in relation to the folded trachea will be treated of in the article on the Organs of Voice.

in the latter there may be observed slight indications of the two ordinary posterior fissures.

The ossification of the perfect sternum of the Bird commences from five centres, — a middle one which supports the keel, termed by by Geoffroy St. Hilaire the *entosternal (a, fig.* 129); two anterior lateral pieces, the *hyosternals (b, b, fig.* 129), and two posterior lateral pieces, the *hyposternals (c c, fig.* 129). The posterior cartilaginous appendages he terms *xiphi-sternals (g g, fig.* 129, 130). If to these be added the two portions or *episternals* of which he supposes the manubrial process to be composed, then *nine* elements may be reckoned to enter into the composition of the sternum; but, hitherto, we have only met with a single ossific centre in the manubrial process. Where the keel is absent, as in the *Cursores*, the entosternal piece appears to be wanting, and the ossification of the sternum here radiates from lateral centres only.

Fig. 130.



Of the anterior extremity.—The bones of the anterior extremity do not present that extraordinary development in the bird that might be expected from the powers of the member of which they are the basis. The great expanse of the wing is here gained at the expense of the epidermoid system, and not exclusively produced by folds of the skin requiring elongated bones to support them, as in the Bats, Dragons, and Flying-fish. The wing-bones are, however, both in their forms and modes of articulation, highly characteristic of the powers and application of the muscular apparatus requisite for their due actions in flight.

The bones of the shoulder consist, on each side, of a *scapula (h, fig.* 130), a *coracoid* bone *(i)*, and a *clavicle (k)*,—the clavicles being mostly anchylosed together at their mesial extremities, constitute a single bone, which, from its peculiar form, is termed the *os furcatorium* or *furculum*. In the Ostrich the two clavicles are distinct from each other, but are severally anchylosed with the coracoid and scapula, so as to form one bone on either side. In almost every other species of bird the scapula, coracoid, and clavicle remain separate or moveably articulated throughout life. In the American Ostrich *(Rhea)* and Java Cassowary *(Casuarius)* the acromial element or clavicle is anchylosed with, or rather is a continuous ossification from, the scapula; but the coracoid bone is free; and this condition is worthy of notice as it is precisely that which the bones of the shoulder present in the Chelonian Reptiles; where the coracoid element has been erroneously regarded as the clavicle, in consequence of its being moveably articulated with the scapular piece. In the Emeu *(Dromaius)* it is interesting to observe that the clavicle commences by a distinct ossification, and long continues separate; it does not reach the sternum, but holds the same relative situation as the continuous acromial or clavicular process of the scapula in the other Struthious birds.

The *scapula (t, fig.* 125, *h, fig.* 130) is most readily recognised as such, in the Penguins of the genus *Aptenodytes*, where it is broader and flatter than in any other bird: in these, however, it is of considerable length in proportion to its breadth, and does not exhibit any trace of spinous process. In the rest of the class it is a simple narrow elongated bony lamina, increasing in thickness as it approaches the joint of the shoulder; there it is extended in the transverse direction, forming externally the posterior half of the glenoid cavity, and being internally more or less produced to meet the clavicle, while it is strongly attached in the remainder of its anterior surface to the coracoid bone. The position of the scapula is longitudinal, being extended backwards from the shoulder, parallel to the vertebral column, towards which, however, it, in general, presents a slight convexity. In birds of strong powers of flight, as in the Swift, *(Cypselus,)* it reaches to the last rib, while in the Emeu, on the contrary, it extends over two ribs only. In the Humming-bird *(Trochilus)* its posterior third is bent downwards at a slight angle.

The *coracoid (u, fig.* 125, *i, figs.* 129, 130), or posterior clavicle, is always the strongest of the bones composing the scapular arch: its expanded extremity is securely lodged below in the transverse groove at the anterior part of the sternum, from which it extends upwards, outwards, and forwards, but frequently almost in the vertical position to the shoulder-joint, where it is united at an acute angle with the scapula and clavicle. It thus forms the main support to the wing, and the great point of resistance to the humeri during the downward stroke of this aerial oar. The superior or humeral end of this bone is commonly bifurcate; the outer process is the strongest, and completes the glenoid cavity anteriorly, (*l*, *fig.* 130,) above which it rises, to a greater or less extent, and affords, on its inner side, an articular surface for part of the acromial end of the clavicle: the inner process is short and compressed, and is also joined by ligament to the acromial end of the clavicle. Just below the origins of these processes an articular surface extends transversely across the posterior part of the coracoid bone by which it is firmly united by fibro-cartilaginous substance to the scapula. The glenoid cavity resulting from the union of these two bones is not, however, always equal to the reception of the entire head of the humerus. In the birds, which Mr. Vigors regards as composing the typical orders of the class, viz. the *Raptores* and *Insessores*, (the *aves aereæ* of Nitzsch,) a small but distinct bone extends between the scapula and coracoideum along the superior part of the articular cavity for the humerus, which it thus completes. Nitzsch, the discoverer of this element of the scapular apparatus, denominates it the capsular bone, (*Schulterkapselbeine*); by Meckel it is called the *Os humero-scapulare*, and is regarded as the analogue of the *scapula inferior* of reptiles. In the Aberrant orders of birds, as the *Rasores*, *Grallatores*, and *Natatores*, there is, in place of this bone, a strong elastic ligament or fibro-cartilage extended between the scapula and coracoideum, against which that part of the head of the humerus rests, which is not in contact with the glenoid cavity.

The *clavicles* (*v*, *fig.* 125, *b*, *fig.* 130) in birfls, as in the mammalia, are the most variable elements of the scapular apparatus. In the Ground Parrots of Australia (*Pezophorus*, Illiger) they are rudimentary or wholly deficient;* they are represented by short processes in the Emeu, Rhea, and Cassowary; they do not come in contact inferiorly in the Ostrich, although they reach the sternum. In the Toucans they are separate, and do not reach the sternum. In the Hornbills and Screech Owl (*Strix ulula*) they are united at their inferior extremities by cartilage. In the rest of the class they are anchylosed together inferiorly, and so constitute one bone, the *furculum*, or *merrythought*. From the point of union a compressed process extends downwards in the *Diurnal Raptores*, the *Conirostral Insessores*, the *Rasores*, most of the *Grallatores*, and *Natatores*, in which a ligament extends from its extremity to the ento-sternum. The process itself reaches the sternum, and is anchylosed therewith in the Pelicans, Cormorants, Grebes, Petrels, and Tropic-bird; also in the Gigantic Crane, and Storks in general. In the Humming-birds, where the sternum is so disproportionately developed, the furculum terminates almost opposite the commencement of the keel, but at some distance before it; in those species in which we have examined it, belonging to the genus *Trochilus*, *Lacèp.* it is of equal length with the coracoideum, and not shorter, as Meckel asserts. As the principal use of this elastic bony arch is to oppose the forces which tend to press the humeri inwards towards the mesial plane, during the downward stroke of the wing, and restore them to their former position, the clavicles composing it are stronger, and the angle of their union is more open, as the powers of flight are enjoyed in greater perfection; of this adjustment the Swifts, Goat-suckers, and Diurnal Birds of Prey afford the best examples.

Notwithstanding the anterior extremity is limited to one function, and the motions of its parts are confined to simple folding and extension, it contains the same number of joints as the arm of the Monkey, or of Man himself. We shall now successively consider the bones of the *Brachium*, *Antibrachium*, *Carpus*, *Metacarpus*, *and Digits*.

The brachium, or *humerus* (*w*, *fig.* 125, *m*, *fig.* 130) is prineipally characterized by the forms of its extremities. The head, or proximal extremity, is transversely oblong to play in the articular cavity formed by the union of the scapula and coracoid bone. It is further enlarged by two lateral crests: of these the superior, or external, which is angular, with the thin margin turned forward, affords an adequate attachment to the great pectoral muscle: the opposite process has its margin rounded and curved backwards, and it is beneath the arch thus formed that the orifices are situated, by which the air penetrates to the cavity of the bone. There is always a deep depression at this part, even in birds which have no air in the humerus, as in the Penguins and Ostrich. The distal end of the humerus is not less characteristic of the bird, and different from that of other vertebrate animals. The articular hinge is divided into two parts, one internal, which is the largest, for the ulna, of an almost spherical form, and one external, for the radius, of an elongated figure, extending for some distance along the anterior surface of the humerus. The radius is thus made to describe in the act of bending a greater portion of a circle than the ulna, and the whole fore-arm moves in a plane which is not perpendicular to the anterior surface of the humerus.

The humerus is not always developed in length in proportion to the powers of flight; for although it is shortest in the Struthious Birds and Penguins, it is also very short in the Swifts and Humming-birds. In the latter, however, it is characterized by its thickness and strength, the size of its muscular processes, and the consequent transverse extension of its extremities; while in the *Cursores* it is as attenuated as it is short, and in the Penguins is reduced to a mere lamina of bone resembling the corresponding part in the paddle of the turtle. In the *Rasores* it rarely equals half the length of the body; in most other birds it is about two-thirds that length; it attains its greatest length in the Albatross. In this and other sea-birds, as the Gulls, Awks, and Petrels,

* Mr. Vigors has noticed the absence of the os furcatorium in *Psittacus mitratus*, *Platycercus eximius*, and *Psittacula Galgula*.

the humerus presents a notable process at the outer side, near its lower extremity; and in the Puffin (*Fratercula arctica*) an ossiculum is moveably articulated to this process.

Another ossiculum may here be noticed, although it belongs rather to the *ulna*, being essentially the separated olecranon of that bone. This detached sesamoid bone is found attached (like the patella of the knee-joint) to the capsular ligament and the tendons of the extensor muscles, in many of the Raptores, and in the Swifts. In the Penguins it is double (*n, n, fig.* 130.)

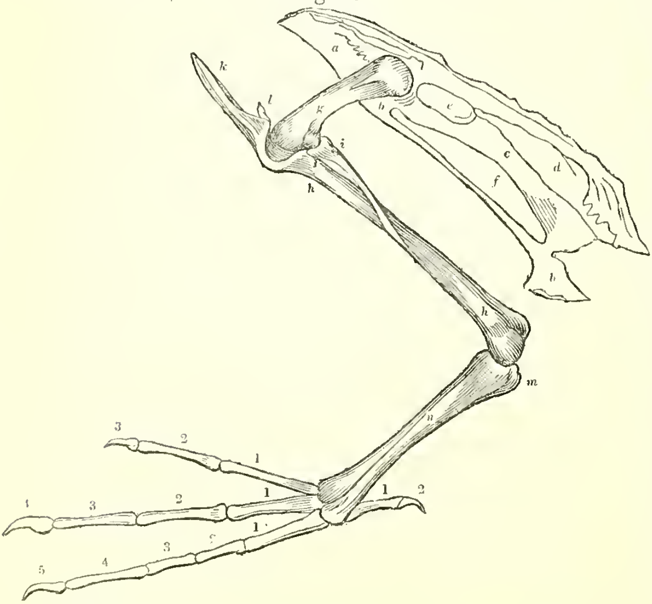
Of the two bones of the antibrachium (*y, fig.* 125) the *ulnar* (*o, fig.* 130) is always the strongest, and especially so in the *Struthiones:* both this and the *radius* (*p, fig.* 130) are in general slender and straight bones, slightly enlarged at their extremities, placed not by the side of, but one in front of the other, and so articulated together, and with the humerus, as to admit of scarcely any degree of pronation or supination, which, as Meckel justly remarks, adds to that firmness and resisting power in the anterior member which are so necessary during the actions of flight. In the Penguins, the bones of the fore-arm present the same modifications as the humerus in relation to the corresponding action in the denser element, or that of swimming: they are flattened, and are articulated with the anterior edge, and not the extremity of the humerus.

The bones of the hand are extended in length, but restricted in lateral development. The *carpus* consists of two bones only, (*q, fig.* 130,) so wedged in between the antibrachium and metacarpus, as to limit the motions of the hand to those of abduction and adduction necessary for the folding up and expansion of the wing; the hand is thus fixed in a state of pronation; all power of flexion, extension, or of rotation, is removed from the wrist-joint, so that the wing strikes firmly, and with the full force of the contraction of the depressor muscles, upon the resisting air.

The *metacarpus* is principally formed of two bones, anchylosed together at both extremities (*r, r, fig.* 130); of these, the one which corresponds to the radius is always the largest, and supports the finger which has the greatest number of phalanges: a third small rudimental bone is in most birds found anchylosed to the outer-side of its proximal extremity, and this supports the single phalanx of what is usually called the thumb. The longest or radial finger is generally composed of two phalanges (*s, s, fig.* 130) of moderate length; to which, in some birds, a third smaller phalanx is added. The ulnar finger consists of a single phalanx only (*t, fig.* 130). These are strongly bound together by ligaments and integument, so that the wing loses nothing of its force, while it preserves in these separated bones its analogy with the anterior extremities in the other vertebrated classes. In Zoology the large feathers that are attached to the ulnar side of the hand, are termed *Primariæ* or primary feathers; those which are attached to the fore-arm *Secundariæ*, or secundaries, and *Tectrices*, or wing-coverts; those which lie over the humerus are called *Scapulariæ*, or scapularies; and those which are attached to the thumb, *Spuriæ*, or bastard feathers. In some birds the wing is armed with a spur attached to a phalanx at the radial side of the so-called thumb, which, as Nitzsch observes, would therefore seem analogous to the index finger.

The bones of the leg or posterior extremity (*fig.* 131) do not exactly correspond, in their divisions or principal groups, to those of the wing, the segment corresponding to the carpus being invariably blended with the one that succeeds.

Fig. 131.



Pelvis and bones of the leg of the Diver, or Loon.—Colymbus glacialis.

The *pelvic bones* present a remarkable contrast to those of the shoulder, being always anchylosed on either side into one piece, but being with one exception; never joined in the mesial line, while this is the only place where the elements of the scapular apparatus are in general united by bone. In the young bird the *os innominatum* is seen to be formed by the usual three bones, viz. the *ilium*, *ischium*, and *pubis*, corresponding respectively to the *scapula*, *coracoid*, and *clavicle*, of the anterior extremity.

The *ilium* (*δ, fig.* 125, *a, fig.* 131.) is the only bone of the pelvis which comes in contact with the vertebral column, and it extends from the posterior dorsal vertebræ along the whole of the sacrum, to which it is early united by anchylosis. At its posterior extremity it is expanded laterally and becomes anchylosed with the ischium (*c*, *fig.* 131) posterior to the ischiadic notch (*e*, *fig.* 131) which is thus converted into a foramen.

The ilium is of a considerable size, of an elongated form, expanded at its extremities and contracted in the middle; the anterior expansion is concave externally, the posterior on the contrary convex. Besides being anchylosed with the ischium and sacrum, the spinous and transverse processes of one or two posterior dorsal vertebræ are commonly joined to it by bony union. In the Penguins, however, where the posterior extremities are ill adapted for supporting the body in progressive motion on land, the ilium appears at no time to be anchylosed with any part of the vertebral column.

The *os pubis* (ζ, *fig.* 125, *b b*, *fig.* 131) does not extend to meet its fellow on the mesial line, but is commonly directed backwards like a long bent styliform process (3, *fig.* 134), adapted to allow a safe passage to the large and fragile eggs. In general it unites with the ischium so as to complete the obturator foramen (*f*, *fig.* 131), behind which another foramen is occasionally formed by a second union with the ischium, as is seen in the Humming-bird; while in other Birds, as the Stork, it is only united to the ischium at the cotyloid foramen, and the obturator hole communicates with a long fissure and is completed posteriorly by ligament only. The cotyloid cavity for the head of the thigh-bone is always incomplete at its posterior or internal part, which is closed in the recent state by a strong aponeurosis.

The *ischium* (*c*, *fig.* 131) is a small elongated bone, slightly convex externally, extending from the acetabulum backwards, parallel with the ilium.

In the Struthious Birds the pelvis is proportionally very long, but narrow; the ossa innominata cover the whole of the sacrum, meeting and joining above that part like the roof of a dwelling. In the *Rhea*, or American Ostrich, the ischiadic bones meet below the sacrum, where they are united for a considerable extent by a symphysis, so that the sacrum is closely surrounded, and in fact its place is almost supplied by the ossa innominata, for the development of the included vertebræ is in consequence so much impeded, that they can scarcely be detected at this part; beyond which, however, the coccygeal vertebræ suddenly resume their ordinary magnitude. This union of the ischia does not take place in the other Struthious birds; but the Ostrich presents the remarkable exception, among Birds, of the completion of the pelvic circle by the anchyloses of the pubic bones at their inferior extremities.

The *femur* (θ, *fig.* 125, *g*, *fig.* 131) is a short cylindrical bone, deviating from the straight line by a very slight anterior convexity. The head is a small hemisphere; joined, without the intervention of a neck, at a right angle, to the shaft of the bone: it presents at its upper part, a considerable depression for the attachment of the round ligament. The single large trochanter generally rises above the articular eminence, and is continuous with the outer side of the shaft. The orifice for the admission of air into the bone is situated anterior to this cavity. The femur is most readily characterised by the form of its lower extremity: this presents as usual two condyles, the inner one corresponding to the tibia, the outer one, which is the largest and the longest, resting both upon the tibia and fibula; upon this condyle a semicircular rounded eminence is observed extending from the front to the back part, and being lost in a depression at both extremities; the result of this structure is to put the external lateral ligament upon the stretch when the fibula is passing over the middle of the condyle, and that ligament, being elastic, pulls the fibula into the cavity in which the ridge terminates, with a jerk—whether the motion be that of flexion or extension, in either of which conditions the leg is by this structure the more firmly locked to the thigh. It has been denied that the spring-joint ever exists at the knee, and it is probable that all birds do not possess the requisite structure in the same perfection; but a common indigenous species, the Water-hen, (*Gallinula Chloropus*) affords a good example of the beautiful mechanism in question. The femur attains its greatest development in the Ostrich; but in this species it is short in comparison to the other bones of the leg, the length of which in the Stilt-bird and other Waders is attained solely by the elongation of the tibia and metatarsus.

The *tibia* (ι, *fig.* 125, *h h*, *fig.* 131) is the principal bone of the leg—the *fibula* (κ, *fig.* 125, *i*, *fig.* 131) appearing as a mere styliform process tapering to a point below, and anchylosed for a greater or less extent to the tibia. The tibia is of a triangular form, especially at its enlarged superior extremity, the articular surface of which is unequal, being flat internally, convex at the centre, and concave externally and in front. The inferior articular surface of the tibia forms a considerable transverse trochlea, above which anteriorly there is a deep depression. In general an osseous bridge extends transversely across this depression, converting it into a foramen through which the tendon of the *Extensor communis digitorum* passes.

In the Divers, Grebes, Guillemots, and Albatrosses the middle and internal crests of the tibia unite superiorly and are extended upwards into a long pointed process (*k*, *fig.* 131) directed inwards and forwards, anterior to, but not supplying the place of, the patella, (*l*, *fig.* 131) which will be always found as a distinct bone behind this process. The process is most developed in the genus *Colymbus*, and affords extensive attachments by way of insertion to the extensors of the tibia, and by way of origin to the extensors of the metatarsus; by means of the latter disposition the power of the back stroke of the foot is increased.

The *Tarsus* can only be recognized as a distinct segment of the leg when the bones of a very young Bird are examined. But in the Ostrich, even when it has attained a third of its natural size, the Astragalus remains ununited to the metatarsus. It is a flattened transversely oval bone, convex in the middle of its upper surface, and irregularly flattened below, where it is adapted to the three still partially separated bones of the metatarsus. A rudiment of the os calcis may be observed in the detached bone which is found in the tendons of the extensors of the foot near their insertion. The Capercailzie (*Tetrao urogallus*) affords a good example of this structure. The process (*m*, *fig.* 131) in which the above tendons are inserted, and which is very prominent in the *Rasores*, *Grallatores*, and *Natatores*, must also be regarded as appertaining to the tarsal series, since it commences by a separate ossification.

In most birds, however, the tendo Achillis has no sesamoid bone to add to its leverage, and in all birds the astragalus is soon anchylosed to the metatarsus, constituting with it one elongated tarso-metatarsal bone (λ, *fig.* 125, *n*, *fig.* 131). Traces of the number of laterally anchylosed pieces of which the metatarsus is composed are always more or less indicated by longitudinal grooves. In the Penguins, indeed, the anchylosis of the three metatarsal bones takes place at their extremities only, and they are consequently separated from each other in the greater part of their extent. They are also disproportionately short, and bent forwards upon the tibia, so as to increase the surface of support required by these birds when standing in their usually erect position. In the *Grallatores* and *Struthiones*, on the contrary, the tarso-metatarsal bone is remarkably elongated, the extraordinary length of leg in these birds depending chiefly upon the extent of this segment of the limb.

In the Stork and congeneric birds, which sleep on one leg, the ankle-joint presents a mechanism analogous to that which we have above described in the knee-joint. Here, however, the projection which causes the extension of the elastic ligaments in the motion of the joint is in the inferior bone. Dr. Macartney thus describes the mechanism: " There arises, from the fore-part of the head of the metatarsal bone, a round eminence, which passes up between the projections of the pulley on the anterior part of the end of the tibia. This eminence affords a sufficient degree of resistance to the flexion of the leg to counteract the effect of the oscillations of the body, and would prove an insurmountable obstruction to the motion of the joint, if there were not a socket within the upper part of the pulley of the tibia to receive it when the leg is in a bent position. The lower edge of the socket is prominent and sharp, and presents a sort of barrier to the admission of the eminence that requires a voluntary muscular exertion of the bird to overcome, which being accomplished it slips in with some force like the end of a dislocated bone."* It must be added, that the elastic lateral ligaments contribute also to jerk the metatarsal tubercle into the tibial cavities, and to resist its displacement.

The lower extremity of the metatarsus is divided into three articular eminences, corresponding to the ordinary number of anterior toes. These eminences are convex from before backwards, and the middle one, which is the longest, is converted into a pulley by a mesial groove which traverses it in the same direction. The lateral surfaces are simply convex, and very narrow; of these the internal is the shortest, except in the raptorial birds. At the extremities of the grooves which indicate the lateral juxtaposition of the metatarsal pieces, there are ordinarily foramina extending from before backwards through the bone.

A fourth articular surface is observable in most birds on the inner and posterior side of the metatarsal bone; this is situated on an accessory piece which always commences by a separate ossification, although in some birds it afterwards becomes anchylosed with the innermost of the other juxtaposed components of the metatarsus. When this does not take place, the metatarsus presents a rough, more or less irregular, oval surface, for the firm ligamentous attachment of the accessory bone which supports the back toe, usually termed the *hallux* or posterior thumb. This articulating surface is important as affording a good distinctive character for identifying the bones of birds in a fossil state, and the more so as its position is indicative of the powers of grasping or perching —being placed low down, on a level with the anterior toes, in those birds which enjoy the insessorial power in the greatest perfection, and being gradually removed higher and higher in the Waders, until it is at length wholly lost, as in the genus *Cursorius*, the Bustards, and the Struthious family. In the Petrel, however, this accessory metatarsal bone is wanting, although the hallux is present, the two bones of which are therefore united to the principal metatarsal bone by long ligaments. The tarso-metatarsal bone is further characterized by sharp longitudinal ridges of bone on the posterior surface, which afford attachment to the aponeurotic thecæ confining the tendons which glide along the metatarsus to the toes.

In birds, as in mammalia, the number of toes is subject to great variety; if the spur of the Gallinaceous tribe be regarded as one, we may then reckon the ordinary number of five in these birds, while in the Ostrich the toes are reduced to two. Birds are, however, the only class of animals in which the toes, whatever be their number or relative size, always differ in the number of their phalanges, yet at the same time preserve a constancy in that variation.

The following is a tabular view of the numerical relation in the osseous parts of the feet of

* See Transactions of the Royal Irish Academy, vol. xiii. p. 20.

birds according to the researches of Cuvier, the discoverer of this remarkable peculiarity in the anatomy of birds.

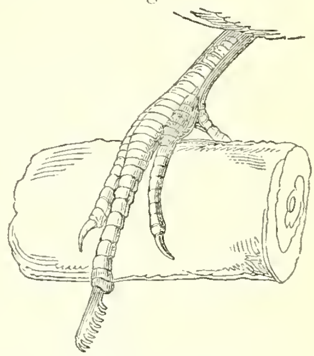
Table of the number of toe phalanges in Birds.

	Number of Phalanges in the				
	First or inner-most toe or *Calcar.*	Second, com-monly called the *Hallux.*	Third.	Fourth.	Fifth or outer-most, or little toe.
1 Cock (*Gallus*), Pheasants (*Phasianus*), Turkeys, Peacocks (*Pavo* and *Lophophorus*) . .	1*	2	3	4	5
2 *Raptores, Insessores, Columbidæ, Cracidæ, Tetraonidæ*, and the rest of the class, except		2†	3‡	4§	5‖
3 The Genera, *Rhea, Dromaius, Casuarius, Otis, Cursorius, Charadrius, Hæmatopus, Arenaria, Falcinella, Himantopus, Halodroma, Diomedea* .			3	4	5
4 The Ostrich (*Struthio*) .				4	5

The above table shows what are the toes which are deficient in those birds that do not possess the ordinary number.

The phalanges are expanded at their extremities, especially at the posterior; the articular surfaces are concave at this end, but divided longitudinally by a narrow convex line, to which a corresponding unequal surface at the anterior end of the preceding phalanx is adapted, constituting a ginglymoid articulation. The ultimate or ungueal phalanges are characterised by their anterior pointed terminations, which correspond in form, in some degree, to the nature of the claw.

Fig. 132.



Foot of the Goat-sucker.

Of the fossil bones of birds.—Birds differ from each other in a much less degree than quadrupeds, less, perhaps, than any other class. The Penguin and the Ostrich have, indeed, but a remote external resemblance with the Eagle or the Swallow, but yet they have never been regarded as other than birds. The Porpesse and the Whale, on the other hand, although their real affinities were pointed out by Aristotle, have been placed by many subsequent Zoologists in a very different class from the Lion or the Ape, and in the older systems of Natural History they always obtained their position among the true fishes.

Osteological characters of the same value with those which serve to distinguish the genera, and for the most part the species of Mammalia, are, therefore, with difficulty found in the Class of Birds. Cuvier has declared that the differences in the skeleton of two species of an ornithological genus are sometimes wholly inappreciable, and that the osteological characters of *Genera* can rarely be detected in any other part than in the bones of the mandibles, which do not always conform in a sufficiently characteristic manner with the modifications of the horny bill.

The determination of the fossil bones of this class is, therefore, conjectural, or, at least, it wants much of that demonstrative character which the bones of quadrupeds afford.

The fossil bones of birds described by Cuvier are considered by him to appertain to a species of Buzzard, Owl, Quail, Woodcock, Ibis, Sea-lark, and Cormorant; and, although not remarkable for their number or for their zoological interest, yet they demonstrate that the species which existed at that remote period, when the Anoplotheriums and other extinct quadrupeds trod the face of the earth, had the same proportion of parts, the same length of wings and legs, the same articulations of the toes, the same form and numerical proportions of the vertebræ; in short, that their whole organization was regulated by the same general

* This is wanting in the Argus Pheasant; the *Pavo bicalcaratus*, on the contrary, has two spurs on each metatarsal bone.

† In the single genus *Ceyx* among the Insessores, and *Hemipodius* among the *Rasores*, this toe is wanting. In all the rest, with the exception of the Swifts (*Cypselus*) it is directed backwards.

‡ In the Dentirostral Insessores this toe is united by one or two phalanges to the fourth.

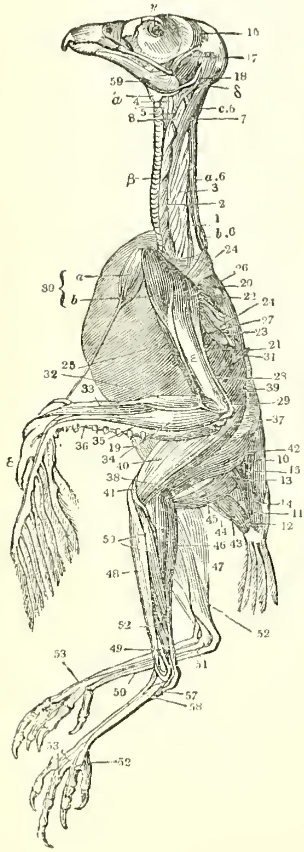
§ According to Cuvier this toe and the fifth in the Swift (*Cypselus*) have only three phalanges like the third. In the Goat-suckers (*Caprimulgus*) and Herons (*Ardea*) the claw of this toe is provided with dentations similar to a comb on its inner side.

‖ This toe is stated by Cuvier to have only four phalanges in the Goat-suckers, and we have ascertained the correctness of the exception, and that it also obtains in the Rhea. This toe is united to the fourth toe as far as the penultimate joint in the Bee-eaters (*Merops*), the Motmots (*Prionites*), the King-fishers (*Alcedo*), the Todies (*Todus*), and the Hornbills (*Buceros*), which form in consequence the family *Syndactyli* of Cuvier. In the *Scansores* this toe is turned backwards, and assists the *Hallux* in opposing the other toes. The Owls have the power of turning back the outer toe at pleasure.

laws of co-existence and all that relates to the nature of the organs and their essential functions, as at the present day. They afford no evidence, not even a trace of any part having been lengthened or curtailed, or otherwise progressively modified, either by the operation of external causes or by internal voluntary impulse.

Myology.—The muscular system of Birds is remarkable for the distinctness and density of the carneous fibres, their deep red colour, and their marked separation from the tendons, which are of a brilliant shining colour, and have a peculiar tendency to ossification. This high degree of development results from the rapid circulation of very warm blood, which is highly oxygenated in consequence of the activity and extent of the respiratory function. The energy of the muscular contraction in this class is in the ratio of the activity of the vital functions, but its permanent irritability is proportionally low, as Carus has justly observed.

Fig. 133.



Muscles of a Sparrow-hawk.

These characteristic properties are manifested in the greatest degree in the muscles of those families of the *Insessores* which take their food on the wing, as the *Hirundinidæ* and *Trochilidæ* (Swallows and Humming-birds); in the *Diurnal Raptores* and in the long-winged *Palmipedes*, as the Albatross, Tropic Bird, &c. In the more heavy and slow-moving Herbivorous families, and in the short-winged *Swimmers*, as the Penguins, &c. the muscles resemble those of the Reptilia in their softness and pale-colour.

The mechanical disposition of the muscular system is admirably adapted to the aerial locomotion of this class; the principal masses being collected below the centre of gravity, beneath the sternum, beneath the pelvis, and upon the thighs, they act like the ballast of a vessel and assist in maintaining the steadiness of the body during flight, while at the same time the extremities require only long and thin tendons for the communication of the muscular influence to them and are thereby rendered light and slender.

Muscles of the trunk.—The muscles of the cervical region are the most developed, as might be expected from the size and mobility of this part of the spine; the muscles which are situated on the dorsal and lumbar regions are, on the other hand, very indistinct, feeble, and but slightly carneous; they are not, however, entirely wanting.

The *Semi-spinalis dorsi* or *Opisthotenar*, is easily recognizable, occupying the space between the spinous and transverse processes, arising from the anterior margin of the ilium and the transverse processes of the sacrum, and attached by means of long tendons to the transverse processes of the costal vertebræ. It is most developed in those birds which have the greatest mobility in this part of the spine, as in the Penguins, in which the external venter of the muscle is well developed, inserted into the vertebral ends of the ribs, and adapted to support the body in the erect position which these birds assume while standing.

On the mesial aspect of this muscle and somewhat covered by it, the *Spinalis dorsi* may be distinctly traced, passing from the spinous processes behind, to those at the anterior part of the trunk and beginning of the neck.

The *Cervicalis ascendens* (1, *fig.* 133) is the chief extensor of the neck: it rises from the spines of the anterior dorsal vertebræ, and is inserted by long and separate fasciculi into the posterior articular processes of the second, third, and fourth cervical vertebræ. In this course it receives descending slips of muscle from the spines of the inferior cervical vertebræ, and ascending fasciculi, which furnish tendons to the fifth and sixth vertebræ, and to the atlas, so that it is enabled to extend the neck even while the head is raised.

Muscles corresponding to the *Intertransversales* (2) are continued on the neck from the external belly of the *Opisthotenar;* these slips extend from the articular processes of the dorsal vertebræ to those of the inferior cervical. Posterior to the *Intertransversales*, the *Semispinalis colli* (3) is seen passing from the transverse to the spinous processes.

The *Longus colli* arises from the anterior spinous processes of the dorsal vertebræ and from the anterior part of the cervical vertebræ, and these slips diverge to be inserted into the transverse processes, and their appended styles or spurious ribs.

A superadded muscle, which may be regarded as a continuation of the preceding, and which corresponds to the increased number of the vertebræ of the neck, passes from the transverse processes of the five superior vertebræ to the anterior spines of the vertebræ immediately anterior—a portion of this muscle is shown at 5.

No. 6 indicates one of the most remarkable muscles in the cervical region of Birds; it is analogous to the *Biventer cervicis* of mammals, but has a much longer and more distinct middle tendon, *a*. 6. Its lower or posterior venter, *b*. 6, arises by a tendon, most commonly from the short spinous processes of the lowest cervical vertebræ, the anterior fleshy part *c* is inserted into the squamous spine of the occiput. This muscle is well developed in the Ostrich, where it arises as low down as from the last lumbar vertebra, by a long tendon, which is continued to the cervical region before it joins the fleshy portion, the whole muscle affording a striking example of the peculiar development of the tendinous over the carneous part which characterizes the muscular system of Birds. In the Parrots and Raptorial birds, however, the carneous exceeds the tendinous part of this muscle.

The *Complexus* (7) arises from the articular and transverse processes of a variable number of the superior cervical vertebræ, and passes obliquely backwards to be inserted into the occiput, crossing exteriorly the upper belly of the preceding muscle.

The *Trachelo-mastoideus* (8) arises from the articular processes of the cervical vertebræ from the second to the sixth, and is inserted into the posterior part of the *basis cranii.*

Anterior to the preceding muscle a portion of the *Rectus capitis anticus major* may be seen at 4. This muscle is largely developed, arising from the anterior part of the sixth, seventh, and eighth vertebræ, and inserted into the basis cranii. There are also muscles analogous to the *Rectus capitis anticus minor*, the *Recti postici majores et minores*, the *Obliquus externus* or *superior*, and in the Penguin, a strong tendon is given off from the Trachelo-mastoideus which represents the *obliquus inferior* of the neck.

When it is remembered that the cervical region of the spine in Birds is subservient and essential to all the movements and functions of the bill, as a prehensile instrument, and a cleanser of the plumage, we cannot sufficiently admire the endowments of length, flexibility, and muscularity, by which it is enabled to fulfil the important functions of an additional extremity.

In the caudal region of the spine the following muscles present themselves. On the dorsal aspect, the *Levator coccygis* (10) extends from the transverse processes and lower extremity of the sacrum to the superior spines of the coccyx and the base of the last or plough-share vertebra. This muscle may be regarded as a continuation of the spinalis dorsi. Beneath it are found strong *Interspinales* muscles.

The *Quadratus coccygis* (11) arises from the transverse processes of the coccygeal vertebræ and is inserted into the shafts of the *rectrices* or tail-quills, which it separates and raises. On the lateral aspect we find the *Pubo-coccygeus* (12) arising from the posterior margin of the pubis, and inserted also into the shafts of the exterior *rectrices;* it is by means of these muscles in conjunction with the two preceding that the Peacock spreads its gorgeous tail.

The *Ilio-coccygeus* (13) extends from the posterior margin of the ilium to the last coccygeal vertebra, and to the small inferior tail-feathers.

On the ventral or inferior aspect of the tail, the muscles are in general more feebly developed than on the opposite side, except in the Woodpeckers, where the tail, by means of its stiff and pointed quill-feathers, serves as a prop to support the bird on the perpendicular trunks of trees on which it seeks its food. In these the *Ischio-coccygeus* (14) is of large size, extending from the lower edge of the ischiadic tuberosity, and from the transverse processes of the anterior coccygeal vertebræ to the inferior spines of the posterior coccygeal vertebræ, and to the sides of the last compressed or plough-share bone.

The *Depressor coccygis* (15) extends from the ventral aspect of the bodies of the anterior coccygeal vertebræ to the inferior spines of the posterior and to the base of the last vertebra.

Of the *Muscles of the head* those which are attached to it for its general motions have already been described; the remaining muscles of this part are devoted to the movements of the jaws, the tongue, the eye, and the ear. The cutaneous muscles of the face are usually described as being entirely deficient, and the only ones that can be regarded as belonging to this series are the slips of panniculus carnosus, analogous to an *occipito-frontalis* (16), which are chiefly developed in order to elevate the crest-feathers in those birds which possess that ornament; there are also cutaneous slips which belong more properly to the organs of hearing, and which raise the auricular circle of feathers in the Owls, Bustards, &c.

The muscles of the jaws are chiefly modified in relation to the moveable condition of the upper mandible and tympanic bone, and the subserviency of the latter to the actions of these parts.

The *Temporalis* (17) fills the temporal fossa, which consequently indicates the bulk of that muscle in the dry skull. It arises from a greater or less extent of the temporal and parietal bones, and, as it passes within the zygoma, becomes closely blended with the *Masseter;* the united muscles derive an accession of fibres from the lower part of the orbit, and are inserted into the raised superior margin, representing the coronoid process;

and into the sides of the lower jaw from the articulation as far forward as the commencement of the horny bill.

In the Cormorant there projects backwards from the spine or squamous element of the occipital bone, an osseous style about an inch in length, of a trihedral figure and tapering to a point. It is not anchylosed as a process of the occiput, but is moveably articulated to it; and its description has been referred to this section because it does not constitute a regular part of the skeleton, not representing any essential element of the bony fabric, but is to be regarded like the bony tendons of the legs as an ossification of the intermuscular aponeurosis of the temporal muscles to which it affords a more extensive and firmer origin. This, indeed, is its essential use,* for the muscles of the upper part of the neck are inserted into the occipital bone, and glide beneath the posterior or superadded fasciculi of the temporal muscle. Analogous parts appended to the true spinous processes of the vertebræ are met with abundantly in the inferior vertebrate classes, especially in fishes, where they extend frequently above the spines of the whole vertebral column, increasing the surface of origin of the lateral series of muscles.

The muscle analogous to the *Biventer maxillæ* (18) arises by two portions, the one from the lateral depression of the occiput, the other from the depression behind and below the external meatus auditorius; they are inserted into the back part and angle of the lower jaw. A similar disposition of the *digastricus* is met with in many of the mammalia; even in the *Orang-utan (Simia Satyrus)* it is equally devoid of a central tendon, and is unconnected with the os hyoides.

The openers and closers of the mandibles present very slight differences of bulk in relation to the development of the parts they are destined to move; their disproportion to the bill is, on the contrary, truly remarkable in the Horn-bills, Toucans, and Pelican, and the bill is but weakly closed in these in comparison with the shorter-billed birds.

The upper mandible is moved by three muscles on either side. The first is of a radiated form, arises from the septum of the orbits, and converges to be inserted into the external and posterior end of the pterygoid bone, just where this is articulated to the tympanic bone. It draws forward the pterygoid bone, which pushes against and raises the upper jaw.

The second muscle analogous to the *External Pterygoid* arises from the space between the posterior part of the orbit and external meatus auditorius, and is inserted into the internal process and contiguous surface of the tympanic bone; it affects the pterygoid process, and consequently the upper mandible in the same way as the preceding muscles, and assists in opening the bill.

The *Pterygoideus Internus* is a long and slender muscle; it arises from the pterygoid process and body of the sphenoid, and is inserted principally into the inner side of the lower jaw and tympanic bone; it also sends off a small tendon to the membrane of the palate. This muscle draws forward the lower jaw and depresses the upper one.

In the Cross-bill *(Loxia curvirostra)* there is a remarkable want of symmetry in the muscles of the jaws on the two sides of the head corresponding to their peculiar position. Those of the side towards which the lower jaw is drawn in a state of rest (which varies in different individuals) are most developed, and act upon the mandibles with a force that enables the bird to dislodge the seeds of the fir-cones, which constitute its food.

The articulation of the lower jaw is strengthened and its movements restrained by two strong ligaments, one of these *(a)* is extended from the ligament completing the lower part of the orbit, or from the zygomatic process of the temporal bone, and is inserted at the outer protuberance near the joint of the lower jaw, and must prevent the bill from being too widely opened. The second ligament extends from the zygomatic process of the temporal bone directly backwards to the posterior part of the articular depression of the lower jaw, and is designed to guard against the backward dislocation of the lower jaw.

The muscles of the ribs. — The *levatores costarum* arise from the posterior part of the extremities of the transverse processes, and converge to be inserted into the anterior margin of the succeeding posterior rib. Those of the first and second ribs represent the *Scaleni*, and are of larger size, arising from the last and penultimate cervical vertebræ.

The *Intercostales externi* appear to be continuations of the *Levatores costarum*, and are usually divided into an anterior and posterior moiety corresponding to the marked separation and moveable articulation between the vertebral and sternal portions of the ribs; the anterior division arises from the costal appendage and extends to the anterior extremity of the rib; to afford a more advantageous origin to this inspiratory muscle would appear, therefore, to be one of the uses of the costal appendages, as well as to strengthen the connection of the ribs to each other.

The *Internal intercostals* commence at the sternal extremities of the ribs, as in mammalia, but extend backwards no farther than the costal appendages; their fibres run in an opposite direction to the external intercostals, and are shorter, the insertion into the posterior succeeding rib being by a thin but wide aponeurosis: in the Penguin they are, however, wholly muscular. Two other layers of intercostal muscles, corresponding to the triangularis sterni, and having the same direction of fibres, are extended from before backwards and outwards to the four anterior sternal portions of the ribs; arising from the superior and external angle of the sternum.

The muscles of the abdomen are small and

* See Yarrell 'On the Anatomy of the Cormorant,' Zool. Trans. v. iv. p. 235.

weak, in consequence of the protection which the extended sternum affords to the viscera of that cavity.

The *External oblique* (19) is chiefly remarkable for the transverse arrangement of its fibres; these arise anteriorly by short fleshy digitations from the inferior ribs, and by a large but very thin tendon from the posterior ribs and the edge of the ilium and pubis; they are inserted by aponeurosis into the anterior margin of the pubis, and join the aponeurosis of the opposite muscle in front of the thin and tendinous *rectus abdominis*. This muscle, by drawing downwards and backwards the posterior part of the sternum and sternal ribs, opens the angle between these and the vertebral ribs, depresses, in consequence, the anterior part of the sternum, and thus dilates the thorax, and becomes a muscle of *inspiration*.

The *Internal oblique* comes off fleshy from the anterior moiety of the edge of the pubis, and tendinous from the posterior moiety of the same bone; it is much smaller than the preceding, and is directed forwards and inwards to the last rib, which it draws backwards, and thus assists the preceding in the compression of the abdomen and abdominal air-cells, and in the dilatation of the thorax.

The *Transversalis* is a muscle of greater extent; it arises from the whole anterior margin of the pubic bones by carneous fibres, and by digitations from the three posterior ribs; its tendon unites with that of its fellow in the mesial line, extends immediately over the peritoneum over the whole abdomen as far as the posterior margin of the sternum to which it is attached.

The *Rectus abdominis* is not intersected by tendinous digitations; its origin is by a broad thin tendon from the lower and posterior half of the pubis; at about the middle third of the abdomen it becomes carneous, and is inserted into the posterior margin of the sternum. A mesial tendon or linea alba separates the fleshy portions of the two muscles.

The *Diaphragm* arises by fleshy digitations from the sternal ribs; in the Ostrich these digitations are five in number on either side: the carneous fasciculi do not, however, extend so far upon the central aponeurosis as even to be united laterally to one another, and consequently this muscle has frequently been denied to birds. From the lungs being confined to the back part of the thorax, the diaphragmatic aponeurosis attached to their inferior surface is not extended as a transverse septum between the chest and abdomen, but allows the heart to encroach upon the interspace of the lobes of the liver, as in reptiles. The contraction of the muscle tends directly to dilate the lungs, but is less perfect as an inspiratory action from the aponeurosis or central tendon being perforated by large cribriform apertures for the passage of the air into the abdominal air-cells.

The Wing-Muscles.—The muscles of the anterior extremity, especially those inserted into the humerus, are prodigiously developed, and form the most characteristic muscles of the bird. The muscles of the shoulder, however, are but small, and those of the distal segments of the wing still more feeble.

The *Trapezius* (20), the lower half of which seems only to be present in birds, arises from the spines of the lower cervical, and a varying number of the contiguous dorsal vertebræ, and is inserted into the dorsal margin of the scapula and the corresponding extremity of the clavicle; the clavicular portion can commonly be separated from the scapular.

The *Rhomboideus* lies immediately beneath the preceding, and is always single; it passes in a direction contrary to the trapezius from the spines of the anterior dorsal vertebræ to the dorsal edge of the scapula.

The *Levator scapulæ* arises by digitations from the transverse process of the last cervical vertebra, and from the first two ribs; it is inserted into the posterior part of the dorsal edge of the scapula, which it raises and pulls forwards.

The *Serratus magnus anticus* (21) is most developed in birds of prey; it arises by large digitations from three or four of the middle ribs, and converges to be inserted into the extremity of the scapula.

The *Serratus parvus anticus* or *Pectoralis minor*, as it is termed in Man, arises by digitations from the first and second ribs, and is inserted into the commencement of the inferior margin of the scapula. This is the largest of the muscles of the scapula in the Penguins.

A muscle, which may be regarded either as a portion of the *Pectoralis minor* or as the analogue of the *Subclavius* muscle, arises from the anterior angle of the sternum, and is inserted into the external margin of the sternal extremity of the coracoid bone.

The *Supra-spinatus* (22) arises from the anterior part of the outer surface of the scapula, and is inserted behind the largely developed internal tuberosity of the humerus.

The muscle which seems to represent both the *Infra-spinatus* and *Teres major* (23) has a more extensive origin from the outer margin of the scapula to its extremity, and is inserted into the internal tuberosity of the humerus.

The *Subscapularis* arises from the anterior part of the inner surface of the scapula, and is inserted into the humeral tuberosity. It is divided into two portions by the *Pectoralis minor*.

The *Latissimus dorsi* (24, 24,) is but a feeble muscle in this class, and is constantly divided into two very distinct slips. The anterior portion arises, more superficial than the trapezius, from the spines of the four or five anterior dorsal vertebræ, and is inserted near the tendon of the deltoid into the outer side of the humerus. The posterior slip comes from the spines of the dorsal vertebræ above the origin of the *glutæus magnus*, and sometimes from the anterior margin of the same muscle, and is inserted by a broad and thin tendon immediately in front of the preceding portion.

The *Deltoides* (26) is comparatively a small muscle; it arises from the anterior part of the scapula, and is inserted along the middle of the outer side of the humerus; it brings the wing upward and backward.

Birds have the *Pectoralis* muscle divided, as in many of the mammalia, into three portions, which are so distinct as to be regarded as separate muscles; they all arise from the enormous sternum, and act upon the proximal extremity of the humerus.

The *first* or *great Pectoral muscle* (25) is extraordinarily developed, and is in general the largest muscle of the body. In birds of flight it often equals in weight all the other muscles of the body put together. It arises from the anterior part of the outer surface of the clavicle or furculum, from the keel of the sternum and from the posterior and external part of the lower surface of that bone; it is inserted by an extended fleshy margin into the inner side of the anterior crest of the humerus. It forcibly depresses the humerus, and consequently forms the principal instrument in flight.

This muscle is very long and wide in the *Natatores* generally, but in many of these birds, as the Penguin, its origin is limited to the external margin of the subjacent pectoral muscle, which is here remarkably developed. The great pectoral is very long, but not very thick in the *Rasores*. In the *Herons* it is shorter, but much stronger and thicker. Its size is most remarkable in the Humming-birds, Swallows, and diurnal Birds of Prey, where it is attached to almost the whole outer surface of the sternum and its crest, and has an extended insertion into the humerus.

In the Ostrich its origin is limited to the anterior and external eighth part of the sternum, and it is inserted by a feeble tendon into the commencement of the crest of the humerus, to which it gives a strong rotatory motion forwards.

The *second Pectoral muscle* is situated beneath the preceding; it has the form of an elongated triangle: it arises from the base of the crest of the sternum and from the mesial part of the inferior surface of that bone; it increases in size as it ascends, then again becomes suddenly contracted, passes upwards and backwards round the coracoideum, between that bone and the clavicle, then turns downwards and outwards, and is inserted, fleshy, above and in front of the great pectoral, into the upper extremity of the humeral crest.

The interspace between the clavicle, coracoid, and scapula, through which its tendon passes, serves as a pulley, by means of which the direction of the force of the carneous fibres is changed, and although these fibres ascend from below towards their insertion, yet they forcibly raise the humerus, and thus a *levator* of the wing is placed without inconvenience on the lower part of the trunk, and the centre of gravity proportionally depressed.

In the Penguins, Guillemots, and Gulls, this muscle is almost the largest of the three, occupying the whole length of the sternum. It is remarkable for the length and strength of its tendon, which is inserted so as to draw forwards the humerus with great force. It is proportionally the smallest in the *Raptores*; and is very small and slender in the Struthious birds.

We have already alluded to the use which the Penguin makes of its diminutive anterior extremities as water-wings, or fins; to raise these after making the down-stroke obviously requires a greater effort in water than a bird of flight makes in raising its wings in air: hence the necessity for a stronger development of the second pectoral muscle in this and other Diving Birds, in all of which the wings are the chief organs of locomotion, in that action, and consequently require as powerful a development of the pectoral muscles as the generality of Birds of Flight.

The *third Pectoral muscle*, which is in general the smallest of the three, arises from the anterior part of the inferior surface of the sternum, and also by a more extended origin, from the posterior moiety of the inferior surface of the coracoid; it is directed forwards, and is inserted by a short and strong tendon into the internal tuberosity of the humerus, which it depresses.

It is proportionally large in the Penguins and Gulls, but attains its greatest development in the Gallinaceous order.

Above the preceding muscle there is another longer and more slender one, analogous to the *Coraco-brachialis*, which arises from the middle of the posterior surface of the coracoid; its direction upwards is less vertical than that of the third pectoral, along the outer side of which it is attached to the anterior tuberosity of the humerus. This muscle is wanting in the *Struthionidæ*, is of small size in the Heron and Goose, is much more developed in the *Raptores* and many *Natatores*, especially the Penguins, and attains its greatest relative size in the *Rasores*, where it arises from almost the whole of the coracoideum.

Birds in general possess two *flexors* and one *extensor* (27) of the fore-arm, analogous to those which are found in the mammalia. They have also the muscles corresponding to the *pronators* and *supinators* of this higher class, but their action is limited in the feathered tribes to *inflexion* and *extension* of the fore-arm, and to *adduction* and *abduction* of the hand.

A remarkable muscle, partly analogous in its origin to the clavicular portion of the deltoid, but differently inserted, is called by Carus *Extensor plicæ alaris* (30, *a b*) and forms one of the most powerful flexors of the cubit. It is divided into two portions, of which the anterior and shorter arises from the internal tuberosity of the humerus; the posterior and longer from the clavicular extremity of the coracoid bone. In the *Ostrich* and *Rhea*, however, both portions arise from the coracoid. The posterior muscle (*b*) sends down a long and thin tendon which runs parallel with the humerus, and is inserted, generally by a bifurcate extremity, into both the radius and ulna. The anterior muscle (*a*) terminates in a small tendon, which runs along the edge of the aponeurotic expansion of the wing. In this situation it acquires exactly the structure and elasticity of the ligamentum subflavum or ligamentum nuchæ; it then resumes its ordinary tendinous structure, passes over the end of the radius, and is inserted into the style of the metacarpal bone. It combines with the preceding muscle in bending the fore-arm; and further, in consequence of the elasticity of its tendon, puckers up the soft part of the fold of the wing. (See 48, *fig.* 133.) An analogous structure is met with in the wing of the bat.

A lesser flexor of the fore-arm, and stretcher of the alar membrane (31) arises, as a portion of the serratus magnus from the ribs, and terminates in an aponeurosis inserted into the alar membrane and fascia of the fore-arm; it is represented in the figure as turned aside.

The *Extensor metacarpi radialis longus* (32) is the first muscle which detaches itself from the external condyle of the humerus (ε), and it forms the radial border of the muscular mass of the fore-arm; it terminates in a large tendon about the middle of the fore-arm, and this tendon passes along a groove of the radius, over the carpus, to the phalanx of the so called thumb, or spurious wing, into the radial margin of which it is inserted. It raises the hand, draws it forwards towards the radial margin of the fore-arm, and retains it in the same plane. In the Penguin this muscle is extremely feeble, and the tendon is lost in that of the *tensor plicæ alaris.*

The *Extensor metacarpi radialis brevis* (33) arises below the preceding from the ulnar edge of the radius, and is inserted into the phalanx of the thumb immediately beyond the tendon of the preceding muscle. The two tendons are quite distinct from one another in the Birds of Prey, the Ostrich and Parrots, but unite at the lower end of the fore-arm in the *Anatidæ*, *Phasianidæ*, and *Gruidæ*.

The muscle analogous to the *Extensor carpi ulnaris* (34) comes off from the inferior extremity of the outer condyle of the humerus, passes along the middle of the exterior surface of the fore-arm, and its tendon, after passing through a pulley at the distal end of the ulna, is inserted into the ulnar phalanx. It draws the hand towards the ulnar edge of the fore-arm, and is the principal abductor or folder of the pinion.

The *Flexor metacarpi radialis* (35) is a short and weak muscle, which arises from the inferior part of the ulna, descends along the internal side of that bone, winds round its lower extremity and the radial edge of the carpus, passes beneath the tendon of the radial extensors, and is inserted, external to the latter, high up into the dorsal aspect of the radial phalanx of the metacarpus. In the Ostrich it arises from the lower third of the ulna. In the Penguin it is wanting.

The *Flexor metacarpi ulnaris* (36) arises beneath the fore-arm from the internal pulley of the ulna, continues fleshy to the pinion, and is inserted, first into the ulnar carpal bone, then into the ulnar phalanx. The latter insertion is wanting both in the Ostrich and Penguin.

The *muscles* of the pinion or hand are few, and very distinct from one another; the thumb or spurious wing is moved by four small muscles, viz. two *extensors*, an *abductor*, which draws the thumb forwards, and an *adductor*. The second digit receives three short muscles, two of which are *extensors*, and the third an *abductor*, in this action it is aided by one and opposed by another of the extensors. The lesser digit receives an *abductor*, which comes from the ulnar edge of the preceding phalanx.

Muscles of the lower extremity.—Notwithstanding the simplicity of the motions of the lower or posterior extremity, the muscles of this part are numerous, and present several peculiarities in birds. The femur can be moved freely forward and backward, but its rotation is limited by a strong *ligamentum teres*, and the structure of the hip-joint does not permit it to be carried under the body, or far outwards.

In consequence of the form of the pelvis, the *psoas magnus* and *parvus*, the *obturator externus* and the *quadratus lumborum* do not exist in birds.

A large muscle, regarded by Cuvier as the *Obturator internus*, takes its origin from the internal surface of the ischio-pubic bone, it is directed from behind forwards, and gives off a strong and long tendon which passes through the small opening at the anterior part of the obturator foramen, which is situated between the *pubis* and *ischium*, (*f*, *fig.* 131.) In this situation a muscle, arising from the external border of the opening, attaches itself to the preceding, and is inserted conjointly with it into the posterior and outer aspect of the trochanter. Meckel compares this muscle with the *pectineus*, especially as it exists in the Saurian Reptiles, but observes that as it arises from both the internal and external surfaces of the circumference of the obturator foramen, it may represent both the internal and external obturator muscles. It is of an extraordinary size in the Ostrich.

The femur is raised by three muscles.

The most superficial and highest of these elevators (37) arises by a broad and thin aponeurosis from the anterior and external surface of the ilium, it is of a square form, descends almost in a straight line, and is inserted into the posterior part of the trochanter. Meckel regards it as analogous to the *Glutæus medius:* Carus calls it the *Glutæus maximus.* But the latter, according to Meckel, is represented by the posterior part of what Carus terms the *Rectus femoris latissimus* (40).

Anterior to the *Glutæus medius* of Meckel, there is a much smaller muscle, which extends from the anterior margin of the ilium to the trochanter, where it is inserted in front of the preceding. It is of an elongated quadrilateral form, and it represents the *Glutæus minor* of quadrupeds. It is wanting in many of the *Natatores*, and arrives at its greatest degree of development in the Raptorial Order.

A third muscle, still smaller and longer than the preceding and situated beneath it, which arises from the outer margin of the ilium, and is inserted into that part of the femur which corresponds to the lesser trochanter, is regarded by Meckel as the *Iliacus internus*, which Cuvier states to be wanting in Birds. It is, however, present in most, and is seen highly developed in the Ostrich.

The muscles analogous to the *Pyramidalis* and *Gemellus superior* exist in Birds.

There are most commonly three adductors of the thigh. The inferior, external, and posterior one arises from the middle of the external surface of the anterior margin of the ischio-pubic bone, and is inserted into the greater part of the lower half of the femur at 38.

The second and third *adductors* are situated internally to the preceding; the latter of these may be compared to the *Pectineus*.

The *Sartorius* (39) arises from the anterior point of the ilium, and passes down to be attached to the head of the tibia; it is an extensor of the leg upon the thigh.

The *Rectus femoris* (40) arises by a thin but wide aponeurosis from the spines of the sacrum, after a short course it joins the *Cruræus* and *Vasti* (42), and is inserted into the head of the fibula. It corresponds according to Meckel with the *Tensor vaginæ femoris* and the *Glutæus magnus*.

The *Gracilis* (41) arises from the superior part of the pubis, descends along the inner side of the thigh and towards the lower extremity of this part, is continued into a long and strong tendon, which passes in front of the knee-joint, and over the extensor tendon of the leg to the outer side of the fibula, whence it proceeds inwards, anterior to the tendon of the peroneal flexor, to become united to the outer origin of the flexor perforatus of the toes. Meckel considers that the muscle now described represents the *Rectus femoris* of mammalia, and regards as the *Gracilis* a small and thin muscle, whose origin has been transferred lower down, from the pubis to the femur, from the internal side of which it passes to the internal and superior part of the tibia. Be this as it may, the disposition of the former muscle is such, passing, viz. first, over the convexity of the knee-joint, and afterwards over the projection of the heel, that from its connection with a flexor of the toes, these must necessarily be bent simultaneously with every inflection of the joints of the knee and ankle. As these inflections naturally take place when the lower extremities yield to the superincumbent weight of the body, birds are thus enabled to grasp the twigs on which they rest whilst sleeping, without making any muscular exertion.

There are three *flexors* of the leg: one (43) which, although single, is from its insertion into the back of the fibula, analogous to the *Biceps flexor cruris* of the human subject: another on the inside is attached to the tendon of the extensors of the foot as well as the tibia; this muscle might be called the *Semimembranosus* (44): the third *flexor* is in the middle (45), it comes from the ischium, and as it descends it receives a broad fleshy slip from the back of the femur. It is inserted on the back of the tibia, the tendon covering those of the extensors of the heel.

The muscles of the feet present in Birds essential resemblances to the same parts in Reptiles. They are divided into muscles of the tarsus, of the metatarsus, and of the toes, the latter being subdivided into long and short. The principal points in which they differ from the same muscles in Reptiles and the Mammalia are the following: their origins and carneous portions are not situated on the foot but higher up on the tibia and even on the femur. The great length of the metatarsus occasions the smaller muscles to be of a greater proportional length than in other animals. The muscular portions are most developed in the *Raptores*, *Scansores*, and *Natatores*; the *Insessores* and *Rasores* present an intermediate proportion; the *Cursores* and *Grallatores* have the longest tendons.

The *Gastrocnemius* (46) has three distinct origins: two of these are superficial, one from the outer, the other from the inner condyle of the femur; the third origin is lower down from the inner side of the tibia and fibula (47). They unite to terminate in a thin and broad aponeurosis, which after becoming closely connected with a fibro-cartilage appertaining to the *flexor digitorum*, proceeds to be inserted into both the outer and inner margins of the tarso-metatarsal bone.

The *Tibialis anticus* (48) arises from the anterior part of the upper extremity of the tibia, below which its tendon passes through an aponeurotic loop extended from the outer to the inner margin of the tibia. It has also a second origin, by means of a slender tendon, from the anterior part of the external condyle of the femur. It is generally inserted pretty high up into the tarso-metatarsal bone between the outer and inner margins; but in the *Psittacidæ* it is attached lower down to the internal border, so as to turn the foot inwards as well as raise it, a disposition which is extremely favorable for the act of climbing.

The *Peroneus* (49) is a much smaller muscle: it extends from the lower region of the fibula, and the outer and anterior edge of the tibia to the tarso-metatarsal bone, into the outer side of the base of which it is inserted.

The *Flexor perforatus seu longus digitorum* (50) forms the superficial and external muscular mass of the leg: it arises by one mass from the posterior part of the external side of the femur, immediately in front of the outer head of the gastrocnemius; another portion arises from the outside of the lower extremity of the femur; these two heads unite below the middle of the leg and constitute one fleshy belly which gives off three tendons; these proceed to the proximal phalanges of the three outer toes where they bifurcate to give passage to the tendons of the *flexor perforans*.

The *Flexor pollicis* (51) arises, by its anterior head, from the anterior and upper part of the tibia, and by its posterior head from the external condyle of the femur; when it has reached the region of the calcaneum, it passes backwards through a synovial capsule, and is inserted into the proximal phalanx of the thumb, where it is perforated by the tendon of the *perforans* muscle.

The *Flexor profundus perforans* (52) arises as two distinct muscles, the one from the back of the femur and the other from the back of the tibia and fibula; the tendons of these two portions unite behind the metatarsal bone, and send off tendons to the last phalanges of the toes, which perforate those of the flexor sublimis.

The *Extensor longus communis digitorum* arises above from the anterior side of the tibia, below the tibialis anticus, passes beneath a strong restraining ligament, then lower down beneath an osseous bridge, and lastly across a strong ligament situated at the inferior extremity of the tarso-metatarsal bone. Below this part its tendon divides into three slips which are inserted into the distal phalanges of the three outer toes (53).

There are six long muscles lying on the metatarsal bone; they are largest and best marked in those birds which walk most, as the *Aves terrestres.* Two of these muscles are on the posterior surface; one goes to the base of the external toe, which it *abducts;* the other is inserted into the root of the back toe, which it *bends.* The other four muscles are on the anterior part of the metatarsus: the first extends the back toe; the second goes to the base of the first toe, and abducts it; the third is spread on the root of the middle toe, which it extends; the fourth lies along the outside of the metatarsus, perforates the end of the bone, and is implanted into the inside of the external toe, and abducts it.

Progression on land is generally effected in birds by the alternate advancement of the two feet; but sometimes they proceed by leaping or hopping, rather than walking; both feet are then firmly fixed on the ground, and the body is propelled forwards by a sudden extension of all the joints of the legs. Birds which have sharp claws, as the *Accipitres, &c.*, retract them when they hop, to prevent their being blunted. The *Cat tribe,* among mammalia, have a mechanism effecting a similar purpose. Some birds derive assistance in terrestrial progression by the flapping of the wings, and this is especially the case with the Ostrich, which runs by the alternate advancement of its legs.

The act of *climbing* is performed by means of a peculiar disposition of the toes, aided by prehension with the beak, as in the Maccaws and Parrots, or by the prop formed by the stiff tail-feathers, as in the Woodpeckers.

The act of *swimming* is rendered easy to birds by the specific levity of their body, arising from the extension of the air-cells; by the shape of the chest, which resembles the bottom of a boat; and by the conversion of the hinder extremities into oars in consequence of the membranes uniting the toes together. The effect of these web-feet in water is further assisted by the toes, having their membranes lying close together when carried forwards, whilst, on the contrary, they are expanded in striking backwards. The oar-like action of the hinder legs is still further favoured by their backward position; and by the metatarsus and toes being placed almost on the same perpendicular or vertical line with the tibia, an arrangement, however, which is unfavourable for walking.

Sailing.—Some birds, as the Swan, partially expand their wings to the wind while swimming, and thus move along the waters by means of sails as well as oars.

The act of *diving* is performed by the rapid and forcible action of the wings, beating the water as in flight, by the feet striking the waters backwards and upwards, and assisted probably by the compression of the air-cells.

Flight, the most important and characteristic mode of locomotion in birds, results principally from the construction and form of the anterior extremities, which have already been described. The form of the body has also especial reference to this power, the trunk being an oval with the large end forwards. The spine being short and inflexible, the muscles act to great advantage, and the centre of gravity is more easily changed from above the feet as in the stationary position, to between the wings as during flight. The head of the bird is generally small, and the beak pointed, which is a commodious form for dividing the air. The long and flexible neck compensates for the want of hands and the rigidity of the trunk, and contributes to change the centre of gravity, according to the required mode of progression, by simply projecting the head forwards, or drawing it back. The position of the great pectoral muscles, as before observed, always tends to keep the centre of gravity at the inferior part of the body. The power which birds enjoy of raising and supporting themselves in the air is undoubtedly aided by the lightness of the body. The large cavities in the bones diminish their weight without taking away from their strength,—a hollow cylinder being stronger than a solid one of the same weight and length. But the specific levity principally depends on the great air-cells, which occupy almost every part of the body, and which are all in communication with the lungs. The air which birds inspire distends these cells, being expanded by the great heat of the body. Lastly, the feathers, and especially the quills, from their lightness and elastic firmness, contribute powerfully to the act of flying by the great extent which they give to the wings, the length and breadth of which are further increased by the expanded integument situated in the bend of the arm and in the axilla.

When a bird commences its flight it springs into the air, either leaping from the ground, or precipitating itself from some elevated point. During this action it raises the humerus, and with it the entire wing, as yet unfolded; it next spreads it horizontally by an extension or adduction of the fore-arm and hand; the greatest extent of surface of the wing being thus acquired, it is rapidly and forcibly depressed; the resistance of the air thus suddenly struck occasions a reaction on the body of the bird, which is thereby raised in the same manner as in leaping from the ground. The impulse being once given, the bird folds the wings by bending the different joints, and raises it preparatory to another stroke.

Velocity of flight depends upon the rapidity with which the strokes of the wings succeed each other. A simple downward stroke would only tend to raise the bird in the air; to carry it forwards the wings require to be moved in an oblique plane, so as to strike backwards as well as downwards. The turning in flight to the right or to the left is principally effected by an inequality in the vibrations of the wings. To wheel to the right the left wing must be plied with greater frequency or force, and *vice versâ.*

The outspread tail contributes to sustain the posterior part of the body; when depressed during a rapid forward flight, the anterior part of the body is raised, and flight retarded; when the tail is raised the anterior part of the body is lowered. Some birds bend the tail to one side, using it as a rudder when the horizontal course of flight is required to be changed.

The first launch of the bird into the air is produced by an ordinary leap from the ground, and depends, in some degree, on the length of the legs. Those birds which have very short legs and very long wings, as the *Swallows*, &c., cannot leap high enough to gain the requisite space for the expansion of their wings, and consequently have much difficulty in raising themselves from the ground, and generally prefer throwing themselves from some high point. The manner of flight varies exceedingly in different birds, some dart forward by jerks, closing their wings every three or four strokes; the Woodpeckers, Wagtails, and most of the small *Insessores* are characterized by this kind of undulatory motion: other birds, as the Swallow, Crow, &c. fly smooth and even: the Kite and Kestrel Hawk and the great Albatross sometimes appear to buoy themselves in the air without any perceptible motion of the wings.

The rapidity with which a strong Bird of Prey flies in pursuit of his quarry is inconceivably great. The anecdote of the Falcon belonging to Henry IV. King of France, which flew in one day from Fontainbleau to Malta, a distance of 1350 miles, is well known, and many similar instances are on record. The flight of a Hawk, when its powers are fully exerted, is calculated at one hundred and fifty miles an hour. The Eider-Duck's usual flight has been ascertained to be at the rate of ninety miles an hour.

The famous Race-horse Eclipse is said to have gone at the rate of a mile in a minute for a very short distance; but this speed, if it could be continued, would not be half so great as that which many birds put in practice during their long journeys of migration.

Of the Nervous System.—There is a remarkable uniformity in the form and structure of the brain (*fig.* 134, *a, b, c, d*) and medulla spinalis (*e, e*) in the different orders of birds. These great divisions of the cerebro-spinal axis are always readily distinguishable from one another by the greater breadth and globular form of the brain, which is proportionally much larger than in the other oviparous vertebrata. The high degree of development which the spinal cord and cerebellum present, as compared with the cold-blooded Reptilia, has an evident relation to the extraordinary locomotive powers with which the feathered class is endowed.

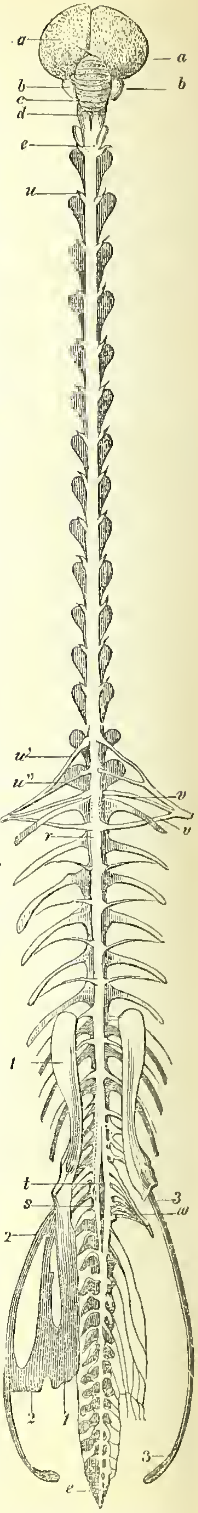
In a Pigeon weighing eight ounces with, and seven ounces without its feathers, or three thousand three hundred and sixty grains, the cerebro-spinal axis weighs forty-eight grains, the weight of the spinal cord being eleven, and that of the brain thirty-seven grains.

Of the Brain.—The brain of the bird differs from that of the reptile in the superior size of the cerebrum, and the more complex structure of the cerebellum; it differs from the brain of a mammal in the smaller size of the cerebellum, resulting from the want of the lateral lobes, and in the absence or rudimentary condition of the fornix; and it differs from the brain of every other vertebrate class in the lateral and inferior position of the optic lobes or bigeminal bodies.*

It cannot be at once distinguished, as Cuvier asserts, by being composed of six outward and visible masses, since the two hemispheres, (*a, a,*) the two optic lobes, (*b, b,*) the cerebellum, (*c,*) and medulla oblongata, (*d,*)

* We have lately ascertained that the corpus callosum is wanting in some of the marsupial animals; its presence is therefore no longer characteristic of the class mammalia.

(*Fig.* 134.)

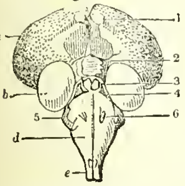


Brain and Spinal Cord of a Goose.

are equally obvious in the brains of reptiles. They are, however, differently disposed in birds; the optic lobes, which in reptiles intervene and are visible between the cerebrum and cerebellum, being in birds displaced, as it were, by the hemisphere and cerebellum coming into close contact, so that the optic lobes are pushed downwards and to one side. The transverse convolutions of the cerebellum at once distinguish, however, the brain of a bird from that of any reptile and most fishes; but it is a curious fact that the cerebellum in the sharks is similarly composed of a vermiform process only, transversely folded or convoluted.

The cerebral hemispheres sometimes present the form of a flattened oval, as in the Parrot tribe, but in general are of a convex cordiform shape, with the apex directed forward.

Fig. 135.



Base of the brain of a Pigeon.

The optic lobes (*b*, *fig*. 135) are rounded tubercles, situated below and behind the hemispheres, in the lateral interspace between these and the cerebellum.

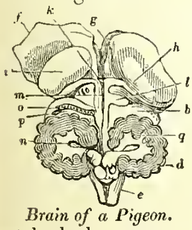
The cerebellum is composed of the middle lobe only, and is of a compressed arched form.

The medulla oblongata presents neither a tuber annulare nor corpora olivaria or pyramidalia, but is a large uniform tract situated between and behind the optie lobes.

On the lower part of the side of each eerebral hemisphere there is a depression which corresponds to the fissura magna Sylvii, and is the only appearance which the hemispheres present of a division into lobes. Elsewhere there are no traces of convolutions, the cerebrum in this respect resembling that of Reptiles and Fishes, and some of the least intelligent orders of Mammalia, as the *Rodentia*, *Marsupiata*, and *Edentata*. The optic lobes are also devoid of the transverse fissure which bisects the optic lobes of mammalia.

The cerebellum is marked by close and transverse anfractuosities, such as characterize the corresponding portion of the cerebellum in mammalia, called the vermiform process.

Fig. 136.



Brain of a Pigeon.

When the cerebral hemispheres are divaricated from each other, (*fig*. 136,) they are seen to be disunited through the whole of their vertical extent, and to be joined only by the round anterior commissure of the brain (*k*, *fig*. 136.) In fact both the corpus callosum and fornix are wanting; or at most a rudiment only of the latter part can be perceived in the brains of some birds, as the Eagles, Vultures, and Parrots. The mesial surfaces of the hemispheres, which are in contact with each other, present a few striæ which diverge from the commissure. These surfaces are composed of an extremely thin layer of medullary substanee, (*g*,) forming the internal parietes of the ventricle, and extended outwardly over the corpus striatum (*i*.) This body is of very great size in birds, constituting of itself almost the entire substance of the hemisphere, projecting into the ventricle, (*h*,) not only from below, but from the anterior and outer sides of the cavity, and being covered by a smooth layer or fold of medullary matter, (*f*,) which increases in thickness anteriorly. The ventricle does not extend below the corpus striatum to form an inferior horn; and, as in most mammalia there is no extension of the cavity backwards to form a posterior horn, there is consequently no *cornu ammonis*. The vessel forming the plexus choroides penetrates the ventricle beneath the posterior part of the thin internal wall, and the lateral ventricles communicate together there, and with the third ventricle. They are continued anteriorly to the root of the olfactory nerve, which is itself a continuation of the apex of the hemisphere.

Just above the orifice of communication there is a smooth flattened projection, rounded externally, which advances into the ventricle from the internal wall; this is a rudiment of the fornix.

The round anterior commissure (*k*) is prolonged on either side into the substance of the hemispheres, as in man and quadrupeds.

The optic thalami (*l*) are of small size, and not united by a soft commissure: between them is the cavity called third ventricle (*m*); and above and behind they give off the peduncles of the pineal gland. This body does not hang freely suspended by the pedicles, but seems to form a rounded and thickened anterior border of the valvula Vieussenii or lamelliform commissure of the optic lobes. Carus describes the pineal gland as adhering firmly to the confluence of the great veins situated at the anterior orifice of the aqueduct of Sylvius. In Pigeons he states that it is composed of many segments, but that in general it is of a simple and conical form; the figure which he gives of it, from the Turkey, exhibits a pyriform shape.* The valve which closes the upper part of the passage from the third to the fourth ventricle, is a thin lamella of great width, in consequence of the distance to which the optic lobes are separated from one another. Anteriorly the third ventricle communicates with the infundibulum.

The fourth ventricle (*n*) resembles that in the brain in mammalia, but is of less width; its floor is indented with the longitudinal fissure called *calamus scriptorius*.

Besides the cavities or ventricles above mentioned, there are also two others situated in the optic lobes (*o*), or bigeminal bodies, each of whieh, when laid open, is seen to be occupied by a convex body (*p*) projecting from the posterior and internal side of the lobe; these ventricles communicate with the others in the aqueduct of Sylvius.

As there is no transverse furrow in the optie lobes, they cannot be distinguished into the protuberanees called 'nates' and 'testes' in

* Anat. Comparée, nouv. ed. i. p. 88, pl. xv. fig. 6.

the human brain; they have most resemblance, however, to the latter bodies.

With respect to the substance of which the brain of birds is composed, we may observe that the bodies analogous to the *corpora striata* do not merit that name, as there are no alternating striæ of grey and white matter. In this respect the bird's brain resembles that of the cold-blooded ovipara and of the human fœtus. The substance of the cerebellum does present the admixture of the two substances, or *arbor vitæ (q)*, but in a less complicated degree than in mammalia.

The brain in birds is invested with the same membranes as are described in Mammalia.

Medulla spinalis.—The spinal cord is continued from the foramen magnum to the canal formed by the coccygeal vertebræ, where, however, it becomes extremely attenuated, and corresponds in extent to the shortness of that division of the vertebral column, terminating in a mere filament which expends itself in distributing a few pairs of nerves through the coccygeal foramina. As in the Mammalia, it appears externally to be composed of the white or medullary matter, but contains a small proportion of grey substance internally. It is of a cylindrical figure, and as in the cold-blooded ovipara, it is of great length in proportion to the brain. An *anterior* and *posterior* fissure may be distinguished, and also a narrow canal which extends through its entire length. Two enlargements occur in the course of the spinal cord, one corresponding to the wings, the other to the legs; and from these swellings the nerves of the brachial and sacral plexuses come off respectively. As might be expected, therefore, these enlargements present differences of relative size corresponding to the different relative development and powers of the anterior and posterior extremities. In general the posterior enlargement is greater than the anterior; and this difference is very remarkable in the Struthious birds in which the whole business of progression falls upon the posterior extremities.

Besides the difference in size, the spinal enlargements or ganglions, as they may be termed, differ also in structure; at the anterior, alar, or thoracic enlargement *(r, fig.* 134) the spinal cord merely receives an accession of grey and white medullary substance; but at the beginning of the sacral swelling *(s, fig.* 134) the canal of the cord enlarges in a remarkable manner, so that the lateral cords separate from one another posteriorly or above, precisely as they do to form the fourth cerebral ventricle: the cavity or spinal ventricle *(s, fig.* 134) thus formed, is filled with a serous fluid inclosed in a pia mater. From the figure of this cavity it has been termed the '*Sinus rhomboidalis.*'

Of the Nerves.—The cerebral nerves correspond in number to those of the Mammalia. The principal difference of form and structure is presented in the *olfactory* or *first* pair (1, *fig.* 135.) These nerves are of a cylindrical figure and small extent, being continued from the anterior extremity or apex of the hemispheres. Instead of separating into filaments to pass out of the skull by a cribriform lamella, each nerve is continued along an osseous canal, accompanied by a venous trunk, as far as the pituitary membrane of the superior spongy bone upon which its filaments are distributed in a radiated manner.

The optic nerves (2, *figs.* 135, 137,) are in general of remarkable size; they arise from the whole of the outer surface of the optic lobes, and form in front of the infundibulum, a perfect union, or *chiasma*, (2*, *fig.* 137,) in which, on making a horizontal section, some transverse striæ may be perceived, apparently resulting from the decussating fibrils of the nerves.

The distribution of the *third*, (3, *figs.* 135, 137,) *fourth*, (4, *figs.* 135, 137,) and *sixth* cerebral nerves, (6, *figs.* 135, 137,) is almost the same as in Mammalia. The course of the fourth pair, immediately above the supra-orbital branch of the fifth pair is shown at 4*, *fig.* 137, as far as its termination in the superior oblique muscle to which it is, as in other vertebrata, exclusively distributed.

The *fifth* or trigeminal nerve (5, *figs.* 135, 137) has nearly the same distribution as in Mammalia.

The first or *ophthalmic* division (5*, *fig.* 137) passes out of the cranium by a peculiar canal situated externally to the optic foramen. It is of large size, and describes in its passage through the orbit a curve corresponding to the roof of that cavity; it generally penetrates the substance of the facial bones above the nasal fossæ. It divides into three branches; the *first* or superior is the smallest and is lost upon the pituitary membrane; the *second* branch is the largest of the three and the longest; it is received into an osseous canal, passes over the nasal organs, and terminates at the extremity of the beak in a great number of divisions; the *third* branch of the ophthalmic nerve is entirely distributed to the skin which covers the circumference of the external nostrils.

The second division, or *superior maxillary* nerve passes out of the same foramen as the *inferior* one (at 5″, *fig.* 137,) immediately above the tympanic bone or *os quadratum;* it passes forwards along the floor of the orbit, and in this part of its course gives off two filaments, of which one joins the ramifications of the ophthalmic nerve, the other ascends, penetrates the substance of the pterygoid muscles and the maxillary bone, to be lost on the lateral parts of the bill. In those birds, as the *Anatidæ* and other Water-fowl, where the upper mandible is notched on the edge, each denticulation receives four or five nervous filaments, and the nerve is proportionally of large size.

The *inferior maxillary nerve* separates from the superior, and proceeds obliquely downwards, dispensing branches to the pterygoid and quadrangular muscles of the jaws; the trunk proceeds outwards to the lower jaw where it divides into two branches an internal and an external. The internal, which is a continuation of the trunk, penetrates the maxillary canal, and is continued to the anterior end of that mandible. In the *Anatidæ* it gives off nerves to the dentations along the edge of the mandible. The external branch recedes from the internal, perforates the jaw, and is distributed on its external surface beneath the tegumentary or horny substance which sheaths the extremity of the mandible. It supplies no gustatory branch to the tongue, which is an organ of prehension, not of taste, in Birds.

The *facial nerve*, or portio dura, exists in Birds, but it is extremely small, its offices being hardly required, in consequence of the structure of the parts of the face in this class. However, a few branches may, with difficulty indeed, be traced, and the trunk of the nerve is constantly present.

The *auditory nerve*, or portio mollis, is large, very soft and pulpy, and of reddish colour; it is received into a deep depression on the internal surface of the cranium (at 7, *fig.* 137), whence it penetrates by several small foramina to the labyrinth.

The *pneumogastric nerve*, or *nervus vagus*, generally passes out of the cranium in two or three filaments, which afterwards rejoin. On leaving the skull, this nerve communicates with the lingual and glosso-pharyngeal nerves. and is situated between them, the lingual being placed in front. Each nerve of the *par vagum* passes as a distinct strong cord along the neck in company with the jugular vein, and descending into the chest forms the cardiac and pulmonary plexuses, as in Mammalia. The two nerves unite behind the heart, and proceed along the œsophagus to terminate in anastomoses with the great sympathetic nerve.

The *glosso-pharyngeal* nerve of the eighth pair passes out of the cranium through the foramen behind the ear, which corresponds to the *foramen lacerum posterius*, by two filaments, which immediately unite to form an elongated quadrangular ganglion; this sends off a small internal branch in front of the muscles of the neck; a small posterior twig which unites with the par vagum, and a large inferior branch to the anterior part of the neck. The latter is a continuation of the nerve itself; it descends along the œsophagus and divides into two principal branches, of which one passes upwards to the muscles of the os hyoides, between which it is included, and this branch is remarkably tortuous in the Woodpecker in order to be accommodated to the extensile motions of the tongue. The other branch descends along the lateral parietes of the œsophagus, and sends off a twig to join the lingual nerve. The termination of the glosso-pharyngeal is expanded upon the œsophagus.

The *hypoglossal* nerve (9th pair) escapes from the cranium posterior to the nervus vagus by the condyloid foramen. It is very slender at its origin; passes to the front of the nervus vagus, partly uniting with, as it crosses over this nerve, and in that situation it detaches a small filament analogous to the *descendens noni*, which accompanies the jugular vein to the chest. The trunk of the hypoglossal next crosses the glosso-pharyngeal nerve, then passes beneath the cornu of the os hyoides, and advances towards the superior larynx, where it terminates by dividing into two principal branches, which are distributed, the one to the anterior and inferior, the other to the superior and internal parts, of the tongue.

Spinal nerves.—These correspond in number to the vertebræ of the spine. They arise, as in the other vertebrata by two roots, the ganglion on the posterior of which is proportionally very large. In the sacral region of the spine, the anterior and posterior roots escape by distinct foramina, and can be separately divided without laying open the bony canal, but they are deeply seated and well protected by the anchylosed processes of the sacrum and the extended iliac bones.

The *cervical* nerves vary considerably in number, the known extremes being from ten to twenty-three, corresponding to the number of vertebræ. They are proportionally larger than in man, are tortuous in their course, to be accommodated to the extensive motions of the neck, and are principally lost in the integument. Only the last, or last two, pairs (*u' u''*, *fig.* 134) of cervical nerves concur in the formation of the brachial plexus, which is completed by the first two pairs of dorsal or thoracic nerves (*v*).

The *dorsal* nerves do not present any notable differences from those of mammalia.

The *sacral* nerves have no other peculiarity than their mode of passing out of the spinal canal: they form exclusively the plexus analogous to the lumbar and sacral (*w*, *fig.* 134).

The nerve analogous to the phrenic nerve is wanting in Birds, in correspondence with the rudimentary condition of the diaphragm.

The *brachial plexus*, formed by the two last cervical and one or two first dorsal nerves, soon becomes blended into a single fasciculus whence all the nerves of the wing are derived. According to Cuvier, the first four that are given off are of large size, and are distributed to the great and middle pectoral and subclavian muscles. A small filament is then detached which supplies the muscles surrounding the head of the humerus and capsule of the joint; this represents the articular nerve. The rest of the plexus divides into two large nerves, which supply the wing.

Macartney describes the course of the *nerves of the wing* in a somewhat different manner, and observes that they more nearly resemble those of the superior extremity in mammalia, than Cuvier has represented. The brachial plexus, according to this author, gives rise to three nerves which are distributed in the following manner:—"The first is a very fine filament, which runs down on the inside of the arm, and is lost about the internal part of the elbow. This is analogous to the *internal cutaneous* nerve. The second is a large cord; it gives off a very large branch, which divides into many others, for the supply of the pectoral muscles; it sends several smaller branches to the muscles under the clavicle and about the joint, and then proceeds to the inner edge of the biceps muscle, along which it descends to the fold of the arm, after giving some large muscular branches. Before it reaches the joint, it divides into two branches; one of which is analogous to the *ulnar* nerve, and the other soon divides again into nerves which are similar to the *median* and *musculo-cutaneous*. The *median* dips down amongst the muscles on the middle of the fore-arm, to which it gives branches, and afterwards runs along the inter-osseous space, passes under the annular ligament of the carpus, and is distributed to the short muscles of the digiti. The branch analogous to the musculo-cutaneous nerve, is expanded upon the muscles on the upper edge of the radius.

"The *ulnar* nerve, although it appears to be incorporated with the *median* on the upper arm, can be easily separated from it, and traced to its proper origin in the brachial plexus. After this nerve leaves the median, it turns over the end of the foramen to get upon the edge of the ulna. It gives filaments to the muscles in this situation; but its chief branch runs down superficially upon the ligaments of the quills in company with a vein, and goes ultimately to be lost upon the ulnar edge of the hand.

"The third cord furnished by the brachial plexus, supplies the place of the *radial* nerve. It detaches several filaments to the muscles on the inside and back of the scapula. It gives off also the *articular nerve*, and then winds round the humerus between the extensor muscles, to which it furnishes some large filaments. On coming to the outside of the humerus, it sends a branch between the integuments of the fold of the wing. The nerve now turns round the neck of the radius, beneath the muscles, and forms two branches; of which one passes under the muscles to the outer side of the ulna, along which it runs superficially to the hand; the other branch passes on the radial side, but more deeply amongst the muscles, goes under the annular ligament of the carpus, proceeds between the branches of the metacarpus, and is finally lost on the back of the digiti." The same anatomist describes the course of the nerves of the posterior extremities as follows.

"Although Cuvier has given a more accurate description of the nerves of the lower extremity than those of the wing, it nevertheless needs correction in several particulars.

"The *obturator* and *femoral* nerves arise from the same plexus which is formed by the two last lumbar nerves, by a communicating branch from the first sacral pair. The obturator nerve passes through the upper part of the foramen ovale, and is distributed to the muscles around the hip-joint, especially the adductor. The femoral nerve passes out of the pelvis in company with the artery, over the upper edge of the ilium. It divides into three branches, which are dispersed among the muscles and integuments on the anterior and inner part of the thigh. Some of these filaments are long, and descend superficially for a considerable way upon the limb.

"The ischiatic nerve is composed of the five superior sacral nerves; and as soon as it departs from the plexus, even within the pelvis, is easily separable into its primary branches. Immediately after it passes through the ischiadic foramen, it sends filaments to the muscles on the outer part of the thigh; it then proceeds under the biceps muscle, along the back of the thigh, about the middle of which it becomes divided into the *tibial* and the *peroneal* nerves.

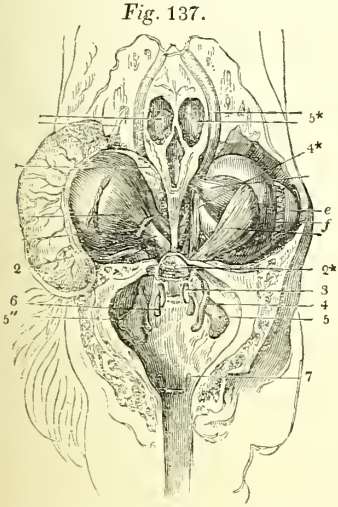
"The *tibial* nerve, even before it arrives in the ham, separates into several branches, which pass on each side of the bloodvessels, and are chiefly distributed to the muscles on the back of the leg. Two of these branches, however, are differently disposed of; the one accompanies the posterior tibial artery down the leg, passes over the internal part of the pulley, and is lost in small filaments and anastomoses, with a branch of the peroneal nerve on the inner side of the metatarsus; the other branch runs down on the peroneal side of the leg, along the deep-seated flexors of the toes, passes in a sheath formed for it on the outer edge of the moveable pulley of the heel, and proceeds under the flexor tendons along the metatarsal bone, to be distributed to the internal part of the two external toes.

"The peroneal nerve is directed to the outer part of the leg; it dips above the gastrocnemii muscles, and runs through the same ligamentous pulley that transmits the tendon of the biceps muscle; it then detaches some large filaments to the muscles on the anterior part of the leg, under which it divides into two branches, which proceed close together, in company with the anterior tibial artery to the fore part of the ankle-joint, at which place they separate; one passes superficially over the outer part of the joint, the other goes first under the transverse ligament which binds down the tendon of the tibialis anticus muscle on the tibia, and then over the inner part of the joint, below which it divides into two branches, the one is distributed to the inner side of the metatarsus and the tibial side of the pollex, and to the next toe; the other turns towards the centre of the metatarsal bone, and penetrates the tendon of the tibialis anticus just at its insertion, and then rejoins the branch of the peroneal nerve it accompanied down the leg. They continue their course together again in the anterior furrow of the metatarsal bone; and at the root of the toes, separate once more, and proceed to the interspaces of the three anterior toes, and each divides into two filaments, which run along the sides of the toes to the nail."—*Rees' Cyclopædia, Art. Birds.*

The *great sympathetic nerve* of birds resembles, in many particulars, that of mammals. It enters the cranium by the same orifice as that by which the nervus vagus and the glosso-pharyngeal make their exit; it there unites with the fifth and sixth pair of nerves. At the base of the cranium the first ganglion, or superior cervical, is of a lenticular form, and communicates at once with the ninth and eighth pairs of nerves, so as to seem as if it were blended with them. The remainder of the chain of cervical ganglions are very remarkably situated, being lodged on either side in the canal of the vertebral artery formed by the transverse processes; into which it passes, or from which it escapes above, at the third cervical vertebra, while below the sympathetic again becomes conspicuous at the commencement of the thorax, where it sends a considerable branch from the first thoracic ganglion to join the pulmonary plexus formed by the par vagum. This ganglion also distributes seven other filaments, one of which goes to join the brachial plexus; a second is lost in the cardiac plexus of the par vagum; three other filaments proceed inwardly to the projection formed by the bodies of the vertebræ to produce the commencement of the splanchnic nerve; lastly, the sixth and seventh serve to unite the first ganglion with the second, one passing above, the other below the head of the rib, which they thus include in a lozenge-shaped space. Each of the succeeding ganglions forms, in like manner, a centre of nervous radiations, which are five, six, or seven in number, of which four, two anterior and two posterior, serve to bring the contiguous ganglia into communication with each other; one or two contribute to the formation of the splanchnic nerve, and one joins the dorsal spinal nerve situated immediately behind the ganglion.

The splanchnic nerves, formed by all the internal thoracic branches of the great intercostal, accompany on either side the trunk of the aorta. When it has arrived at the cœliac axis, they surround it and form one, two, or three ganglions from which an immense number of filaments are thrown off, which surround the different arteries of the abdomen. These ganglions are evidently the analogues of the semilunar ganglions of man, and the filaments proceeding from them correspond to the solar plexus. The trunk of the sympathetic continues along the bodies of the vertebræ, but the ganglions become less marked after the ribs cease to be given off; two or three filaments are given off from each of these small swellings, which, by uniting with the filaments of the opposite side, form a plexus around the aorta. The termination of the sympathetic may be readily traced along the coccyx, where four pairs of ganglions are observable in the Swan, the last of which join to form a *ganglion impar*.

Fig. 137.



Cerebral nerves, eyes, &c. in situ of a Goose.

Organs of Vision.—The eye in Birds presents many peculiarities, which chiefly relate to the extraordinary powers of locomotion in this class, tending to accommodate vision to a rapid change of distance in the objects viewed, and to facilitate their distinct perception through a rare medium.

There is no species of bird in which the eyes are wanting, or are rudimentary, as occurs in the other vertebrate classes.

The eyes of Birds are, in the first place, remarkable for their great *size*, both as compared with the brain and with the entire head, (*fig.* 137,) being analogous, in this respect, to the eyes of some of the flying insects. Their *form* is admirably adapted to promote the objects above named. The anterior segment of the eye is more prominent than in any other class of animals, and is in many birds prolonged into a tubular form, terminated by a very convex cornea (*e, fig.* 137.) Dr. Macartney observes that " the owl furnishes the most striking example of the disproportion between the anterior and posterior spheres of the eye, the axis of the anterior portion being twice as great as that of the other. The obvious consequence of this figure of the globe of the eye is to allow room for a greater proportion of aqueous fluid, and for the removal of the chrystalline lens from the seat of the sensation, and thus produce a greater convergence of the rays of light, by which the animal is enabled to discern the objects placed near it, and to see with a weaker light; and hence *owls*, which require this sort of vision so much, possess the structure fitted to effect it in so remarkable a degree."

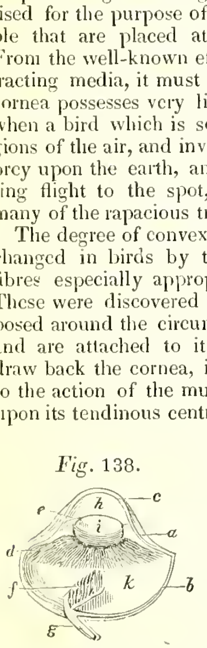
The anterior division of the eye is least convex in the swimming birds. The sclerotic coat is divisible into three layers. It is thin, flexible, and somewhat elastic posteriorly, where it presents a bluish shining appearance, without any distinct fibres, but anteriorly its form is maintained by a circle of osseous plates or scales (*f, fig.* 137) interposed between the exterior and middle layers. These plates vary from thirteen to twenty in number, and are situated immediately behind the cornea, with their edges overlapping each other. They are in general thin, and of an oblong quadrate figure, becoming elongated from before backwards in proportion as the bird possesses the power of changing the convexity of the cornea. In the nocturnal *Raptores* the bony plates are strong and thick, and extend from the cornea over the whole of the anterior projecting division of the eye to the posterior hemisphere, which they also contribute to form. The figure of the eye is thus maintained, notwithstanding its want of sphericity; and in other classes, as Reptiles and Fishes, where the eye recedes from the spherical figure from an opposite cause, viz. the extreme flattening of the cornea, that form is also preserved by the introduction of an osseous structure in the sclerotic.

The bony plates are capable of a degree of motion upon each other, which is, however, restrained within certain limits by the attachments of their anterior and posterior edges to the sclerotic coat; and by their being bound together with a tough ligamentous substanec, which seems to be the continuation of the selerotic between the edges that overlap each other.

The *cornea* possesses the same structure as in mammalia, but differs with respeet to form. When the posterior part of the eye is eompressed by the muscles, the humours are urged forwards and distend the cornea; which, at that time, becomes much more prominent in most birds than it is ever observed in mammalia; and under such circumstances, the eye is in a state for pereeiving near objects. When the muscles are quite relaxed, the contents of the eye-ball retire to the posterior part, and the cornea beeomes flat or even depressed: this is the condition in whieh we always find the eye of a dead bird, but we can have no opportunity of perceiving it during life. It is only practised for the purpose of rendering objects visible that are placed at an extreme distance. From the well-known effects of form upon refracting media, it must be presumed, that the cornea possesses very little, if any, convexity, when a bird which is soaring in the higher regions of the air, and invisible to us, discerns its prey upon the earth, and deseends with unerring flight to the spot, as is customary with many of the rapacious tribe.

The degree of convexity of the eornea is also changed in birds by the aetion of muscular fibres especially appropriated to its motions. These were discovered by Crampton; are disposed around the circumference of the cornea, and are attached to its internal layer; they draw back the cornea, in a manner analogous to the action of the muscles of the diaphragm upon its tendinous centre.

Fig. 138.



The *choroid coat* resembles in its structure that of mammalia; it is copiously covered with a black pigment, similar to that in the human eye. Opposite the bony circle the choroid separates into two layers; the external layer is the thinnest, and adheres at first firmly to the sclerotica, after which it is produced freely inwards to form, or be continuous with, the iris.

The *iris* (*c*, *fig.* 138) is delicate in its texture, which under the lens appears composed of a fine net-work of interlacing fibres, but it is remarkable for the activity and extent of its movements, which seem in many birds to be voluntary. The contraction and dilatation of the pupil, independent of any change in the quantity of light to which the eye is exposed, is most conspicuous and remarkable in the Parrot tribe, but we have observed it also in the Cassowary and some other birds.

The colour of the iris is subject to many varieties, which frequently display great brilliancy, and afford zoologists distinguishing specific characters of birds; although these cannot always be implicitly relied upon.

The breadth of the iris varies in different species, but is greatest in Birds whieh take their food in the gloom of evening, as the Owls and Night-jar, in order that the pupil may be proportionally enlarged to admit as much light as possible to the retina. Carus observes that in the eye of the Owl is exhibited with peculiar distinetness the remarkable distribution of the ciliary nerves and vessels, which, running in the form of single trunks between the choroid and sclerotica, terminate anteriorly in several ring-shaped plexuses for the supply of the iris and of the muscular circle of the cornea. The pupil is usually round: in the Goose and Dove it is elongated transversely, and in the Owls is vertically oval.

The inner layer of the choroid is thicker than the external, and is disposed in numerous thickly set plicæ radiating towards the anterior part of the chrystalline lens, where they terminate in slightly projecting *ciliary processes*, (*d*, *fig.* 138,) the extremities of which adhere firmly to the capsule of the chrystalline. These processes are the most numerous, close set, and delicate in the Owl; they are proportionally larger and looser in the Ostrich.

The chief peculiarity in the eye of the Bird is the *marsupium* or *pecten*, (*f*, *fig.* 138,) which is a plicated vascular membrane analogous in structure to the choroid, and equally blackened by the pigmentum; situated in the vitreous humour anterior to the retina, and extending from the point where the optie nerve penetrates the eye to a greater or less distance forwards, being in many birds attached to the posterior part of the capsule of the chrystalline. As its posterior point of attachment is not to the choroid but to the termination of the optic nerve, this requires to be first described.

When the optic nerve arrives at the sclerotic, it tapers into a long conical extremity, which glides into a sheath of a corresponding figure, excavated in the substance of that membrane, and directed downwards and obliquely forwards. The central or inner layer of this sheath is split longitudinally, and the substance of the nerves passes through this fissure. A similar but longer fissure exists in the corresponding part of the choroid: so that the extremity of the optic nerve presents in the interior of the eye, instead of a round disc, as in mammalia, a white narrow streak, from the extremities and sides of which the retina is continued. Branches of the ophthalmic artery, which are quite distinct from the vessels of the choroid, and analogous to the *arteria centralis retinæ*, enter the eye between the laminæ of the retina, along the whole extent of the oblique slit above mentioned, and immediately enter or compose the folds of the marsupial membrane, upon which they form most delicate and beautiful arborescent ramifications.

The marsupium is lodged like a wedge in the substance of the vitreous humour, in a vertical plane, directed obliquely forwards. In those species in which the marsupium is widest, the angle next the cornea reaches the inferior edge of the capsule of the chrystalline; but where it is narrow, the whole anterior surface is in contact with the same point. This contaet is so close in some birds, as the Vulture, Parrot, Turkey, Cassowary, Stork, Goose, and Swan, that the marsupium seems absolutely to adhere to the capsule of the lens; but in many other birds, on the contrary, it does not extend further than two thirds of the distance from the back part of the eye, and is attached at its anterior extremity to some of the numerous laminæ of the hyaloid membrane which form the cells for the lodgment of the vitreous humour. In these cases the marsupium can have no influence on the movements of the lens, unless it be endowed with an erectile property, and be so far extended as to push forward the lens. The researches of Bauer* have shewn that there is no muscular structure in the marsupium, and its changes of form, if such occur in the living bird, must be effected by changes in the condition of the vessels of which it is almost exclusively composed.

The form of the marsupium varies in different birds; it is broader than it is long in the Stork, Heron, Turkey, and Swan; and of the contrary dimensions in the Owl, Ostrich, and Cassowary. The plicæ of the membrane are perpendicular to the terminal line of the optic nerve; they are of a rounded figure in most species, but in the Ostrich and Cassowary they are compressed, and so far inclined from the plane of the membrane, that their convergence towards its extremity gives it a resemblance to a close-drawn purse.† The folds vary in number, being four in the Cassowary, seven in the Great Horned Owl, eight in the Goose, from ten to twelve in the Duck and Vulture, fifteen in the Ostrich, sixteen in the Stork, and still more numerous in the Insessorial Birds, amounting to twenty-eight, according to Soemmerring, in the Fieldfare.

The exact functions of the marsupial membrane are still involved in obscurity. Its position is such that some of the rays of light proceeding from objects laterally situated with respect to the eye must fall upon and be absorbed by it; and Petit accordingly supposed that it contributed to render more distinct the perception of objects placed in front of the eye. The theory originally proposed by Sir Everard Home,‡ which attributed to the marsupium the office of retracting the lens for the purpose of distant vision by its muscular contraction, is opposed by the numerous examples in which it does not extend to the chrystalline, and by the manner of its attachment in those cases in which it does; since, as in these the marsupium adheres to the side of the chrystalline, it can only move it obliquely.

Some physiologists have supposed that this black membrane was extended towards the centre of the eye, where the luminous rays are most powerfully concentrated in order to absorb the excess of intense light to which birds are exposed in soaring aloft against the blazing sun. Others have considered it as the gland of the vitreous humour, and that, as this fluid must be rapidly consumed during the frequent and energetic use made of the visual organ by Birds, it therefore might require a superadded vascular structure for its reproduction.

We are inclined to consider the marsupium as an erectile organ, adapted to receive a varying quantity of blood, and to occupy a variable space in the vitreous humour; when fully injected, therefore, it will tend to push forward the lens, either directly or through the medium of the vitreous humour, which must be displaced in a degree corresponding to the increased size of the marsupium; the contrary effects will ensue when the vascular action is diminished. From the analogy of other structures introduced by Supreme Wisdom into the mechanism of organized bodies, it may reasonably be supposed that the marsupium is not limited to a single function.

The *retina* is continued from the circumference of the base of the marsupium, and after forming a few slight folds expands into a smooth layer of medullary matter, which seems to terminate at the periphery of the corpus ciliare. In the Owls, as Haller has observed, not more than half the globe of the eye is lined by the retina; it ceases in fact where the eye loses the spherical form at the base of the anterior cylindrical portion.

The humours of the eye no less correspond to the peculiar vision of the bird, and the rare medium through which it is destined to move, than the shape of the globe and the texture of its coats.

The *aqueous humour* is extremely abundant, owing to the extent of the anterior chamber gained by the convexity of the cornea, and its refractive power must be considerable in the higher regions of the atmosphere. The membrane inclosing it can be more readily demonstrated in birds than in most mammals, especially where it adheres to the free edge of the iris. The large size of the ciliary processes may have the same relation to the reproduction of the aqueous, as the marsupium is supposed to have with reference to the vitreous humour.

The *chrystalline lens* is remarkable for its flattened form, especially in the high-soaring Birds of Prey; it is also of a soft texture, and is without any hard nucleus, as in the eyes of Fishes and Reptiles. In the Cormorant and other birds which seek their food in water, the chrystalline is of a rounder figure, and this is peculiarly the case in the near-sighted Owls which hunt for prey in obscure

* Philosophical Transactions, 1822, p. 76.

† The Parisian Academicians, who took their description of this part from the Ostrich, first applied to it the name of *Marsupium* or *Bourse*. The original description is as follows:—"De cét entonnoir (the termination of the optic nerve) sortoit une membrane plissée, *faisant comme une bourse* qui aboutissoit en pointe vers le bord du Christallin le plus prochain de l'entrée du nerf optique. Cette bourse, qui estoit large de six lignes par le bas, à la sortie du nerf optique, et qui alloit en pointe vers le haut, estoit attachée par sa pointe au bord du Chrystallin, par le moyen de la membrane qui le couvroit du costé de l'humeur vitrée, et qui couvroit aussi toute la bourse qui estoit noir mais d'un autre noir que n'est celuy de la choroïde."—Duvernoy, in 'Mémoires pour servir à l'Hist. Nat. des Animaux,' p. 375.

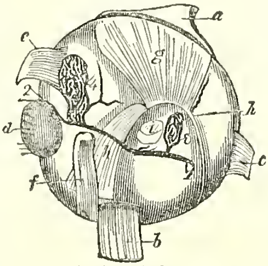
‡ Croonian Lecture, Phil. Trans. 1796.

light. It is inclosed, as in Mammalia, in a distinct capsule, which adheres very firmly to the depression in the anterior part of the vitreous humour; the capsule is itself lodged between two layers of the membrana hyaloidea, which, as they recede from each other to pass—the one in front and the other behind the lens,—leave round its circumference the sacculated canal of Petit.

The vessels of the lens are derived from those of the marsupium, which, as we have before observed, are ramifications of the analogue of the arteria centralis retinæ. With respect to this vessel we may here observe, that it is not continued as a simple branch from its origin to the marsupium,—such a course would be inconsistent with the important functions it is destined to fulfil in the present Class. Immediately before penetrating the coats of the eye it breaks into numerous subdivisions, the aggregate of which is much greater than the trunk whence they proceed, and these again unite, forming a plexus (ε, *fig.* 139) close to the external side of the optic nerve. The artery of the marsupium proceeds from this plexus, and runs along the base of the folds, giving off at right angles a branch to each fold, which in like manner sends off smaller ramuli. The plexus at the origin of the marsupial artery serves as a reservoir for supplying the blood required for the occasional full injection of the marsupium; and a similar but larger plexus (4, *fig.* 139) is formed at the origins of the ciliary arteries which supply the erectile tissue of the ciliary processes and iris. These plexuses are described by Barkow, from whose Memoir* the subjoined figure is taken, but their relation to the erectile powers of the parts they supply appears to have escaped his notice.

The *vitreous humour* presents few peculiarities worthy of note; compared with the aqueous humour, it is proportionally less in quantity than in the eyes of Mammalia. The outer capsule formed by the hyaloid membrane is stronger, and can be more easily separated from the humour.

Fig. 139.



Muscles of the eye.

The Eye-ball is moved in Birds by four straight and two oblique muscles. The *Recti muscles* arise from the circumference of the optic foramen and expand, as they pass forward, to be inserted into the soft middle part of the sclerotic. We have not been able to trace their insertion distinctly to the osseous circle; their aponeurosis cannot be reflected forwards from the sclerotica without lacerating that membrane.

The *Obliqui* both arise very near together from the anterior parietes of the orbit, and go to be inserted, the one into the upper, the other into the lower part of the globe of the eye; the superior obliquus does not pass through a pulley, as in Mammalia.

All the muscles are proportionally short in this class, but especially so in the Owls, in which the eye, from its large size and close adaptation to the orbit, can enjoy but very little motion.

In the subjoined figure and in *fig.* 140, *a′* is the *rectus superior* or *attollens; b′* the *rectus inferior* or *deprimens; c′* the *rectus externus* or *abducens; d′* the *rectus internus* or *adducens; e′* the *obliquus superior; f′* the *obliquus inferior; g′* the *quadratus; h′* the *pyramidalis.*

The accessory parts of the eye in Birds are similar to those of the higher Reptiles. There are three eye-lids, two of which move vertically, and have a horizontal commissure, while the third, which is deeper-seated, sweeps over the eye-ball horizontally, from the inner to the outer side of the globe. The vertical, or upper and lower eye-lids, are composed of the common integument, of a layer of conjunctiva, and between these of a ligamentous aponeurosis, which is continued into the orbit, and lines the whole of that cavity. The lower eye-lid is the one which generally moves in closing the eye in sleep, and it is further strengthened by means of a smooth oval cartilaginous plate, which is situated between the ligamentous and conjunctive layers.

The *orbicularis* muscle is so disposed as by means of this plate to act more powerfully in raising the lower than in depressing the upper eye-lid. In the latter it is continued immediately along the margin: in the lower eye-lid the tarsal cartilage intervenes between the muscle and the ciliary margin.

The *levator palpebræ superioris* arises from the roof of the orbit, and is inserted near the external angle of the lid.

There is also an express muscle for depressing the lower eye-lid, as in the Crocodile.

In the Owls and Night-jar *(Caprimulgus)* the eye-lids are closed principally by the depression of the upper one. There are but few birds that possess eye-lashes; of these the Ostrich is an example, as also the Horn-bills and the Owls, in which they are arranged in a double series; but in these they are rather to be considered as feathers with short barbs, than true eye-lashes.

The third eye-lid, or membrana nictitans, is a thin membrane, transparent in some birds, in others of a pearly white colour, which, when not in action, lies folded back by virtue of its own elasticity on the inner or nasal side of the globe of the eye, with which it is in close contact.

Two muscles are especially provided to effect its movements, but are so placed as to cause no obstruction to the admission of light to the eye during their actions. One of these is called the *Quadratus nictitantis,* (*g, fig.* 139;) it arises from the sclerotica at the upper and back part of the globe of the eye, and its fibres slightly converge as they descend towards the optic nerve, above which they terminate in a

* Meckel's Archiven, B. xii, pl. x.

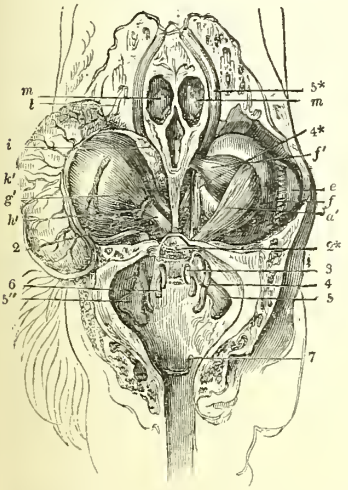
semilunar tendinous sheath, having no express or fixed insertion. The second muscle, called *Pyramidalis nictitantis*, (*h*, *fig.* 139,) arises from the sclerotica from the lower and nasal side of the eye-ball; its fibres converge as they pass to the upper side of the optic nerve, and there terminate in a small round tendon, which glides through the pulley at the free margin of the quadratus, and winding round the optic nerve, passes along a cellular sheath at the lower part of the sclerotica, and is inserted into the lower part of the margin of the third eye-lid, along which it is continued for some distance, and is gradually lost.

By the simultaneous action of the two muscles, the membrana nictitans is drawn forcibly outwards and with an oblique inclination downwards over the anterior part of the eye.* The tendon of the pyramidalis gains the due direction for that action by winding round the optic nerve, and it is restrained from pressing upon that nerve during the action of the pyramidalis muscle by the counteracting force of the *quadratus*, which thus augments the power of the antagonist muscle, while it obviates any inconvenience from pressure on the optic nerve, which its peculiar disposition in relation to that part would otherwise occasion.

To examine this singular and beautiful mechanism, it is necessary to remove the muscles of the eye-ball, especially the *recti*.

Lachrymal Organs.—There are two glands which secrete a fluid to lubricate the ball of the eye, and facilitate the movements of the eye-lids; one of these relates more especially to the movements of the nictitating membrane, and is called from its discoverer the *Harderian Gland;* the other corresponds to the ordinary *Glandula lachrymalis.*

Fig. 140.



* This oblique motion is most remarkable in the Owls, in which the nictitating membrane is accompanied by the upper eye-lid in its sweeping movement across the eye-ball.

The *Glandula Harderiana* (*i*, *fig.* 140) is a conglomeration of mucous follicles, which compensates for the absence of Meibomian glands in Birds; it is generally of large size, situated at the internal angle of the eye, and pours out a thick viscid secretion by a small duct which opens beneath the nictitating membrane. The surface of the gland is divided into many small lobules, which, when injected with mercury, are seen to be composed of still smaller vesicles.

It is interesting to find that some of the Rodentia, which manifest so many affinities to the Class of Birds, have a corresponding gland; in the Hare, for example, it is of large size and bipartite, situated at the internal angle of the orbit, and opening beneath the internal eye-lid.

The true *lachrymal gland* is situated at the external angle of the eye. In the Goose it is of a flattened form, about the size of a pea, opening upon the inside of the outer angle of the eye-lids by a short and wide duct. Its secretion is less viscid than that of the Harderian gland: but this is not uniformly the case.

The lachrymal duct consists of a wide membranous canal commencing by two apertures at the nasal canthus of the eye, and terminating below and a little before the middle or great turbinated cartilage. In the Ostrich there is a glandular prominence at the commencement of each of the lachrymal canals; these seem analogous to the caruncula lachrymalis. In other birds this structure is wanting.

Nasal gland. (*k*, *fig.* 140.)—Besides the lachrymal glands, or those which furnish a fluid for the purpose of lubricating, defending, and facilitating the movements of the eye-ball, there exists another gland, which, from its position within or near the orbit, seems at first sight to appertain to the preceding series, but the secretion of which is exclusively employed in lubricating the pituitary membrane of the nose. This gland, which corresponds to the nasal glands of serpents, and those described by Jacobson* in Mammalia, is situated in many aquatic and marsh birds above the supra-orbital ridge in a depression noticed in the description of the skull, (*p.* 278.) In most birds it is lodged within the orbit itself; in some it is found under the nasal bone, or in the cavity analogous to the maxillary sinus. In the Woodpeckers it is found in the subocular air-cell. It appears to be present in every order of Aves.†

In the Anserine Birds this gland is so situated as to complete the superior margin of the orbit, (*k'*, *fig.* 140,) and is inclosed in an extremely dense fibrous membrane. Its duct (*l*, *fig.* 140) is long, and passes to the nose along an osseous groove, behind the lachrymal bone. Its structure is simple, like that of the salivary glands in the same class, being composed of ramified follicles from which the

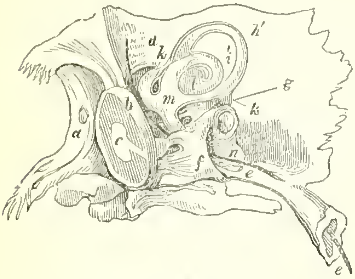
* Nouv. Bullet. des Sc. par la Soc. Philomath. iii. an 6. p. 267.

† *Nitzsch*, Meckel's Archiv. vi. p. 234.

acini of the cells proceed. In the Albatross and Penguin we have traced two or three distinct ducts leading from this gland to the nose.

Organ of Hearing.—The structure of the organs of hearing in Birds resembles most closely that in the higher Reptiles, especially the Crocodile. There is no concha, or projecting

Fig. 141.



Organ of hearing. Owl.

auricle in this class, for collecting and condensing the rays of sound; but to compensate for this deficiency, the labyrinth, and especially the semicircular canals, are of large size in proportion to the cranium. In those Birds, however, which enjoy the locomotive or visual faculties in a less perfect degree than in the rest of the class, there is found a peculiar arrangement of the feathers around the external meatus auditorius, which serves in some degree the office of an external ear. The Ostrich and Bustard (*d, fig.* 155) are so provided, and these birds can raise the auditory circle of plumes to catch distinctly any distant sound that may alarm them. The Owls, again, are furnished with a large crescentic membranous flap, or valve; and the membrana tympani is situated at the bottom of a cavity (*a, fig.* 141), the lining membrane of which is disposed in folds analogous to those of the human auricle. The opercular flap is largely developed in our common Barn-owl (*Strix flammea*). This species is also remarkable in having the membrana tympani attached exclusively to the bony meatus (*b, fig.* 141), and not to the tympanic bone or os quadratum.

The bony framework of the membrana tympani is sunk below the surface of the head, and rarely projects so far from the tympanum as to deserve the name of a meatus or canal: it is deficient anteriorly, where it is bounded by the tympanic bone, to which, with the exception above mentioned, the membrana tympani is attached for a greater or less extent of its anterior circumference.

The drum of the ear (*c, fig.* 141) is more or less of an oval shape; it has the same structure as in Mammals, but is extremely delicate; it is convex externally, as in the Reptiles, not concave, as in most Mammals.

The cavity of the tympanum is widest at its outer part, and very irregular in the rest of its extent. It communicates by the usual foramina with the internal ear, and is connected with the fauces by means of the Eustachian tube. It also communicates by three other apertures with the cells of the bones of the cranium. "These," Macartney observes, "are widened into something like canals, where the holes open into them. The largest of the foramina is in the back of the tympanum, and leads to the posterior cells, and communicates above the foramen magnum with the cellular canal of the other side. The second opening is placed at the anterior part of the tympanum, and conducts to the cells on the lower and anterior part of the cranium. The third foramen is continued amongst the cells which surround the labyrinth. Thus each tympanum has a communication with the interior of all parts of the cranium, and with each other, from which they might be reckoned as making only one cavity. The end of the tympanic bone, also, where it contributes to form the parietes of the tympanum, has a foramen by which it derives its supply of air. The auditory cells of the cranium of birds are analogous to the mastoid of the human subject; but from their extent they multiply sound much more. They are of the greatest magnitude in the nocturnal birds of prey; the Night-jar (*Caprimulgus*) has them also very large: they diminish in size in other birds, in which the posterior canals have no direct communication with each other; they are little observable in the Struthious Birds, and are wanting in the Parrots, but in their place the cavity of the tympanum is enlarged posteriorly."

The *Eustachian tube* (*e, e, fig.* 141) is very large in birds; it is an osseous canal, and terminates by a small aperture close to the one of the other side, within the fissure of the posterior nares. In the Swan the Eustachian passages, after having reached the base of the skull, pass forwards for about half an inch and then unite to form one common tube, which gradually expands until it terminates just behind the posterior apertures of the nose.

The foramina, which lead from the tympanum into the labyrinth, are situated within a fossa. They do not merit the distinctions of *foramen ovale* and *foramen rotundum*, being both oval, and only separated by a small bony process.

The ossicula auditûs are supplied by a single bone, analogous to the stapes, and some cartilaginous processes representing the rudiments of a malleus and incus. The ossiculum consists of a stalk or pedicle, crowned by an oval plate, which is applied to the foramen that leads into the vestibule of the labyrinth. At the other extremity it is united to two or three cartilaginous processes, which form a triangle that is attached to the membrana tympani.

The elongated stapes, or tympanic ossicle, is moved by one muscle (*f, fig.* 141), which comes from the occiput and penetrating the cavity, is affixed to the triangle that is connected to the membrana tympani. This muscle, in consequence of the connections of the ossiculum, is a tensor, and draws the membrana tympani outwards. It is counteracted by two small tendinous cords that are extended to the internal parietes of the tympanum.

The labyrinth of the ear of birds consists of the vestibule, the three semicircular canals, and the rudiment of the cochlea. These parts are included within the bones of the cranium, which form a dense vibratile case *(d)* around the whole internal ear.

The *vestibule* is small in proportion to the other parts, but is more elongated than in the cold-blooded Reptilia.

The *semicircular canals* have been termed by Scarpa, from their gradation in bulk, canales major, minor, and minimus. The largest is most superior, and has a vertical position* *(h, fig.* 141). The smallest is situated horizontally *(k, k)*. The canalis minor or second canal (*i*) is vertical, it ascends upon the horizontal canal, and opens into its side at *m*. They contain corresponding tubes of vascular membrane, and they also possess enlarged ampullæ (*l*), on which the nerves are distributed in the same manner as in mammalia.

The place of the *cochlea* is supplied by a short obtuse osseous conical tube (*n*, *fig.* 141), as in the Crocodile, very slightly bent, with the concavity directed backwards. Its interior is occupied by two small cylinders of fine cartilage, each a little twisted, and united by a thin membrane at their origin and termination. They proceed from the osseous bar, which separates the two foramina, corresponding to the foramen ovale and rotundum. The sulcus, which is left between the cartilages, is dilated near the point, and accommodates the same branch of the auditory nerve, which is sent to the cochlea in mammalia. This nerve spreads in fine filaments upon the united extremity of the cartilaginous cylinders. The tube is divided by the presence of the cartilages into two scalæ, the anterior of which communicates with the vestibule and is not closed; the posterior scala is shorter, and communicates with the tympanum by the foramen rotundum, which is closed by a membrane. Besides these parts the cochlea still contains a trace of the cretaceous substance which forms so conspicuous a part of the organization of the internal ear in Fishes.

The Struthious birds manifest their close relation to the Reptilia by having the tube corresponding to the cochlea, very small in proportion to the other parts.

The seventh cerebral nerve is received into a fossa, and there divides into five branches; one is the facial, or portio dura, and the others are sent to the semicircular canals and the tube. The facial nerve receives a filament from the par vagum, which traverses the ear, and is afterwards distributed to the palate.

Comparetti has described two canals leading from the labyrinth of birds, which correspond with the aqueducts of the mammalia.*

Organ of Smell.—The close affinity subsisting between the cold and warm-blooded ovipara is no where more strongly manifested than in the olfactory organs. The external nostrils are simple perforations, having no moveable cartilages or muscles provided for dilating or contracting their apertures, as in mammalia. The extent of surface of the pituitary membrane is not increased by any large accessory cavities, but simply by the projections and folds of the turbinated bones. The olfactory nerve is simple, as in the Tortoise, and passes out of the skull, as before observed, by a single foramen.

The external nostrils vary remarkably both in shape and position, and serve on that account as zoological characters. They are placed at the sides of the upper mandible in the majority of birds, but in some species are situated at or above the base of the bill; the latter is the case in the Toucans; in the *Apteryx Australis* they are found at the extremity of the long upper mandible.

In general they are wide and freely open to facilitate the inhalation of air during the rapid motions of the bird, but sometimes they are so narrow that, as in the Herons, they will scarcely admit the point of a pin; and in the Gannet they have been supposed, but erroneously, to be wanting altogether.†

In the *Rasores* the nostrils are partially defended by a scale. In the *Corvidæ* they are protected by a bunch of stiff feathers directed forwards. In the Petrels the nostrils are produced in a tubular form, parallel to one another for a short distance along the upper part of the mandible, with the orifices turned forwards *(a, fig.* 142.)

The septum narium is, in general, complete, and is partly osseous, partly cartilaginous. It is perforated in the Swan just opposite the external nostrils. The surface of the septum is very irregular in this bird, and the pituitary membrane which covers it is highly vascular.

The outer side of each of the nasal passages gives attachment to three turbinated laminæ. The inferior one is a simple fold adhering to the septum narium as well as to the side of the nose; the middle one is cartilaginous and is the largest. It is of an infundibular figure, and adheres by its base to the septum of the nose, and externally to the cartilaginous *ala* or side of the nostril. It is convoluted with two turns and a half in the Anserine Birds, but in the *Grallatores* it is compressed and forms only one turn and a half. The superior turbinated lamina *(m m, fig.* 140) generally presents the form of a bell; it is also cartilaginous, and adheres to the ethmoidal and lachrymal bones. It is hollow, and divided into two compartments, which are prolonged in a tubular form; the internal one extends to

* In the Insessores this canal is generally the smallest of the three.

* See Cuvier, Leçons d'Anat. Comp. tom. ii., and Macartney in Rees' Cyclopædia, Art. *Birds*.

† See Montague's Ornithological Dictionary.

the orbit, the external terminates behind the middle turbinated lamina in a cul-de-sac. These olfactory laminæ differ in regard to texture. In the Cassowary and Albatross they are said to be membranous. Cuvier states that they appeared to him to be bony in the Hornbill and Toucan. We have found this to be the case in the recent Toucan. The organ of smell in this singular species is confined to the base of its enormous beak, (*d, e, fig.* 150.) The canal, which is traversed by the air and odorous particles in inspiration, forms a sigmoid curve in the vertical direction. The external orifice is on precisely the same perpendicular line as the internal, or, as it is generally termed, the posterior nasal aperture. The external nostril (*d, fig.* 150) being situated on the posterior surface of the upper mandible, where it is raised above the level of the cranium, is consequently directed backwards, secure from all injury to which it might be exposed while the bill was used in penetrating dense and interwoven foliage. The olfactory canal is at its commencement of a cylindrical form, and about two lines in diameter. It passes forwards for about half an inch, receiving the projection of the first spongy bone, then bends downwards and backwards, and is dilated to admit the projections of the two other spongy bones. From this point it descends vertically to the palate, at first contracted and afterwards dilating to form the internal or posterior orifice, (*e, fig.* 150.) The first or outermost spongy bone is almost horizontal, and has its convexity directed outwards. The second is nearly vertically placed, with its convexity directed backwards: it terminates in a narrow point below. The superior spongy bone is about the size and shape of a pea. All these bones are processes from the inner and posterior parietes of the nasal passage; they are cellular, and air is continued into them from the cranial diploë; but the parietes of the nasal passage are entire and smooth, and lined by a delicate pituitary membrane, so that there is no direct communication between the cells, the turbinated bones, or of the mandible and the nasal passages.

In most birds the nasal cavities communicate with the pharynx by two distinct but closely approximated apertures. In the Cormorant, however, these join into one before their termination posteriorly, which is consequently by a single aperture. The olfactory nerves are distributed exclusively to the pituitary membrane covering the septum narium and the superior spongy bone. The pituitary membrane is of the most delicate structure, and is most vascular, where it covers the superior turbinated lamina, and becomes thicker and more villous as it descends upon the middle one. It everywhere displays numerous pores of muciparous glands, which bedew it with a lubricating secretion.

According to Scarpa the acuteness of smell is exactly in proportion to the development of the superior turbinated lamina, to which the size of the olfactory nerve corresponds. The following is the order in which, according to his experiments, birds enjoy the sense of smell, beginning with those in which it is most acute: *Grallatores, Natatores, Raptores, Scansores, Insessores, Rasores.*

There is still, however, much obscurity with reference to the extent to which Birds make use of their olfactory organs. It has been generally asserted that birds of prey are gifted with a highly acute sense of smell, and that they can discover by means of it the carcass of a dead animal at great distances; but those who have witnessed the rapidity with which the Vultures descend from invisible heights of the atmosphere to the carcass of an animal, too recently killed to attract them by putrefactive exhalations, have generally been led to consider them as being directed to their quarry by sight. "That this is the case," Dr. Roget observes, "appears to be now sufficiently established by the observations and experiments of Mr. Audubon, which show that these birds in reality possess the sense of smell in a degree very inferior to carnivorous quadrupeds, and that so far from guiding them to their prey from any distance, it affords them no indication of its presence even when close at hand. The following experiments appear to be perfectly conclusive on this subject. Having procured the skin of a deer, Mr. Audubon stuffed it full of hay; after the whole had become perfectly dry and hard, he placed it in the middle of an open field, laying it down on its back in the attitude of a dead animal. In the course of a few minutes afterwards he observed a vulture flying towards and alighting near it. Quite unsuspicious of the deception, the bird immediately proceeded to attack it as usual in the most vulnerable points. Failing in this object, he next with much exertion tore open the seams of the skin where it had been stitched together, and appeared earnestly intent on getting at the flesh, which he expected to find within, and of the absence of which not one of his senses was able to inform him. Finding that his efforts, which were long reitcrated, led to no other result than the pulling out large quantities of hay, he at length, though with evident reluctance, gave up the attempt, and took flight in pursuit of other game to which he was led by the sight alone, and which he was not long in discovering and securing.

"Another experiment, the converse of the first, was next tried. A large dead hog was concealed in a narrow and winding ravine, about twenty feet deeper than the surface of the earth around it, and filled with briers and high cane. This was done in the month of July, in a tropical climate, where putrefaction takes place with great rapidity; yet, although many vultures were seen from time to time sailing in all directions over the spot where the putrid carcass was lying, covered only with twigs of cane, none ever discovered it; but in the meanwhile several dogs had found their way to it and had devoured large quantities of the flesh."*

* See Roget, Bridgewater Treatise, vol. ii. p. 406.

Organ of Taste.—The gustatory sense is very imperfectly enjoyed in birds, which, having no manducatory organs, swallow the food almost as soon as seized. The tongue is organized chiefly to serve as a prehensile instrument, and its principal modifications will be treated of under the head of the *Digestive Organs.* It is generally sheathed at the anterior part with horn (*h*, *fig.* 152), and is destitute of papillæ except at its base (*o*, *fig.* 152) near the aperture of the larynx; these papillæ are not, however, supplied by a true gustatory nerve, but by filaments of the glossopharyngeal. No branch of the fifth pair goes to the tongue.

The tongue is proportionally largest and most fleshy in the Parrot tribe, and the food is detained in the mouth longer in these than in other birds. It is triturated and comminuted by the mandibles certainly, and turned about by the tongue, which here seems to exercise a gustatory faculty, since indigestible parts, as the coat of kernels, &c. are rejected. In the Lories the extremity of the tongue is provided with numerous long and delicate papillæ or filaments projecting forwards.

Organs of Touch.—With respect to the tactile instruments, but few observations can be made in the class of Birds. The anterior extremities have their digital extremities undivided and entirely unfitted for the exercise of this sense, and the posterior extremities are but little better organized for the purpose. The integument covering the toes is very sparingly supplied with nerves, and is of a texture scarcely fitted for ascertaining the superficial qualities of bodies. However, the villi on the under surface of the toes are observed to be remarkably long in the Capercailzie (*Tetrao urogallus*), but this is probably for the purpose of enabling them to grasp with more security the frosted branches of the Norwegian pine-trees. The Parrots seem to use their feet more like instruments of touch, but in them the action may be merely prehensile.

The only organ of touch respecting which there can be no doubt is the bill. Even where this is covered with a hard sheath of horn, some filaments of the fifth pair (*c*, *fig.* 150) may be traced terminating in small papillæ; but in the Lamelli-rostral water-birds the bill is covered by a softer substance, and is plentifully supplied by branches of the fifth pair of nerves. (See *Nerves.*) In the Woodcocks and Snipes the long bill is so organized that it is used as a probe in marshes and soft ground to feel for the small worms and slugs that constitute their food.

The cire in the *Falconidæ*, the *wattles* of the Wattle-birds (*Philedon carunculatus* and *Glaucopis cinerea*) and of the Cock, the caruncles of the King-Vulture and Turkey, may also be regarded in some degree as organs of touch.

Organs of Digestion.—The digestive function in birds is necessarily extremely powerful and rapid in order to supply the waste occasioned by their extensive, frequent, and energetic motions, and in accordance with the rapidity of their circulation and their high state of irritability.*

The parts to be considered with reference to this function are the rostrum or beak, the tongue, the œsophagus, the stomach which is always divided into a glandular and muscular portion, the intestines, and the cloaca.

The glandular organs of the digestive system are the salivary glands, the proventricular follicles, the liver, pancreas, and spleen.

The *beak* consists of the maxillary and intermaxillary bones, which in place of teeth are provided with a sheath of horny fibrous material, exactly similar to that of which the claws are composed: this sheath is moulded to the shape of the osseous mandibles, being formed by a soft vascular substance covering these parts, and its margins are frequently provided with horny processes or laminæ secreted by distinct pulps, and analogous in this respect to the whalebone laminæ of the Whale: M. Geoffroy St. Hilaire has described a structure in the bill of birds which presents a closer approach to a dentary system. In a fœtus of a Perroquet nearly ready for hatching, he found that the margins of the bill were beset with tubercles arranged in a regular order and having all the exterior appearances of teeth: these tubercles were not, indeed, implanted in the jaw-bones, but formed part and parcel of the exterior sheath of the bill. Under each tubercle, however, there was a gelatinous pulp, analogous to the pulps which secrete teeth, but resting on the edge of the maxillary bones, and every pulp was supplied by vessels and nerves traversing a canal in the substance of the bone. These tubercles form the first margins of the mandibles, and their remains are indicated by canals in the horny sheath subsequently formed, which contain a softer material, and which commence from small foramina in the margin of the bone.

The different degrees of hardness and varieties of form of the beak exercise, Cuvier observes,† as much influence upon the nature of birds as the number and figure of the teeth do upon that of Mammals.

The beak is hardest in those birds which tear their prey, as in Eagles and Falcons; or in those which bruise hard seeds and fruits, as Parrots and Gros-beaks; or in those which pierce the bark of trees, as Woodpeckers, in the larger species of which the beak absolutely acquires the density of ivory.

The hardness of the covering of the beak gradually diminishes in those birds which take less solid nourishment, or which swallow their food entire; and it changes at last to a soft skin in those which feed on tender substances, or which have occasion to probe for their food in muddy or sandy soils, or at the bottom of the water, as Ducks, Snipes, Woodcocks, &c.

Cæteris paribus, a short beak must be stronger than a long one, a thick one than a thin one, a solid one than one which is flexible; but the

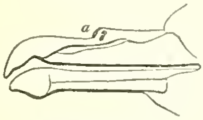
* The Cormorant readily devours six or eight pounds of fish daily.

† Anatomie Comparée, tom. ii. p. 192.

general form produces infinite variety in the application of the force.

A compressed beak with sharp edges and a hooked extremity characterizes both the Birds of Prey properly so called, which destroy the smaller quadrupeds and birds (*fig.* 112); and also the carnivorous species of a different order that live on fish, as the Petrels (*fig.* 142), Al-

Fig. 142.



Bill of the Petrel.

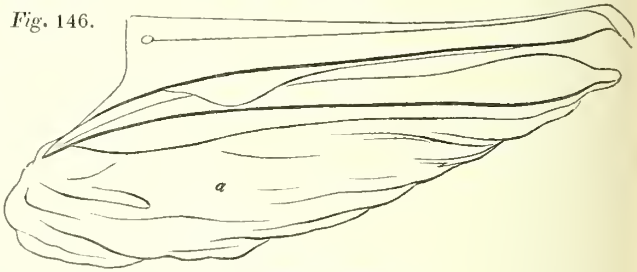
batrosses, Frigate-bird, and Tropic-bird. But in the *Raptores* it is comparatively shorter and stronger, and in some genera a tooth-like process on either side adds considerably to its destructive powers: hence the Falcons which possess this armature are reckoned the more 'noble' and courageous Birds of Prey.

The Insessorial Shrikes which have their bill similarly armed do not yield in courage to the Hawks, notwithstanding their small size, and the comparative feebleness of their wings and feet: (*fig.* 115.)

As the bill becomes narrower and straighter, it characterizes birds of a voracious habit, but less daring in their attacks on other birds, such as the Crows, Magpies, &c., (*fig.* 116); and the compressed knife-shaped bill is associated with similar habits in the Water-birds, as the Gulls, Grebes, Dabchicks, &c.

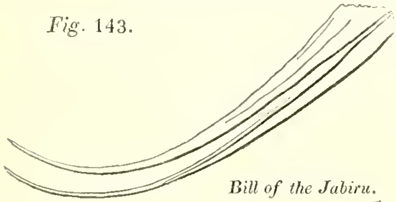
Another kind of strong and trenchant bill, which is more elongated and without a hook, serves to cut and break, but not to tear: this form of bill characterizes the Waders which frequent the water and prey upon animals that make resistance in that element, as reptiles, fishes, &c. In the Herons and Bitterns the bill is straight; in the Ibis it is curved downwards (*fig.* 123); in the Jabiru (*fig.* 143) it is curved in the contrary direction.

Fig. 146.



Bill of the Pelecan.

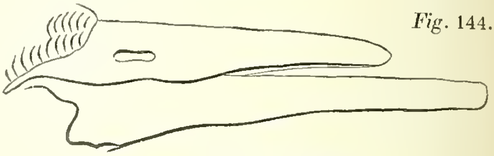
Fig. 143.



Bill of the Jabiru.

Some trenchant or sharp-edged bills are so compressed as to resemble the blade of a knife, and can only serve to seize small objects, which are immediately swallowed: such is the form of the beak in the Auks, Puffins, Coulterneb, (where it has the further peculiarity of being as deep as it is long), and the Skimmer (*Rhyncops*), in which the still more singular structure obtains of an inequality in the length of the two mandibles, the upper one being considerably the shortest; so that this bird can only get its food, which consists of floating marine animals, by pushing them before it as it skims along the surface of the water.

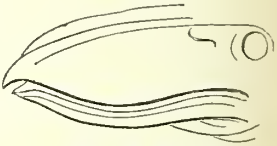
Fig. 144.



Bill of the Skimmer.

Lastly, there are trenchant bills which are depressed or flattened horizontally; they serve to seize fishes and reptiles, and other large objects; the Boat-bill (*Cancroma*) exhibits a bill of this kind (*fig.* 145), which is also serrated at the edges. Some species of Fly-catcher and Tody have this form of beak on a small scale.

Fig. 145.

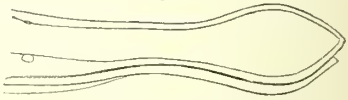


Bill of the Boat-bill.

Of the blunt-edged bills we may first notice those which are flattened horizontally. When a bill of this description is long and strong, as in the Pelecan (*fig.* 146), it serves to seize a large but feebly resisting prey, as fishes.

When it is long and weak, as in the Spoonbill, which derives its name from the dilated extremity of the mandibles, it is only available to seize amid sand, mud, or water, very small Crustaceans, Mollusks, &c. (*fig.* 147.)

Fig. 147.



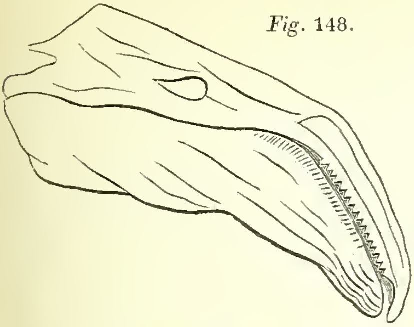
Bill of the Spoonbill.

The more or less flattened bills of Ducks, the more conical ones of Geese and Swans, and that of the Flamingo,* of which the extremities

* It is singular that it should ever have been supposed that the upper mandible was alone moveable, and the lower mandible perfectly immoveable, in the Flamingo, since precisely the contrary is the

of the mandibles are bent downwards abruptly (*fig.* 148), have all transverse horny laminæ

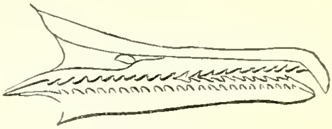
Fig. 148.



Bill of the Flamingo.

arranged along their edges, which, when the bird has seized any object in the water, serve, like the whalebone laminæ of the Whale, to give passage to the superfluous fluid. The aquatic habits of all these birds are in harmony with this structure. In the Goosanders (*Mergus*), which are nearly allied to the *Anatidæ*, the lateral laminæ are developed into small conical tooth-like processes, which serve to hold fast the fishes, which the Goosander destroys in great numbers.

Fig. 149.

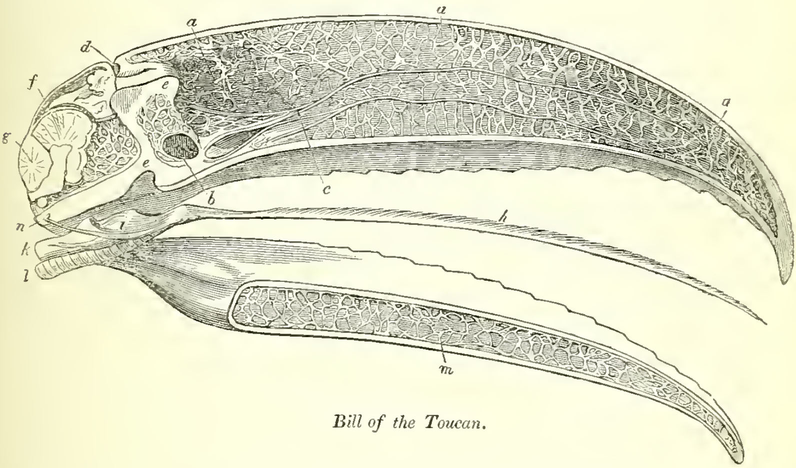


Bill of the Goosander.

The bills of the Toucans and Hornbills are remarkable for their enormous size, which is sometimes equal to that of the whole bird. The substance of the beak in these cases is extremely light and delicately cellular, without which the equilibrium necessary for flight would have been destroyed. The singularity of the structure of these bills demands a more particular consideration.

The osseous portions of the mandibles of the Toucan (*fig.* 150) are adapted to com-

Fig. 150.



Bill of the Toucan.

bine, with great bulk, a due degree of strength and remarkable lightness, and their structure is consequently of a most beautiful and delicate kind. The external parietes are extremely thin, especially in the upper beak: they are elastic, and yield in a slight degree to moderate pressure, but present considerable resistance if the force be increased for the purpose of crushing the beak. At the points of the mandibles the outer walls are nearly a line in thickness; at other parts in the upper beak they are much thinner, varying from one-thirtieth to one-fiftieth part of an inch, and in the lower beak are from one-twentieth to one-thirtieth of an inch in thickness.

On making a longitudinal section of the upper mandible (*a*, *fig.*150) in the *Rhamphastos Touco*, its base is seen to include a conical cavity about two inches in length and one inch in diameter, with the apex directed forwards. The walls of this cone consist of a most beautiful osseous net-work, intercepting irregular angular spaces, varying in diameter from half a line to two lines. From the parietes of the cone a net-work of bony fibres is continued to the outer parietes of the mandible, the fibres which immediately support the latter being almost invariably at right angles to the part in which they are inserted. The whole of the mandible anterior to the cone is occupied with a similar net-work, the meshes of which are largest in the centre of

case. In the specimen which we dissected (see Proceedings of the Zoological Society, Part ii. p. 141) the upper mandible was so firmly fixed to the cranium as only to be moved with that part, while the lower mandible was freely moveable when the head was fixed. The Flamingo is remarkable for applying the upper mandible to the soil, which it shovels backwards in searching for its food.

the beak, in consequence of the union which takes place between different small fibres as they pass from the circumference inwards. It is worthy of observation that the principle of the cylinder is introduced into this elaborate structure: the smallest of the supporting pillars of the mandibles are seen to be hollow or tubular when examined with the microscope. The structure is the same in the lower mandible (*m*, *fig*. 150), but the fibres composing the net-work are in general stronger than those of the upper mandible.

The medullary membrane lining these cavities appears to have but a small degree of vascularity. Processes of the membrane, accompanying vessels and nerves, decussate the conical cavity at the base of the beak. The air is admitted to the interior of the upper mandible from a cavity (*b*, *fig*. 150) situated anterior to the orbit, which communicates at its posterior part with the air-cell continued into the orbit, and at its anterior part with the maxillary cavity. The nasal cavity is closed at every part except at its external and internal apertures by the pituitary membrane, and has no communication with the interior of the mandible.*

The horny sheath of the mandibles in the Hornbills and Toucans is so thin that it often becomes irregularly notched at the edge from use. The Hornbills have, besides, upon their enormous beak, horn-like prominences of the same structure and of different forms, the use of which is not known.

The Trogons, Touracos, Buccos, &c. exhibit forms of the bill which are intermediate to that of the large but feeble bill of the Toucans, and the short, but hard, strong, and broad bill of the Parrot-tribe, which is also hooked, so as to assist in climbing, like a third foot: (*fig*. 128.)

The short, conical, and vaulted beak of the *Rasores* (*fig*. 121) serves to pick up with due rapidity the vegetable seeds and grains which constitute their food, as well as small insects, as ants, &c. with which the young are frequently nourished.

The bills of the small Insessorial or Passerine birds present every gradation of the conical form, from the broad-based cone of the Hawfinch to the almost filamentous cone of the Humming-birds (*fig*. 117, 125), and each of these forms influences the habits of the species in the same manner as in the larger birds. The short and strong-billed Insessores live on seeds and grains; those with a long and slender bill on insects or vegetable juices. If the slender bill be short, flat, and the gape very wide, as in Swallows, the bird takes the insects while on the wing (*fig*. 118); if the bill be elongated and endowed with sufficient strength, as in the Hoopoes, it serves to penetrate the soil and pick out worms, &c.

Of all bills, the most extraordinary is that of the Cross-bill, in which the extremities of the mandibles curve towards opposite sides and cross each other at a considerable angle—a disposition which at first sight seems directly opposed to the natural intention of a bill. With this singular disposition, the Cross-bill, however, possesses the power of bringing the points of the mandibles into contact with each other; and Mr. Yarrell, in his excellent paper on the Anatomy of the Beak of this bird, observes that, notwithstanding M. Buffon's assertion to the contrary, it can pick up the smallest seeds, and shell or husk hemp and similar seeds like other birds. He further shows that the disposition and power of the muscles is such that the bill gains by its very apparent defect the requisite power for breaking up the pine-cones that constitute its natural food. In a pair of Cross-bills which were kept for some time in captivity, one of their principal occupations, Mr. Yarrell observes, "was twisting out the ends of the wires of their prison, which they accomplished with equal ease and dexterity. A short flat-headed nail that confined some strong net-work was a favourite object upon which they tried their strength, and the male, who was usually pioneer in every new exploit, succeeded, by long-continued efforts, in drawing this nail out of the wood, though not without breaking off the point of his beak in the experiment. Their unceasing destruction of cages at length brought upon them sentence of banishment." He concludes his memoir by observing that "the remarks of Buffon on the beak of this bird, which he characterizes as 'an error and defect of nature, and a useless deformity,' exhibit, to say the least of them, an erroneous and hasty conclusion, unworthy of the spirit of the science he cultivated. During a series of observations on the habits and structure of British Birds, I have never met with a more interesting or beautiful example of the adaptation of means to an end than is to be found in the tongue, the beak, and its muscles, in the Cross-bill."*

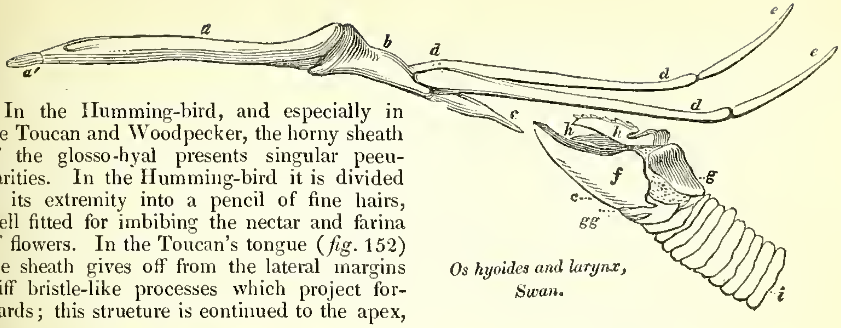
The *tongue*, as has been already observed, can hardly be considered as an organ of taste in Birds, since, like the mandibles, it is generally sheathed with horn. It is principally adapted to fulfil the offices of a prehensile organ in association with the beak, and it presents almost as many varieties of form. Ornithologists have not yet perhaps derived all the advantages which a study of the modifications of the tongue might afford in determining the natural affinities of birds.

The os hyoides very much resembles that of Reptiles. Its parts have been minutely studied by Geoffroy St. Hilaire, who has bestowed upon them separate names: (*a*, *fig*. 151) is the glosso-hyal, *b* the basi-hyal, *d d* the apo-hyals, *e e* the cerato-hyals, *c* the uro-hyal. The body, or basi-hyal element, is more thickened than the rest: in some birds it is cylindrical. The length of the tongue depends chiefly on that of the lingual process or glosso-hyal element. In most birds it is lengthened out by a cartilage *a'* appended to its extremity. This is remarkable in the Swan and other *Lamelli-rostres*.

* See Anatomical Appendix to Gould's Monograph on the *Ramphastidæ*, fol.

* Zool. Journal, vol. iv. p. 464.

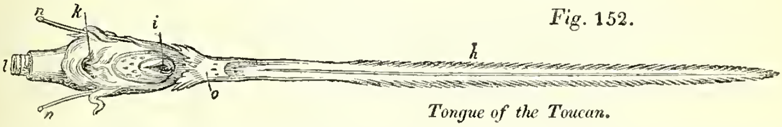
Fig. 151.



Os hyoides and larynx, Swan.

In the Humming-bird, and especially in the Toucan and Woodpecker, the horny sheath of the glosso-hyal presents singular peculiarities. In the Humming-bird it is divided at its extremity into a pencil of fine hairs, well fitted for imbibing the nectar and farina of flowers. In the Toucan's tongue (*fig.* 152) the sheath gives off from the lateral margins stiff bristle-like processes which project forwards; this structure is continued to the apex,

Fig. 152.

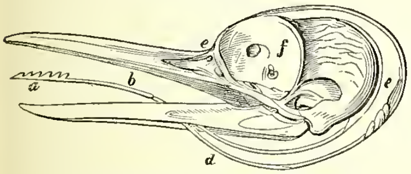


Tongue of the Toucan.

and the tongue so provided becomes an instrument for testing the softness and ripeness of fruit, and the fitness of other objects for food, thereby acting as a kind of antenna or feeler. A similar but less developed structure is found in the tongue of the frugivorous Touraco.

In the Woodpeckers the apex of the horny sheath (*a, fig.* 153, 154) gives off at the sides short-pointed processes directed backwards, which thus convert it into a barbed instrument, fitted for holding fast the insects which its sharp point has transfixed, after the strong beak has dislodged them from their hiding places. The cornua of the os hyoides in the Woodpecker extend backwards to the vertebral column, wind round the back of the head, and converge as they pass forwards to be inserted in a canal generally on the right side of the upper mandible (*d, e, fig.* 153, 154.)

Fig. 153.



Cranium and tongue of a Woodpecker.

One of the most remarkable structures which the tongue presents in this class is met with in the Flamingo, where it is remarkable both for its size, texture, and singular armature. The tongue is almost cylindrical, slightly flattened above, and obliquely truncate anteriorly, so as to correspond with the form of the inferior mandible. The pointed extremity of the truncated part is supported beneath by a small horny plate. Along the middle of the upper surface there is a moderately deep and wide longitudinal furrow; on either side of which there are from twenty to twenty-five recurved spines, from one to three lines in length. These spines are arranged in an irregular alternate series: the outer ones being the smallest, which may almost be considered as a distinct row. At the posterior part of the tongue there are two groups of smaller recumbent spines directed towards the glottis. The substance of the tongue is not muscular, but is chiefly composed of an abundant elastic cellular substance, permeated by an oily fat.

In the *Raptores* the tongue is of a moderate length,—broad, and somewhat thick, and has a slight division at the tip. In the Vultures its sides can be voluntarily approximated so as to form a canal, and its margins are provided with retroverted spines. In the Raven it is bifid at the apex.

In the Struthious birds, in many of the Waders, and in the *Pelecanidæ*, the tongue is remarkably short.

In the Parrots it is thick and fleshy, serves admirably to keep steady the nut or seed upon which the strength of the mandibles is exerted, and is applied to the kernel so extracted, as if to ascertain its sapid qualities.

The following are the muscles of the tongue in birds.

1st. The *Genio-hyoideus* of Vicq d'Azyr, or the *Mylo-hyoideus* according to Cuvier. This is a thin layer of fibres attached to the lower and inner border of the lower jaw, and running transversely to a mesial tendon which separates them, and extends to the uro-hyal. It raises the tongue towards the palate.

2d. The *Stylo-hyoideus* arises from the upper and back part of the lower jaw, and divides into three or more portions: the *posterior* descends obliquely forwards, and is inserted into the tendinous commissure of the preceding muscle; the *middle* portion is inserted into the 'uro-hyal:' the *anterior* fasciculus is inserted into the side of the basi-hyal above the transverse hyo-glossus. The actions of these different portions vary according to their insertion; the first and second depress the apex of the tongue by raising its posterior appendage, (uro-hyal,) the third raises the tongue and os hyoides, and draws it to one side when it acts singly.

3d. The *Genio-hyoideus* arises by two fleshy bands from the lower and internal edge of the lower jaw; these unite and surround the cerato-hyals or cornua of the os hyoides; and as they draw forward the os hyoides, protrude the tongue from the beak.

4th. The *Cerato-hyoideus* passes from the cerato-hyal to the uro-hyal, and is therefore subservient to the lateral movements of the tongue.

5th. The *Sterno-hyoidei* are replaced by a slip of muscle which extends from the anterior surface of the upper larynx to be attached to the base of the glosso-hyal.

6th. A small and short muscle is single or azygos; it passes from the basi-hyal to the under part of the glosso-hyal; it depresses the tip of the tongue and elevates its base.

7th. A short muscle which arises from the junction of the basi-hyal with the cerato- and uro-hyals, and is inserted into the upper and outer angle of the base of the glosso-hyal.

All these muscles are remarkably large in the Woodpecker, in which there is a singular pair of muscles that may be termed *Cerato-tracheales*, (*h*, *fig.* 154.) They arise from the trachea about eight lines from the upper larynx, twist four times spirally round the trachea, and then pass forward to be inserted into the base of the cerato-hyals. This is the principal retractor of the singular tongue in this species.

Salivary glands.—The salivary organs, being in general developed in a degree corresponding to the extent of the changes which the food undergoes in the mouth, and the length of time during which it is there detained, are by no means so conspicuous a part of the digestive system in Birds as in Mammals. Glands which pour out their secretion upon the food prior to deglutition are, however, met with in every bird, but vary in number, position, and complexity of structure.

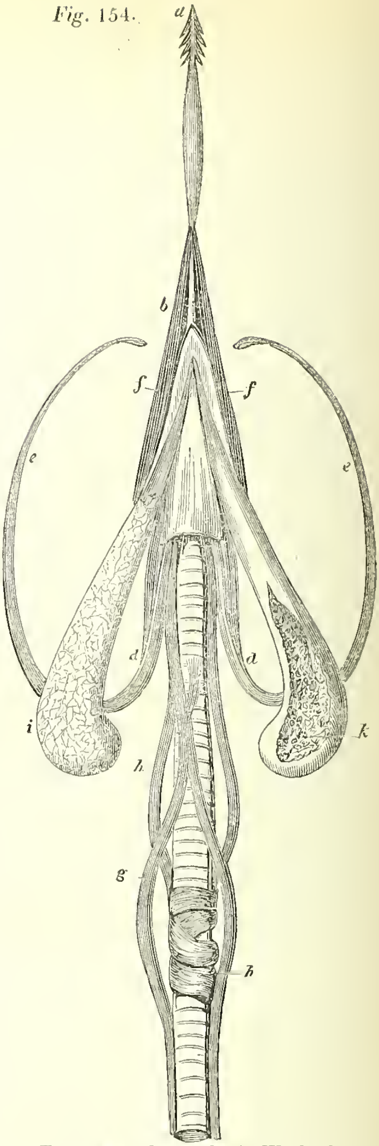
In some species, as the Crow, they are of the simplest structure, consisting of a series of unbranched, cone-shaped follicles or tubules, opening separately upon the mucous membrane of the mouth, along the sides of which cavity they are situated. They pour out a viscid mucus, and are the only traces of a salivary system met with in this bird.

In many other birds, and especially in the Scratching, Wading, and Swimming Orders, glands of the conglomerate structure are found beneath the lower jaw, analogous to the submaxillary glands of quadrupeds.

In the Goose they occupy the whole of the anterior part of the space included by the rami of the lower jaw, being of an elongated form, flattened and closely united together at the middle line. On either side of this line the mucous membrane of the mouth presents internally a series of pores, each of which is the terminal orifice of a distinct gland or aggregate of ramified ducts.

A third and higher form of salivary gland, in which the secretion of the conglomerate mass is conveyed into the mouth by a single duct, is found in the Woodpeckers and some species of the Rapacious Order. In the latter birds these glands are termed, from their situation, *anterior palatine*: in the *Picæ* they correspond to the parotid and sublingual of Quadrupeds.

Fig. 154.



Tongue and salivary glands, Woodpecker.

The sublingual glands of the Woodpecker are of extraordinary size, extending from the angle to the symphysis of the lower jaw. The single ducts of each gland unite just before their termination, which is a simple orifice at the apex of the mouth. The structure of these glands is shown at *i*, *k*, *fig.* 154.

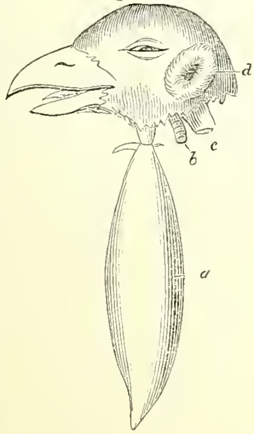
Besides the preceding, which may be considered as the true salivary glands, there are numerous accessory follicles in different parts of the oral apparatus of birds. In the Water-hen (*Gallinula chloropus*) there is a series of cœcal glandular tubes along each side of the tongue; and it is interesting to note that glandular follicles are found abundantly developed on the tongues of the Chelonian and Saurian reptiles. Similar elongated follicles are situated along the margin of the lower jaw, resembling in their parallel pectinated disposition the branchiæ of Fishes. In the Goose the corresponding follicles are longer and wider, and are situated near the sides of the tongue. In the Raven these mucous follicles are narrower but longer.

The food, after being embued with the secretion of the preceding glands, is poised upon the tongue and swallowed partly by means of the pressure of the tongue against the palate, partly by a sudden upward jerk of the head. The posterior apertures of the nostrils being generally in the form of narrow fissures are undefended by a soft palate or uvula; and the laryngeal aperture, which is of a similar form, is in like manner unprovided with an epiglottis, but is defended by the retroverted papillæ at the base of the tongue. In many birds, indeed, as the Albatross and Coot, there is a small cartilage in the usual place of an epiglottis, but insufficient to cover more than a very small part of the laryngeal aperture. Nitzsch has devoted a treatise to these rudimentary epiglottides in Birds.*

With respect to the fauces the remarkable instance of a dilatation of these parts in the Pelecan must not be forgotten. The extensibility of the membrane between the rami of the lower jaw admits of its formation into a bag (*a*, *fig.* 146), which is calculated to contain ten quarts of water, and serves as a receptacle for fishes, making in that state a conspicuous appendage to the huge bill; when empty it can be contracted so as to be hardly visible. By means of this mechanism a quantity of food can be transported to the young; and, as in disgorging the bleeding fishes the parent presses the bottom of the sac against her breast, this action has probably given rise to the fable of her wounding herself to nourish the young with her own blood.

A remarkable provision of an analogous nature is met with in the Bustard as a sexual peculiarity (*fig.* 155). In the male there is a membranous sac extending for some way down the anterior part of the neck capable of holding several quarts of water; it communicates with the mouth by an aperture beneath the tongue. It is not found except in the mature bird. It is supposed to serve the purpose of providing the female and young during the breeding season with water, and hence may not be developed to its full extent except at that period.

Fig. 155.



Faucial bag of the Bustard.

* See Meckel's Archiven, 1826, p. 613.

The Swift presents an analogous dilatation of the membrane of the fauces at the base of the lower jaw and upper part of the throat: it is most developed at the period of rearing the young, when it is generally found distended with insects in the old birds that are shot while on the wing. This receptacle is of a rounded form, and communicates with the fauces by a wider opening than that of the Bustard; it is also proportionally of less extent. A similar structure obtains in the Rook and probably in other Insectivorous birds.

The œsophagus (*H*, *fig.* 171: *a*, *fig.* 156, 158), like the neck, is usually very long in birds: as it passes down, it generally inclines towards the right side; it is partially covered by the trachea (*G*, *fig.* 171), and connected to the surrounding parts by a loose cellular tissue. It is wide and dilatable, corresponding to the imperfection of the oral instruments as comminutors of the food. In the rapacious and especially in the piscivorous birds it is of great capacity, enabling the latter to swallow the fishes entire, and serving also in many Waders and Swimmers as a temporary repository of food.

When the Cormorant has by accident swallowed a large fish, which sticks in the gullet, it has the power of inflating that part to its utmost, and while in that state the head and neck are shaken violently, in order to promote its passage. In the Gannet the œsophagus is extremely capacious, and, as the skin which covers it is equally dilatable, five or six herrings may be contained therein. In both these species it forms one continued canal with the stomach.

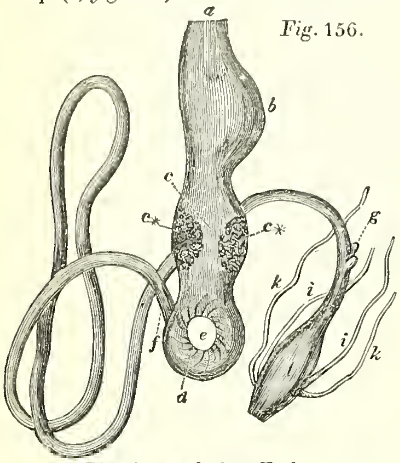
In the Flamingo, on the contrary, the diameter of the gullet does not exceed half an inch, being suited to the smallness of the objects which constitute the food of this species.

Besides deglutition the œsophagus is frequently concerned in regurgitation; and in the Birds in which this phenomenon occurs, the muscular coat of the gullet is well developed, as in the Ruminant Mammalia. The *Raptores*, for example, habitually regurgitate the bones, feathers, and other indigestible parts of their prey, which, in the language of the falconer, are called 'castings.' A Toucan, which was preserved some years alive in this country, was frequently observed to regurgitate partially digested food, and after submitting it to a rude kind of mastication by its enormous beak, again to swallow it.

The œsophagus possesses an external cellular covering, a muscular coat, an internal vascular tunic, and a cuticular lining. The muscular coat consists of two layers of fibres; in the external stratum they are transverse (*a*, *fig.* 159), in the internal longitudinal (*b*, *fig.* 159); the reverse of the arrangement observed in the human subject.

Ingluvies.—In those birds which are omnivorous, as the Toucans and Horn-bills, in the frugivorous and insectivorous birds, and in most of the *Grallatores*, which find their food in tolerable abundance, and take it in small quantities without any considerable inter-mission, it passes at once to the stomach to be there successively digested, and the gullet presents no partial dilatations to serve as a temporary reservoir or macerating receptacle. But in the larger Raptorial Birds, as the Eagles and Vultures, which gorge themselves at uncertain intervals from the carcasses of bulky prey, the œsophagus does not preserve a uniform width, but undergoes a lateral dilatation anterior to the furculum at the lower part of the neck. This pouch is termed the *ingluvies* or crop (*b*, *fig*. 156).

Fig. 156.

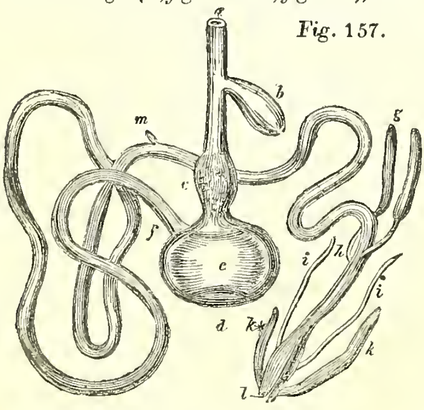


Digestive canal of an Eagle.

In those birds, again, the food of which is exclusively of the vegetable kind, as grains and seeds, and of which consequently a great quantity must be taken to produce the adequate supply of nutriment, and where the cavity of the gizzard is very much diminished by the enormous thickness of its muscular coat, the crop is more developed, and takes a more important share in the digestive process. Instead of a gradual cylindrical lateral dilatation of the gullet, it assumes the form of a globular or oval receptacle appended to that tube, and rests upon the elastic fascia which connects the clavicles or two branches of the furculum together.

In the common Fowl the crop is of large size and single (*b*, *fig*. 157 : *I*, *fig*. 171), but in the Pigeon it is double, consisting of two lateral oval cavities (*b c*, *fig*. 158).

Fig. 157.



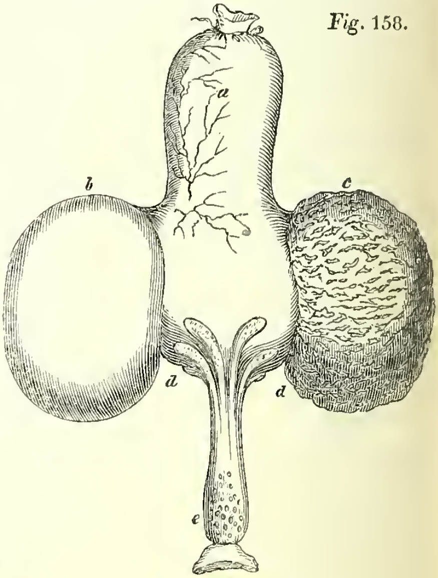
The dilatation of the œsophagus to form the crop is more gradual in the Ducks than in the Gallinaceous birds. The crop is wanting in the Swans and Geese.

The disposition of the muscular fibres of the crop is the same as in the œsophagus, but the muciparous follicles of the lining membrane are larger and more numerous. This difference is most conspicuous in the ingluvies of the granivorous birds, where it is not merely a temporary reservoir, but in which the food is mixed with the abundant secretion of the glands, and becomes softened and macerated, and prepared for the triturating action of the gizzard and the solvent power of the gastric secretion.

The change which the food undergoes in the crop is well known to bird-fanciers. If a Pigeon be allowed to swallow a great quantity of peas, they will swell to such an extent as almost to suffocate it.

The time during which the food remains in the crop depends upon its nature. In a common Fowl animal food will be detained about eight hours, while half the quantity of vegetable substances will remain from sixteen to twenty hours, which is one among many proofs of the greater facility with which animal substances are digested. Mr. Hunter made many interesting observations on the crop of Pigeons, which takes on a secreting function during the breeding season, for the purpose of supplying the young pigeons in the callow state with a diet suitable to their tender condition.* An abundant secretion of a milky fluid of an ash-grey colour, which coagulates with acids and forms curd, is poured out into the crop and mixed with

Fig. 158.



Crop of a Pigeon.

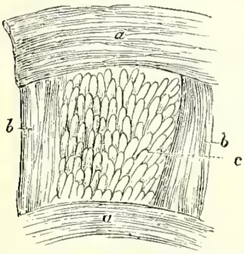
* Animal Economy, p. 235.

the macerating grains. This phenomenon is the nearest approach in the class of Birds to the great characteristic function, the presence of whose special apparatus, the mammæ, has afforded the universally recognized title of the higher division of warm-blooded Vertebrata; and the analogy of the 'Pigeon's milk' to the lacteal secretion of the mammalia has not escaped popular notice. In the subjoined figure one side of the crop (*b*), shows the ordinary structure of the parts, the other (*e*), the state of the cavity during the period of rearing the young (*fig.* 158).

The canal which is continued from the ingluvies to the stomach was called by Hunter the second or lower œsophagus; at its commencement it is narrower and more vascular than that part of the gullet which precedes the crop, but gradually dilates into the first or glandular division of the stomach, which is termed the 'proventriculus' (*ventriculus succenturiatus, bulbus glandulosus, echinus, infundibulum*, the 'cardiac cavity' of Home), (*c, fig.* 156, 157, 166).

In birds with a wide œsophagus (*a, fig.* 165), as the omnivorous and piscivorous tribes, the commencement of the proventriculus (*e, fig.* 165), is not indicated by any change in the direction or diameter of the tube, but only by its greater vascularity, by the difference in the structure of the lining membrane, and by the stratum of glands which open upon its inner surface, and which are its essential characteristic (*c. fig.* 159). Hence it is by some comparative anatomists regarded as a part of the œsophagus.

Fig. 159.



Part of the proventriculus of a Swan dissected.

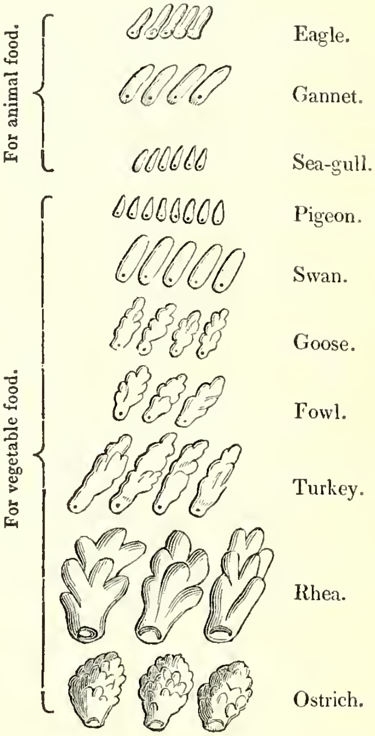
The proventriculus varies, however, in form and magnitude in different birds. In the *Rasores* it is larger than the œsophagus, but much smaller than the gizzard. In the *Psittacidæ* and *Ardeidæ* (Parrot and Stork tribe) it is larger than the gizzard and of a different form. In the Ostrich the proventriculus is four or five times larger than the triturating division of the stomach, being continued down below the liver, and then bent up upon itself towards the right side before it terminates in the gizzard, which is placed on the right and anterior part of this dilatation.

The experiments of Reaumur, Spallanzani, and Hunter, and those of Tiedemann and Gmelin, prove that the secretion of the proventricular or gastric glands is analogous to the gastric juice in man and mammalia.

In the majority of birds the gastric follicles are simple, having no internal cells, dilated fundus, or contracted neck; but from their external blind extremity proceed with an uniform diameter to their internal orifice. This form obtains in the zoophagous and omnivorous birds. In the Dove-tribe the follicles are of a conical shape. In the Swan they are tubuliform; in the Goose and Turkey they present internal loculi; in the Ostrich and Rhea these loculi are so developed that each gland forms a racemose group of follicles, terminating by a common aperture in the proventriculus.

The subjoined figures from Home's Comparative Anatomy (vol. ii. pl. lvi.) show the different forms of the solvent or proventricular glands in different birds.

Fig. 160.



The gastric glands are variously arranged. Among the *Raptores*, we find them in the Golden Eagle disposed in the form of a broad compact belt; in the Sparrow-Hawk this belt is slightly divided into four distinct portions.

In the *Insessores* the glands are generally arranged in a continuous zone around the proventriculus; but in some of the *Syndactyli*, as the Hornbill, the circle is composed of the blending together of two large oval groups.

Among the *Scansores* the Parrots have the gastric glands disposed in a continuous white circle, which is at some distance from the small gizzard. In the Woodpeckers the glands are arranged in a triangular form, with the apex towards the gizzard. In the Toucan they are dispersed over the whole proventriculus, but are more closely aggregated near the gizzard; the lining membrane of the cavity is reticulate, and the orifices of the glands are in the interspaces of the meshes.

Among the *Rasores* the Pigeon shows its affinity to the Passerine Birds in having the gastric glands of a simple structure, and arranged in a zonular form: they are chiefly remarkable for their large cavity and wide orifice. In the Common Fowl and Turkey the glands are more complex, and form a complete circle.

In the *Cursores* the arrangement of the glands is different in almost every *genus*.

In the Ostrich they are of an extremely complicated structure, and are extended in unusual numbers over an oval space on the left side of the proventriculus, which reaches from the top to the bottom of the cavity, and is about four inches broad.

The Rhea differs from the other Struthious birds in having the solvent glands aggregated into a single circular patch, which occupies the posterior side of the proventricular cavity.

In the Emeu the gastric glands are scattered over the whole inner surface of the proventriculus, and are of large size; they terminate towards the gizzard in two oblique lines.

In the Cassowary the glands are dispersed over the proventriculus with a similar degree of uniformity; but they are smaller, and their lower boundary is transverse.

Among the *Grallatores*, the Marabou, or Gigantic Crane, (*Ciconia Argala* and *Marabou*,) has the nearest affinity to the Rhea in the structure and disposition of the gastric glands; they are each composed of an aggregate of five or six follicles, terminating in the proventriculus by a common aperture; and they are disposed in two compact oval masses, one on the anterior, the other on the posterior surface of the cavity. In the Heron (*Ardea cineria*) the solvent glands are of more simple structure, and are more dispersed over the proventriculus; but still they are most numerous on the anterior and posterior surfaces. In the Flamingo the gastric glands are short and simple follicles, arranged in two large oval groups, which blend together at their edges.

The *Natatores* present considerable differences among themselves in the disposition of the solvent glands. In the Cormorant (*Phalacrocorax carbo*) they are arranged in two circular spots, the one anterior and the other posterior; while in the closely allied genus the *Sula*, or Gannet, they form a complete belt of great width, and consequently are extremely numerous. In this respect the Gannet, or Solan Goose, has a nearer affinity to the Pelecan, with which both birds were generically associated by Linnæus.

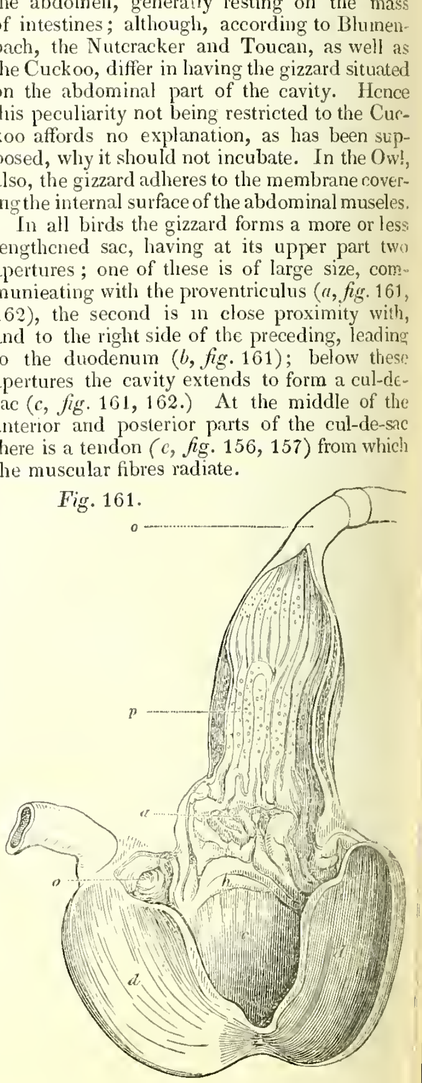
In the Sea-Gulls the gastric glands form a continuous zone; and in the Little Auk (*Alca Alle*) they are spread, according to Sir Everard Home, over a greater proportional extent of surface than in any other bird that lives on animal food, and the form of the digestive organs is peculiar to itself. The cardiac cavity or proventriculus appears to be a direct continuation of the œsophagus, distinguished from it by the termination of the cuticular lining and the appearance of the solvent glands. The cavity is continued down with very gradual enlargement below the liver, and is then bent up to the right side, and terminates in the gizzard. The solvent glands are situated at the anterior or upper part of the cavity every where surrounding it, but lower down they lie principally upon the posterior surface, and where it is bent upwards towards the right side they are entirely wanting. In the graminivorous lamellirostral Water-birds, as the Swan, Goose, &c. the gastric glands have a simple elongated exterior form, but have an irregular or cellular internal surface: they are closely arranged so as to form a complete zone.

In general the muscular or pyloric division of the stomach immediately succeeds the glandular or cardiac division; but in some Birds, as the Auk and Parrots, there is an intervening portion without glands. It is always widely different in structure, and hence has received a distinct name, the 'gizzard' (*gigerium*, *ventriculus bulbosus*).

The *gizzard* is situated below or *sacrad* of the liver, on the left side and dorsal aspect of the abdomen, generally resting on the mass of intestines; although, according to Blumenbach, the Nutcracker and Toucan, as well as the Cuckoo, differ in having the gizzard situated on the abdominal part of the cavity. Hence this peculiarity not being restricted to the Cuckoo affords no explanation, as has been supposed, why it should not incubate. In the Owl, also, the gizzard adheres to the membrane covering the internal surface of the abdominal muscles.

In all birds the gizzard forms a more or less lengthened sac, having at its upper part two apertures; one of these is of large size, communicating with the proventriculus (*a*, *fig.* 161, 162), the second is in close proximity with, and to the right side of the preceding, leading to the duodenum (*b*, *fig.* 161); below these apertures the cavity extends to form a cul-de-sac (*c*, *fig.* 161, 162.) At the middle of the anterior and posterior parts of the cul-de-sac there is a tendon (*c*, *fig.* 156, 157) from which the muscular fibres radiate.

Fig. 161.



Gizzard of a Swan.

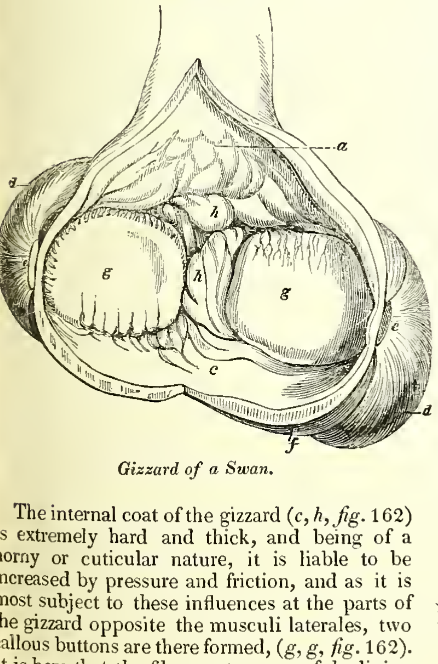
The differences in the structure of the gizzard resolve themselves into the greater or less extent of the tendons, and the greater or less thickness of the muscular coat, and of the lining membrane.

In the *Raptores* the gizzard (*d, fig.* 156) assumes the form of a mere membranous cavity, in accordance with the animal and easily digestible nature of their food. The muscular coat is extremely thin; the fibres principally radiate from small tendons (*e, fig.* 156), and there are some longitudinal fibres beneath the radiating or external layer.

In the *Rasores* and lamellirostral *Natatores* it exhibits the structure to which the term gizzard can be more appropriately applied. The muscular fibres are distinguished by their unparalleled density of texture and deep colour, and are arranged in four masses; two are of a hemispherical form, and their closely-packed fibres run transversely to be connected to very strong anterior and posterior tendons (*e, fig.* 157, 162); they constitute the sides of the gizzard, and are termed the digastric muscles or 'musculi laterales' (*d, fig.* 161, 162): between these, at the end of the gizzard, are the two smaller and thinner muscles called 'musculi intermedii' (*f, fig.* 162). There are likewise irregular bands placed about the circumference of the gizzard.

Fig. 161 shows the relative thickness of the musculi laterales in the gizzard of a Swan, and *fig.* 162 that of the musculi intermedii and tendon.

Fig. 162.



Gizzard of a Swan.

The internal coat of the gizzard (*c, h, fig.* 162) is extremely hard and thick, and being of a horny or cuticular nature, it is liable to be increased by pressure and friction, and as it is most subject to these influences at the parts of the gizzard opposite the musculi laterales, two callous buttons are there formed, (*g, g, fig.* 162). It is here that the fibrous structure of the lining membrane can be most plainly seen:—and it is worthy of observation that the fibres are not perpendicular to the plane of the muscles but oblique, and in opposite directions, on the two sides. Elsewhere the cuticular lining is disposed in ridges and prominences (*h, fig.* 161, 162), which vary in different birds, but are pretty constant in the same species. Carus* has recently figured the gizzard of a Petrel (*Procellaria glacialis*), the lining membrane of which is disposed in a pavement of small square tubercles, like the gastric teeth of some Mollusca.

The cavity of the gizzard is so encroached upon by the grinding apparatus, that it is necessarily very small, the two horny callosities having their internal flat surfaces opposed to one another, like 'millstones.' A crop is as essential an appendage to this structure as the 'hopper' to the mill; it receives the food as it is swallowed, and supplies it the gizzard in small successive quantities as it is wanted.†

Between the stomach of the carnivorous Eagle, and that of the graminivorous Swan, there are numerous intermediate structures, but it is necessary to observe that the animal or vegetable nature of the food cannot always be predicated of from the different degrees of strength in the gizzard. Hard-coated coleopterous insects, for example, require thicker parietes for their due comminution than pulpy succulent fruits.

In the subgenus *Euphones*, among the Tanagers, the muscular or pyloric division of the stomach is remarkably small and not separated from the duodenum by a narrow pylorus.‡

The parietes of the gizzard, like those of other muscular cavities, become thickened when stimulated to contract on their contents with greater force than usual. In the Hunterian collection this fact is well illustrated by preparations of the gizzard of the Sea-gull in the natural state, and that of another Sea-gull which had been brought to feed on barley. The digastric muscles in the latter are more than double the thickness of those in the Sea-gull which had lived on fish.§

The immediate agents in triturating the food are hard foreign bodies, as sand, gravel, or pebbles. The well-known habit in the granivorous birds of swallowing stones with their food has been very differently explained. Blumenbach observes that 'Cæsalpinus considered it rather as a medicine than as a common assistance to digestion; Boerhaave, as an absorbent for the acid of the stomach; Redi, as a substitute for teeth; Whytt, as a mechanical irritation, adapted to the callous and insensible nature of the coats of the stomach.' Spallanzani rejected all supposition of design or object, and hazarded the stupid observation that the stones were swallowed from mere stupidity.

* Tabulæ Anatomiam Comparativam illustrantes, fol. pars iv. 1835.

† Thus we find in Parrots, where the gizzard is remarkably small, that a crop is present. A like receptacle exists also in the Flamingo, in which the gizzard is small but strong.

‡ Carus ut supra, tab. vi. fig. iv.

§ See Home, Comp. Anatomy, vol. i. p. 271, and Hunter, Animal Œconomy, p. 221, where it is related that a similar change was effected by changing the food of a tame Kite.

Pigeons, however, are known to carry gravel to their young. Gallinaceous birds grow lean if deprived of pebbles; and no wonder, since experiment* shows that unless the grains of corn are bruised, and deprived of their vitality, the gastric juice will not act upon or dissolve them. The observations and experiments of Hunter have completely established the rationality and truth of Redi's opinion, that the pebbles perform the vicarious office of teeth.

Hunter inferred from the form of hair-balls occasionally found in the stomach of Cuckoos,† that the action of the great lateral muscles of the gizzard was rotatory. Harvey appears to have first investigated, by means of the ear, as it were in anticipation of the art of auscultation, the actions which are going on in the interior of an animal body, in reference to the motions of the gizzard. He observes, (*De Generatione Animalium, in Opera Omnia*, 4to. p. 208,) "Falconibus, aquilis, aliisque avibus ex preda viventibus, si aurem prope admoveris dum ventriculus jejunus est, manifestos intus strepitus, lapillorum illuc ingestorum, invicemque collisorum percipias." And Hunter observes, (*Animal Œconomy*, p. 198,) "the extent of motion in grindstones need not be the tenth of an inch, if their motion is alternate and in contrary directions. But although the motion of the gizzard is hardly visible, yet we may be made very sensible of its action by putting the ear to the sides of a fowl while it is grinding its food, when the stones can be heard moving upon one another."

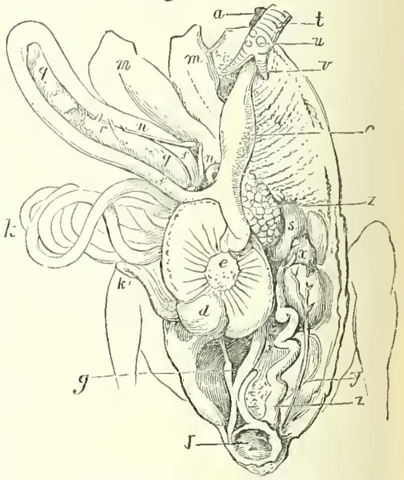
Tiedemann believes that the muscles of the gizzard are in some degree voluntary, having observed that when he placed his hand opposite the gizzard, its motions suddenly stopped.

The pyloric orifice of the gizzard is guarded by a valve in many birds, especially in those which swallow the largest stones. This valve in the Ostrich is formed by a rising of the cuticle divided into six or seven ridges, which close the pylorus like a grating, and allow only stones of small size to pass through. In the *Touraco* the pylorus projects into the duodenum in a tubular form. There is a double valve at the pyloric orifice in the Gannet, and a single large valvular ridge at the same part in the Gigantic Crane. In this species and some other Waders, as the Heron and Bittern; also in the Pelecan, and, according to Cuvier, in the Penguin and Grebe, there is a small but distinct cavity interposed between the gizzard and intestine. An analogous structure is found in the Crocodile.

The *intestines* reach from the stomach to the cloaca; in relative length they are much shorter than in the mammalia. In the Toucan, for example, the whole intestinal canal scarcely equals twice the length of the body, including the bill. The canal is divided into small and large intestines, sometimes by an internal valve, sometimes by the insertion of a single cæcum, but most generally by those of two cæca, which are always opposite to one another. In a few instances there is no such distinction. The small intestines and cæca are longest in the vegetable feeders. The large intestine is, with one or two exceptions, very short and straight in all birds.

The course of the small intestine varies somewhat in the different orders of Birds; it is always characterized by the elongated fold or loop made by the duodenum, (*f f*, *fig.* 163,)

Fig. 163.



Abdominal viscera of a Pigeon.

which fold receives the pancreas (*q q*) in its concavity.

In the *Raptores* the intestines are generally disposed as follows:—

The duodenum forms a long and broad fold, the lower part of which is commonly bent or doubled upon itself: the intestine then passes backwards on the right side of the abdomen, crosses to the left, and is disposed in deep folds upon the edge of a scolloped mesentery; towards its termination the ileum passes up behind the stomach and adheres to it, having here but a narrow mesentery; then passing down the posterior part of the abdomen the ileum makes another loose fold and ends in the rectum, which is continued straight to the cloaca.* In the Owls the last fold of the ileum is nearly as long as the duodenal fold, and the cæca adhere to each side of the fold.

In the *Diurnal Raptores* the intestinal canal

* Grains of barley, inclosed in strong perforated tubes, pass through the alimentary canal unchanged. Dead meat, similarly introduced into the gizzard, is dissolved.

† The hairs of caterpillars devoured by this bird are sometimes pressed or stuck into the horny lining of the gizzard, instead of being collected into a loose ball. They are then neatly pressed down in a regular spiral direction, like the nap of a hat, and have often been mistaken for the natural structure of the gizzard. One of these specimens exhibited as such to the Zoological Society was sent to me for examination, when, upon placing some of the supposed gastric hairs under the microscope, they exhibited the peculiar complex structure of the hairs of the larva of the Tiger-moth *(Arctia Caja)*, and the broken surface of the extremity which was stuck into the cuticular lining was plainly discernible. See *Proceedings of Zool. Soc.* 1834, p. 9.

* In *fig.* 156 the intestines are not represented according to their natural arrangement.

is only twice the length of the body, except in the fish-eating Osprey, in which the intestines are very narrow, and are to the length of the bird itself as eight to one.

In the *Insessores* the scolloped folds of the small intestine are narrower and longer than in the *Raptores,* and the ileum generally adheres to the duodenal mesentery and pancreas instead of to the stomach, prior to passing down to form its last fold and to terminate in the rectum. In the Raven the small intestines are disposed at their commencement in concentric folds.

Among the *Scansores* the Cuckoo presents the following disposition of the intestinal canal: after the usual long and narrow duodenal fold, the ileum* makes a fold which is widened at the end, it then forms a close fold upon itself, at the termination of which the rectum commences. In the Maccaw the course of the small intestine is somewhat peculiar: after forming the duodenal fold, it is disposed in three distinct packets of folds: the intestine, after forming the first two, passes alternately from one to the other, describing shorter folds upon each; it then forms the third distinct fold, which is a long one, at the termination of which the ileum adheres closely to the right side of the gizzard, and then passes backwards and dilates into the rectum.

In the *Rasores* the Dove-tribe have the small intestines disposed in three principal folds; the first is the duodenal fold *(f f, fig.* 163); the second is a long and narrow fold, coiled and doubled upon itself, with the turns closely connected together, *(k, fig.* 163); the third is also a long fold, which is bent or twisted, *(k', fig.* 163.) In the common Fowl the duodenum is disposed in a long simple loop; the ileum passes towards the left, and is disposed in loose folds on the right and lower edge of the mesentery; the ileum before its termination passes up behind the preceding folds, and is accompanied as far as the root of the mesentery by the two cœca, which there open into the commencement of the large intestine.

The Ostrich presents the most complicated course of the intestinal canal in the whole class of birds. The duodenal fold is about a foot in length, and the returning part makes a bend upon itself before it reaches the pylorus; the intestine then turns down again behind the duodenal folds and gradually acquires a wider mesentery. The ileum after a few folds ascends towards the left side, accompanied by the two long cœca, and becomes again connected with the posterior part of the duodenal mesentery; beyond which the cœca enter the intestine behind the root of the mesentery, and the large intestine commences. This part differs from the rectum in other birds in its great extent, being nearly double the length of the small intestines, and being disposed in folds upon a wide mesentery. It terminates by an oblique valvular aperture in a large urinary receptacle. In the Bustard the rectum is a foot in length, which is the nearest approach to the Ostrich which the rest of the class make in this respect.

The small intestines in the *Grallatores* are characterized by their small diameter and long and narrow folds; these are sometimes extended parallel to one another, as in the Crane and Coot; or folded concentrically in a mass, as in the Curlew and Flamingo. In the latter species the duodenal fold is four inches in length; then the small intestines are disposed in twenty-one elliptical spiral convolutions, eleven descending towards the rectum and ten returning towards the gizzard in the interspaces of the former.

Many of the *Natatores* present a concentric disposition of the folds of the small intestines similar to the Flamingo. Home* has given figures of this structure in the intestines of the Sea-mew *(pl.* cviii.); the Gannet or Solan Goose *(pl.* cvi.); and the Goose *(pl.* cxi.). It likewise obtains in the Pelecan and Cormorant.

The arrangement of the muscular fibres of the intestine is the same as in the œsophagus, the external layer being transverse, the internal longitudinal.

The villi of the lining membrane manifest an analogy with the covering of the outer skin, being generally much elongated, so as to present a downy appearance when viewed under water. There are, however, great varieties in the shape and length of the villi. In the Emeu they consist of small lamellæ of the lining membrane folded like the frill of a shirt. In the Ostrich the lamellæ are thin, long, and numerous. In the Flamingo they are short and arranged in parallel longitudinal zig-zag lines.

In many birds a small diverticulum is observed in the small intestine, which indicates the place of attachment of the pedicle of the yolk-bag in the embryo (*m, fig.* 157). We have found this process half an inch in length in the Gallinule, and situated seventeen inches from the pylorus. In the Bay Ibis *(Ibis falcinella)* the vitelline cœcum is an inch in length.

The birds in which the *cœca coli* have been found wanting are comparatively few, though such examples occur in all the orders. These exceptions are most frequent among the *Scansores,* in which the cœca are absent in the Wrynecks, the Toucans, the Touracos, the Parrot tribe, and according to Cuvier in the Woodpeckers.† In the *Insessores* the cœca are deficient in the Hornbill and the Lark. Among the *Grallatores,* we have found them wanting in a Spoonbill. In the *Natatores* they are absent in the Cormorant. The Herons, Bitterns, and, occasionally, the Grebes afford the rare examples of a single cœcum, which is also remarkably short.

In the *Raptores* the diurnal and nocturnal tribes differ remarkably in the length of the cœca. They are each less than half an inch in length in the Eagles and Vultures, but are occasionally wanting in the latter. Cuvier states

* There is seldom any part of the small intestine empty so as to merit the name of *jejunum.*

* Comparative Anatomy, vol. ii.

† In the Poppinjay *(Picus viridis,* Linn.) we have found two small cœca, so closely adhering to the intestine as easily to be overlooked.

that the cœca are deficient in the greater part of the Diurnal Raptores, but we have observed them in the *Haliætus Albicilla*, *Aquila Chrysaetos*, *Astur palumbarius*, and *Buteo nisus*. They seldom exceed the length above-mentioned (*g, fig.* 156), and in the Secretary Vulture they form mere tubercles. In the Barn Owl the cœca severally measure nearly two inches in length, and are dilated at their blind extremities; they are proportionally developed in the larger *Strigidæ*.

In the *Insessores* they are invariably very short where present. Among the *Scansorial Genera* which possess the cœca, these parts are found to vary in length, measuring in the Cuckoo and Wattle-bird (*Glaucopis*), each half an inch; while in the *Scythrops*, or New-Holland Toucan, the cœca are each two inches long, and moderately wide.

In the *Rasores* the cœca present considerable varieties. In the Pigeons (*g, fig.* 163) they are as short as in the Insessorial order, and are sometimes wanting altogether, as in the Crown-pigeon. In the Guan (*Penelope cristata*) each cœcum is about three inches in length; while in the Grouse each cœcum measures a yard long, being thus upwards of three times the length of the entire body. The internal surface of these extraordinary appendages to the alimentary canal is further increased in the Grouse by being disposed in eight longitudinal folds, which extend from their blind extremities to within five inches of their termination in the rectum. We have always found the cœca in this species filled with a homogeneous pultaceous matter without any trace of the heather buds, the remains of which are abundant in the fœcal matter contained in the ordinary tract of the intestines.

In the Peacock the cœca measure each about one foot in length; in the Partridge about four inches; in the common Fowl and other *Phasianidæ* the cœca are each about one-third the length of the body; they commence by a narrow pedicle, which extends about half their length, and then they begin to dilate into reservoirs for the chyme (*g, fig.* 157).

In the *Cursores* the cœca again present very different degrees of development. In the Emeu they are narrow and short. In the Cassowary they are wholly deficient; while in the Ostrich they are wide and upwards of two feet in length, and their secreting and absorbing parietes are further increased by being produced into a spiral valve, analogous to that which exists in the long cœcum of the Hare and Rabbit.

In the *Grallatores* the two cœca are generally short where present; they attain their greatest development in this order in the Demoiselle, where the length of each cœcum is five inches; and they are also large in the Flamingo, where they each measure nearly four inches, and are dilated at their extremities, presenting with the gizzard, crop, lamellated beak, and webbed feet, the nearest approach to the *Anatidæ* of the following order.

In the *Natatores* the cœca, where they are present, vary in length according to the nature of the food, being very short in the fish-eating Penguin, Pelecan, Gull, &c. and long in the Duck, Goose, and other vegetable feeding *Lamellirostres*.

In the crested Grebe (*Podiceps cristatus*), Yarrell detected two cœca, each measuring 3-16ths of an inch in length. In the Canada Goose the same indefatigable observer found the cœca each nine inches in length, and in the White-fronted Goose the same parts measured severally thirteen inches. They have the same length in the Black Swan. In the Wild Swan the cœca measure each ten inches in length, while in the tame species they are each fifteen inches long.

As digestion may be supposed to go on less actively in the somnolent, night-flying Owls, than in the high-soaring Diurnal Birds of Prey, an additional complexity of the alimentary canal for the purpose of retaining the chyme somewhat longer in its passage, might naturally be expected; and the enlarged cœca of the Nocturnal Raptores afford the requisite adjustment in this case. For, although the nature of the food is the same in the Owl* as in the Hawk, yet the differences of habit of life call for corresponding differences in the mechanism for its assimilation.

In the *Rasorial Order*, where the nature of the food differs so widely from that of the Birds of Prey, the principal modification of the digestive apparatus obtains in the more complex structure of the crop, proventriculus, and above all the gizzard; but with respect to the cœca, as great differences obtain in their development as in the *Raptores*. Now these differences are explicable on the same principle as has just been applied towards the elucidation of the differences in the size of the cœca in the *Raptores*. Where the difference in the locomotive powers is so great in the Dove-tribe and the common Fowl; where the circulating and respiratory systems must be so actively exercised to enable the Pigeon to take its daily flights and in some species their annual migrations—a less complicated intestinal canal may naturally be supposed with such increased energy in the animal and vital functions to do the business of digestion, than in the more sluggish and terrestrial vegetable feeders; and accordingly we find that the requisite complexity of the intestinal canal is obtained by an increased development of the cœcal processes in them, while in the *Columbidæ* the cœca remain as little developed as in the *Insessores*, which they resemble in powers of flight. If we regard the cœca as excretive organs, their differences in the above orders may be in like manner explained by their relations to the locomotive and respiratory functions.

In the *Cursores* the development of cœca seems to have reference to the quantity of food, and the ease with which it may be obtained, according to the geographical position of the species. In the Cassowary, which is a native

* The indigestible parts of the prey of the Owl do not pass into the intestine, but are regularly *cast* or regurgitated from the stomach; the length of the cœca cannot, therefore, be accounted for on Macartney's supposition of their being receivers of those parts.

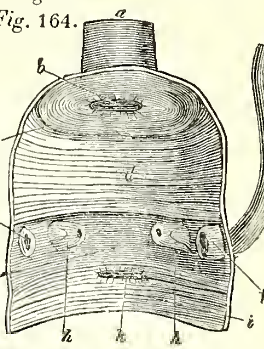
of the fertile districts of a tropical country, vegetable food of a more easily digestible nature may be selected, and it need not be detained unnecessarily long, where a fresh supply can be so readily procured. But in the Ostrich, which dwells amidst arid sands and barren deserts, every contrivance has been adopted in the structure of the digestive apparatus to extract the whole of the nutritious matter of the food which is swallowed.

In the *Grallatores*, where no material differences of locomotive powers or means of obtaining food exist, the cœca present in their development a direct relation to the nature of the food, and are most developed in the *Gruidæ*. The same holds good in the *Natatores*.

Why the increased extent of intestinal surface in the above different cases should be chiefly obtained by the elongation of the cœca, will appear from the following considerations. In consequence of the stones and other foreign bodies which birds swallow, it is necessary that there should be a free passage for these through the intestinal canal, which is therefore generally short and of pretty uniform diameter. In the Omnivorous birds of the tropics, as the Hornbills, Toucans, Touracos, and Parrots, which dwell among ever-bearing fruit-trees, the rapid passage of the food is not inconsistent with the extraction of a due supply of nourishment, but is compensated by the unfailing abundance of the supply. But where a greater quantity of the chyle is to be extracted from the food, and where, from the nature of the latter, a greater proportion of foreign substances is required for its trituration,—while the advantages of a short intestinal tract are obtained, the chyme is at the same time prevented from being prematurely expelled by the superaddition of the two cœcal bags which communicate with the intestines by orifices that are too small to admit pebbles or undigested seeds, but which allow the chyme to pass in. Here, therefore, it is detained, and chylification assisted by the secretion of the cœcal parietes, and the due proportion of nutriment extracted.

The large intestine is seldom more than a tenth part of the length of the body, and, except in the Ostrich and Bustard, is continued straight from the cœca to the cloaca; it may therefore be termed the rectum rather than the colon. It is usually wider than the small intestine, and its villi are coarser, shorter, and less numerous. The rectum (*a*, *fig.* 164) terminates by a valvular circular orifice (*b*), in a more or less dilated cavity, which is the remains of the allantois, and now forms a rudimental urinary bladder, (*c d*). The ureters (*h h*), and efferent parts of the generative apparatus (*f*, *g*,) open into a transverse groove at the lower part of the urinary dilatation, and beyond this is the external cavity which lodges, as in the Reptiles and Marsupial and Monotrematous Quadrupeds, the anal glands and the exciting organs of generation. The anal follicles in Birds are lodged in a conical glandular cavity, which communicates with the posterior part of the outer compartment of the cloaca, and has obtained from its discoverer the name of *Bursa Fabricii* (*k*). Berthold considers this part as a subdivision of the urinary bladder in Birds, and Geoffroy St. Hilaire as the analogue of Cowper's glands.

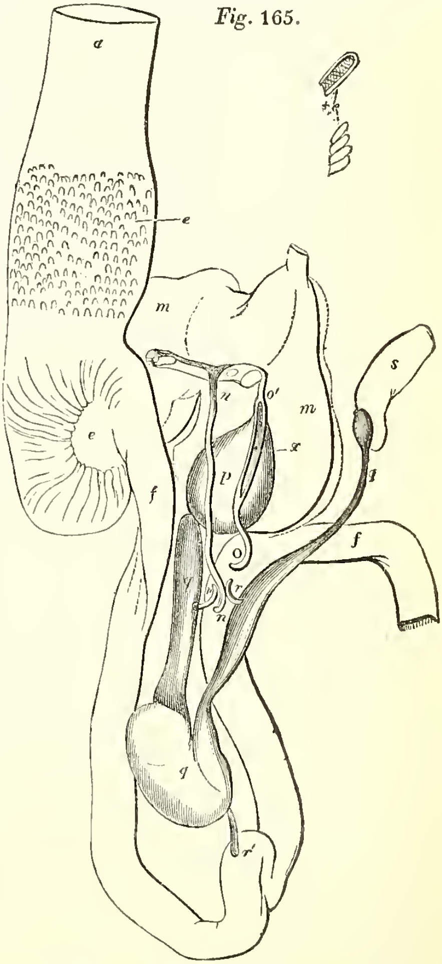
Fig. 164.



Cloaca of the Condor.

Digestive glands. — The *liver* is large in Birds, and proportionally larger in the Aquatic species than in Birds of Prey. In the former

Fig. 165.



Posterior view of the biliary and pancreatic duc in the Hornbill.

it bears a proportion of one-tenth, in some of the latter of one-twenty-ninth part of the entire body.

The liver *(m m, fig.* 163, 165) is situated a little above the middle of the thoracic-abdominal cavity, with its convex surface towards the abdominal parietes, and its concavity turned towards the subjacent viscera: the right lobe covers the duodenum, pancreas, and part of the small intestines; the left lobe covers the proventriculus and part of the gizzard; and the apex of the heart is received between the upper ends of these principal lobes. The liver is, as it were, moulded upon all these parts, and presents corresponding depressions where it comes in contact with them.

It is generally divided into two nearly equal lobes, which are often separated for a short extent, and connected together by a narrow isthmus of the glandular substance. In some birds, however, as in the Pigeon, Cormorant, Swan, and Goose, there is a third, smaller lobe, situated at the back of the liver between the lateral lobes, which from its situation appears analogous to the lobulus Spigelii of Mammalia. In the Common Fowl the left lobe is occasionally cleft so deeply as to form two lobes on that side. In some species the right lobe exceeds the left in size; this is most remarkable in the Bustard, in which the right lobe extends into the pelvis. In the Eagle, however, the left lobe has been observed to be the largest. Each lobe is invested by a double membranous tunic, one embracing it closely, the other surrounding it loosely, like the pericardium of the heart. They are formed by laminæ of the peritoneum, which seems to split at the exterior thin edge of the liver into four layers, two being continued upon the anterior and posterior surfaces adhering to them, the other two forming the loose exterior capsule.

The principal ligament of the liver is formed by a large and strong duplicature of the peritoneum, which divides the abdomen longitudinally like the thoracic mediastinum in Mammalia. It is reflected from the linea alba and middle line of the sternum upon the pericardium, and passes deeply into the interspace of the lobes of the liver; it is attached to these lobes through their whole extent, and connects them below to the gizzard on one side and to the duodenal fold on the other: the lateral and posterior parts of the liver are attached to the contiguous air-cells; and the whole viscus is thus kept steady in its situation during the rapid and violent movements of the bird. The ligament first described is analogous to the falciform ligament of Mammalia; and, although there is no free margin inclosing a round ligament, yet the remains of the umbilical vein may be traced within the duplicature of the membranes forming the septum. As the muscular septum between the thorax and abdomen is wanting, there is consequently no coronary ligament; but the numerous membranous processes which pass from the liver to the surrounding parts amply compensate for its absence.

The liver is of a lighter colour in Birds of flight than in the heavier Water-fowl. Each lobe has its hepatic artery and vena portæ. The hepatic arteries are proportionally small, but the portal veins are of great size, being formed not only by the veins of the intestinal canal, pancreas, and spleen, but also by the inferior emulgent and sacral veins. The blood, which has circulated in the liver, is returned to the inferior cava by two venæ hepaticæ. There are occasionally some smaller hepatic veins in addition to the two principal ones. The coats of the portal and hepatic veins appear to be equally attached to the substance of the liver.

The biliary secretion is carried out of the liver by two and sometimes three ducts; one of these terminates directly in the intestine, and is a 'hepatic duct' (*n, n, fig.* 165); the other enters the gall-bladder, and is a 'cyst-hepatic duct' (*o′, fig.* 165); the cystic bile is conveyed to the duodenum by a 'cystic duct' *(o, fig.* 165). Where, as in a few instances, the gall-bladder does not exist, both hepatic ducts terminate separately in the duodenum (*n, n, fig.* 163); but in no case is there a single ductus communis choledochus as in Mammalia.

The *gall-bladder (p, fig.* 165) is situated near the mesial edge of the concave or under side of the right lobe, and is commonly lodged in a shallow depression of the liver; but sometimes, as in the Eagle, Bustard, and Cormorant, only a very small part of the bag is attached to the liver. It has the same structure as in Mammalia, manifesting no visible muscular tunic, and having its inner surface delicately reticulated.

The gall-bladder is present in all the *Raptores, Insessores,* and *Natatores.* It is wanting in a great proportion of the *Scansores,* as in the Genus *Rhamphastos* and in the whole of the *Psittacidæ* and *Cuculidæ.* Among the *Rasores* the gall-bladder is constantly deficient in the *Columbidæ* or Dove-tribe alone, in which the cœca are shorter than in any other vegetable feeder: *(n n, fig.* 163, are the two hepatic ducts terminating apart from one another in the Pigeon.) The gall-bladder is occasionally absent, according to the French Academicians, in the Guinea-fowl; and they also found it wanting in two out of six Demoiselles *(Anthropoides Virgo).* The gall-bladder is small and sometimes absent in the Bittern: it is always wanting in the Ostrich.

The bile, as before observed, passes directly into the gall-bladder, and not by regurgitation from a ductus choledochus; the cyst-hepatic duct arises from the right lobe, and is continued in some birds along that side of the bag which is in contact with the liver, where it penetrates the coats of the cyst and terminates about one-third from the lower or posterior end. In the Horn-bill we found it passing over the upper end of the bladder to the anterior or free surface, and the cystic duct continued from the point where the cyst-hepatic duct opened into the bladder; so that the cystic duct had a communicaton both with the reservoir and the cyst-hepatic duct; being somewhat analogous to the ductus communis choledochus;

(see *fig.* 165, where *x* represents the orifice by which the bile passes both in and out of the gall-bladder.)

In the Goose the cyst-hepatic duct terminates by a very small orifice, surrounded by a smooth projection of the inner membrane, which, aided by the obliquity of the duct, acts as a valve and prevents any regurgitation towards the liver. The cystic duct here passes abruptly from the posterior extremity of the gall-bladder, which is not prolonged into a neck. The duct makes a turn round the end of the bag, and is so closely applied to it, as to require a careful examination to determine the true place of its commencement.

The hepatic duct (*n*, *fig.* 165) arises by two branches from the large lateral lobes of the liver, which unite in the fissure or ' gates' of the gland. Two hepatic ducts have been found in the Curassow; but these and the cystic duct terminate separately in the duodenum.

The place of termination of the cystic and hepatic duct is generally, as shown in *fig.* 163 and 165, pretty close together at the end of the fold of the duodenum; but in the Ostrich one of the hepatic ducts, which is very large and short, terminates in the commencement of the duodenum about an inch from the pylorus; while the other enters with the pancreatic duct at the termination of the duodenum.

Both the cystic and hepatic ducts undergo a slight thickening in their coats just before their termination; and it is remarkable that, in some of the Marsupiata, as the Kangaroo, the termination of the ductus choledochus is similarly thickened and glandular. The passage of the bile-ducts in birds through the coats of the intestine is oblique, as in the Mammalia, and they terminate upon a valvular prominence of the lining membrane of the gut.

The *Pancreas* (*q*, *q*, *fig.* 163, 165) consists of two and sometimes of three distinct portions in Birds; but these are so closely applied together at some point of their surface as to appear like one continuous gland. It is of a narrow, elongated, trihedral form, lodged in the interspace of the duodenal fold, and generally folded upon itself like the duodenum, as in the Hornbill (*fig.* 165).

The structure of the pancreas is conglomerate, like that of the salivary glands, but the ultimate follicles are differently disposed. In the salivary glands these are irregularly branched, while those of the pancreas in Birds diverge in the same plane from digitated and pinnatifid groups.*

The ducts (*r r*, *fig.* 163, 165) formed by the reiterated union of the efferent branches from the component follicles of the pancreas are in general two in number, which terminate separately in close proximity to the hepatic and cystic ducts; but occasionally there are three pancreatic ducts, as in the common Fowl, Pigeon, Raven, and Horn-bill; in which case the third duct commonly terminates at a distance from the other two: in the Horn-bill it proceeds from an enlarged lobe of the pancreas at the end of the duodenal fold, and entering that part, as at *r'*, *fig.* 165.

* Müller de Gland. Struct. Pen. fol. p. 66.

The *Spleen* (*s*, *s*, *fig.* 163, 165) is comparatively of small size in Birds; it is generally of a round or oval figure, but sometimes presents an elongated and vermiform shape, as in the Sea-Gull, or is broad and flat as in the Cormorant. It is situated beneath the liver, on the right side of the proventriculus. It is, however, somewhat loosely connected to the surroundiug parts, so that its position has been differently described by different authors. We have generally been able to trace a process of the pancreas passing into close contact with it, and connected to it by a continuation of vessels, as in the Horn-bill (*fig.* 165, *q*, *s*), where it has been turned aside to show the hepatic and pancreatic ducts. The texture of the spleen is much closer in Birds than in Mammalia; but a minute examination proves that the blood of the splenic artery is ultimately deposited in cells, from which the splenic veins arise. These veins in the Swan and some other Lamellirostres form a network on the exterior surface of the spleen, as in the Chelonian Reptiles.

Absorbents.—The presumed absence of absorbent vessels in the Oviparous Vertebrata was cited by the supporters of the theory of venous absorption in the time of William Hunter as strong evidence in favour of their views; and the same assertion has again been repeated in the present day by Majendie,* who, in subsequently admitting† the existence of lymphatics in Birds, still contends against their being the exclusive instruments of the function of absorption.

Traces of the lymphatic system in the present class appear to have been observed by Swammerdam‡ as early as 1676, who sent his preparation ' Lymphaticum peculiare ex abdomine Gallinæ' to the Royal Society of London; the lacteals were afterwards noticed in the Stork by Jacobæus§ in 1677, and traces of lymphatics are described by Lang‖ in 1704, and by Martin Lister¶ in 1711. Lymphatic vessels and glands, however, considered as such, according to the Hunterian doctrine of absorption, were first undoubtedly seen by John Hunter in the neck of a Swan, and the lacteals of Birds were afterwards re-discovered by Hewson, who made the first attempt to give a detailed account of the absorbent system in Birds. Our knowledge of this system has since been greatly enlarged by the labours of Tiedemann,** Fohmann,†† Lauth,‡‡ and Panizza.§§

The species in which the absorbent system has been investigated are the Buzzard, Woodpecker, Turkey, Common Fowl, Bittern, Heron, Stork, Duck, Swan, Wild and Tame Goose, but especially in the latter.

The absorbents of Birds differ from those of Mammals in having fewer valves, which are also less perfect, being so loose as frequently to permit for a certain extent a retrograde passage of the injected fluid. The lacteals, lymphatics, and thoracic ducts have very thin parietes, so as easily to be ruptured, but they are composed, as in Mammals, of two tunics, of which the internal is the weakest.

The lymph resembles that of Mammals, but the chyle differs essentially in its transparency and want of colour. The lacteals have, however, been observed to contain an opake white fluid in a Woodpecker that had been killed after swallowing a quantity of ants.

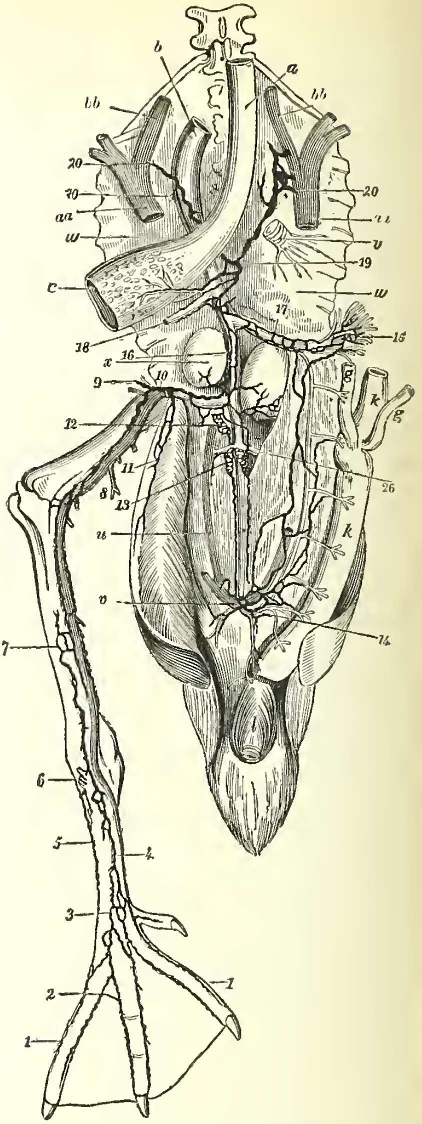
With respect to the disposition of the absorbents, they do not form in Birds two strata, as in Mammals; at least those only have been observed which correspond to the deep-seated absorbents which accompany the large vessels.

The lymphatic glands or ganglions are also much less numerous in Birds than Mammals, being in the former generally restricted in their position to the anterior part of the chest or the root of the neck. In the Penguin, however, a femoral and two axillary absorbent glands have recently been described.* They have the same structure as in Man, but are softer. In other parts of the body the absorbent glands are replaced by plexuses of lymphatic vessels surrounding the principal bloodvessels. It frequently happens, as in Mammalia, that two large absorbents form by their union a trunk, which is of smaller diameter than either of the vessels composing it.

The absorbents of Birds terminate principally by two thoracic ducts, one on either side, which enter the jugular veins by several orifices. But besides these communications, Tiedemann, Fohman, Lauth, and Lippi state that the lymphatic plexuses of the posterior part of the body communicate with the contiguous sacral and renal veins. And Lauth describes several intercommunications in other parts of the body; these, however, are denied by Panizza, whose careful and elaborate researches seem to prove that the passage of the lymph into the venous system takes place in Birds only in two places in the pelvic region in addition to those by the two thoracic ducts in the neck.

The lymphatics of the foot unite to form the vessels which are found running along the sides of each toe (1, 1, *fig.* 166). In the *Palmipedes* there are anastomosing branches which pass from the lateral vessel of one toe to that of the adjoining toe, forming arches in the uniting web (2). These branches form a small plexus (3) at the anterior part of the digito-metatarsal joint, from which three or four lymphatics are continued. The anterior and internal branches (4) accompany the blood-vessels, and form a network around them; the posterior and external branches (5) receive

Fig. 166.



*Absorbents of a Goose.**

the lymphatics of the sole of the foot, then ascend along the metatarsus, and form at its proximal articulation a close network (6); all the vessels then ascend the tibia, forming a plexus (7) around it as far as the middle of the leg; then they unite into two branches, of which the smaller passes along the anterior part of the depression between the tibia and fibula as far as the knee-joint, where it joins the other branch which accompanies the blood-vessels. The trunk formed by the union of the two preceding branches accompanies the femoral vessels, forming plexuses in its course

* Reid, in Proceedings of Zool. Soc. Sept. 1835.

* From Lauth's Monograph, Annales des Sciences Nat. t. iii. pls. 23 and 25.

(8), which receive tributary absorbents from the surrounding muscles, and a large branch (9) corresponding to the deep-seated femoral vessels.

The iliac trunk (10) accompanies the great femoral vein into the abdomen, which it enters anterior to the origin of the pubis; it there receives branches from the lateral parts of the pelvis (11) and afterwards separates into two divisions.

The posterior division receives some lymphatics from the anterior lobes of the kidneys, and those of the ovary or testicles; it communicates anteriorly with a branch from the absorbents which surround the great mesenteric artery, and posteriorly with large vesicular plexuses or receptacles (12, 13) surrounding the aorta and its branches, and which receives the lymphatics from the renal plexus, and those accompanying the arteria sacra media (14).

The sacral or pelvic plexiform vesicles of the lymph are described by Panizza in the Goose as being two in number, situated in the posterior region of the body, in the angle between the tail and the thigh. Each vesicle is little more than half an inch long and a quarter of an inch broad, and is shaped somewhat like a kidney-bean. Panizza laid them bare in several living Geese and punctured them, upon which the lymph issued in considerable quantity, and coagulated into a jelly like the lymph from ordinary lymphatics. Fluids thrown into the lymphatics leading to the vesicles not only filled these cavities, but passed from them into the veins. There are analogous vesicles in the Reptiles, which are endowed with a pulsatile power, and propel their contents into the pelvic veins *per saltum;* but the recent researches of Müller (Archiv. für Physiol. 1834, p. 300) show that the pelvic lymphatic vesicles of Birds are not endowed with a power of motion like that belonging to those of Reptiles, he having satisfied himself, by repeated examination of the living Goose, that the alternate contraction and dilatation of these vesicles in this animal, which Panizza conceived to depend on an automatic power within them, corresponds exactly with the motions of respiration, and no longer continues when they are interrupted.*

The anterior division of the femoral lymphatic trunk (16) accompanies the aorta, upon which it forms a plexus with the branch of the opposite side, and with the intestinal absorbents (15).

These vessels, which from the transparency of their contents can scarcely be termed with propriety 'lacteals,' commence from a plexiform continuous network situated between the mucous and muscular coats of the intestine; they are larger here than when they quit the intestine to pass upon the mesentery. They accompany the branches of the superior mesenteric artery, there being many absorbents for one artery, which by their anastomoses form plexuses surrounding the bloodvessels. Before reaching the aorta, these absorbents communicate with the inferior or posterior division of the femoral trunk, and with the absorbents of the ovary or testicles, after which they pass upon the aorta (16, 17), where they receive the lymphatics of the pancreas and duodenum, and terminate by uniting around the cœliac axis (18) with the lymphatics of the liver, the proventriculus (*c*), the gizzard, and the spleen, forming a considerable plexus, from which, according to Lauth, it is by no means rare to see branches passing to terminate in the surrounding veins.

The aortic plexus (19), which may be regarded as analogous to the receptaculum chyli, always gives origin to two thoracic ducts (20, 20) of varying calibre, but often, as in the Goose, exceeding a line in diameter. They are situated at their origin behind the œsophagus (*a*) and in front of the aorta (*b*); they advance forwards, diverging slightly from each other, pass over the lungs (*w w*), from which they receive some lymphatics, and terminate severally, after being joined by the lymphatics of the wing, in the jugular vein of the same side. The left thoracic duct, before entering the vein, receives the trunk of the lymphatics of the left side of the neck; the right thoracic duct receives only a branch of those of the same side.

The lymphatics of the wing follow the course of the brachial artery, forming a plexus around it, especially at the elbow-joint. Their principal trunk, to which all the collateral branches are united about the upper third of the humerus, is here of large size, but its diameter soon begins to be diminished, and it is very small at the head of the humerus. When it reaches the parietes of the chest, it receives two or three large lymphatics from the pectoral muscles, and a branch which accompanies the brachial plexus. Soon after a small lymphatic gland is sometimes formed on the trunk, which lastly unites with the thoracic duct of its own side.

The lymphatics of the head accompany the branches of the jugular vein, and are readily discerned upon those which are situated between the rami of the lower jaw. They form, by uniting with the cervical absorbents, two lateral branches on each side, which accompany the corresponding jugular vein, being situated, one in front, the other behind that vessel. These lymphatics communicate together, at the anterior and posterior parts of the neck, by transverse or oblique branches. They receive in their progress absorbents from the muscles, and from the peculiar glands which are seen beneath the skin of the neck. The internal branch on the left side receives also a considerable absorbent from the œsophagus. At the lower part of the neck both branches receive a notable branch which accompanies the carotid arteries, and a little further on they form on each side a lymphatic gland situated on the jugular vein. On the right side the trunk of the cervical lymphatics terminates in the jugular vein, after having furnished a communicating branch with the thoracic canal of that side; on the left side it terminates at once in the corresponding thoracic duct.

Vascular system.—*Heart.*—The heart in Birds is divided, as in Mammals, into four

* See Allen Thompson, in Edinb. Med. and Surg. Journ. No. 125.

distinct cavities, which have the same relations to each other, and impress the same course on the circulating fluid.*

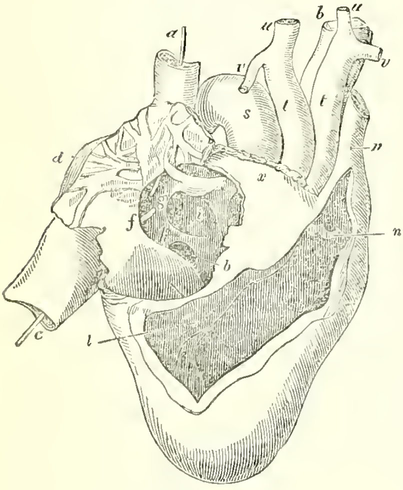
The form of this viscus is always that of a cone, sometimes wide and short, as in the Ostrich and Crane; sometimes more elongated, as in the Emeu (*fig.* 167) and Vulture; or still more acute, as in the Curlew, Common Fowl, &c.

Its situation is more anterior and mesial than in Mammalia, and its axis is always parallel with the axis of the trunk. It is not contained with the lungs in an especial cavity, but its apex is lodged between the lobes of the liver; the diaphragm not being so far developed as to separate the chest from the abdomen.

As the lungs are confined to the dorsal part of the chest, the whole of the anterior surface of the *pericardium* is exposed when the sternum of the bird is removed. The pericardium is thin, but of a firm texture, and adheres by its external surface to the surrounding air-cells. It is of considerable size, and commonly prolonged for some way between the lobes of the liver.

The *auricles* of the heart in Birds have not externally such distinct *appendices* as in Mammals. The right auricle is much larger than the left; it is more distinctly divided internally into a sinus (*d*, *fig.* 167) and auricle proper

Fig. 167.



Heart of the Emeu.

than in Mammals, and these parts are separated by a more complete valvular structure; in which respect Birds bear a closer analogy to Reptiles.

Three veins terminate in the sinus, there being in Birds always two superior cavæ, as in Reptiles. The right superior cava (*a*), which returns the blood from the right wing and right side of the neck, terminates in the upper and anterior part of the sinus; the left superior cava (*b*, *b*) winds round the posterior part of the left auricle to open into the lower part of the sinus; just before its termination it receives the coronary vein, so that this does not open separately into the auricle as in most Mammalia.* The inferior cava (*c*) terminates in the sinus just above the orifice of the left superior cava, and a semilunar valvular fold (*h*), analogous to that of the coronary vein in man, is extended forwards between these orifices so as to separate them, and afford a protection to the mouth of the left superior cava, in addition to that which it derives in common with the other veins from the larger valves at the mouth of the sinus.

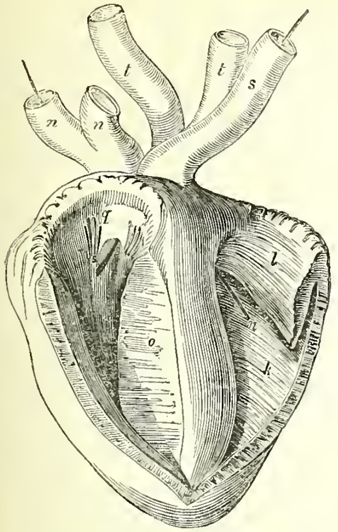
The disposition of the valves between the sinus and auricle seems more especially destined to prevent regurgitation into the sinus, when the pulmonary circulation may be impeded, rather than to impress any definite course on the current of blood flowing through the auricle, as Cuvier supposes. A strong oblique semilunar muscular fold (*g*) commences in the Emeu by a band of muscular fibres running along the upper part of the auricle, and expanding into a valvular form extends along the posterior and left side of the sinus, terminating at the lower part of the fossa ovalis (*i*). A second semilunar muscular valve (*f*), of equal size, extends parallel with the preceding along the anterior border of the orifice of the sinus, its lower extremity being fixed to the smooth floor of the auricle, its upper extremity being continued into a strong muscular column running parallel to the one first mentioned across the upper and anterior part of the auricle, and giving off from its sides the greater part of the *musculi pectinati*. From this structure it results that the more powerfully the musculi pectinati act in overcoming the obstacle to the passage of the blood from the auricle to the ventricle, the closer will the valves be drawn together, and the stronger will be the resistance made by them to the regurgitation of the blood from the auricle into the sinus. The parietes of the auricle in the interspaces of the muscular fasciculi are thin and transparent, consisting in many parts only of the lining membrane of the cavity and the reflected layer of the pericardium blended together. The *fossa ovalis* (*i*) is a deep depression situated behind the posterior semilunar valve, which, we may observe, bears nearly the same relation to the fossa as the annulus ovalis in the human heart. The membranous septum closing the foramen ovale is complete and strong, but thin and semi-transparent. The *appendix auriculæ* (*x*) is the most muscular part of the cavity; it does not project freely in front of the great vessels arising from the ventricles, but is tightly tied down to them by the reflected layer of the pericardium. The auriculo-ventricular orifice is an oblique slit (*k*, *fig.* 169; a bristle is passed through it in *fig.* 167). The manner in which re-

* The blood of Birds differs from that of the other Vertebrate classes in the greater number of globules, and from that of Mammalia in their form, which is oval instead of round. See BLOOD.

* In those Mammalia which approach nearest to the oviparous vertebrata, as the *Monotremata* and *Marsupiata*, there are always two superior cavæ, as in Birds and Reptiles; a similar structure obtains in some of the *Rodentia*, as the Porcupine; and also occurs in the Elephant. In all these cases we have found that the coronary vein terminates in the left superior cava.

gurgitation by this orifiee is prevented is one of the chief peculiarities in the heart of Birds.

Fig. 168.

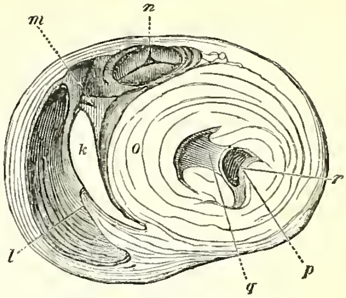


Ventricles of the heart of a Swan.

The right ventricle (*k*, *fig.* 168) is a narrow triangular cavity, applied as it were to the right and anterior side of the left ventricle, but not extending to the apex of the heart. The parietes are smooth, and, except at the septum ventriculorum, they are of pretty uniform thickness, but weaker in comparison to those of the left ventricle than in Mammalia. A number of short fleshy columns extend from the septum to the free parietes of the ventricle at the angle of union of these two parts, leaving deep cells between them; a strong fleshy column (*m*, *fig.* 169) also extends from the right side of the base of the pulmonary artery to the upper extremity of the auriculo-ventricular valve; but these are the only *columnæ carneæ* in the right ventricle; there being none of a pyramidal form projecting into the cavity, nor any *chordæ tendineæ*. The principal valve which guards the auricular aperture is a strong muscular fold (*l*, *fig.* 167, 168, 169), nearly as thick as the walls of the ventricle itself, extending from the fleshy column above mentioned obliquely downwards and backwards to the angle formed between the septum cordis and the wall of the ventricle at the lower and posterior part of the cavity. The free rounded edge of this muscular valve is turned towards the convex projection made by the septum, and must be forcibly applied to this part during the systole of the ventricles, so that, while all reflux into the auricle is prevented, additional impulse is given to the flow of blood through the pulmonary artery; the muscular parietes of the ventricle being thus complete at every part except at the orifice of the artery.

The small muscular column (*m*, *fig.* 169) at the upper part of the auricular orifice is analogous in its position to the single valve which guards the corresponding orifice in Reptiles; in which class the Crocodiles alone present a second muscular valve, which, though small, is

Fig. 169.



Section of the ventricles, Pelecan.

analogous in its position, and evidently a rudimental form of the large muscular valve in Birds.

The right ventricle is remarkable for the smoothness and evenness of its inner surface. The pulmonary artery is provided at its origin with three semicircular valves (*n*, *fig.* 169). It divides, as usual, into two branches (*n*, *n*, *fig.* 168), one for each lung; the right branch passes under the arch of the aorta.

The aerated blood is returned from the lungs by two veins which open into the back part of the left auricle; a strong semilunar ridge, which is hardly sufficiently produeed to be called a valve, divides the cavity of the auricle in which the veins terminate from the muscular part or appendix. The fleshy columns are very numerous and complicated in this part of the auricle, which is closely tied down to the ventricle by the serous layer of the periearдium and dense cellular tissue.

The left ventricle (*o*, *fig.* 168, 169) is an elongated conical cavity, the parietes of which are three times as thick as those of the right ventricle, and exhibit strong fleshy columns extending from the apex towards the base; two of the largest of these columns present in the Emeu a short convex eminence towards the auriculo-ventrieular orifiee (*r*, *fig.* 169), and give off short thick tendons to the margin and ventricular surface of two membranous folds, (*p*, *q*, *fig.* 168, 169) which correspond to the mitral valve in Mammalia. Of these valves, the one next the aorta (*q*) corresponds to the single valve which guards the auricular opening in the heart of Reptiles, and is most developed in Birds; the opposite valve is of much less size. In many Birds the chordæ tendineæ pass from the valves at once to the parietes of the ventricle, and are not attached to columnæ carneæ. The surface of the ventricle formed by the septum is smooth from the orifice of the aorta down to the apex of the heart. The aorta is provided, as in Mammalia, with three semicircular valves. In Reptiles, even in the Crocodile, the great arteries arising from the ventricles are each provided with two valves only.

We have observed that in general the valves at the base of the pulmonary artery were thicker and stronger than those at the origin of the aorta, and our lamented and talented friend Mr. Home Clift discovered some years ago that the extremities of the semilunar valves in Birds were connected to small, firm, and sometimes ossified styles imbedded in the fibrous coat of the vessels.

The arrangement of the muscular fibres of the ventricle in Birds is such that the right ventricle appears to be formed by a partial secession of the outer from the inner layers of the parietes of the left ventricle at the anterior and right side of that cavity. See the transverse section, (*fig.* 169.)

Arteries.—The distribution of the arterial system has been described in a general manner by Cuvier, Tiedemann, and Nitzsch, and has subsequently been very completely elucidated by Barkow in the 12th Volume of Meckel's Archives of Physiology; where the different varieties which various species of birds present in the course of individual arteries are laboriously pointed out. In our own dissections we have been guided by the excellent description long ago given by Dr. Macartney, (*Art.* Birds, Rees' Cyclopædia) which we shall here give verbatim, with some general remarks and additional particulars afforded by the researches of Barkow and our own dissections. The description will be aided by the subjoined beautiful figure taken from Barkow's Monograph (*fig.* 170).

The arterial system in Birds is essentially distinguished from that of Mammals by the following differences:—

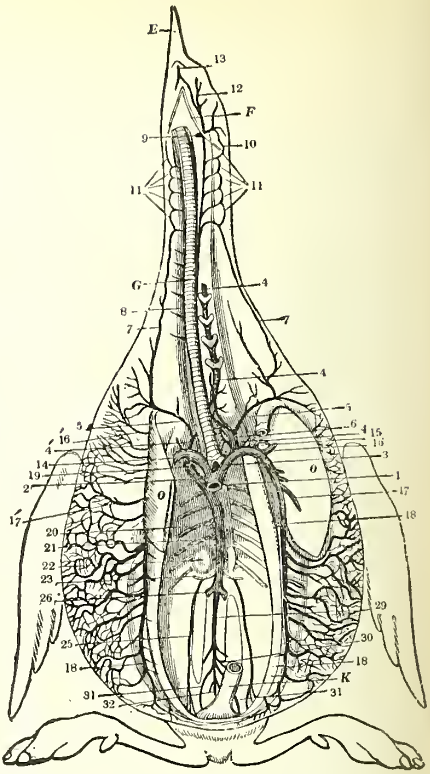
1st. The division of the aorta into three principal branches, almost immediately at its origin.

2d. The course of the arch of the aorta over the right instead of the left bronchus to become the descending aorta.

3d. The origin of the arteries of the posterior extremities, which do not come off from a single branch analogous to the external iliac of Mammalia, but from two arteries which are detached successively from the aorta at a great distance from each other, and pass from the pelvis by two separate apertures.

The arteries of the systemic circulation proceed, Macartney observes, "from a single trunk, which arises from the left ventricle of the heart. This trunk, the aorta, (1, *fig.* 170) is so short that it is concealed by the other parts on the basis of the heart, and is only brought into view after the reflections of the pericardium and the adjoining vessels are detached by dissection. It is from thence that as the parts are commonly beheld, there appear to be three great arteries issuing together from the middle of the heart, which are the primary branches into which the aorta is divided. The first branch is to the left side, and after it is sent off, the trunk affects to turn over the auricle before it gives the branch of the right side; these two branches pass in a curved manner from the heart towards the axilla in the form of horns, and each is analogous to the arteria innominata of the human subject, so that instead of one there may be reckoned two *arteriæ innominatæ* in Birds (*t t*, *fig.* 167, 168). After these branches are parted with, the arterial trunk (*s*, *fig.* 167, 168, 2, *fig.* 170) is continued over the auricles," and the right bron-

Fig. 170.



Arteries of the Trunk, Grebe.

chus, "and, on reaching the back part of the heart, becomes *the descending aorta.*

"The *arteria innominata* (3) first sends off the common trunk of the carotid and vertebral arteries (4), which before its division gives off one or two small branches; one of these runs down upon the lungs in company with the par vagum, and appears to supply branches to the aponeurosis of the lungs, and the air-cells at the upper part of the thorax; the other branch, after supplying the lymphatic gland of the neck with several small arteries, ascends upon the side of the œsophagus, to which, and the inferior larynx, the divisions of the trachea, and to the parts and integuments of the side of the neck, its branches are distributed, anastomosing with the superior œsophageal and tracheal arteries. This branch is often not sent off until the trunk divides into the vertebral and carotid, in which case it comes from the latter artery. Sometimes in the Duck, the *suprascapular* artery, which is usually divided from the vertebral, is a branch of the common trunk."

The *carotid* arteries (4, 4, *fig.* 170, *u u*, *fig.* 167) are frequently of unequal size; in the Dabchick the left is by much the largest; in the Emeu we found it the smallest. "In the Common Fowl, each carotid, after parting from the vertebral artery (6), proceeds to the middle of the neck and soon disappears; becoming covered by the muscles of the anterior part of the neck, and entering the canal formed by the inferior spinous processes of the cervical vertebræ, within which it lies hidden, and in close contact with its fellow of the other side, to very near the head." In the Bittern the two carotids are situated one behind the other, and adhere so intimately together in this situation that they have been erroneously described as a single trunk.

"The carotid artery emerges from between the muscles of the neck, at about the third or fourth vertebra from the head (9); and after giving a branch (10, 11), *Arteriæ cutaneæ colli laterales*, downwards, to the lateral muscles and integuments of the neck, it runs along the outer edge of the rectus major anticus muscle to behind the angle of the jaw, where it divides into its several branches.

"An artery (*arteria occipitalis*) first goes off posteriorly, which passes a little forwards under the branch of the os hyoides, and after sending some blood to the muscles of the neck, makes a turn backwards, enters the foramen in the transverse process of the second vertebra, and terminates by a singular anastomosis in the vertebral artery.*

"The next branch is analogous to the *internal carotid;* it goes forward also under the os hyoides, and passes behind the muscles of the jaws close upon the lower part of the skull, at which place it sends a branch upwards, which appears to penetrate the bones on the outside of the ear, and supply the organ of hearing, sends a branch into the skull and another through the articulation of the jaw, to unite with the ophthalmic, and contribute to the plexus at the back of the orbit (*Rete ophthalmicum* of Barkow). The internal carotid then enters an osseous canal, which runs along the basis of the cranium, between the tables of the bone; and at the lower and back part of the orbit, the artery receives a remarkable anastomosing branch of the internal maxillary, which almost equals in size the carotid itself, and these two vessels produce by their union one which passes almost directly into the cranium at the usual place for the entrance of the carotid artery. This vessel forms within the skull an anastomosis similar to the circle of Willis; but the branch which occupies the place of the *basilar artery* is very small, and appears to be furnished entirely from the anastomosis of the carotids, and designed only to supply the medulla oblongata and spinal marrow. The branches of the internal carotid are thickly spread in an arborescent form upon the surfaces of the brain; some on the outside and others on the internal superficies of the ventricles, and the fissure between the two hemispheres." The orbital plexus formed by the carotid sends off the *inferior palpebral, ethmoidal, lachrymal*, and *ophthalmic* arteries. The ophthalmic artery forms two remarkable plexuses at the posterior part of the globe of the eye; the first is situated close beside the inner side of the optic nerve, and is formed by an artery analogous to the *arteria centralis retinæ*, and gives off the artery to the base of the marsupial membrane; the second plexus is situated more exteriorly, and gives off the ciliary arteries.

"After the trunk of the carotid has sent off the internal carotid, it passes for a little way downwards and forwards behind the angle of the jaw, and divides at once into different branches, corresponding to those of the *external carotid* in mammalia; the first of which might be called the œsophageal or laryngeal artery. This vessel sends a branch to the muscles upon the horn of the os hyoides, and then turns downwards and divides into two branches, one to the trachea (*G, fig.* 170), and the other to the œsophagus, upon the side of which parts they descend to near the thorax," forming a series of arches (11, 11), and ultimately inosculate with the tracheal and œsophageal branches of the common trunk of the carotid and vertebral arteries.

"The external *maxillary artery* (12) dips in between the pterygoid muscle and that which is situated at the back of the lower jaw for opening the mouth; it then passes behind the tympanic bone, and gives twigs upwards to the muscles of the jaws, and to the plexus at the back of the orbit: upon emerging from behind the tympanic bone, it lies under the zygomatic or jugal bone, and sends an artery upwards, which is distributed to the temporal and masseter muscles, and proceeding under the triangular tendon that comes from the inferior margin of the orbit to the lower jaw, it divides into two principal branches; one of these passes along the side of the upper jaw, gives a branch upwards to the fore part of the orbit which unites with the ophthalmic artery, and is lost at the top of the head. This branch is very large in birds with combs, as in conjunction with the ophthalmic, it furnishes numerous vessels to these vascular parts. The artery then goes on and supplies branches to the sides of the head before the orbits, and to the integuments and substance of the upper mandible, inosculating with the palatine branches of the internal maxillary artery. The second portion of the external maxillary proceeds to the lower jaw, to which, and the lower part of the masseter muscle, it is distributed. The external maxillary supplies the place of the *temporal*, *labial*, *angular*, *nasal*, and *mental* arteries of mammalia.

"The *laryngeal* or *posterior palatine* artery is a little branch of the external carotid, which is sent off posteriorly opposite to the external maxillary artery. Its branches are exhausted upon the back part of the fauces, the muscles for moving the upper jaw, and posterior nares.

"The *lingual* or submaxillary artery (13) passes under the muscles which connect the os hyoides to the lower jaw, and close upon the back of the membrane of the lower part of the mouth, it sends a branch to the œsophagus and trachea, supplies the muscles of the os hyoides (*F*),

* Dr. Barkow has subsequently established the accuracy of this observation, having found this singular anastomosis of the occipital with the vertebral artery in all the birds which he has injected. Tiedemann is therefore inaccurate in saying that the vertebral artery has the same termination in birds as in man.

the tongue (*E*, *fig.* 170), the lower surface of the mouth, and furnishes the artery which enters the substance of the lower jaw.

"Just at the origin of the submaxillary artery there is another little branch of the carotid, which is lost upon the muscles of the os hyoides.

"The *internal maxillary* artery is, as usual, the continuation of the trunk of the external carotid; it runs forwards between the pterygoid muscle, and the lining of the mouth, upon the side of the long muscle for moving the upper jaw, and divides into two principal branches; one of them proceeds under the tendon of the long muscle to get upon the palate, where it forms two branches, of which one runs along the external side of the palate, between the membrane and the bone of the mandible to the extremity of the bill, where it becomes united to the same branch of the opposite side, as also to the middle artery of the palate. The other branch lies also superficially under the membrane which lines the mouth. It passes onwards to meet its corresponding vessel of the opposite side, with which it becomes actually incorporated, and by their union a single artery is generated, which runs along the middle line of the palate to the end of the mandible, where it unites with the lateral branches, as already mentioned. At the junction of the vessel of each side to form the middle palatine artery, two branches go off, which are lost upon the lining of the mouth, and the interior of the organ of smell.

"The other branch of the internal maxillary artery is reflected upwards towards the orbit, below which it divides and unites again, forming a triangle, through which the vein passes: at this place it produces a remarkable plexus of vessels, like the rete mirabile of the carotid artery of quadrupeds, which is increased by branches from the ophthalmic and the palatine arteries, and from which the back part of the organ of smell receives its supply of blood.

"The internal maxillary artery then runs directly backwards below the orbit, passes between the radiated or fan-shaped muscle which moves the upper jaw and the pterygoid process; and turning inwards round the basis of the cranium, becomes incorporated with the *internal carotid* artery just as it enters the bony canal which conducts it to the brain.*

"The *vertebral artery* (6), soon after it parts from the carotid, sends off a branch backwards, which passes over the neck of the scapula and is lost among the muscles on the posterior part of the shoulder, inosculating with the articular and other arteries about the joint: this branch might be called the *supra-scapular* (5). In the *duck* we have observed it, before it makes the turn over the scapula, to send an artery upwards along the muscles of the neck. The trunk of the vertebral artery proceeds obliquely upwards, and having entered the foramen in the transverse process of the second cervical vertebra, gives off a large branch downwards, which is distributed between the vertebræ, and to the spinal canal, in the manner of the intercostal arteries, with which it anastomoses upon arriving in the thorax. The remainder of the vertebral artery is continued upwards in the canal formed in the transverse processes of the cervical vertebræ, diminishing gradually in consequence of the branches it sends off between each vertebra to the spinal marrow and the muscles of the neck. Near the head the artery is found considerably reduced, and within the last foramen in the transverse processes terminates entirely by inosculation with the reflected occipital branch of the carotid, as before noticed.

"The extraordinary anastomosės and the plexuses which are to be observed in the arteries of the head in birds are not easily accounted for. It seems possible that they may be required in consequence of the great length of the neck in these animals, it being well known that frequent communication amongst the vessels, although it diminishes the impetus of the circulation, ensures a free and uninterrupted motion of the blood.

"After the common trunk of the carotid and vertebral is detached from the arteria innominata, this vessel may assume the name of the *subclavian* (14). While passing under the clavicle it sends off some important branches: the first might be called the *pectoral artery;* it proceeds upwards upon the internal surface of the pectoralis minimus muscle, which it supplies, and then dividing into two branches, one passes over the anterior edge of the clavicle, and under the pectoralis medius, between which and the sternum it runs, detaching its branches to the muscle; the other sends first along the under side of the clavicle a branch which is again subdivided and distributed to the outside of the shoulder-joint and to the deltoid muscle, in which it inosculates with the articular artery. The vessel then passes between the clavicle and the fork-shaped bone, and on a ligament which connects the head of the clavicle to that of the scapula, and disperses its branches upon the upper part of the shoulder-joint, forming anastomoses with the neighbouring arteries.

"The next branch of the subclavian is the *humeral artery* (15); it arises from the upper side of the vessel, and makes a slight curve to reach its situation on the inside of the arm in order to disperse its branches in the manner hereafter described.

"The *internal mammary* artery (24, *fig.* 171) is given off just as the subclavian leaves the chest. It divides into three branches; one ramifies upon the inner surface of the sternum, another upon the sternal ribs and the intercostal muscles, and the third runs along the anterior extremities of the vertebral ribs, supplying the intercostal muscles, &c.

"The chief peculiarity of the arteries of the superior extremities in birds consists in the great magnitude of the vessels which supply the pectoral muscles; these, instead of being inconsiderable branches of the axillary artery

* Barkow describes the internal maxillary artery as wanting in birds, and its place being supplied by branches of both the external and internal carotids and the facial artery, all of which sometimes unite to form the maxillary plexus of vessels, which is very conspicuous in the Goose and Duck.

are the continuations of the trunk of the subclavian, of which the humeral is only a branch.

"The *great pectoral* or *thoracic artery* passes out of the chest over the first rib and close to the sternum, and immediately divides into two branches. One of them (16) ramifies in the superior part of the pectoralis major, and the other (17) is exhausted in the lower part of the muscle, and sends off a branch analogous to the long thoracic artery of mammalia." Nos. 16 and 17 show the distribution of these arteries to the skin after perforating the *pectoralis* muscle.

"The *humeral artery*, while within the axilla, gives a small branch backwards to the muscles under the scapula, and upon reaching the inside of the arm produces an artery that soon divides into the articular and the profunda humeri. The *articular* artery passes round the head of the humerus, underneath the extensors; its branches penetrate the deltoid muscle, and anastomose with the other small arteries around the joint.

"The *profunda humeri*, as usual, turns under the extensor muscles to reach the back of the bone, at which place, in birds, it separates into two branches, of which one descends upon the inside, and the other upon the outside of the articulation of the humerus with the radius and ulna, and there inosculate with the recurrent branches of the arteries of the fore-arm.

"After the humeral artery has sent off the profunda, it descends along the inner edge of the biceps muscle, detaching some branches to the neighbouring parts: upon arriving at the fold of the wing, it divides into two branches; one of these is analogous to the *ulnar* artery, and the other fiom its position deserves to be called rather the *interosseous* than the radial artery.

"At the place where the humeral produces the two arteries of the fore-arm, a small branch is sent off, which is lost upon the fore-part of the joint, and in anastomoses with the recurrent of the ulna and profunda humeri.

"The *ulnar artery* is the principal division of the humeral; it proceeds superficially over the muscles which are analogous to the pronator, sends a large recurrent branch under the flexor ulnaris to the back of the joint, upon which it ramifies and forms anastomoses with the profunda humeri. The artery then proceeds along the inner edge of the ulnar muscles, to which it distributes branches. It is afterwards seen passing over the carpal bone of the ulnar side, and under the annular ligament, at which place it sends off some branches which spread upon the joint and inosculate with the similar ones of the interosseous artery. Very soon after the ulnar artery gets upon the metacarpus, it dips in between the bones, and re-appears upon the opposite side, lying under the roots of the quills, to each of which it sends an artery; it preserves this situation to the end of the metacarpal bones, where it passes between the style analogous to the little finger and the principal or fore-finger, and pursues its course along the edge of the latter, to the extremity of the wing, supplying each of the true quills with an artery, and sending at each joint of the finger a cross branch to communicate with the anastomosing branches on the opposite side.

"The *interosseous* artery detaches first a branch of some size to the membrane which is spread in the fold of the wing, upon which it forms several ramifications. (See *o*, *fig.* 171.) After this the artery dips down behind the pronator muscles to get into the space between the ulna and radius. It here gives a branch backwards to communicate with the others about the joint, and proceeds in the interosseous space as far as the carpal joint, during which course they become much diminished from giving off several branches which are distributed to the integuments and the quills placed upon the outside of the ulna. The remainder of the interosseous artery is expended in small branches upon the back of the carpal joint, the bastard quills, and along the radial edge of the metacarpus and bones of the fore-finger, where it forms communications with the cross branches of the ulnar artery already mentioned.

"From this description it will be perceived that no artery exists in birds strictly analogous to the radial; that there are no palmar arches; and that the size of the interosseous artery, and the course of the ulnar, along the outside of the metacarpus, are peculiarities which arise from the necessity of affording a large supply of blood to the quills during their growth.

"The *descending aorta* (19, *fig.* 170) makes a curve round the right auricle and right bronchus, in order to get upon the posterior surface of the heart, after which its course is close along the spine, in which situation it is bound down by cellular substance, and the strong membrane or aponeurosis, which covers the lungs on their anterior part. The first branches which this vessel appears to send off are *bronchial arteries;* they arise from the fore part of the aorta, just when it arrives upon the spine; and having entered the lungs, their ramifications accompany those of the pulmonary arteries. They appear also to send branches to the spine and the spaces between the ribs.

"The *intercostal arteries* do not take their origin from the aorta in numerous and regular branches as in mammalia, but consist originally of but few vessels, which are multiplied by anastomoses with each other, and with the arteries which come out of the spinal canal. An arterial plexus is thus formed round the heads of the ribs, from which a vessel is sent to each of the intercostal spaces. Many of these branches, besides supplying the intercostal muscles and ribs, are continued into the muscles upon the outside of the body and the integuments. The anastomosis of the intercostal arteries round the ribs is very similar to the plexus, which is produced by the great sympathetic nerve in the same situation.

"The aorta produces no branch which deserves the name of the *phrenic artery*, as birds do not possess that muscular septum of the body to which the artery of this name is distributed in other animals.

"The *cœliac artery* (20, *fig.* 170) is a very large single trunk, and arises from the fore part of the aorta, even higher than the zone of the gastric glands. It descends obliquely for a short way, and then gives off a branch which soon divides into two or three others that are spread upon the lower part of the œsophagus, and the side of the zone of the gastric glands, uniting with the other arteries of the œsophagus above, and extending downwards upon the posterior side of the ventricle, and anastomosing with the anterior gastric artery. The trunk of the cœliac now divides into two very large branches, which from their distribution we have chosen to call the posterior and the anterior gastric arteries.

"The posterior *gastric artery*, almost as soon as it is formed, detaches the *splenic* artery; and very soon after it furnishes from the posterior side of the vessel the right *hepatic artery*. This branch proceeds to the right lobe of the liver, which it enters on the side of the hepatic duct; after having divided into two or three minute arteries on its way to the liver, it supplies the hepatic duct with a branch which accompanies the duct to the intestine, and is there lost. The posterior gastric artery then runs down upon the back of the gizzard, and opposite to the origin of the first intestine it sends off an artery, which proceeds directly to one of the cœca (in the Fowl), upon which and the side of the next intestine it is expended, inosculating at the end of the cœcum with branches of the mesenteric artery, which are distributed to the adjoining portion of the small intestine. The posterior gastric then furnishes a large vessel which runs upon the gizzard, and divides into two chief branches, which penetrate the substance of the digastric muscle, in which they are lost.

"The next branch of the posterior gastric artery is the *pancreatic*. It runs between the two pancreatic glands, dispensing branches to each and to the duodenum. After this the trunk of the posterior gastric divides into two branches, which furnish twigs to the muscular parietes of the ventricle, and run along the margins of the upper and lower portions of the digastric muscle. Supplying them with numerous twigs, and anastomosing with the ramifications of the other gastric arteries.

"The *anterior gastric artery* descends to the angle formed by the bulbus glandulosus and the gizzard, and there sends off a small branch which spreads upon the zone of the gastric glands, and inosculates with the first ramifications of the cœliac, and immediately afterwards it detaches a large artery, which runs round the superior margin of the digastric muscle, which it furnishes with many twigs, and communicates freely with the corresponding branch of the posterior gastric artery.

"Three *small hepatic arteries* take their origin from this branch of the anterior gastric, just as it passes over the highest part of the margin of the gizzard; these vessels enter the fissure in the left lobe of the liver. The anterior gastric artery now proceeds along the fore part of the gizzard, sending one or two branches into the muscular substance, and near the tendon it terminates in two large vessels, one of which is distributed upon the left side of the digastric muscle, and the other passes a little over the tendon, and then divides into two arteries, which produce several branches that disappear in the substance of the gizzard, and between the digastric muscles and the parietes of the ventricle, anastomosing with the vessels of the posterior side.

"The *superior mesenteric artery* (21, *fig.* 170) takes its origin from the fore part of the aorta, a little below the cœliac, and proceeds for some way without detaching any branches; after which it experiences the same kind of division and subdivision that takes place in mammalia; and the numerous arteries which are thus ultimately produced are spent upon the small intestines. One of the first and largest branches of the superior mesenteric, however, is allotted to supply one of the cœca, and to establish a communication with the inferior mesenteric and gastric arteries. This branch, soon after it leaves the trunk of the superior mesenteric, divides into two. One descends upon the rectum, where it meets with the inferior mesenteric artery, with which it produces a very remarkable anastomosis, similar to the mesenteric arch in the human subject; this united artery supplies the rectum and origin of the cœca. The second portion of this branch of the superior mesenteric runs in the space between the last part of the small intestine and the cœcum of one side, sending numerous branches to each, and at the end of the cœcum communicates in a palpable manner with another branch of the superior mesenteric artery, which runs upon the adjoining part of the small intestine.

"A branch (22, *Arteria spermatica*) arises from the anterior part of the aorta, just below the lungs; it is designed for the nutrition of the organs of generation, and except in the season for propagation, it is so small as to be discovered with difficulty; but when the testicles become enlarged, it is considerably increased in size in the male bird, and much more so in the female, when the ovary and oviduct are developed for producing eggs. It nearly equals the superior mesenteric artery during the period of laying, in which state we shall describe it. It is a single artery, like the cœliac and mesenteric, proceeds at a right angle from the aorta, and soon sends off a branch, which goes into the kidney of the left side, to which it gives some twigs, and afterwards emerging from the kidney, it runs in the membrane of the oviduct, upon which it is distributed. After this branch is detached, the artery projects a little farther forwards into the cavity, and divides into two branches; one of these goes to the ovary, in which it ramifies, and furnishes an artery of some size to each of the cysts containing the ova. The other is distributed in numerous branches to the membrane and superior parts of the oviduct, and inosculates with the other arteries of the oviduct. It deserves to be remarked, that this and all the other arteries which are furnished to the oviduct have a tortuous or undulating course, in the same manner as the vessels of the uterus of the human subject.

"There are no regular *emulgent* arteries in birds; the kidneys deriving their blood from various sources, which will be pointed out as they occur

"The inferior extremity is supplied with two arteries, which have a separate origin from the aorta. One corresponds with the femoral artery, and the other deserves the name of ischiadic artery.

"The *femoral artery* (23, *fig*. 170, 171) is a small trunk, which takes its origin from the side of the aorta, opposite to the notch in the bones of the pelvis immediately under the last rib. This notch is formed into a round hole in the recent subject by a ligament which is extended from it to the rib; and it is through this hole that the femoral artery makes its exit from the pelvis; just before it passes out upon the thigh, it sends off a long branch (25), which runs backwards the whole length of the margin of the pelvis, dispensing arteries to the abdominal muscles on one side, and the obturator internus on the other. This branch also appears to supply one to the oviduct. The femoral artery, immediately after leaving the pelvis, separates into two branches; one goes upwards and outwards, ramifying amongst the muscles in that situation; the other turns downwards, and is distributed to the flexors of the limb and round the joint, and sends an artery to the edge of the vastus internus, which can be traced as far as the knee. The kidneys appear to derive some irregular inconsiderable branches from the femoral artery while it is within the pelvis.

"The *ischiadic artery* (26, *fig*. 166, 170) is the principal trunk of the lower extremities, exceeding very much in size the femoral. When it is produced by the aorta, it appears to be the continuation of that trunk; the remaining part of the aorta becomes so much and so suddenly diminished, and seems, as it were, to proceed as a branch from the back part of the vessel.

"The ischiadic artery, while in the pelvis, is concealed by the kidneys, in which situation it gives a branch from its lower side, which divides into three others that are distributed to the substance of the kidneys; one of these on the left side is continued out of the kidney to be lost upon the oviduct. The artery leaves the pelvis by the ischiadic foramen in company with the great nerve, while, within the foramen, it gives a branch obliquely downwards under the biceps to the muscles lying in the pelvis; and as it passes over the adductor it sends off another along the lower edge of that muscle, which is chiefly lost in the semi-membranosus. It then detaches several small branches to the muscles on the outer and fore part of the thigh, some of which anastomose round the joint with the branches of the femoral artery. Just as the ischiadic arrives in the ham, it furnishes a very large branch downwards, which divides into two; one goes under the gastrocnemius, to which and the deep-seated flexors its branches are distributed as far as the heel; the other is analogous to the *peroneal artery;* it goes to the outside of the leg, supplies the peroneal muscles posteriorly, and passes along the outer edge of the flexors of the toes to the heel, above which, and behind the flexor tendon, it divides, running on each side of the heel, and forming several articular arteries around the joint, and communicating with the other branch, and with the anterior tibial, and the metatarsal branch of the plantar artery.

"The *articular arteries* go off next from the artery in the ham; the two principal ones are deep-seated. One proceeds under the vastus internus to the external part of the joint; the other is large, and situated upon the inside. It forms two vessels: one is the true articular artery, and spreads upon the ligaments of the joint; the other is distributed in the substance of the flexor of the heel, which is placed upon the inside and fore part of the leg, and comes out upon the edge of this muscle to be lost in the integuments.

"The *posterior tibial artery* (28, *fig*. 171) is extremely small; it only supplies muscular branches to the internal head of the gastrocnemius, and some of the flexors of the toes; it is lost on the inside of the heel in anastomoses with the peroneal artery, and other small superficial branches.
