CONTRIBUTORS.

JOHN ADAMS, Esq.
Surgeon to the London Hospital, and Lecturer on Anatomy.

ROBERT ADAMS, M.D.
Surgeon to the Richmond Hospital, and Lecturer on Anatomy and Surgery, Dublin.

B. ALCOCK, M.B.

W. P. ALISON, M.D. F.R.S.E.
Formerly Prof. of the Pract. of Med. in the Univ. of Edin. &c.

JOHN ANDERSON, Esq. M.E.S.

J. APJOHN, M.D. M.R.I.A.
Prof. of Chem. in the University of Dublin.

VICTOR AUDOUIN, M.D. Paris.
Professeur-Administrateur au Musée d'Histoire Naturelle.

B. G. BABINGTON, M.D. F.R.S.
Late Physician to Guy's Hospital.

LIONEL S. BEALE, M.B. F.R.S.
Prof. of Physiology in King's College, London.

THOMAS BELL, Sec. R.S.
Professor of Zoology in King's College, London.

CHARLES BENSON, M.D. M.R.I.A.
Prof. of Med. to the Royal Coll. of Surgeons, Ireland.

J. BISHOP, F.R.S., London.

JOHN BOSTOCK, M.D. F.R.S. (the late), London.

W. BOWMAN, F.R.S.
Surgeon to the King's College Hospital and to the Royal Ophthalmic Hospital, Moorfields, and late Professor of Physiology, King's College, London.

J. E. BOWMAN, Esq. (the late).
Prof. of Practical Chemistry in King's Coll., London.

W. T. BRANDE, F.R.S.
Formerly Professor of Chemistry to the Royal Institution, &c.

J. E. BRENAN, M.D. (the late).

W. BRINTON, M.D.
Lect. on Physiology at St. Thomas's Hosp., London.

W. B. CARPENTER, M.D. F.R.S.
Prof. of Med. Jurisprudence, Univ. Coll., London.

T. SPENCER COBBOLD, M.D. F.L.S.
Lecturer on Botany at St. Mary's Hospital, London.

JOHN COLDSTREAM, M.D.
Fell. Roy. Coll. Phys. Edinb. &c.

W. WHITE COOPER, F.R.C.S.
Sen. Surgeon to the North London Eye Infirmary, Ophthalmic Surgeon to St. Mary's Hospital.

DAVID CRAIGIE, M.D. F.R.S.E.
Fellow of the Royal Coll. of Physicians, Edinb. &c.

T. BLIZARD CURLING, F. R. S.
Lect. on Surg., and Surgeon to the Lond. Hospital.

F. CUVIER, Paris.

G. P. DESHAYES, M.D., Paris.

A. T. S. DODD, Esq. (the late).

I. DRUMMOND, M. D., Edinburgh.

P. M. DUNCAN, M.D.
Physician to the Infirmary, Colchester.

H. DUTROCHET, M.D.

W. F. EDWARDS, M.D. F.R.S. (the late).

H. MILNE EDWARDS, M.D.
Prof. of Nat. History to the College of Henry IV., and to the Central School of Arts and Manufactures, Paris.

ARTHUR FARRE, M.D. F.R.S.
Professor of Midwifery in King's College, and Physician Accoucheur to King's College Hospital.

HEINRICH FREY, M.D.
Prof. of Gen. and Comp. Anat. at Zurich.

R. D. GRAINGER, F.R.S.
Lect. on Anat. and Phys. at St. Thomas's Hospital.

R. E. GRANT, M.D. F.R.S. L. & E.
Fell. of the Roy. Coll. of Physicians, Edinb., and Prof. of Comp. Anatomy and Zoology in Univ. College, &c.

W. A. GUY, M.D.
Prof. For. Med. King's College, London, and Physician to King's College Hospital.

M. HALL, M.D. F.R.S. L. & E., Lond. (the late).

HENRY HANCOCK, Esq.
Lect. on Surgery at, and Surgeon to, the Charing-Cross Hospital.

R. HARRISON, M.D. M.R.I.A. (the late),
Prof. of Anat. and Surg. in the Univ. of Dublin.

JOHN HART, M.D. M.R.I.A.
Prof. of Anat. to the Royal Coll. of Surg., Dublin.

A. HIGGINSON, Esq., Liverpool.

J. HUTCHINSON, M.D., London.

T. HUXLEY, Esq., F. R.S., London.

ARTHUR JACOB, M.D. M.R.I.A.
Professor of Anatomy and Physiology to the Royal College of Surgeons in Ireland.

GEORGE JOHNSON, M.D.
Physician to King's Coll. Hosp., Lond.

C. HANDFIELD JONES, M.D. F.R.S.
Physician to St. Mary's Hospital, London.

T. RUPERT JONES, Esq.
Assistant Sec. Geolog. Soc. London.

T. RYMER JONES, F.R.S.
Prof. of Comp. Anat. in King's College, London.

T. WHARTON JONES, F.R.S., London.

SAMUEL LANE, Esq.
Lecturer on Anatomy, St. George's Hospital, London.

EDWIN LANKESTER, M.D. F.R.S.
Lecturer on Materia Medica and Botany.

J. LEUCKARDT, M.D., Göttingen.

A. KÖLLIKER,
Prof. of Anat. and Phys. in the Univ. of Wurzburg.

Right Rev. F. T. MACDOUGALL, D.C.L.
Lord Bishop of Labuan and Sarawak, Borneo.

BENJ. M'DOWEL, M.D.
Professor of Anatomy in the University of Dublin, and Physician to the Whitworth Hospital, Dublin.

JOSEPH MACLISE, Esq., London.

JOHN MALYN, Esq. (the late).

ROBERT MAYNE, M.D.
Lect. on Anat. & Phys. Richmond Hospital, Dublin.

W. A. MILLER, M.D. F.R.S.
Professor of Chemistry in King's College, London.

W. F. MONTGOMERY, M.D. M.R.I.A.
Fellow of, and Professor of Midwifery in, the King and Queen's College of Physicians in Ireland.

GEO. NEWPORT, F.R.S. F.L.S. (the late).

R. OWEN, F.R.S. F.G.S.
Late Hunterian Professor of Comparative Anatomy and Physiology to the Royal College of Surgeons, London.

JAMES PAGET, F.R.S.
Surgeon to, and Lect. on Anat. & Phys. at, St. Bartholomew's Hospital.

RICHARD PARTRIDGE, F.R.S.
Prof. of Descrip. and Surg. Anat. King's College, and Surgeon to King's College Hospital, London.

BENJAMIN PHILLIPS, F.R.S. London,
Surgeon to the Westminster Hospital.

SIMON ROOD PITTARD, Esq.
Associate of King's College, London.

W. H. PORTER, Esq.
Prof. of Surgery to the Royal Coll. of Surg. in Ireland.

G. OWEN REES, M.D. F.R.S.
Physician to Guy's Hospital.

J. REID, M.D. (the late),
Prof. of Medicine in the University of St. Andrews.

EDWARD RIGBY, M.D. F.L.S.
Late Lect. on Midwifery at St. Bartholomew's Hosp.

J. FORBES ROYLE, M.D. F.R.S. F.G.S.
Prof. of Materia Medica in King's College, London.

H. HYDE SALTER, M.D. F.R.S.
Physician to Charing-Cross Hospital.

S. JAMES A. SALTER, M.B., London.

HENRY SEARLE, Esq., London (the late).

W. SHARPEY, M.D. F.R.S.
Prof. of Anat. and Physiol. in Univ. Coll., London.

JOHN SIMON, F.R.S.
Surgeon to, and Lect. on Path. at, St. Thomas's Hosp.

J. Y. SIMPSON, M.D.
Fellow of the Royal College of Physicians, and Professor of Midwifery in the University of Edinburgh.

SAMUEL SOLLY, F.R.S.
Surgeon to St. Thomas's Hospital.

GABRIEL STOKES, M.D.

J. A. SYMONDS, M.D.
Physician to the Bristol General Hospital.

ALLEN THOMSON, M.D. F.R.S.
Prof. of Anatomy in the University of Glasgow.

JOHN TOMES, Esq. F.R.S.
Surgeon-Dentist to the Middlesex Hospital.

WM. TREW, Esq. (the late).

W. VROLIK,
Prof. Anat. and Phys. at the Athenæum of Amsterdam.

RUDOLPH WAGNER, M.D.
Prof. of Anat. and Phys. in the Roy. Univ. Göttingen.

W. H. WALSHE, M.D.
Prof. Med. Univ. Coll. London, Physician to University College Hospital, &c.

N. WARD, Esq.
Demonstrator of Anatomy, and Assistant Surgeon to the London Hospital.

R. WILLIS, M.D.

THOMAS WILLIAMS, M.D., Swansea.

W. J. ERASMUS WILSON, F.R.S.
Consulting Surgeon to the St. Pancras Infirmary.

J. WOOD, Esq.
Demonstrator of Anatomy in King's Coll. Lond., Assistant Surgeon to King's Coll. Hospital.

THE SUPPLEMENTARY VOLUME.

SUPPLEMENT.

OVUM.—In Animal Anatomy and Physiology, the Egg, the product of parental sexual generation, from which the young of animals are produced.

The Functions of Reproduction, as observed in the higher orders of animals and in the human species, are generally divided into two classes of processes; the one of which comprehends those operations by which the parents contribute to the production of the germs from which the young are formed; the other, those processes or changes which occur more immediately in the product of generation itself, and which relate to the formation or development of the new being from a germ or ovum. In the Article Generation of this Cyclopædia, the functions belonging to the first of these divisions have been described; and it is proposed in the present Article to treat of the second class of reproductive phenomena, or those which relate more immediately to the origin, formation, and growth of the new being, and which are usually described under the titles of Ovology, Embryology, and Fœtal Development.

In this, as in the former article, the history of the functions as they occur in the human species will receive the greatest share of our attention; but in describing the process of development of the young, still more than in the history of the functions of the parents that are preliminary to the production of a perfect germ, it is necessary to extend our observations to the various members of the animal kingdom, and even in some degree also to plants, from which, as much as from direct observations or experiments in man, has been derived our knowledge of the individual facts and of the general laws relating to the process of embryonic development.

The arrangement followed in that part of the article which treats of Development will be adapted more immediately to the consideration of human reproduction; and the statements in regard to animals, or to organised beings in general, will be made chiefly subordinate to, or illustrative of, the functions in the human species; but the facts in human and comparative embryology are so intimately connected, that it will be expedient to incorporate with the article such a description of the formative process in different animals as may present a sketch of the general nature of this interesting process in the whole animal kingdom.*

In pursuing this plan, the topics to be discussed may be arranged under the following heads: viz.—

1st. Nature of the Ovum in general, with reference to the different forms of the reproductive function in various animals.

2nd. The structure, properties, mode of origin, and formation of the Ovum.

3rd. The changes which the ovum undergoes in the process of Fecundation, and (in so far as the ovum itself is concerned) the circumstances which influence that process.

4th. The external circumstances which influence the development of the ovum and embryo, especially Incubation and Utero-gestation.

5th. The Phenomena of Fœtal Development in general, and the history of the origin and development of each system, organ, and texture of the body in particular.

6th. The Functions of the Embryo or Fœtus as compared with those of the adult.

The wide-spread importance of embryological anatomy and physiology is now so generally acknowledged by all who have made them a subject of study, that to them no apology is required for the length of this treatise. To those who have not made them an object of their special attention, it will be enough at this place to advert to the extensive range of topics which must be embraced in an attempt to trace the history of the first origin and subsequent evolution of all the parts of so complex and various a structure as the body of animals; and to remind them that this department of science professes to describe not merely the successive changes of external form and relation by which the several organs, springing from imperceptible beginnings, arrive at their perfect condition, but also the more minute phenomena of histological development, or changes of the several textures, which accompany the more obvious formative processes; that, as in many instances the complete knowledge of

* It was originally intended to have treated in the same article of the embryology of plants; but the extent and importance of that subject in connection with general physiology makes it necessary to postpone its consideration to a separate article, under the head of Vegetable Ovum.

the structure and function of an organ is only to be obtained by the observation of its fœtal conditions, the study of development is accessory or supplementary to many departments of anatomy and physiology; that, in recent times, no branch of inquiry relating to organic nature has made more rapid progress, has presented a greater amount of new discoveries, or has influenced in a greater degree the views of scientific men on allied subjects, than the science of embryology; that it is coextensive with, and illustrative of, the whole range of comparative anatomy; that no system, therefore, of zoological classification can be regarded as philosophical or complete which neglects the facts and principles of fœtal development: finally, that some departments of pathological anatomy receive considerable illustration from our science, and that more especially the scientific study and comprehension of teratology or congenital malformations is founded entirely on an accurate knowledge of the phenomena and laws of development. Our subject, therefore, is not only interesting by itself, but deeply important as an essential branch of philosophical anatomy and physiology.*

Before proceeding with the particular history of the ovum, and its development in man and the higher animals, which will form the greater part of the following article, some topics of a general and preliminary nature present themselves for our consideration.

The investigation of the process of reproduction in the lower animals has made so much progress during the last few years, that it becomes necessary to place before the reader a sketch of the aspect in which more modern researches enable the physiologist to view the relation of the ovum to the sexual generative function, and to the other means by which individuals are multiplied, or species are reproduced in the whole animal kingdom. In the Article GENERATION, the commonly received distinction was drawn between the sexual and the non-sexual modes of generation; and under the latter form a variety of processes of Gemmation and Division were alluded to as occasional or constant substitutes in a certain number of animals for the more permanent sexual form of the reproductive process. At the time of the publication of that article, the sexual organs had not been discovered in a considerable number of the lower animals: but since then, the assiduous and accurate researches of embryologists have gradually diminished the number of animals so situated, by bringing to light the male and female reproductive organs, or their essential products, in nearly every species of the animal kingdom; so that now only a very few, and those of the simplest organisation, remain, in which the bisexual condition has not been detected. These animals belong exclusively to the division of the animal kingdom recently established by Zoologists, as Protozoa, comprehending the Polygastric Infusoria, Rhizopoda and Porifera.*

In all other animals it is now ascertained that fecundated ova, formed by an act of sexual generation, are the means of securing the permanent reproduction of the species; but in several of them, as is especially well known among the Polypine tribes, a vast multiplication of individuals, sometimes living separately, but more frequently associated in groups, or living in united colonies, takes place by a non-sexual process of reproduction, which may be compared in many instances to the growth or repetition of the parts of a tree or plant by budding.

Recent investigations have made it more and more apparent, that the non-sexual multiplication of animals ought to be distinguished into several kinds, according to the different circumstances in which it may occur. In a few, as already remarked, it is entirely without known sex: in others, the non-sexual process of gemmation, or division, gives rise to new individuals, which are simply the repetitions of the perfect or complete animals; and in a third set, the non-sexual multiplication occurs more frequently in an incomplete condition of the animal, and often consists in the production of one or more series of dissimilar forms of animals, the last generation of which alone becomes sexually complete, and propagates the species by fecundated ova. This constitutes the variety of the reproductive process recently distinguished by the name of Alternating Generation.

Three forms, therefore, of non-sexual animal reproduction, or multiplication, are to be distinguished from the sexual mode of generation, as in the following enumeration:—

I. True sexual generation, direct or indirect, in all animals, excepting the Protozoa.

II. Non-sexual multiplication, occurring only in some of the invertebrated animals;

1st. In Protozoa, in which sexual organs have not yet been discovered.

* A variety of circumstances have contributed to cause delay in the appearance of the present article, some of them of a nature beyond the control of the author. He is sensible, however; that an apology is due by him to the readers of this work on account of the protraction of that delay. He has only to say, that in the contemplation of the vastness and imperfectly known condition of the subject, he has ever felt more disposed to engage in the investigation of some of its details, than to appear before the public as a systematic writer in regard to it. The delay may have this advantage, however, that it will enable him to introduce a greater number of new discoveries, a more accurate statement of individual facts, and more correct and extended general views of the subject than might have been possible at an earlier period, and that it will afford him an opportunity of correcting and amplifying various statements contained in the previous Article GENERATION, which the progress of discovery since the time of its publication has rendered necessary.

* The first two of these divisions may be described as simple unicellular microscopic animalcules, the third rather as a compound or congeries of microscopic animalcules: the Porifera, or Sponges, are included in this division of Protozoa, because the balance of evidence is decidedly in favour of their animal nature.

2nd. In Animals known to be capable of sexual generation; including two varieties, viz.

a. Multiplication of similar individuals, either in a mature or immature condition.

b. Multiplication of individuals, generally dissimilar from those producing them, and becoming at last mature or complete in the exercise of the true generative function.

Some account of these various forms of the reproductive process, and especially of the last, as established by recent discovery, supplementary to that contained in the Article Generation, may be introduced here, with a view to serve as a foundation for general views of the nature of the ovum, and its relation to the reproductive process in general.

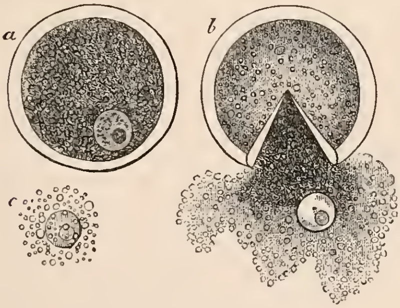
I. Of the Ovum in general, as related to the sexual Process of Generation.

The term *ovum* is in this article entirely restricted to the product of sexual generation. This body is formed in the ovary of the female parent (or in the female organ of a hermaphrodite parent) by a gradual process of growth or development. When it arrives at a state of maturity, it is spontaneously discharged from the place of its formation, a process which in the higher animals has received the name of *Ovulation.* If left to its own unassisted powers, no organic change of importance follows in the ovum, and it remains incapable of producing an embryo. But if, at or near the time when the ovum, in a state of maturity, leaves the ovary, it be subjected to the influence of the male product or sperm by the contact of a very minute portion of that substance, it then undergoes the change of Fecundation, by which it has communicated to it the power of having developed within it a new being specifically resembling its parents.

Although there are many great apparent differences in the form and structure of the ova of animals*, yet a general comparison of their organisation shows that they consist in nearly all of parts that are essentially the same. These parts in the ovarian ovum are the following, beginning with that which appears most essential: 1st, The *Germinal Vesicle*, or *Germ-cell;* a nucleated organic cell of microscopic size, generally situated near the surface of the ripe ovarian ovum: this is embedded superficially in, 2nd, The *Vitellus*, *Yelk*, or *Yolk*, a mass of oleo-albuminous matter, partly fluid, and partly cellular and granular, generally of proportionally much greater size than the germ-cell, and serving to furnish materials for the changes of that body, and for the development of the new being. Both of these parts are enclosed by, 3rd, The *Vitelline*, or *Yolk-Membrane*, a vesicular, nearly structureless, membrane, which contains the rest, and gives to the whole usually more or less of a spherical form. To the assemblage of these parts, constituting the ovarian ovum, and which may be looked upon as most immediately important in connection with the formative process, there are generally added, after it has left the ovary, and in the progress of its descent through the female passages, some others, such as the albumen, outer membrane and shell of the bird's egg. In their simplest form these additional parts constitute an external covering of the egg, to which the name of *Chorion* is often applied.

If the ovum be traced back to its earliest origin in the ovary, it is found to consist at first of the germinal vesicle, germ-cell or its nucleus (*fig.* 1, c.). To this cell the substance of the yolk is added in the progress of its formation, generally in a gradual manner, but in some animals more suddenly.

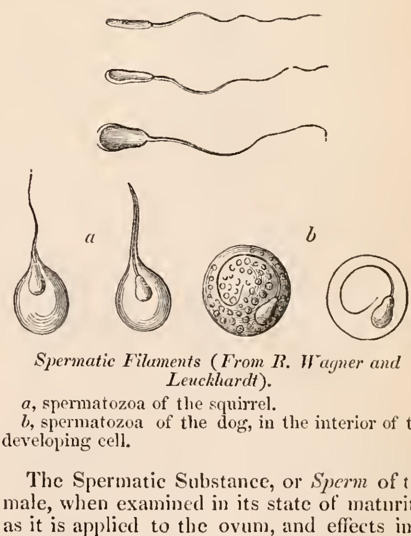
Fig. 1.



Ovarian Ovum of a Mammifer.

a, entire; *b*, burst, showing the germ-cell, with yolk granules flowing out of the vitelline membrane; *c*, the ovarian ovum at an early stage of its formation, consisting of the germ-cell surrounded by a few yolk granules.

Fig. 2.



Spermatic Filaments (From R. Wagner and Leuckhardt).

a, spermatozoa of the squirrel.
b, spermatozoa of the dog, in the interior of the developing cell.

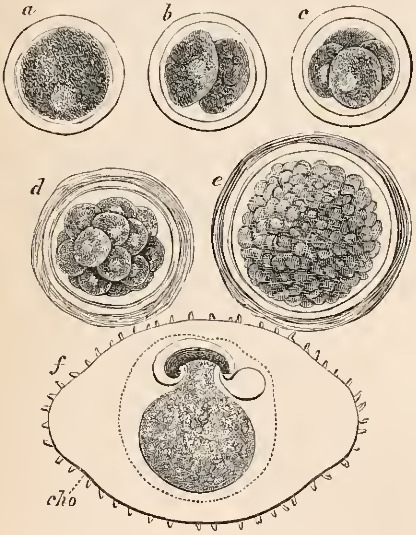
The Spermatic Substance, or *Sperm* of the male, when examined in its state of maturity, as it is applied to the ovum, and effects in it the peculiar change of fecundation, is observed to consist essentially of an immense number of minute bodies, generally consisting of a thicker particle, with a fine filament attached,

* The most important of these will be noticed in a later part of the article.

and almost always exhibiting, when recently mixed with water, vivid vibratory or undulatory movements, but in a few animals presenting other forms, and without motion. These spermatic filaments or particles are developed by a peculiar process in the interior of the cells (*sperm-cells*) secreted in the male organ or testis.

When the ovarian ovum has arrived at maturity, the germ cell disappears as such, and if fecundation shall have taken place, that vesicle is succeeded by another minute cell, with which the origin and development of the new animal are most intimately associated. This secondary organic cell of the fecundated ovum has therefore been called the *Embryo-cell.* The first changes, preparatory to the commencement of the development of an embryo, consist in the formation out of the embryo-cell and yolk substance of an organised cellular mass, or of a membranous covering of the whole or a part of the yolk: this is the *germ-mass*, *Blastoderm*, or *germinal membrane.*

Fig. 3.



Fecundated Ovum of a Mammifer, with the Embryo Cell and its division.

a, ovum with the first embryo-cell ; *b*, division of embryo-cell and cleavage of the yolk round it ; *c*, second division and cleavage ; *d*, farther division ; and *e*, germ-mass or Blastoderm forming ; *f*, diagram of the embryo with its membranes, the amnion, allantois, &c., within the chorion.

The process by which this primary organised part is produced varies somewhat in different animals; but it appears to consist in a multiplication of the embryo-cell by changes of the nature of cytogenesis, accompanied with more or less of a cleavage or sub-division of the substance of the yolk, and its combination with the progeny of the embryo-cell. The general result is, that the first rudiments of the new being take their origin in organic cells, which are descended from the original embryo-cell.

From this blastodermic mass or membrane, the embryo, or fœtus, or new animal, and in the higher animals some accessory parts, which are temporarily united with the embryo previous to its birth, originate, and are gradually formed, by a various process of progressive organic growth of an epigenetic character, which is termed *Development*, or *Embryo-genesis.*

In by far the greater number of animals an ovum gives rise to only one embryo or individual, and this one becomes by itself, when its growth is complete, the perfect sexual animal, capable of contributing its share to the production of fecundated ova. But in a certain number of animals, to which allusion will be made more fully afterwards, the immediate product of development from the ovum is not at once, and by itself, converted into a complete sexual individual; but by an intermediate non-sexual process of production, one or more new individuals are formed out of the body of that first developed, and to the last so formed is committed the office of sexual reproduction, or true generation.

The essential conditions and phenomena, therefore, of the sexual process of generation, as related to the ovum, and as limited by the foregoing considerations, may be shortly stated to be the following:—

1st. The formation of the ovarian ovum of the female sex, containing the germ-cell.

2nd. The formation of the sperm-cells of the male sex, and the development of their peculiar spermatic elements.

3rd. The mutual action of these two products in the fecundation of the ovum.

4th. The disappearance of the germ-cell of the ovarian ovum, and the formation of the embryo-cell in the fecundated egg.

5th. The multiplication of the embryo-cell by cytogenesis, and the formation from that body, and from the yolk, or a part of it, of the blastodermic mass or membrane.

6th. The process of embryo-genesis, or development of the systems, organs, and textures of the new animal.

It is right to state that the original germ-cell has not yet been ascertained to exist in the ovum of every animal, nor has its successor, the embryo-cell, been observed in all instances; but they have been detected in so very large a proportion, that it appears extremely probable that in all sexual animals the generative process consists in the process above described, or in some modification of it. I refrain at present from farther details as to these phenomena, and have stated the results only in their most general form, because I shall have occasion to return upon some of them in a subsequent part of the article. Looking back on this general statement of the commencement and progress of the genetic process in animals, it will be seen that the new being may be considered as taking its immediate origin from the progeny of cells descended from the embryo-cell. That cell appears with great probability to take its origin from the germ-cell, or its nucleus, or from some part of it, in combination with a determinate portion of the sperm product, or descendent of the sperm-cell; and we are so far justified, therefore, in ascribing the genetic process by which the new being is formed to the mutual action of the products of two different kinds of cells, viz., the germ-cell and the sperm-cell.*

In conclusion, the ovum may be defined to be a distinct vesicular body originally formed from a cell, presenting throughout its existence the organic cellular structure, consisting of oleo-albuminous materials, formed by the female of an animal species, and capable, when acted on by the spermatic product of the male, of undergoing the successive changes of embryo-genesis, by which, either directly or through intervening generations, the species of animals is reproduced and continued.

The structural distinctive characters of an ovum are, therefore, its enclosure within a distinct vesicular covering, and its original organic cellular constitution in the germ-cell: its most important physiological characteristic is its susceptibility of the changes of embryonic development under the influence of the sperm-cell or its product.

II. Of the non-sexual Mode of Generation.

The necessity of distinguishing several kinds of non-sexual reproduction according to its occurrence in animals entirely without sex, or believed to be so, and in those which may also be propagated in the sexual mode, has already been adverted to. A farther distinction of the non-sexual reproduction may be made according to the nature of the process itself: thus, some forms of it consist in the development of buds, so intimately united with the parent substance, that scarcely any difference can be perceived between their mode of formation and that of continuous growth, as in Hydra and various Polypes: other forms consist in the development of new individuals from germs so isolated in their form and cellular in their structure, that it might seem at first sight arbitrary to distinguish them from ova, as in Aphides; others appear to hold an intermediate place and character between these two forms, as in Salpa: while, in a fourth set, a more complex and varied series of changes occurs, which may be regarded with probability as modifications of the gemmal or germinal processes, as in Medusoid Polypi, Taenia, &c. But it will be apparent from what follows that we are as yet very far from that exact knowledge of the nature and first origin of buds, gemmæ, or other kinds of germs, from which animals may be multiplied in the non-sexual modes, which would enable us to form satisfactory general conclusions as to their mutual relations, and their similarity or difference, as compared on the one hand with organic growth, and on the other with oval development.

As the accurate determination of these relations is in a great measure impossible, it will be expedient for the present to state only very briefly the general characters of the several non-sexual modes of reproduction, before selecting for more particular consideration some varieties of the process, the recent investigation of which seems calculated to influence in a considerable degree future general views of the whole subject of reproduction. We shall also defer for the present any minute consideration of the relation of these processes to the growth or development of cells, for we shall have occasion to treat more at length of that subject in a subsequent part of this article, and in that of vegetable ovum.*

At this place it is only necessary to remind the reader, that all processes of development, whether in the earliest or at more advanced stages of formation, appear to consist essentially in, or are more or less intimately connected with, a multiplication of organic cells in the parts that are developed. In the unicellular beings, fissiparous and gemmiparous multiplication may easily be recognised to be processes of cell growth; the one consisting in the division of the parent cell into a progeny of two by a nearly equal partition of its substance; the other, in an extension and gradual enlargement of a small or limited portion of the original cell. But in many of the instances of fission and gemmation on the larger scale with which we are acquainted, observation has not yet pointed out the primary cell, if it exists, from which the process of division or extension begins; and, indeed, most instances of fissiparous division may, as Dr. Carpenter has remarked, be referred to a peculiar modification of gemmation.

The process of budding or gemmation is usually stated to occur in one of two modes. 1st, by the extension of a part of the parent body which remains in organic connection with it during the development of the new individual from the bud; the attached bud either sprouting from the exterior, or being developed in the interior of the parent stock. 2nd, by the development of the new individual from a small detached portion of the substance of the parent, which undergoes the principal formative changes after its separation. These separate buds have been called gemmae, gemmules, bulbils, &c., and two kinds of them may also be distinguished according as they are thrown off from the external surface of the parent body, or are formed and become loose within its interior. These gemmules have frequently attained to some degree of development by the time of their separation, and very often are provided with cilia over their surface, which cause them to move

* These views have been stated with great clearness by Prof. Owen in his various writings, especially in his Essay on Parthenogenesis, and Lectures on Generation, &c., in Medical Times, 1849, and by Dr. Carpenter in his Principles of Physiology, General and Comparative. 1851.

* For a very lucid and agreeable statement of these relations the reader is referred to Dr. Carpenter's able Treatise on General and Comparative Physiology. 1851.

rapidly through fluids. From the first they exhibit a minutely cellular and granular structure: but it does not appear that they are originally formed from any single nucleated cell: they appear rather from the first to be a congeries of cell progenies. They are destitute of an external envelope; but, nevertheless, it may often be difficult to distinguish between them and true ova.

The tendency to the multiplication of individuals by non-sexual reproduction is greatest among those animals which are of the simplest organisation, and more especially among those in which the cellular structure predominates; not that it is confined to them, nor that it occurs in all animals so constituted, but that it is much more frequent and complete in the simplest animals of each class in which it has been observed; as if it were more liable to occur in those species in which the process of individual development had proceeded to the least extent of advancement in the formation of the living textures of their bodies. There is accordingly a remarkable similarity in the nature of the processes of non-sexual multiplication and ordinary growth in these very simple animals; and it is well known that the same relation subsists between a low organisation of animals, and their disposition or power to repair individual parts of their bodies lost by injury or accident.*

1st. *Of the Process of Reproduction in Protozoa, or animals in which the sexual distinction has not yet been discovered.*

Among the Protozoa reproduction takes place in two modes, viz., 1st, by the process of gemmation or fission, and, 2nd, by development from separated gemmules or germs. For an account of the first of these processes, the reader is referred to the articles POLYGASTRIA and PORIFERA.†

Among the Polygastria multiplication by division is much more frequent than that by gemmation. It consists in the fission or division of the whole unicellular body into two nearly equal parts, each of which becomes, when separate, a perfect animalcule like the original one: in some the division is transverse, in others longitudinal, and occasionally it occurs in either of these modes in different individuals of the same species. The nucleus of the unicellular polygastria has been frequently observed to undergo division previous to the formation of the fissure, by which the division of the external wall is completed,— a fact which has led some physiologists, as Ehrenberg, M. Barry, and Owen, to attribute to the nucleus an important influence in this process of cleavage; the first of these observers having even conceived the nucleus to act the part of a male or fecundating organ. This latter view is not, however, adopted by many of those who have made a study of this class of animals.

In some of the polygastria in which the process of multiplication is either of a fissiparous or gemmiparous kind, as in Vorticella, Uvella, and Polythalamous Rhizopoda, the new individuals remain in connection, and are associated together in branched pediculated groups, in connected masses of a globular form, or in regular spiral united series.*

The Porifera, or sponges, appear to be reproduced by a different kind of gemmation from that now described in polygastria,—viz., by separate gemmules or small portions of the substance of the sponge, which, soon after having been detached from the main stock, are moulded into a spherical form, and, being provided with cilia, move about in the water with great vivacity for a considerable period. These gemmules are thrown off in numbers proportional in some measure to the activity of the nutrition of the sponge, and therefore principally during the early part of summer. Towards the approach of winter a different kind of reproductive bodies is observed to be formed,— viz. small capsules containing globular germs, which, after development within the capsule, pass out of it and produce a new sponge for every capsule or germ. These bodies have been called ova, and certainly they bear very great resemblance to them; but too little is known of their nature and origin to enable us to form an opinion whether they are to be regarded as precisely of the same nature as ova or not. In the mean time they may be named the capsular germs.†

But it appears that, among the polygastria, and rhizopoda also, there are sometimes formed, by a peculiar process not ascertained to be of a sexual kind, minute reproductive bodies of a cellular structure, which, if they are not true ova, are at least substitutes for them.‡

* See Mr. Paget's recent interesting lectures on this subject, published in Medical Gazette, 1849.

† A considerable number of the polygastric infusoria described by Ehrenberg in his great work on that class, are now very generally regarded as belonging to the vegetable rather than to the animal kingdom, such as the families Closterina, Volvocina, and Bacillaria.

* See an interesting paper by Dr. Carpenter on the Genus Nummulina and other Foraminifera in Quart. Journ. of Geol. Soc. Feb. 1850. Some judicious and interesting remarks on this class of animals, and on the relations and characters of the Protozoa in general, are contained in a recent paper by Mr. Huxley in the Annals of Natural History (1851, vol. viii. p. 437.), in which he has described a curious monocellular genus named Thalassicolla, which occurs in masses, and forms spicula somewhat like a minute sponge.

† See Laurent's elegant memoir, Recherches sur l'Hydre et l'Eponge d'eau douce. 1842.

‡ Allusion is not made here to the production of granules by the diffluence of an infusorian animalcule erroneously taken by Ehrenberg for the deposition of ova, but to a very different process. Dujardin, who pointed out this error (Hist. Nat. des Infusoires, p. 101.), is of opinion that, besides the processes of fission and gemmation, we know nothing with certainty of the reproduction of infusoria; but he admits that it is possible that the minute bodies into which an infusorian breaks up by diffluence might prove the germs of new individuals. Dr. Carpenter has mentioned several instances of a kind similar to those alluded to in the text, and has expressed the opinion that something of the nature of sexual production may yet be discovered to take place in these animals (Prin. of Gen. and Comp. Physiol. p. 249, and p. 917.). Observations of a similar kind are re-

Some recent observations appear to throw additional light on this subject, and to make it probable that in some circumstances this process is in some sort analogous, or at least equivalent, to one of sexual reproduction.

The first accurate observation of the development of a progeny of young cells within the body of a polygastrian was communicated by Focke in 1844 to the meeting of naturalists at Bremen, and the fact of the production of internal germs or bodies resembling ova or spores within the body of these animalcules has recently received full confirmation from the observations of Stein and of Cohn.*

In Cohn's observations, which were made on a paramaecian polygastrian, the Loxodes

a, animalcule, containing two young; *b*, containing six; *c*, one of the embryos escaping; *d*, *e*, two ciliated embryos.

bursaria, which is usually multiplied like the rest, in the fissiparous mode, sometimes by longitudinal, at others, by transverse division, it was found that at certain periods there were formed within the bodies finely granular colourless cells, in some only one, more frequently several, and occasionally as many as six or seven, nearly of a uniform size, and

ferred to under the head of 'sporiferous reproduction,' by Prof. Rymer Jones, in the article POLYGASTRIA.

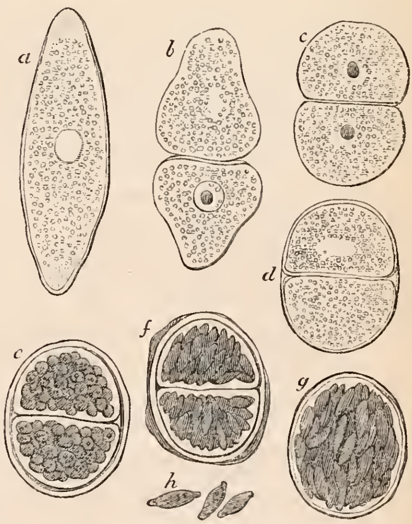
* Stein, Untersuch. üb. die Entwick. der Infusorien, Wiegmann's Archiv., 1849, vol. I. p. 134. in Actinophrys, Acineta, and Chilodon uncinatus. Cohn, in Zeitsch. für Wissensch. Zoologie, Nov. 1851, p. 257.

each presenting two contractile vesicles like the parent. The escape of these bodies, by their passage through an aperture temporarily formed in the wall of the infusorian, was carefully observed; the exit of each embryo occupied about twenty minutes. Soon after their escape they exhibited active ciliary motion, and moved about with all the appearance of embryo-infusoria. Although the farther development of these bodies was not traced, the observations on this animal, and on another, the Urostyla grandis, afford sufficient proof that the infusoria may be propagated by minute separate germs, as well as by division of their bodies.

A similar production, but more numerous, of an internal progeny, has been observed in the microscopic parasitic animalcule termed Gregarina, which infests the intestinal canal of a number of insects, earth worms and some other invertebrate animals.*

The simple Gregarina consists of a single cell filled with granular substance, and containing a distinct nucleus. It has no intestinal canal, nor other internal organisation; is generally of an elongated shape, and creeps about by motions of slow contraction of its substance. The formation of the progeny or smaller bodies within the Gregarina is attended with a remarkable change in the parent animal, which has been carefully observed by Stein. This change, in which the animal appears double for a time, had been previously noticed by Kölliker and others, and had been interpreted by Kölliker as the conversion of a single animal into two, by a process analo-

Fig. 5.



Gregarinæ (from Kölliker.)

a, single; *b*, *c*, *d*, united; *e*, *f*, *g*, the formation of the navicella-like progeny; *h*, three of these navicellæ (from Stein).

* These animals were first accurately described by Leon Dufour in 1837 (Ann. des Sc. Nat. vol. vii. p. 10.). They have since been studied with great

gous to transverse fission. Stein, on the other hand, has been convinced by a very attentive observation of the different stages of this process, that it is of an opposite character, and that, previous to the development of the young progeny, two of the Gregarinæ have become fused, or united into one. As the two are about to unite, they gradually change their form from that of elongated planaria-like animalcules, to that nearly of hemispheres, closely pressed together; then a complete fusion or union occurs, and the whole of the granules of both having become amalgamated in one sphere, the development of the internal progeny takes place gradually from the mass. This progeny consists in a vast multitude of minute bodies, shaped like the Navicellæ (among the Diatomaceæ), but different from these bodies, and very probably constituting the reproductive germs or embryos of Gregarinæ. The development of this Navicella-like progeny into the Gregarina does not appear as yet to have been traced; as in this animal, like many other parasites, the progeny is required to migrate during its development from one stage to another, and the little bodies are passed out of the alimentary canal of the insect before undergoing farther changes.

The views and observations of Stein, however, should they be confirmed by others, would prove the very remarkable fact, that the phenomenon of conjugation, or fusion of two unicellular individuals, hitherto supposed to be confined to some of the simpler plants, as Closterium, Spirogyra and Zygnema, &c., may occur also in animals of a similar simple structure.

These observations on the Gregarina are not altogether of an isolated kind. In a recent interesting notice of this subject by V. Siebold *, he has called attention to the observation of Kölliker on the conjugation or fusion of two individuals of Actinophrys †, a spherical infusorian animalcule analogous to the Amœba or Rhizopoda, by its slowly contractile, amorphous texture, and its long, radiating, contractile processes. Kölliker observed two individuals of this animalcule to approach each other, adhere, and gradually to fuse into one, which soon assumed the same globular form, with the radiated contractile processes, as each of the two that formed it, and differing only from them by the increase of size which it sustained. This very curious observation has been confirmed by Stein, in an allied genus Podophyra, both of the sessile and pediculated kind; and V. Siebold has observed the same phenomenon in a species of Acineta belonging to the same family of Infusoria. Cohn, also, has repeated and confirmed Kölliker's observations in the Actinophrys sol, and has made a farther discovery of great interest in connection with the process of conjugation in these animals, having observed after the union, both in the Acineta and Actinophrys, the development, at certain periods, between the united individuals, of a spherical body of considerable size, vesicular form, and containing within it a nuclear formation of variable magnitude.

Although the farther development of this body has not yet been traced, it seems not improbable to V. Siebold that it may be analogous to the reproductive capsule or sporo-cyst of the conjugating Closterium or Zygnema*, from which bodies it seems to be certain that a number of reproductive spores are produced.

Since the foregoing was written, indeed, renewed researches by Stein † have come under my notice which are confirmatory of the view previously stated as to the reproductive process in Gregarina, and explain in a great degree the apparently incomplete observations of Pineau ‡ and others as to the varying conditions of Vorticella, and also extend our knowledge of the production of germs of the Infusoria. Stein observed the Vorticella microstoma to lose its pedicle, become free, assume the globular form, and at last to be enclosed in a cyst produced by exudation from its own body. After a time the band-like nucleus of the encysted Vorticella is divided into a number of small discoid bodies, not by a regular or progressive process of cell-cleavage, but at once and directly. These minute bodies gradually increase in size at the expense of the granular and fluid substance surrounding them in the cyst, and ultimately escape in the form exactly of Monas colpoda (of Ehrenberg). These very soon fix themselves; and a fine pedicle is developed at the place of attachment. In other instances the Vorticella-cyst was observed to send forth long contractile processes from its surface, and then assumed very much the form and appearance of an Acineta or Actinophrys; and in this case a new Vorticella was formed in the interior in the manner of a bud. The Vorticella, therefore, it would appear, is capable of reproduction in two modes,—by the development of embryoes from the divided nucleus, which Stein on this account proposes to call nucleus germinativus (the testis of Ehrenberg); and by gemmation from an intermediate Acineta form. The first form Stein would regard as the equivalent of sex-

success by various observers, as V. Siebold (Beitrag. Z. Naturgesch. Wirbellos. Thiere, 1839, p. 63.). Henle (Müller's Archiv, 1845, p. 369.), and Stein in the same, 1848, p. 182. Kölliker (Zeitsch. f. Wiss. Zool. 1848 and 1849), and as many as eighty different species of them have now been discovered.

* Zeitsch. f. Wissensch. Zool. March, 1851, p. 62.

† Op. cit. 1849, p. 207. In this very interesting memoir Kölliker has proved the animal nature of the Actinophrys by his observations on its contractility, and on the manner in which the particles of solid matters, vegetable and animal, are involved in its substance for the purpose of digestion, and their remains again rejected when that process is completed.

* See the Article Vegetable Ovum for an account of this process in the lower forms of plants.

ual production ; the second as coming under the category of alternate generation ; and the Vorticella embryo of the Acineta-form either repeats its gemmal multiplication, or becomes encysted, and gives rise then by its nuclear division to embryonal production. Other new forms of Infusoria are described by Stein under the names Spirochona gemmipara, Dendrocometes paradoxus, and Lagenophrys vaginicola, ampulla, and nassa, in which the mode of reproduction is somewhat similar.

These observations at once show the importance of the views entertained by some authors as to the share the nucleus may take in new production, and strongly indicate that much still remains to be known from observation of the processes of reproduction among the Infusoria.

Should these observations be confirmed, another analogy, in addition to those already observed, will be shown to exist between the organisation and functions of the Protozoa, and those of the lowest plants.* The tendency of various other recent researches, to which it has been impossible to refer more particularly in this place, seems to be to show that, in addition to the more common and obvious mode of multiplication by division and gemmation, by which the Infusoria, when vigorous and well nourished, are reproduced, there are other means by which, in different circumstances, the more permanent reproduction of the species may be secured; that minute cells are formed within them for that purpose, which may at present be called reproductive cell-germs rather than ova, till a more complete knowledge shall have been obtained of their nature and of the circumstances attending their formation; and that it is very probable that in the protozoa, as in the simplest plants, the combination of the contents of two cells, to all appearance similar, may, as in the process of conjugation, be the necessary preliminary step to the development of the reproductive germs.

It ought at the same time to be kept in view that the Infusoria may, like many other animals, be subject, some to metamorphosis, and others to alternate generations. Already, since the publication of the great work of Ehrenberg, most important modifications of his system of these animals have been found necessary, and it seems almost certain that it is destined to undergo still farther changes, many of those forms which are now recognised as belonging to distinct genera and species being possibly no more than different stages of development of the same animal.

2nd. *Of the possibility of primary, direct, or non-parental production of animals, or of so-called spontaneous and equivocal generation.*

From what has before been stated as to the very general, and almost universal, existence of the sexual mode of generation among animals, and from the reasons that have been given for the belief that in those few and simple animals in which a sexual distinction has not yet been ascertained, there may still be propagation by means of minute germs, the reader will already have drawn a conclusion as to the very insufficient nature of the proof that can now be adduced in favour of the view that certain animals may arise independently of pre-existing individuals of the same species. The hypothesis might, perhaps, be at once dismissed with the remark of a recent writer*, "that it is safer to trust to generally prevailing laws, than to confide in such of our observations as are contrary to them." But as in the article GENERATION†, the author was led by a careful examination of the evidence then available on the subject, to admit the probability of the non-parental mode of production as an exceptional occurrence, at least among the lowest tribes of animals and plants, and as that hypothesis has since gradually lost more and more of its probability, from the accumulated opposing proofs resulting from more recent researches, so as, in his opinion, to be now no longer tenable, it may be proper at this place to review briefly the bearing of the present more advanced knowledge of the generative process upon this long and keenly debated question.

Admitting, in the meantime, that the ova, or separate germs of Infusoria, have not yet been discovered with certainty, there are not wanting direct experiments which demonstrate that in an infusion of organic matter which would, when exposed to the air, naturally furnish a rapid succession of these productions, the development of living organisms is entirely suspended, if the arrangements are made such as to render it impossible for any germ or other part of a previously existing infusorian animalcule or plant to be communicated to the infusion. The experiments of Schultze and of Schwann are valuable, as appearing to have secured, in a great measure, the above-mentioned conditions, without otherwise interfering with the validity of the result. The first of these ob-

† P. 429.

servers* placed in a glass flask an infusion of organic matter, a portion of which was known from comparative trials, when left exposed to the open air, soon to have animalcules developed in it in great quantity, and he connected this vessel with a tubular apparatus, by two apertures, in such a manner that the air, which was made to pass frequently through the vessel containing the infusion, should be drawn through strong sulphuric acid, or potash solution, before reaching it; and Schwann † arranged a similar experiment, having in view to secure the like conditions, by causing the air, which had access to the infusion, to be previously passed through an iron tube at a red heat. Before the commencement of these experiments, the infusion and the apparatus were carefully subjected to the temperature of boiling-water, by which it was presumed the vitality of all ova, or germs, or other organic particles must have been destroyed: and the result was the same in both the series of experiments, — viz., that, after a considerable lapse of time, no animalcules nor confervoid plants were formed: but when the atmospheric air was afterwards allowed to pass freely over the same infusion, without being subjected to the processes before mentioned, a rapid production of infusory animalcules took place in the usual manner.

The results of these experiments appear to be on the whole satisfactory, and nearly to decide the question as far as relates to the probability of the introduction of the germs of Infusoria, &c., into infusions by the air. But, indeed, the failure of many experiments of this kind, when not performed with the most scrupulous accuracy, need not excite surprise, when the very indestructible nature of some kinds of infusory animalcules is considered. It has long been known, and has been ascertained by the careful experiments of Spallanzani, Bauer, and Doyère, that some of the Rotifera and Tardigrada are capable of supporting a high temperature without loss of life, and of being kept for years even in the state of complete dryness, without loss of vitality: and, although it must be admitted that these animals differ greatly in their organisation from the Polygastric Infusoria, and the latter appear to be very liable to destruction from slight causes, yet it is possible that their germs may resist destruction in a greater degree than their adult forms: and, should only one of these animalcules, or its germ, be left in any situation favourable to its development, it is easily understood, from what is known of the production of these beings, with what rapidity a vast multitude of them may be brought into existence by their ordinary process of fissiparous increase.

Most physiologists are inclined to reject as fanciful and inaccurate the alleged observations of the actual conversion of particles of organised or organic matter into living infusoria. At all events, statements of this kind are to be received with the greatest caution: such, for example, as the observations stated to have been made by Pineau*, who affirms that he has seen the direct conversion of particles of disintegrating muscular fibre, isinglass, and wheat-flour, into various forms of living infusoria.

The spermatic filaments also, which, so long as they were looked upon as independent animals, were referred to as examples of an undoubted spontaneous generation, furnish no evidence in favour of that hypothesis in the view in which they are now regarded by physiologists: for they are to be considered rather as a peculiar product of organic growth within the spermatic cells, somewhat analogous to the fine moving processes of the ciliated texture, than as distinct organisms.†

In so far, therefore, as the theory of spontaneous generation may have been supposed to derive support from the formation of the lower forms of plants and animals in infusions of organic matter, that hypothesis must be considered as having lost the greater share of its probability, if, indeed, it has not been entirely disproved: but it must at the same time be admitted that a more precise acquaintance with the nature of the germs from which these organisms take their origin is still required to render the arguments derived from this source entirely conclusive.‡

The external and internal parasites which infest the bodies of almost all animals have in former times been held to afford a still stronger presumption in favour of spontaneous generation than the production of infusoria; but it will be found that in this instance, to a much greater extent than in the other, the probability of the view has gradually passed away before the increasing knowledge which modern research has afforded of the various modes of propagation of these animals.

The ready communication of various Epizoa, or external parasites, from one animal to another is now well known, and accurate observations have demonstrated that in almost all instances this communication may be traced to the implantation of ova, or pregnant individuals into their parasitic abode, as in the researches on the Sarcoptes scabiei, &c.

The parasitic fungi, also, of various cutaneous diseases, as tinea, porrigo, plica polonica, foul ulcers, &c.; the yeast-plant, the vinegar-plant, and other minute fungi connected with fermentation; the contagious algæ of the batrachia and fishes; the muscardine of the silkworm, are all well proved to be communicable by the deposit of their spores, or some part of their substance, upon the external surfaces of the bodies of the animals on which they grow, or by their introduction into cavities opening on the exterior.

All the internal parasites, or Entozoa strictly

so called, are now known to be capable of true sexual generation, by means of ova, in their perfect or complete condition, and the whole class is remarkable for the great development of the sexual organs, and the prodigious numbers of ova which they bring forth. But it has been ascertained that their ova are rarely developed into new beings in the place of the abode of the adult entozoa: they are commonly subject, therefore, to migration from one organ to another in the same individual, or from one animal to another, or from the parasitic to the free-living condition; and they have recently been discovered to present very remarkable changes of external form and internal organisation in their various habitations; so great, indeed, that many of them, previously believed to belong to species, and even to genera and families widely different, are now recognised as different conditions of the same animal or species, and that many forms, whose mode of generation was unknown, are found to be derived by indirect production from ova, in a manner which will be more particularly described under the next section.

Thus it appears that the only entozoa which are destitute of sexual organs, viz. those belonging to the division cystica, are very probably only imperfect forms of Taenia or other cestoids, which, so long as they are in the encysted or confined condition, do not reach their full development: but many of which, during their incomplete condition, are capable of being multiplied by a process analogous to gemmation.

The greater number of the entozoa breed only when in the alimentary canal of animals, and the ova are excreted along with the fœces: it is obvious, therefore, that very many ova must be destroyed, and that a few only are liable to gain those peculiar situations which are fitted to maintain them in their earlier conditions, or in their later stages, to bring them, as parasites, to their full state of development.

The entozoa are usually found, therefore, in their most advanced stage, in the alimentary canal. There seems, on the whole, little difficulty in accounting for the entrance of entozoa from without into the alimentary canal, or the pulmonary air-cells and other open cavities: and every new fact that has been observed relative to the occurrence of entozoa in man and animals, leads to the conclusion that the ova, or perhaps more frequently the earlier larval or undeveloped forms of the entozoa, gain access to these situations by introduction from without, and most frequently along with food and drink; in those instances at least in which the entozoa migrate from one animal to another, or from an animal to the free state before returning to the parasitic condition. But the entozoa, which are, in general, in an incomplete state when situated in the close cavities or solid textures of the organs of animals, sometimes make their way from these situations into the alimentary canal, there to undergo their final development. Such appears to be the case with the Strongylus armatus, living in an incomplete state in aneurismal sacs of the blood-vessels of the horse, and in a fully developed state in the intestine; the Strongylus vagans, in cysts of the porpoise, and afterwards free in the lungs; the Ligula or Bothriocephalus solidus, in cysts of the abdominal cavity of fishes, and afterwards in their perfect state in the alimentary canal of sea-birds. The Trichina and Echinorrhynchi, imbedded in the muscular flesh in great quantities, are no doubt imperfect forms of other worms, which must migrate from these situations to attain to their complete state.

With regard to the manner in which the entozoa inhabiting the close cavities of the body, or imbedded in the solid substance of organs, either in the free or encysted condition, gain access to these situations, which has to many appeared inexplicable, excepting on the hypothesis of their arising actually in the places which they inhabit, observations are no less decided in proving them to be of external introduction.

In the first place it may be stated that, although the ova of a considerable number of the entozoa are of so considerable a size as to render it improbable that they have passed as such through the capillary vessels, yet few, if any, of these larger kinds are observed encysted, and in others the ova are extremely minute, and might, without difficulty, be carried through most of the capillary vessels.

In the next place it may be mentioned that the embryoes, or earlier forms of various parasites, and the ova of others, have been observed in considerable numbers in the circulating blood of various animals *, as showing that by this means the entozoa may be carried in their small and early condition into any part of the body of an animal which is fitted to afford the conditions favourable to their farther development.

But in what manner have these bodies gained an entrance into the blood-vessels, or, in other instances, how may entozoa have penetrated into cavities or the parenchyma of organs, without being conveyed through the blood-vessels? To this question, also, recent observations seem to furnish a satisfactory answer: for it has been ascertained that, in a number of instances, smaller or larger entozoa, but especially the former, pierce the tissues of animals with great apparent facility, being frequently provided in the young state with an apparatus of sharp hooks for that special purpose. Some of them have been observed in the act of passing through the

* I may here refer to the original observations of Schmitz, (Berlin, 1826), and the more recent ones of Valentin Gruby, Gluge, Vogt, and others. See Valentin, Repertorium for 1842 and 1843. The Annual Report in Müller's Archiv. for the same years, and in Wiegmann's Archiv. for Naturgesch. Valentin's account of the Ova of Distoma in the fluid covering the medulla oblongata of a fœtal sheep (Müller's Archiv. 1840, p. 317), and V. Siebold's Article 'Parasites' in R. Wagner's Handwörterbuch der Physiologie.

solid substance of organs or through membranes; and from the various stages of advancement of others already referred to, seen in different parts of the same animal, little doubt can prevail that they must have done the same: but the aperture through which they make their way, besides being in most instances very minute, seems to close very rapidly and completely after them. So that the occurrence of entozoa in entirely isolated cavities — such as the aqueous chamber of the eye, or in the parenchyma of solid organs, — does not now present to our minds any valid objection to the view that in all instances they are introduced from without; and it will be apparent, from the same considerations, that even the occurrence of entozoa in the fœtus, of which there are undoubted instances, and to which great importance has been attached as an argument in favour of their spontaneous origin, may be explained on the supposition of their ova, or young, passing from the maternal parent, through the blood-vessels of the umbilical cord, as is known to happen with various poisons.

The whole history, then, of this remarkable class of animals, as it is now known, tends to support the general conclusion that they are all capable in their complete state of sexual reproduction, and that they gain the various sites of their parasitic habitations by introduction of their ova, or embryoes, or of more advanced stages of their growth from without, either directly into the open cavities, or more indirectly, by piercing the coats of vessels, membranes, &c., into the close cavities and the parenchyma of solid organs.*

A candid review of the whole evidence on this question leads to the inevitable conclusion, that, though all the difficulties or doubts which surround it are by no means completely removed, the hypothesis of primary or spontaneous generation receives little or no direct support from the accurate observation of the mode of origin of those animals which alone were supposed to afford proofs of such a kind of production; and that this view must, therefore, on the strongest grounds of analogy, be in the meantime abandoned, for that which attributes the origin and reproduction of all organised beings to an undeviating connection through ova or germs, seeds or spores, between new individuals and others of identical species which have previously existed. And if the present somewhat imperfect state of knowledge does not permit us to affirm this absolutely, as the result of direct observation, the exceptions are so few and unimportant, that they may be disregarded in the overwhelming evidence of a positive character in favour of the opinion, derived from analogy, that every organic being, if not produced in actual union with another, derives its origin from a germ or some such connecting part that has proceeded from a being of the same kind.

If this be the present state of the argument in respect to the hypothesis of the first origin of organic beings, it need scarcely be added that the opinion which has attributed the production of various animals to conversion or gradual transmutation out of other species or genera, has still less of real to be adduced in its support. In the long series of ages in which authentic observations have been made on animals, no such examples have been ascertained, and there are no established facts which give any substantial grounds for believing that in the natural or wild state of animals there is any departure from that undeviating succession of specific resemblance between parent and offspring, which seems to form one of the most constant of the laws of organic nature with which we are acquainted.

3rd. *Production of dissimilar individuals among sexual animals by a non-sexual process: so-called Alternate Generations.*

From the foregoing general views it appears that in all Vertebrated Animals, and in by far the greater number of Invertebrated animals, the process of permanent reproduction consists in the development of the new being from the blastodermic mass formed by a peculiar process of cytogenesis in the fecundated ovum. But, as has already been shortly stated, there are some varieties among them in regard to the degree of directness with which the product of development from the ovum arrives at that state of maturity, or sexual completeness, in which it is capable of renewing the act of sexual generation. These varieties may be classed as follows:—1st. The product of the ovum, being single, attains by a gradual process of development, when it leaves the ovum at birth, to nearly the same form and structure as its parents: this is generally called *Embryological Development*. 2nd. The product of the ovum, being single, is born or leaves the egg at an early period, and while comparatively imperfect, or, as it is called, in a *larva* state, and by one or more successive changes of development of a marked kind, afterwards reaches the specific or typical form: these changes are usually called *Metamorphoses*. 3rd. The product of development from the ovum does not itself become a complete animal, but gives rise, by a peculiar mode of generation of a non-sexual character, and therefore different from that by which fecundated ova are formed, to a new body, or to successive progenies of new bodies, one or more of which ultimately attains to the specific resemblance of the sexual parents by which

* As to the bearing of a knowledge of the habits &c. of the Entozoa upon the question of their spontaneous origin, consult the able essay by Eschricht; "Inquiries concerning the Origin of Intestinal Worms &c." in Edin. New Phil. Journ. vol. xxxi. p. 314. 1841, the article on Parasites by V. Siebold, in R. Wagner's Handwört. der Physiol.; E. Blanchard's Researches on the Structure &c. of Intestinal Worms, in Ann. d. Sc. Nat. 1848 and 1849, particularly vol. vii. p. 121. Dujardin's systematic work, Hist. Nat. des Helminthes, 1845. And in connection with this and the whole subject of spontaneous generation, the Systematic Treatises on Physiology of Burdach, J. Müller, Valentin, and Longet.

the ova were produced. This is the "Alternating Generation" of Steenstrup, or what we might with Mr. Owen, in contrast to Metamorphosis, call a process of *Metagenesis**; and of which the single and multiple varieties might be distinguished according as the intermediate progeny consists of one or of successive new productions.

In the two first and best known forms of sexual generation, the term Development has been usually given to a gradual process of changing and advancing growth by which the new animal is formed out of the ovum, till the period when it leaves it, or is said to be born; and the term Metamorphosis has been generally applied to certain more marked and sudden changes of growth, apparently depending on the circumstance of the embryo or young animal having left the ovum, or having been born, at an early period in a comparatively incomplete state of growth. But in establishing such a distinction between these terms, it is not meant to be affirmed that the changes which a young animal subject to metamorphosis undergoes are individually or on the whole greater than those which occur in an animal which attains to its full growth by a process of development; but merely that the one series of changes is less gradual than the other; and that the more marked changes which accompany metamorphoses are related to certain conditions necessary to enable the animal which is born at an early period immediately to perform those acts which belong to its independent existence. It would indeed not be difficult to show that the changes which a mammal or a bird undergoes during its viviparous or oviparous development, are quite as remarkable and complete as those which occur in the change of a Batrachian reptile from its aquatic to that of its air-breathing condition, or of an insect from its larva to its complete form.

In both of these instances one individual only is developed from the ovum, and that individual itself at last reaches sexual completeness, and as being well understood they need not be longer dwelt upon here. But in the varieties of the reproductive process which are now to be more particularly noticed, the individual that proceeds directly from the ovum does not itself pass through the whole series of changes which are necessary to bring it to the form of the fully developed animal; but before it possesses any sexual organs, or has attained to sexual maturity, it produces from a minute germ formed in its body by a non-sexual process, a new individual, or a succession of individuals, the last of which only attains to the specific resemblance of the parents, and acquiring sexual organs propagates the species by means of ova. This is the modification of the reproductive process already termed *Metagenesis*, and which has received so much attention under the name of "Alternate Generations" since the publication of Steenstrup's celebrated treatise under the title of "Generations-Wechsel" in 1842.*

No examples of this peculiar modification of the reproductive process have been known to occur in the Vertebrata, and with one exception they are confined to the lower and simpler of the classes of Invertebrated animals. They are not, however, entirely confined to the very lowest classes of these animals as distinguished by the Zoologist, but rather to the simpler and less developed members of each of the several classes in which instances of them have been hitherto observed.

The essential nature of this form of reproduction consists, then, in the development from the ovum of an individual which is dissimilar from the parent or parents producing the ovum, and in the succeeding production from that individual, by a non-sexual process, of a progeny of one or more, or a succession of individuals, of which the last of the series resumes the parental form. While in animals, therefore, reproduced by the ordinary form of generation, the species is composed of entirely similar individuals, or of individuals differing only in sex; in those animals which are subject to the alternate or intermediate generation, the species includes a variety of individuals usually of dissimilar form; of which some are without sex, and others are complete as regards the development of sexual organs.

It has appeared to some authors that the phenomena in question are to be regarded as no more than peculiar modifications of the processes of development or metamorphosis, of such a nature that the product of the ovum becomes multiple instead of, as is more usual, remaining in its single individuality. But to admit the correctness of this view, it would be necessary to employ these terms in a sense widely different from that commonly given to them; and, indeed, to modify the ideas of these processes of embryological development in a greater degree than seems warranted by what is at present known of their nature.

The name of *larva* is usually given to the imperfectly developed animal that is born or leaves the egg at a comparatively early period, and fitted for independent existence in that state; and in the changes of metamorphosis by which that larva attains to the complete specific form, great as these changes may in some instances be, we recognise that it is the individual produced from the ovum which itself undergoes these changes; whereas in the various kinds of alternate generation, it is always by the formation of an entirely new individual, arising from a minute germ connected with the first, but to be distinguished from its parts, and without a sexual process, that the species is at last completed. The new individual may be single or there may be a multitude of them; they may remain connected with the one producing them or they

* Adopting a term which has been used by Mr. Owen in his Lectures. Med. Times, vol. xx. 1849.

* A work which appeared originally in the Danish language, and in German in 1842, and of which an excellent translation into English has been published by the Ray Society in 1845.

may be detached and live independently, but they nevertheless constitute different animals, and cannot be regarded in any other light than as so many individuals distinct from the one producing them, although all are descended from one ovum, or all are necessary to make up the entire species.

And it is further to be observed that each of these several animals may be subject to individual metamorphosis, and that in some classes there is so gradual a transition from individual change to new production that it may be difficult to determine to which of these forms of reproductive development their phenomena ought to be referred.

In that part of the article which treats specially of development our attention may again be called to some of the more remarkable examples of individual metamorphosis that are known: at present it is intended rather to bring prominently forward those instances of alternate generation which have been discovered since the publication of the Article GENERATION, or which, if previously known. may now be viewed in a different light, in consequence of being brought into comparison with other observations of a similar kind and of more recent discovery.

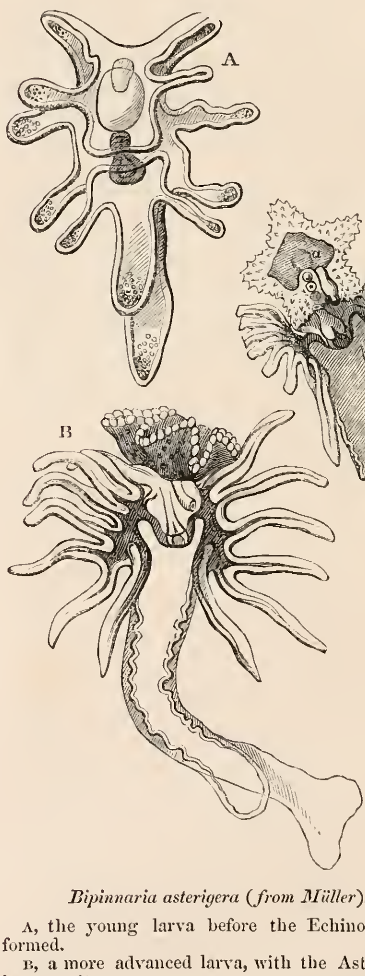
We may first consider some examples of this process, or of one very analogous to it, in which the new animal is single.

Echinodermata.— In several orders of this class a variety of the reproductive process has of late years been pointed out, in regard to which it may be doubted whether it is most of the nature of a metamorphosis or a metagenesis, but which, as it has been considered by J. Müller, the discoverer of the most interesting and remarkable of its phenomena, as in some measure analogous to the alternating generation, I will mention in this place; the more so, that it might almost be looked upon as forming the connecting link between the direct and the alternating processes of reproduction.

In some of the Echinodermata it appears from the earlier observations of Sars that the young produced from the ova are developed directly into the parental form, passing however through several marked modifications in the early stages of development. Thus, some of the star-fishes (*Asteracanthion glacialis*, Sars) leave the egg as a ciliated free moving animalcule, then they become pediculated and attach themselves, have four club-shaped processes developed on them, and, lastly, they pass by the development of the rays and the internal organs into the complete form; but here the whole, or nearly the whole, germinal mass of the ovum is converted into the embryo or larva, and the whole, or nearly the whole, of this undergoes the farther changes of conversion into the complete and sexual animal.*

From the researches of J. Müller it appears that the mode of development now described is exceptional among the Echinodermata, and that in other families of the order Asteriadæ, and in the Ophiura and Echinidæ, an embryo or larva of a peculiar kind, is formed by direct development from the fecundated ovum, which is not itself converted into the complete animal, but rather serves as a temporary stock from which the perfect animal is subsequently formed in a manner that may be compared to gemmation. But it does not appear that more than one individual is developed from each primary larva stock, and this gradually dies away, so soon as its attached offspring has made some advance in its formation. This body, described under the name of Bipinnaria asterigera, as connected with an Asterias, is a comparatively large animal, with a long pediculated body, twelve or fourteen tentacles, an alimentary canal, consisting of mouth, gullet, stomach, in

Fig. 7.



Bipinnaria asterigera (*from Müller*).

A, the young larva before the Echinoderm is formed.

B, a more advanced larva, with the Asterias on its summit.

C, the Asterias torn up to show its stomach, a continuation of the alimentary canal of the larva.

* Sars, Fauna Littor. Norvegiæ, 1846; and Ann. des Sciences Nat.; Agassiz, Lectures on Comparative Embryology, New York, 1849; and a Letter from Desor to J. Müller, in Archiv. für Physiol. 1849, p. 79.

testine, and anus, and moves actively through the water. Sars who had observed this body in 1835, was the first to suggest in 1844 that it might be the early condition of a star-fish *, and this view was confirmed by the admirable researches of J. Müller †, and by observations of Koren and Danielson ‡, who have shown that the Asterias is gradually formed out of a small granular mass which surrounds the stomach of the Bipinnaria, and becomes separated from the stock when in a comparatively early state of advancement. The larva stock moves about afterwards for a few days,

‡ Ann. des Sc. Nat. 1847, p. 348.

and then appears to die without giving rise to any farther progeny.

The gemmiparous larva of some other kinds of the Echinodermata was first described by J. Müller as a distinct animal, under the name of Pluteus, before he was acquainted with the phenomena of its subsequent development: in 1846 he traced the relation between one kind of this body which he had called Pluteus paradoxus, and the Ophiura, and between another kind of Pluteus and Echinus, ascertaining it to be the same that has just been stated to exist between the Bipinnaria and the Asterias. The Pluteus presents the form of a quadrangular pyramidal frame, with four large ciliated limbs at the angles, and four smaller ones suspended from the middle below, while the upper part is surmounted by a sort of dome. It bears some resemblance to a Beroë, and might be described as the ciliograde larva of an Echinoderm. The form differs, however, somewhat for various species of Ophiura and Echinus.

In the centre of the dome and round the mouth of the Pluteus a granular mass is described, and from the side of this, non-symmetrically, the gemmation of the new individual proceeds. The Pluteus moves at first with great activity through the water, propelled by its ciliated limbs and cirrhi; but as the new Ophiura or Echinus buds from it and spreads more and more over its dome, the Pluteus shrinks, becomes less active, and at last disappears.*

Various other forms of the Pluteus-like animal have been described by Müller, and the process of gemmation has been traced by which the new Echinoderm takes its rise within them. The result of these discoveries is already to throw an entirely new light on the nature and organisation of this class of animals; but the species of all of those observed is not yet determined, and something still remains to be learned of the exact mode of origin of the new animal. By some † the process has been looked upon merely as a secondary development from the remains of the yolk attached to the parts first formed; but the researches of Müller do not appear to give support to such a view; and would rather appear to show (as in Auricularia, *fig.* 9.), that the new animal is formed from a minute germ in a determinate part of the parent animal without that germ being traced to the yolk of the egg.

In a farther series of researches on the larvæ and metamorphoses of the Echinodermata ‡, J. Müller has pointed out that the Holothuridæ are formed from a larva body somewhat analogous to the Pluteus, but that, instead of a process of new formation, the whole of the larva is converted by a very remarkable metamorphosis into the Holothuria; and he has been enabled, from his

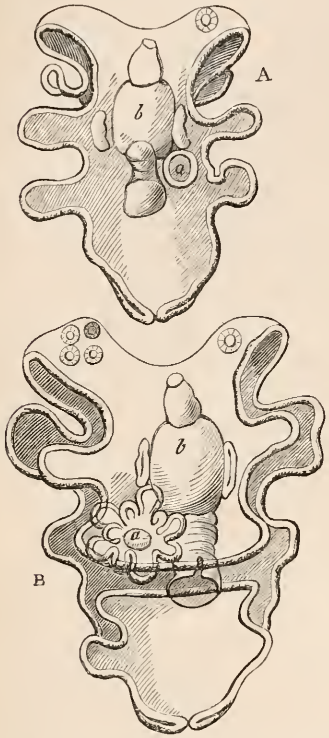
‡ Memoirs of the Acad. of Scien. of Berlin, Nov. 1849, and April 1850, published in 1851, p. 35.

own researches and the comparison of some others, to bring the whole of the Echinodermata under a general view, the result of which is the determination of the three following varieties of metamorphoses and production among them. In all of them the embryo, immediately developed from the ovum, has a bilateral symmetrical form, and passes by the subsequent metamorphosis into the radiated type. This change is, however, more or less direct, or by intermediate forms.

Fig. 9.



Auricularia, or larva of Echinoderm (*from Müller*).

A, young larva of Auricularia. *b*, alimentary canal; *a*, Echinoderm beginning to be formed.

B, larger larva of the same kind, *a* Echinoderm farther advanced.

1. In the first variety the change of the bilateral larva, or embryo, into an Echinoderm takes place at its earliest period, when the embryo has a general covering of cilia, but not the special ciliated borders or limbs of the Pluteus. A part of the body of the embryo takes the form of the Echinoderm; the rest of it is absorbed into the body of the new animal. This occurs in a part of the Asteriadæ, as in Echinaster, Asteracanthion, and others, described by Sars, Agassiz, Desor, and Müller.

2. In the second variety the change occurs when the larva is fully organised, that is, when it possesses digestive organs and a special motor apparatus of ciliated borders or limbs. The Echinoderm is placed upon the Pluteus somewhat in the manner of a picture on an easel, or a piece of embroidery in its frame and stand, and incorporates a part of the digestive cavity with itself. The remains of the larva gradually disappear, as in Ophiura and Echinus; or are broken off and die, as in Bipinnaria.

3. In the third variety the change of the larva takes place twice. First, it passes from the bilateral type with ciliated borders into the radiate type, and having taken something of the shape of a barrel, it acquires a larval locomotive apparatus consisting of ciliated hoops; and then from this state the Echinoderm is developed without any part of the larva being separated. Either the Echinoderm is formed of a part of the Vermiform larva, and the rest of the larva is absorbed into the Echinoderm, as in Tornaria; or the whole larva is simultaneously transformed into the Echinoderm, as in Holothuria.

From Busch's observations it appears that the Comatula passes very rapidly through the stage of the bilateral form into that which Müller has called pupa with ciliated crowns. It is also an interesting fact in connection with the history of animal metamorphoses, that the early condition of the Comatula is that of a pedunculated Crinoid.

Müller has remarked that these phenomena partake in part of the nature of metamorphosis, and in part of that of the non-sexual gemmation of the alternate generations. As the Echinoderm arises like a bud in the larva, there is alternate generation; but as the essential internal organs (that is, the alimentary canal from the stomach to the anus, but not the mouth and gullet) are taken into the new animal, there is also true metamorphosis. "I understand," says he, "by alternate generations nothing more than the succession of two forms of organism, of which the one arises in or upon the other as a minimum, or as a bud; the second, that is, the developed bud, is destined for sexual generation, producing from its ova the non-sexual larva, which again is destined for gemmation."*

Adopting the view that the Echinodermata present an example of alternate generation, it is to be observed that the product is single in all the instances known: but in all the other forms of intermediate or alternate generation hereafter to be noticed, the product of non-sexual gemmation is multiple.

Polypina. — The animals usually comprehended in the general denomination of Polypes or Polypina present very various kinds of structure and degrees of complication in their organisation; and recent researches, as to their mode of development, which point out that some of them are subject to a process of alternate or dissimilar generation, would appear to indicate a very different distribution

* Loc. cit. p. 106. The researches of J. Müller on this subject have been published in a separate form, as well as in the Mem. of the Berlin Acad. These Memoirs, and others on the same subject, will be found also in Müller's Archiv. 1846, p. 108; 1847, p. 160; 1848, p. 113; 1849, pp. 79. 84. 364. 400; and 1850, p. 452.

of these animals in the zoological system than that which has hitherto been followed. Most Naturalists are now disposed to separate from the true Polypina the Bryozoa, or so-called Ciliobrachiate Polypes, which, though presenting a considerable resemblance to the Polypes in their external anthoid appearance, yet approach much more nearly to the Tunicated Acephalous Mollusca by their internal organisation; and remarkable affinities have been pointed out between some of the Polypina and Acalephæ, which show that these classes, though very dissimilar in their external forms and mode of life, are in reality very closely allied in structure.

The greater number of the Polypina are aggregate or compound animals, that is, consist naturally of groups of individuals united or associated together on a common stem and branches, or on a more solid stock. But the common fresh water Polype, or Hydra, and the various Actiniæ of the sea coast, are, to a certain extent, exceptions to this general rule, and, as we shall see, differ also in regard to their mode of reproduction from most of the other families of this division of animals. The Actinia is usually a single animal: no doubt it is multiplied occasionally by buds, but these are thrown off and become developed usually in an isolated position. The Hydra sometimes occurs as a single animal, but more frequently during summer, and when well nourished, as a compound one; the multiple individuals being developed by gemmation from the first or principal stock, and also themselves forming younger progenies by budding; but the individuals so formed on the Hydra generally

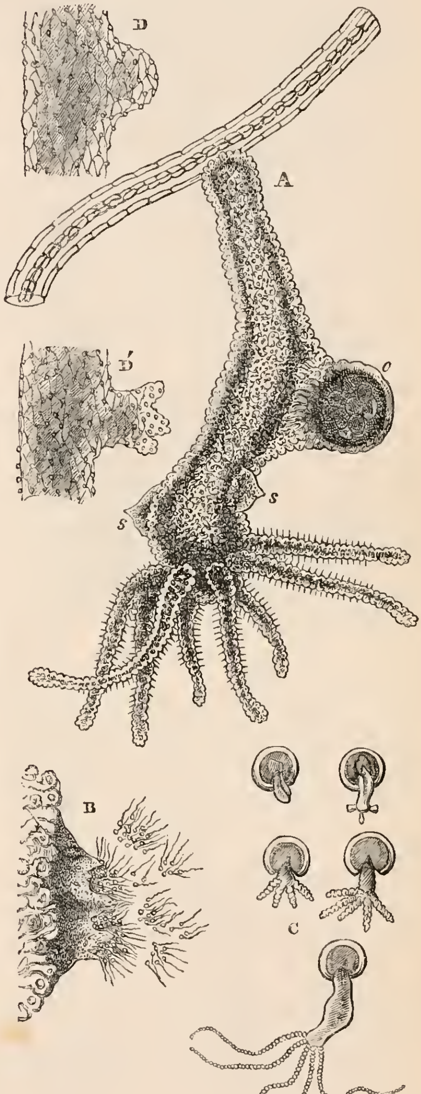
Fig. 10.

Hydra viridis in different stages of extension and contraction, reproducing gemmiparously, attached to the roots of duck-weed. (*From Roesel.*)

separate from the parent stock when they have attained to maturity, migrate, and establish themselves as independent animals, to form new buds.

Both of these animals are capable of propagation by ova formed in the sexual way: in Actinia this seems to be the more common mode of its multiplication, the ova being fecundated and developed within the body of the hermaphrodite parent; but in Hydra it would appear that it is principally in the autumn, on the approach of cold weather, that the sexual mode of propagation is substituted

Fig. 11.



Hydra viridis.

A, Hydra of autumn, bearing an ovum, *o*, and two spermatic capsules, *s*, *s*. B, spermatic capsule burst artificially, showing spermatozoa.

C (from Laurent), ova with young Hydra in various stages of development hanging out of them.

for that of gemmation which takes place throughout the whole of the summer.*

The ova of Hydra are simple vesicular capsules of a brownish colour formed in the substance of the wall of the animal's body, and separated from it previous to the development of the young; while the spermatic filaments are formed in smaller conical capsules placed nearer to the base of the tentacula either in the same or in different individuals.† The formation of the young Polype has been observed by Laurent ‡ to take place directly from the internal substance of the ovum, in which, however, he has not traced in a sufficiently complete manner the individual steps of the changes of development (*see fig.* 11. c.). The origin of the ovum in this animal is shown to be quite different from that of a bud: the former having the shape of a distinct vesicle from an early period, the latter not being perceptibly more than an extension of some part of the substance of the wall of the body, and precisely of the same colour and structure (*see fig.* 11. D, D′.).

The Hydra, therefore, while propagating very frequently by gemmation, is capable of reproduction also by fecundated ova, which are directly developed into the parental form. But many of the true Compound Polypes present examples, in their multiplication by gemmation, of the production of intermediate forms of animals between the ova and the perfect sexual individual, — a mode of reproduction, therefore, which may be referred to Steenstrup's general law of Alternate Generations.

Thus, to begin with the simplest form of these animals bearing the nearest resemblance to the Hydra, in the Coryne and Syncoryne, at certain seasons of the year, multiplication takes place from the stem or root by gemmation, the buds being developed in the form of attached Polypes; but at other times there are developed from the buds, without the concurrence of sexual organs, a set of delicate Medusa-like animals, similar to the Oceania, or those of the naked-eyed kind: these soon become detached, swim about freely in the water, acquire some of them male and others female sexual organs, and produce fecundated ova. These ova give rise, by their development, to a ciliated moving embryo: this soon becomes fixed to a spot, and is gradually converted into a Polype, similar to that from which the Medusa-like animals were formed.*

Fig. 12.

B, a portion enlarged, showing the budding of Medusoids in different stages.

C, one of the Medusoids, naturally detached.

D, another, farther advanced; *o t*, ovary, or testicle, placed on the alimentary canal; *o′*, ova.

R. Wagner appears to have been the first to observe Medusoid bodies produced from the Polype animals, as in Coryne aculeata, in 1833†, but the more full observation of the remarkable phenomenon of their formation is due to the researches of Sars, Löwen, Steenstrup, and Van Beneden, who have ascertained the relations of the Polype larva and Medusoid progeny, and the production of ova from the latter. Dujardin‡ has also carefully traced the production of the free Medusoid bodies from a Syncoryne, which he has called Stauridia, and has farther ascertained the sexual condition of these Medusoids, observed the formation of their ova, and the subsequent development of these ova into Polypes.

* This effect of the cold season in changing the mode of production from gemmation to oviparous formation, thus checking growth, but providing for the preservation of the species through the winter, is, as remarked by Dr. Carpenter, an interesting analogy with the change that is known to occur in the mode of production of the Aphis insect; see Principles of Physiology.

† The co-existence of ovigerous and spermigerous capsules on the body of the Hydra has been observed by many, as, first by B. de Jussieu, in 1743; (Abhand. der Swed. Acad. 1746, vol. viii. p. 211): by Trembley, in 1744 (Mém. sur les Polypes d'Eau douce); by Rösel (Insecten-Belustigung); Pallas, in 1776 (Karakteristik der Thier-pflanzen, p. 53); and more recently by Ehrenberg, in 1836 and 1838 (Verhand. der Naturforsch. Freunde in Berlin, 1838, p. 14); V. Siebold (Lehrbuch der Vergleich. Anat.); and by myself (Edin. New Phil. Journ. 1847).

‡ Annal. des Sc. Nat. 1845.

In a certain number of the Campanulariæ, Sertulariæ, and Tubulariæ, of which the internal structure is more complex than in the Coryne, and in which the Polype always naturally presents a branched form, or groups of distinct Polype heads formed upon a common stem by gemmation, it is now well ascertained that the Polype state is not the only nor the complete condition of the animal, but that by

Fig. 13.

Branch of Sertularia geniculata, magnified, shewing polypes, and ovigerous capsules.

a process, in some instances similar to that above described, in others, somewhat different from it, a set of bodies, charged with the office of the sexual production of the ova, are developed in place of the more ordinary Polype heads or individuals. In the Campanularia gelatinosa, according to Van Beneden, the generative heads are close bell-shaped capsules, within which small Medusoid bodies are developed by a process apparently analogous to gemmation, or, at all events, without sexual generation, and each of these Medusoids becoming free, move about in the adjacent fluid as independent animals. The farther destination or changes of these Medusoid bodies have not yet been observed, but from parallel observations in other similar animals, it is believed that they afterwards attain to sexual completeness, and form ova which are developed into the Polype form.*

But the interesting observations of Lovèn*, and also some previous observations of Lister †, would show that in the Campanularia

geniculata, and in Tubularia, the Medusa-like bodies may in some instances not be detached from the Polype heads or capsules, and may even not be developed fully into the Medusa form, but nevertheless produce their ova in that attached situation, and thus give rise to ciliated embryoes, which, when excluded, move for a time, and then, like the others arising from the detached Medusæ, become converted into Polypes.

According to Désor, of Boston ‡, the same Campanularia may at one time produce two kinds of capsules, the one set containing ova the other spermatozoa; the Medusoid progeny not being developed, and the ova giving rise to forms similar to the parent Polype: and M. S. Schultze, of Greifswald, has confirmed this statement§, apparently without the know-

ledge of Désor's observations, and has farther proved the necessity of fecundation for the development of the ova so produced in the Campanularia geniculata (*see fig.* 15. C.).

The various modes of production as they have been observed in the Tubularia by Van Beneden*, have been so fully detailed in the Article POLYPIFERA, that the reader is referred to that article for an account of them. But it is to be observed that the reconversion of the Medusoid progeny of this animal into the Polype form described by that author (see Article POLYPIFERA, *fig.* 50., p. 45.), has not received confirmation from the researches of other naturalists.

Much remains still to be learned of this remarkable process; but enough has been ascertained to show that in a certain number of animals, usually known as passing the greater part of their lives in the Compound Polype condition, the state of sexual completeness frequently belongs not to the Polype, but to a progeny having the form of a Medusa, and produced by a non-sexual process of development from the Polype stem.

Acalephæ. — Some time before the peculiar history of the development of the Polypina, now sketched, was discovered, an equally curious and unexpected phasis in the generation of some Acalephæ or Medusæ had been established by the concurrent researches of several inquirers; by which it was shown that the animals familiarly known as sea nettles existed for a time in the early stages of their development in the form of an attached polypoid, and were produced by a process analogous to gemmation, or transverse fission, in numbers from this Polype stock.†

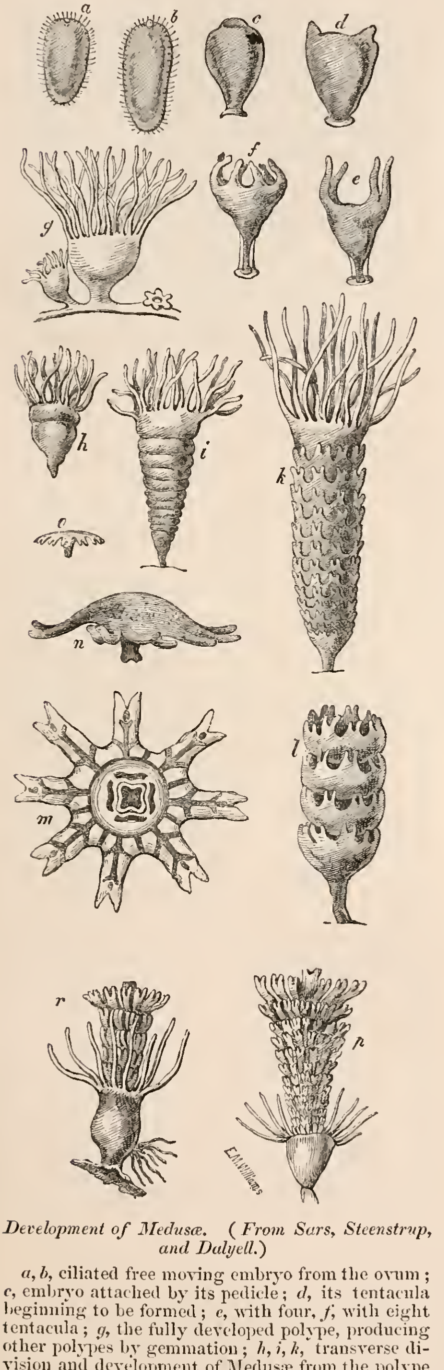
Adult Medusæ are perfect animals in which the male and female sexual organs are placed on distinct individuals. The fecundated ova which they produce are first developed into a ciliated moving animalcule somewhat like a polygastric infusorian. This creature, after

* Mém. de l'Acad. de Bruxelles, tom. xvii.

† The Swedish naturalist Sars appears to have taken the lead in this discovery, as early as 1828, by his observation of the Compound Polypoid, from which the Medusæ are thrown off; and subsequently, in 1835, by the discovery that this animal, or strobila, is really the young condition of a Medusa, or rather a colony of Medusæ. Very interesting observations of a similar kind were published by Dalzell on this body, under the name of Hydra tuba, in 1836, but his observations probably date from an earlier period (Edin. New Phil. Journ. vol. xxi. 1836). Sars pursued the investigation of the process further, and published the results in Wiegmann's Archiv, 1837; but the complete account of his observations was not published in the same Journal till 1841; see also Ann. des Sc. Nat. for 1841. In the meantime V. Siebold had arrived at precisely similar conclusions, and subsequently their views have been fully confirmed by Dalyell (Remarkable Animals of Scotland); J. Reid (Ann. of Nat. Hist. 1848, and Physiolog. Researches); Steenstrup (Alternations of Generation); and Huxley (Phil. Trans. 1849, part ii.) See also Dujardin, Mém. sur le Développement des Méduses et des Polypes Hydraires, Ann. des Sc. Nat. 1845. The reader is also referred to Dana's great work on Zoophytes in the United States Exploring Expedition. Philad. 1848.

undergoing a slight change of form, fixes itself by the narrowest end, and acquires tentacles like a Polype at the other, amounting for some time to eight. In this condition it appears to

Fig. 16.



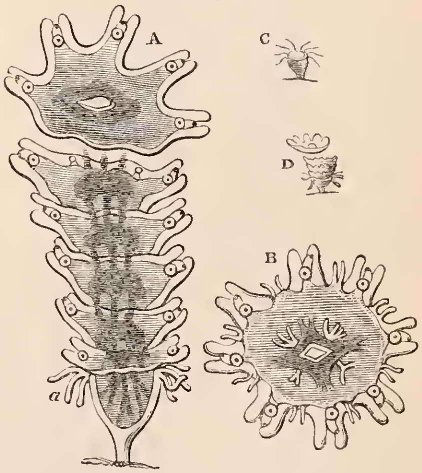
Development of Medusæ. (*From Sars, Steenstrup, and Dalyell.*)

a, b, ciliated free moving embryo from the ovum; *c,* embryo attached by its pedicle; *d,* its tentacula beginning to be formed; *e,* with four, *f,* with eight tentacula; *g,* the fully developed polype, producing other polypes by gemmation; *h, i, k,* transverse division and development of Medusæ from the polype stock or strobila; *l,* a pile consisting of four Medusoids just about to separate; *m, n,* and lower lateral view of Medusæ separated from the polype stock; *o,* more advanced, natural size: *p, r,* (*from Dalyell*), *p,* a pile of medusa discs separating, and new tentacula formed on the polype at the base; *r,* the same, with more of the discs separated; the strobila returning to its polype state and budding at the side.

be capable of multiplying itself, or producing other similar attached Polypes by gemmation from its side or base, or from a running stolon below it. The subsequent change of each of these polypoids is remarkable. It has been described by Sars and Dalyell as follows: — The body undergoing some elongation becomes partially divided by transverse grooves, into a range or column of imperfect Medusæ, attached still to each other by their adjacent surfaces, but presenting at their borders, in various degrees of advancement, the division into rays or lobes which belong to the Medusa; the upper or terminal one having developed upon it a set of radiated processes distinct from the tentacles of the Polype and much longer than those of the rest. These young Medusæ are successively separated from the stock by the deepening of the transverse clefts between them. They then move about as independent animals, and proceed in their farther growth and development to sexual and other completeness. These bodies, therefore, are subject to two kinds of multiplication, which are very different: by simple gemmation a number or a colony of Strobilæ may be produced, and by transverse fission and development a number of Medusæ may be thrown off from each Strobila.

A considerable number of the Medusa progeny having been separated, the Strobila stock generally returns to its polypoid condition,

Fig. 17.



Production of Medusæ (*Aurelia aurita*) *from Polype stock.* (*From Désor.*)

C, D, natural size. Young Medusæ forming from the polype above its disc.

and may remain for a long time in that state; continuing to multiply by budding into others of the same kind, and occasionally giving rise by the process of fission to its Medusa progeny. The observations of J. Reid * have shown that the Polype or polypoid stock may remain for a very long time in this condition without forming any Medusa progeny; and these observations, as well as those of Steenstrup and of Désor, appear to show that these Polypes bear a considerable resemblance in their internal structure to the Medusæ which they produce by gemmation. The latter author, indeed, is inclined to believe that the new Medusa animals are produced not by a mere transverse fission of the Polype, but by successive gemmation on its summit, that is, round its mouth and within the tentacula; and he states that he has observed the Polype remaining with its tentacles at the base of the Strobila of Medusæ. The observations of Dalzell and

B, the strobila or larva forming Medusæ.

C, lower surface of one of the young Medusæ, after separation.

J. Reid appear, however, inconsistent with this view; but it is possible that there may be varieties in respect to the mode of formation of the Medusa progeny, so that in one set the tentacles of the Polype may be included in the upper Medusa, and when all the progeny is separated, new tentacles may be formed on the Polype stock at the base, while in others the budding Medusa may be within the circle of the tentacula of the Polype.

It appears from recent investigations that others of the Acalephæ also undergo remarkable processes of non-sexual multiplication. According to Huxley's recent most interesting researches *, the Physsophoridæ, Diphydæ, and Physalia, are to be regarded as compound organisms in which the floating processes of most various form are analogous to Polype or attached Medusa individuals, which are the bearers of sexual organs, in some of one kind, in others of both, and others of which are neuter, on the same compound stock.† These are probably a progeny developed by budding from a single individual, which is the parent stem.

By these discoveries a remarkable relation is shown to exist between the medusoid and polypoid animals. Some we have been accustomed to see principally in their largest and most developed condition as Medusæ, others are best known in that polypoid condition in which they remain for the longest time; but we must regard that condition in which sexual reproduction takes place as the complete one, and this we have seen is in both the Acaleph or Medusa form, while the Polype or polypoid state, however permanent it may appear, is to be looked upon as a preparatory stage, in which, it is true, multiplication of its own kind may occur by gemmation, but which can only effect the true reproduction of the species by forming its progene of Medusans to which is committed the offic of producing the fecundated ova. This, therefore, is another example of multiple metagenesis, or alternating generation.‡

Mollusca. — Among the Mollusca the only examples of alternate generation that are yet known have been observed in the Tunicated Acephala: and among these, three modifications of the reproductive process are known in the Bryozoa, Ascidia, and Salpidæ.

The Bryozoa, or so-called Ciliobrachiate Polypes, long ranked with the Polypes on account of their union in branched groups, their radiated arms, and retractile body, but now regarded as more nearly allied by their internal organisation to the Tunicated Mollusca, present a very marked example of the multiplication by budding of the progeny of a single ovum. These animals never continue for any considerable time as single or distinct individuals, but, multiplying by gemmation, form numerous colonies, in which the new individuals remain connected with the primitive one from which they have proceeded and with each other. They thus always constitute compound groups spreading from the first individual as from a centre. All the individuals of the group may acquire sexual completeness, and the male and female organs are united in each individual: the ova are fecundated within the cavity of the mantle;

* Ann. and Mag. of Nat. Hist. 1848.

* Phil. Trans. 1849, Pt. ii.

† Professor Goodsir has informed me that his observations on Stephanomaia are quite confirmatory of this view.

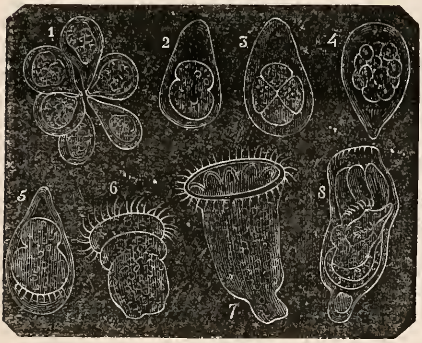
on leaving the parent body they become developed into a ciliated embryo, which, for a time, moves freely about, then becomes fixed, undergoes farther changes in being developed,

Fig. 19.



A series illustrating the development by ova of Pedicellaria. (*After Van Beneden.*)

and now from its own body in some, and in others only from the spreading part of the stem or base which supports it, proceeds the gemmation of other individuals of the colony, all of which apparently are capable of sexual generation when they arrive at maturity.‡

The Ascidian Tunicata present another modification of the reproductive process now under consideration. Two forms of these animals exist, both perfect, viz. the simple and the compound; but these are not related to each other in the same manner as the two kinds of Salpians; for each kind is capable of propagating its like by generation. The solitary ones rarely multiply by gemmation, and when they do so the individuals separate from the stock; but the compound animals always undergo this mode of multiplication, and the multitude of individual Ascidians are in this form collected together in a mass of various shape, in which the circulation of fluids is for a time common among the different individuals. The individual animals produced from the stock by gemmation attain to sexual completeness, and propagate by means of ova, in the same manner as the solitary or distinct Ascidiæ do.

The young of these animals undergo a remarkable metamorphosis: they are first excluded from the egg in the form of a moving tailed body, somewhat like a minute tadpole; and this caudal organ of motion is lost previous to their becoming fixed, and the development of the more complex organisation.†

Although the changes to which both the Bryozoa and Ascidian Tunicata are subject in their early state present some very striking phenomena of metamorphosis, yet there is nothing in either which fully deserves the name of alternate generation, for all the individuals of which these compound animal structures consist are alike sexually perfect, and there does not appear to subsist any necessary connection between the nonsexual process of multiplication, and the subsequent exercise of the sexual function. There are, in fact, scarcely any intermediate stages of non-sexual existence such as are described in the true instances of alternate generation. It is deserving of notice, however, that Löwig and Kölliker are of opinion that in some of the Botryllidæ numerous embryoes are at once developed from a single ovum by its division, these individuals subsequently multiplying by gemmation into the perfect sexual animals.

a, one of the animals fully expanded.
b, a similar animal completely retracted.
c, an immature animal.
d, one of the gemmæ in its earliest state.

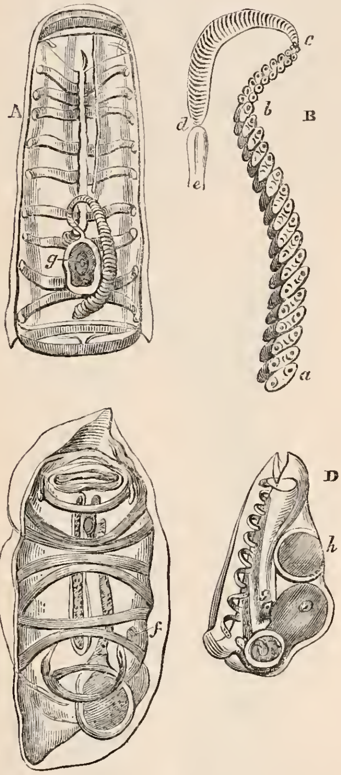
Salpidæ. — The most marked example of alternating generation among the Tunicata is that which, since its first discovery by Chamisso, in 1819, has been known to occur in the Salpidæ. This process has been so well and fully described in the article TUNICATA, that it is not necessary to give more than a short outline of it in this place. These animals are known in two states, viz. solitary and ag-

* Van Beneden, in Mém. de Bruxelles, tom. xviii. See the Article Polypifera, for an account of these researches.

† See Mr. Rupert Jones's excellent Article TUNICATA for an account of these phenomena, and the special Memoirs of Milne-Edwards, sur les Ascidies Composées, &c., Paris, 1832; Löwig and Kölliker, in Ann. des Sc. Nat. April, 1846; Van Beneden, sur les Ascidies Simples, Brussels, 1847.

gregated; the latter being not organically united like the compound polypes, but merely adhering more or less strongly to one another so as to form a chain. The aggregated, but not the solitary kind, possess sexual organs; and it would appear, though this is not yet determined with certainty, that all the individuals of one chain are of a similar sex either male or female.

Fig. 21.



Solitary and aggregated Salpæ. (*From Sars.*)

A, solitary Salpa, with chain of aggregated ones, *g*, budding from it.

B, this chain magnified, shewing the successive sets in different stages.

C, one of the more advanced aggregated Salpæ from a chain, *f*, the place of a fœtus formed by sexual generation.

D, fœtus from another more advanced, magnified; *h*, the yolk, by which it adhered to the parent; *g*, the place of the germ for the aggregated chain.

All the individuals of a chain of aggregated Salpæ are produced from a solitary one by a process of internal gemmation, or gradual development from an internal stolon, or germ-stock, from which they are detached gradually and in successive groups: all the individuals of the chain are contained within a tube, and become united to each other after their development, presenting a series of groups of different degrees of advancement; but the individuals in each group being nearly at the same stage of development.

The distinct or single Salpæ, which, with the exception of the want of the sexual organs, do not differ materially from the individuals of the aggregated chain, are produced from fecundated ova which are developed within the body of the parent. These ova differ from the germs from which the aggregated individuals take their origin in the possession of a yolk, and external envelope. Their development proceeds to its termination within the parent body, and the young Salpa is already provided with the internal stolon for the gemmation of its chain progeny, before it passes into its separate state of existence.

The solitary Salpæ may be looked upon, therefore, probably as incomplete or larva forms, and the aggregated are the fully developed sexual individuals. The generation of this animal, therefore, is precisely an example of that succession of two different kinds of individuals which has been distinguished as alternation of generations; each fecundated ovum of the sexual individuals being developed into an animal which never acquires sexual organs, and which produces by a process apparently of the nature of gemmation, a numerous brood of individuals associated in a chain; all of which are sexually perfect, one set developing only spermatozoa, and the females among them being the producers of the ova, which are the source of the new generation.*

Although no other instances of alternate generation have yet been observed in the class of Mollusca, yet it is possible that modifications of this process may hereafter be discovered. An observation related by Agassiz†, in regard to the development of the ovum in one of the Eolidæ, deserves to be recorded, as it may be found to constitute an approach to the metagenetic process. After having described the usual process of division of the yolk in which the first stages of development consist, and the farther progress of formation in the Eolis, he says, — "But the most curious phenomenon which takes place is this; that the whole yolk does not constantly go to form one single individual. But there may be instances when the mass of yolk, which has been subdivided into cells, is itself divided into two or three or more masses, which grow independently, several individual animals arising from one mass of yolk, which thus divides."

Entozoa.—Among the Entozoa the process of reproduction is effected by very various means. All the Nematoidea, or round worms, are of distinct sexes; and their fecundated ova are developed into the parental form without any metamorphosis of a marked kind, (excepting perhaps in the Echinorrhynchi, the

* See Savigny, Mém. sur les Anim. sans Vertèb. 1816; Chamisso, De Salpis, 1819; Meyen, Ueber die Salpen; Eschricht, in the Isis, 1842; Sars, Fauna Littor. Norvegiae, 1846; Krohn, Ann. des Scien. Nat. July, 1846; who first pointed out the existence of spermatozoa in certain individuals of the aggregated chain.

† Lect. on Comparative Embryology, Boston, 1849, p. 81.

process of generation in which is not fully understood,) nor any intermediate process of gemmation. A few of them, however, appear to become encysted in the parenchyma of organs in their young or undeveloped condition, and some in a form different from the parent, as in the Trichina of the muscles, the so called Filaria of the peritoneal cavity of fishes, and the Vibrio tritici. These encysted Nematoidea have not been observed to be possessed of sexual organs *, and they are not known to be multiplied by gemmation; it is probable, therefore that, to attain the place of their full development, they must be subject to migrations from one animal to another, either directly or in other ways, as through water and vegetables. The ova of these animals appear to possess a remarkable tenacity of life, as exhibited by their long and obstinate resistance to the noxious effects of external agents. †

The Cystic, Cestoid, and Trematode orders of the Entozoa present a more varied process of generation, the investigation of which has of late years attracted considerable attention, and which has led to most interesting results as to the nature and relations of several forms of these animals, which were previously regarded as of a most anomalous kind. The Cestoid and Trematode Entozoa have long been known to possess the sexual organs in the hermaphrodite arrangement, and to produce fecundated ova; while the Cystic Entozoa have been observed to multiply only without sexual organs, and by a process analogous to gemmation, and their first origin has been till lately involved in the deepest obscurity. We shall presently see that many, if not the whole of them, may be either undeveloped or metamorphosed aberrant forms of cestoid or trematode animals. ‡

This view appears first to have been suggested by Steenstrup, in connection with his researches on alternate generations §; and it has since been adopted, in somewhat different forms, by V. Siebold, Blanchard, Dujardin, and Van Beneden, and rendered extremely probable by the researches of these and some other observers. Previous to the adoption of this view, helminthologists, looking upon the Cystic Entozoa as distinct and independent animals, were at a loss whether to regard them as ascertained exceptions to the sexual mode of propagation, or to continue to prosecute their inquiries in the hope of being able to discover a process of generation in them analogous to that prevailing in the greater majority of the animal kingdom; and many were thus misled into the error of searching for ova where none existed or were required. Thus Gulliver erroneously described certain calcareous particles in the membrane of Cysticercus as the ova of the animal*, and H. D. Goodsir, in his instructive paper on the production of the young in that animal, and in the other forms of Cystic Entozoa †, failed to distinguish between that which might be merely a process of gemmation and the origin of the embryoes from true ova.‡

Cystic Entozoa. — The Cystic Entozoa present themselves in three principal forms, viz. Acephalocyst, Cænurus, and Cysticercus. The two first are usually found as compound or aggregated animals; the last is more frequently seen in the single or isolated condition.

Some of the vesicular hydatid tumours, constituting the various kinds of so called acephalocysts, have long been known to contain small Echinococci floating in the fluid of their interior. Repeated observations have demonstrated the existence of these animals in the acephalocysts; and it seems very probable that, in the end, it will be necessary to withdraw the distinctions between the various kinds of these cysts, as they will all, by sufficiently accurate observation, be found, at some period of their growth, to contain in a more or less complete condition, the small animals of Echinococci, or their remains. §

The Echinococci are produced by nonsexual generation, or by gemmation from the membrane of the vesicle, probably from the middle or germinal membrane, as it has been

* See a Memoir by V. Siebold, on the Nonsexual Nematoidea, in Wiegmann's Archiv, 1838.

† Dr. Henry Nelson and I have observed the development of the ova in Ascaris mystax to proceed for several days, while the parent bodies containing them were immersed in oil of turpentine.

‡ For a notice of the generation of the minute parasitic animalcule called Gregarina, see the previous account of the reproduction of Infusoria.

§ See Ray Society's Translation, 1845, p. 100. "It is not unlikely," says Steenstrup, "that in course of time, it may happen with them (Cystic Entozoa), as it has with the whole division of the asexual Trematoda of Siebold, viz. Cercaria, &c., that they must be rejected from the system as being earlier forms of development, or earlier generations of other animals." V. Siebold remarks in a note at p. 157, of his Lehrbuch der Vergleich. Anat. part i. published in 1845, "Here the doubt arises whether the asexual Cystica really deserve to be considered as independent animals. It is very probable that the vesicular worms are undeveloped Cestoids," &c. See also note at p. 111. Von Siebold has developed these views more fully in a recent Mem. in the Zeitsch. für Wissensch. Zool. July, 1850, translated in the Ann. des Scien. Nat. vol. xv. 1851, p. 177; and in the article Parasites, in Wagner's Handwörterbuch der Physiologie. E. Blanchard in his Rech. sur l'Organis. des Vers, in Ann. des Scien. Nat. 1847 vol. vii. p. 120. excludes entirely the Cystica from a separate place in the systematic arrangement, bringing them under Cestoidea, and affirms decidedly that the distinction between them ought now to cease, as they are shown to be different states of the same animals. He refers to De Blainville as having previously entertained the same view. See also Dujardin, in Annal. des Scien. Nat. for 1843, and Hist. Nat. des Helminthes, 1845; Miescher, Bericht üb. die Verhand. der Naturforsch. Gesellsch. in Basel, 1840; and Van Beneden, Ann. des Scien. Nat. 1851, p. 309; and a work on the Entozoa, published at Brussels, in 1850, which I have not seen.

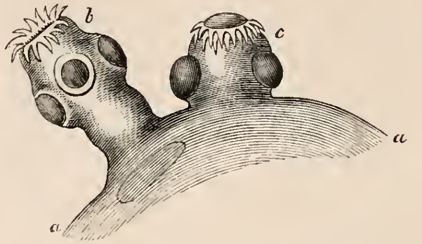
surface of the cyst.* While enclosed in the pediculated vesicles, the head of each echinococcus is retracted within the short vesicular body in a manner which seems to be general among the young of encysted Entozoa. They are afterwards set free, and in this state are found floating as minute whitish particles in the fluid of the cyst. They then present the appearance of minute heads of Tæniæ, with a short body scarcely larger than the head; the latter part being furnished with a terminal double circle of hooklets, and four suckers.†

The mode of gemmation may probably vary in different circumstances, more particularly in regard to the extent to which the progeny of gemmation may or may not repeat the formation of others of the same kind; but every thing that is known of the acephalocystic productions seems to point to the view that they are all nearly allied, and that they are abnormal or aberrant conditions of Tænia-larvæ, which, when they become encysted, are incapable of development into the cestoid form which belongs to those that have reached the free intestinal habitation.

The Cænurus, which has been met with principally in the brain and some other parts of the sheep and some other Ruminating animals, consists of a large cyst or vesicle with a number of small heads projecting on its external surface: each head resembles closely that of an echinococcus animalcule, presenting the same circle of hooklets and four suckers. According to H. D. Goodsir, they are attached to the middle membrane of the cyst, from which they sprout at first, carrying the outer one along with them: the neck contains cells, from which it is supposed other young animals or heads may be formed.*

Fig. 23.

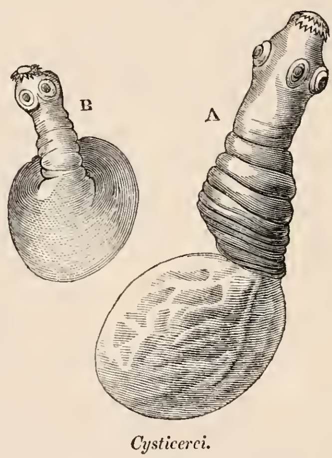


Cænurus cerebralis, magnified. (*After Bremser.*)

a a, part of the general vesicle; *b*, an expanded head; *c*, a shorter head, showing the double circle of hooklets.

The Cysticercus has been described in two forms; 1st, in its simply vesicular state, and 2nd, in its fasciolated condition, or in its transition, as it may be held, to the cestoid, or tape form. The vesicular Cysticercus has

Fig. 24.



Cysticerci.

A, Cysticercus longicollis (from Bremser), enlarged. B, Cysticercus from the human eye (extracted by Dr. Mackenzie), magnified five diameters.

only one head; but the structure of that part is precisely the same as in the Cænurus and Echinococcus, and, we may add, not far different from that of the Tænia itself. They are usually developed singly, that is each vesicle with one head: but some observers† allege that they have seen internal vesicles near the neck, which they look upon as young, or as a progeny of gemmation in that situation.

The Cysticercus fasciolaris, as it has been observed in the rat and mouse, presents the remarkable fact of a Tænia in various states of development, from the vesicular condition of

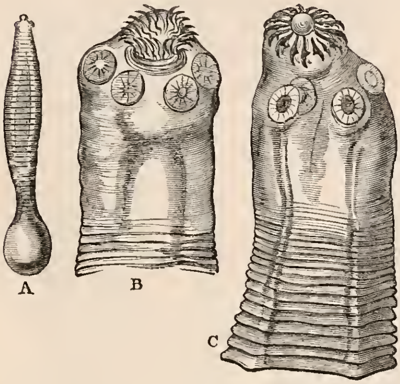
the true Cysticercus, to a form in which the caudal vesicle has diminished to such an extent as almost to have disappeared, while at the same time the body has been divided into segments by transverse grooves, as in the Tænia; and in some instances these segments have even acquired sexual organs while the animal was still encysted, a circumstance which has never been observed in any true Cysticercus.

Fig. 25.



Cysticercus fasciolaris of the Mouse, and Tænia crassicollis of the Cat.

C, head and first segments of the body of Tænia crassicollis of the cat, showing the double circle of hooks; a few of the smaller under circle being seen where one or two of the larger ones have fallen off.

A close comparison of the structure of the Cysticercus fasciolaris of the rat and mouse in its various stages of development with the Tænia crassicollis of the domestic cat, has shown an almost complete similarity between these animals, and has suggested the view that the encysted Tænia (which the Cysticercus fasciolaris in truth is) may attain its full development as a Tænia in the intestinal canal of those animals which prey upon the smaller Rodentia, in whose liver it begins to be developed in its first simple vesicular form, and gives the greatest probability to the supposition that there may be a similar general relation between the Cystic and Cestoid Entozoa, not of the same animals, but between the tapeworms of different tribes of predaceous animals and the vesicular worms of others serving them as food.*

The different phases of development, therefore, in which the so-called Cysticercus fasciolaris has been seen in the same and in different animals which they inhabit, leave little doubt that they are encysted Tæniæ, which proceed to a much more advanced stage of development than is usual with the vesicular and encysted form of these Entozoa; and we are warranted, from the great similarity of structure, in adopting the view that the true vesicular Cysticerci, the Cænuri and Echinococci, are morbid or metamorphosed and aberrant conditions of the embryoes of various Tæniæ, which may be capable, to a greater or less degree, in different kinds of animals, of multiplying their own incomplete forms by a process of non-sexual gemmation, but which never, in the encysted condition (except in the instances already referred to of the fasciolated kind), attain to sexual completeness; but which either undergo a retrograde change, and thus form tumours and various pathological deposits in the seat of their cysts, or become developed to such an extent as to be injurious or destructive to the animal in which they reside.*

Free Tapeworms.—Three principal forms of cestoid worms are now distinguished from one another, viz. Tæniæ, Bothriocephali, and Tetrarhynchi; the two first have long been known and sufficiently well characterised in their fully grown condition, though little understood in their early or incomplete states; the history of the third, until recently, has been involved in great obscurity, as it has been most variously described by different observers both in the earlier and more advanced stages of its growth. It appears now to be ascertained that all of these cestoids are complete animals, with a single head, a body composed of a multitude of segments, each of which contains male and female sexual organs, which are developed only when the entozoon is living free in the alimentary canal of animals belonging principally to the Vertebrata. The Tæniæ inhabit chiefly the alimentary canal of mammals and birds; the Bothriocephali and Tetrarhynchi more frequently that of fishes and reptiles, and the latter a few mollusca. The Tetrarhynchi have been more frequently described in the encysted and imperfect condition than in the full-grown form, and in such varieties, that V. Siebold has mentioned about sixty different kinds of worms described by various authors under distinct appellations, which might, according to him, be

* Dujardin, Hist. Nat. des Helminthes, 1845. E. Blanchard (who does not appear to have fully appreciated the necessity of change of habitation for the entire development of the tænia), Sur l'Organisation des Vers, Ann. des Scien. Nat. 1848, tom. x. p. 348. V. Siebold, in Zeitsch. f. Wiss. Zool. 1850, and Ann. des Sciences Nat. 1851. I am indebted to Dr. Henry Nelson, for an account of some interesting researches on this subject which formed a part of his Inaugural Dissertation "On the Development of the Entozoa," on obtaining the degree of M. D. at the University of Edinburgh, in 1850. The limits of this article prevent me from entering into the details of Dr. Nelson's observations, which have not yet been published. It is enough to mention that a very careful comparison of the Cysticercus fasciolaris of the mouse and rat, in various stages of its development, with the Tænia crassicollis of the cat, enabled him to confirm, in a most satisfactory manner, the view which, unknown to Dr. Nelson, had previously been taken by V. Siebold, that these cystic and cestoid forms are different stages of one and the same animal. See also *Leuckart* on Cysticerci, in Wiegmann's and Erichson's Archiv for 1848.

* See Gulliver, in Med. Chir. Trans. 1841.

brought under the genus Tetrarhynchus. In fact, this kind of animal undergoes such remarkable changes in its transition from its first simple Echinococcus-like encysted form to its free segmented sexual Tænia-like shape, that it is not wonderful that its history should have been obscure, and that great doubts should still prevail with some Helminthologists as to its origin, development, and zoological relations.*

It has already been observed, that none of these three kinds of Cestoid Entozoa attain to sexual completeness while they are encysted ; and it seems probable that they are all subject, more or less, to migration, in order to gain their free habitation in the alimentary canal of animals, where their segments acquire the male and female generative organs. The fecundated ova, produced in enormous numbers from each segment, do not in general, so far as is known, become developed into embryoes in the intestine of the animal inhabited by the Cestoid, but are evacuated along with the fæces, either separately after being discharged from the oviducts of the Cestoid, or before their discharge by the disjunction of the more ripe terminal segments from the rest of the animal. The migrations to which the ova and young of the Tænioid animals are thus made subject have hitherto opposed so great an obstacle to the observation of their development, that we are as yet in possession of very few continued series of observations in which the whole progress of development from the ovum to the complete segmented animal has been traced. Some important contributions of this kind have, however, recently been made, and the great modifications which the views of comparative embryologists have undergone, from the novel and various aspects in which many of the phenomena of development are to be regarded in instances of alternate generations, have already indicated paths of inquiry by which this very curious and intricate history may ere long be completely unravelled. The accompanying figures from Dujardin's work show the progress of formation of a small Tænia inhabiting the Shrew, and give a sufficiently good idea of the nature of this process in a Tænia, which consists of comparatively few segments (*fig.* 96. *a* to *i*.).

Von Siebold has traced with care a part of the process of development of a minute Cestoid inhabiting the pulmonary sac of the red snail (*Arion empiricorum*) in the encysted condition. Into this situation the minute Tæniæ are introduced from the exterior : they consist of the head with its double circlet of ten hooks each, and four suckers, and a body which is at first entirely destitute of segments, not longer than the head, and forming a soft vesicle, within which (as in other Cystic Entozoa previously mentioned) the head is retracted, so as to give the whole a globular shape. V. Siebold regards it as nearly certain that these minute Tæniæ only attain to their segmented and complete sexual condition when they have been located in the alimentary canal of Vertebrata (Birds and others) preying upon the snails in which the younger forms of the Tæniæ reside.

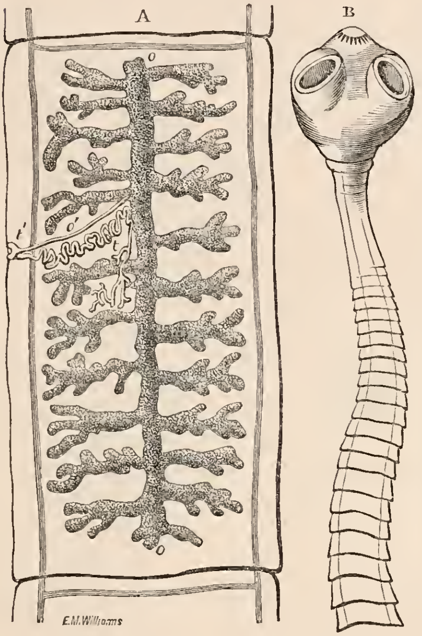
(From Dujardin.)

a, embryo within the ovum, just about to quit it, with three pairs of hooks; *b*, embryo that has left the ovum, the hooks capable of rapid and extensive movements; *c*, embryo moving freely (of the Tænia serpentulum of the magpie) ; *d*, *e*, very young embryoes of Tænia pistillum ; *f*, *g*, *h*, *i*, different stages of growth of this Tænia ; the separation of the segments gradually increasing, and the development of the reproductive organs in the posterior ones ; *k* (more magnified), the proglottis, or free moving separated segment of this Tænia.

* Von Siebold proposes to substitute the genus Tetrarhynchus for the following five genera distinguished by Dujardin, viz., Rhynchobothrius, Anthocephalus, Tetrarhynchus, Gymnorhynchus, and Dibothriorhynchus. Zeitsch. f. Wiss. Zool. 1850, and Ann. des Sc. Nat. 1851.

The instance already referred to, of the identity of the Cysticercus of the liver of the mouse and rat with the Tænia crassicollis of the cat, and a variety of detached observations which prove that the Bothriocephalus and Tetrarhynchus pass through similar changes from a small Echinococcus-like animalcule to the developed cestoid form, lead to the corroboration of the same general view that the encysted condition of these Entozoa is an incomplete non-sexual embryo or larva, from which, when it passes into the free state, there is formed by a process of transverse

Fig. 27.



Tænia solium. (*From Blanchard.*)

B, head, neck and anterior recently formed segments.

fission a segmented individual or compound animal, in which each segment, as it arrives at maturity, attains to sexual completeness. In this process the new segments are always developed between the head and those already formed. If the character of sexual completeness is to be taken as the distinguishing mark of individuality, each segment of the Cestoid may be looked upon as a distinct animal, and the separation of them by transverse fission may be compared to the separation of Medusa individuals from the Strobila polype stock. The Cestoid Entozoa might in the same manner be considered as subject to a peculiar process of alternate generation.

In the preceding sketch of the nature of the reproductive process in the Cestoid Entozoa, I have followed chiefly the views of V. Siebold as explained in the interesting Memoir already referred to. It is right to state, however, that the phenomena have been viewed in a different light by several observers of high authority. Thus, Blanchard and Van Beneden consider the first stage of the Tetrarhynchus-embryo to be a Scolex, in which, after it has been encysted, the Tetrarhynchus is formed: this, according to Blanchard, is its complete condition; but, according to Van Beneden, the so-called Tetrarhynchus is converted into a Rhynchobothrius, and this is in the last place changed into a separate Trematode animal.* Dujardin had previously taken the same view as applied to the separate and independent nature of the joints of the Tænia, which he regarded as individual Trematode animals, and described under the name of Proglottis (see *fig.* 26. *k.*)†; but though there may be some points of analogy between the single segments of Tænia and a Trematode, yet the absence of head, differences in the alimentary canals, and other circumstances, render the correctness of this view, at all events, still doubtful.‡

Trematoda. — These animals, the most common of which are known as Flukes (excluding the Planariæ), comprehend a set of internal parasites of a structure bearing some resemblance to the Cestoidea, but single, that is, not jointed or segmented. The nervous and vascular systems attain to a considerable degree of development: the alimentary canal, which has a mouth but no anus, is in some bifurcated, and in others more or less ramified. The male and female generative organs are united in one individual, and pervade a large portion of the body of the adult animal.

The facts which have been ascertained in recent times concerning the generation of some of the Trematoda constitute one of the most remarkable parts of the history of this process among the Invertebrata. Their general result may be shortly stated thus: — the fully grown and sexual Trematode animal, as observed chiefly in the Distomata, produces ova, which may pass through the earlier stages of their development either in the viviparous or oviparous mode, more frequently the latter. Each of these ova has formed from it an embryo in which no resemblance to the Trematode parent is to be recognised, but presenting the simple structure of a ciliated animalcule like a polygastric infusorian or a Gregarina. This embryo is

not itself converted by any direct process of development or metamorphosis into a perfect Distoma, but has gradually formed from germ-cells within it a progeny, sometimes of one, more frequently a number of bodies, which, when they arrive at maturity, present each one an external form and internal structure and locomotive powers, entitling them to be considered as independent animals. Nor are these directly converted into Distomata; but again there is formed within the body of each, and in the same gradual manner from germ-cells, a new progeny of animals nearly similar to those producing them and equally differing from the complete Distomata. Each of this new progeny, as it increases in size, has formed within it by development from germ-cells the third progeny of the series, and the last of the cycle; but these are different from their immediate parents, and in their internal organisation soon manifest the type of the true Trematode. These animals are endowed for a time with very active locomotive powers, to which a long caudal appendage contributes; their two progenitors have been confined in the parasitic condition, but these

Series of changes in the development and generations of Distoma. (From Steenstrup.)

O, Ovum with embryo or larva developed in it. *e*, this embryo in a free moving state; *e'*, another embryo in its interior. (These are of Monostomum mutabile, from V. Siebold.)

E, this last embryo farther advanced. 1, first stage, soon after it becomes free; 2 and 3, farther on, with *g*, the second generation, within them in various stages.

G, 1, one of this second generation at an early period of its advancement; 2 and 3, farther on, with *c*, *c*, Cercariæ or Distoma-larvæ, within them; *g'*, one of the granular globules from which the Distoma larvæ and previous generations arise near the posterior part of the body.

C, one of the Cercariæ or Distoma larva with its caudal appendage. P, the same, passed into its encysted or pupa state, having previously lost its tail.

D, Distomata. 1, young Distoma immediately after it has quitted the cyst, and has penetrated a short distance into the body of the snail; 2, Distoma found deep in the viscera.

are in general freed from confinement, and move about with great vivacity for a time in the water surrounding the animals which their progenitors have infested. In this state they have long been known as Cercariæ, and as they have been supposed to be the young of Distomata, have attracted peculiar notice among Helminthologists.*

The free Cercariæ are not, however, directly converted into Distomata; but appear always to undergo a previous metamorphosis in a chrysalis state, or enclosed in a pupa cyst. Previous to the formation of this cyst the Cercariæ adhere to, and bore into, the substance of the animal infested by the Distomata; the tail is cast off, an exudation from their own bodies forms the cyst, which encloses them: within this they remain for many weeks, and even months, moving all the while, and undergoing changes of development, by which they are at last converted into the complete Distoma.

The greater number of the observations from which this remarkable process of generation has been ascertained to occur are due to V. Siebold and Steenstrup; but the whole succession of changes has not yet been observed in any one species, and it is to the latter observer especially that the scientific world is indebted for the ingenious combination and interpretation of the scattered

* Nitsch, Beitrag zur Infusorienkunde, &c., Halle, 1817; Bojanus, in Isis, 1818; A remarkable and interesting series of papers by V. Baer, in Nov. Act. Nat. Curios. 1826, vol. xiii.; Rud. Wagner, in Isis, 1834; V. Siebold, in Burdach's Physiol. vol. ii. of German edit. p. 187., or vol. iii. of French transl., p. 32., &c.

observations of previous inquirers, as well as the addition of new facts, from which an almost entire certainty is acquired that the various phenomena do actually succeed each other in the order above stated, and that the occurrence of alternate or intermediate generations in these animals is established.

Von Siebold had in 1835 described in the Monostomum mutabile the development of the first embryo from the ovum in the Gregarina-like or animalcular form, and had shown the next change to consist in the formation within the first embryo of a second body endowed with locomotive power, and independent vitality, and differing both from its immediate parent and from the adult.* V. Siebold, as well as others, had ascertained the Cercariæ to be themselves incomplete animals, and to proceed from others by a process of internal production of a non-sexual kind. Steenstrup therefore directed his attention particularly to trace these Cercariæ on the one hand, in their development into complete Distomata, and on the other, backwards through their progenitors towards the first origin from an ovum. His observations were made principally in three kinds of Cercaria, which, along with their antecedent and succeeding conditions, are found in great numbers in the fresh water snails, Lymneus stagnalis, Paludina vivipara, Planorbis, &c., and which had been previously named Cercaria echinata, C. armata, and C. ephemera. In these, especially in the first, the conversion of an encysted Cercaria by metamorphosis into a Distoma, and the descent of the Cercaria (by metagenesis) through two progenitors, not themselves Distomata, was ascertained, but he did not succeed in tracing these bodies back to their origin from ova. By a comparison, however, of the body formed within the animalcular embryo of the ovum of the Monostomum mutabile, as observed by V. Siebold, with the first progenitor of the Cercaria, to which it was found to present a remarkable similarity, the chain of evidence seemed to be complete, and Steenstrup found himself in a position to announce the general views of alternate generation, which have ever since their first publication attracted the greatest attention, and contributed in a powerful degree to modify and direct the investigation of the generative processes in the lower animals.

To the immediate progenitor of the Cercaria Steenstrup gave the name of nurse (altrix, Amme), in allusion to its nursing or nourishing function, and to the immediate progenitor of this one he gave the appellation of "parent or grand-nurse." These terms may be objectionable, but an unnecessary amount of criticism seems to have been bestowed on them by some writers. They are adopted hypothetically by Steenstrup; they do not appear to withdraw him from the matter-of-fact statement of his observations; and they seem to be, in many respects, short and convenient terms in the description of the phenomena. These bodies have in the Cercaria echinata all the appearance of distinct animals, that is, a body with a head separated by a neck or collar, a tail or caudal projection, and two processes of the integument similar to limbs, a mouth and alimentary cavity, and they move with all the appearance of spontaneity; but it ought to be remarked that the form and powers of these nursing or formative cases differ considerably in various other species, and in some present so little of the external form or endowments of an independent animal, that the more general appellations of germ-cases, or germ-sacs, or sporo-cysts, may be more appropriate to them.*

It is chiefly among the aquatic Gasteropod Mollusca, and a few land ones, that these observations have been made; but V. Siebold has extended them to some of the Trematoda inhabiting the air-sacs and other parts of water fowls, which no doubt come from the same Mollusca, and obtain access to the seat of their final parasitic habitation from the water or along with food, into which they have come as Cercariæ, after having previously been parasitic in the Mollusca. It is easy to understand how the ova of the Distomata discharged from the bodies of the water fowl may gain their place in the Mollusca. V. Siebold has observed in a very interesting manner also the passage of the Cercariæ into the bodies of water insects (larvæ of Ephemera and Perlida), which he placed together with a quantity of Lymneus stagnalis, from the various parts of whose bodies the Cercariæ were discharged in numbers out of their nursing capsules: the penetration of the integument of the insect by the Cercaria and the mode of casting its tail being precisely the same as that observed by Steenstrup in the Mollusca.†

Both these observers agree that the first and second germ-cases (or nurses), and the Cercariæ, or Distoma-larvæ, arise by a process of gradual development from extremely minute granular spherules, which are at first situated in the posterior region of the body, or between the alimentary cavity and the integument. These are certainly not ova: but we are at a loss to state to what class of reproductive germs they may be referred with greatest accuracy.‡

It is known that the bodies which inhabit the aqueous chamber of the eyes of many fishes are imperfect Distomata. Steenstrup has frequently observed these larvæ in the pupa state adhering to the inside, and sometimes to the outside, of the cornea, and he has occasionally noticed a delicate streak through the cornea, indicating the track through which the animal has penetrated; and he considers it as extremely probable that all the Trematoda of the eyes of fishes, of which a vast variety has been described by Nordmann§, are

§ Mikographische Beitrage, &c., 1832.

at one time encysted, and that of the two principal forms distinguished by that observer, the one is the more advanced and the other is the larva.

From what has already been observed it seems probable that other productions previously described as Entozoa of various kinds, may, in reality, be nurses or larvæ of different Distomata; and that many of these may be brought under their several specific distinctions, when the new paths of investigation pointed out by the suggestions of Steenstrup and V. Siebold have been diligently pursued.

Von Siebold has recently related* a very interesting observation on the remarkable double Trematode animal, discovered and described by Nordmann†, under the name of Diplozoon paradoxum, from which it seems to be ascertained that this double animal is produced by the actual union of two nearly similar simple ones, by a process of partial fusion, which, though much less complete, seems to partake in some degree of the nature of conjugation, such as occurs in the Closterium and some of the lower vegetable bodies. The single animal, first described by Dujardin, under the name of Diporpa ‡, was observed infesting the minnow (Leuciscus phoxinus) in the same streams with the gudgeon (Gobio fluviatilis). This animal corresponds nearly in form and structure with the half of the Diplozoon, with the exception of its smaller size, and the absence of generative organs. On the side of the Diporpa a projecting sucker exists, and the union between two of these animals which gives rise to the Diplozoon, begins by a mere adhesion of this sucker, which becomes more and more complete, so as at last to lead to that entire fusion and combination of the adjacent parts of the intestinal canal and some other organs, which has excited so much surprise in the Diplozoon. The development of the genital organs in both of the two united animals succeeds to this union.

Annelida. — Some phenomena in the reproduction of the Annelida are to be referred to the indirect mode of generation now under consideration. The most of these animals are hermaphrodite; they are all more or less jointed, or formed in the adult of repetitions of segments of similar structure, the anterior and posterior alone differing from the rest. The jointed structure does not exist in the embryo when it first leaves the egg; but is gradually produced by a process of gemmation, which may be styled intervening rather than fissiparous. In the multiplication of these segments the new ones are always formed in the interval between the caudal segment and that which is next to it; the seat of new production differs therefore in the Annelida and Cestoid worms; for in the latter

* Zeitschrift für Wissensch. Zool. 1851.

† Op. cit.

‡ Hist. Nat. des Helminthes, 1845. Dujardin had noticed the resemblance between this body and the two parts of the Diplozoon, and had conjectured that it might be in some way the young of the Diplozoon.

of these animals the new joints are developed at the cephalic extremity, and there is also some difference in its nature, as the multiplication of joints in the Tænia is in some degree truly fissiparous.

A few of the jointed Annelida have long been known to be subject to another kind of development, by which one or more complete segmented individuals are formed close to their caudal extremity, and spontaneously separate to enjoy for a time an independent life. This remarkable fact was first described by Otto Fred. Müller, in the small Nais proboscidea*; and Gruithuisen described accurately the same phenomenon in a Nereis or Chætogaster.† This process was looked upon by these observers as an instance of accidental fissiparous generation; but it has received a different signification and a greater interest from the more recent researches of Quatrefages and Milne-Edwards.

The first of these naturalists observed in a number of individuals belonging to the genus Syllis‡, at a certain period of their life, a new individual to be formed at the caudal extremity of each. The part was first marked off by a notch or transverse groove, the form of the parent individual gradually appeared in it, with the head, eyes, the same joints, limbs, &c., and it was ultimately separated by spontaneous fission. But the resemblance between the original individual and its offspring was chiefly external; for it was found that while the parent animal continued to exercise as before the functions of nutrition it was not possessed of generative organs; and, on the other hand, the new individuals seemed destined alone to perform the reproductive functions, and contained the fully formed sexual organs, while their alimentary canal appeared to become atrophied, and was not employed in the digestion of any newly assumed food. These individuals lived long enough after separation to complete the reproductive process by the formation of fecundated ova.

Milne-Edwards observed in the Myrianida fasciata §, a similar, but more numerous gemmiparous production of sexual individuals. In this animal, as many as six new individuals were observed to be formed in gradual succession, one before the other, and between the caudal and terminal segments of the original body. Each one of these new individuals, as it

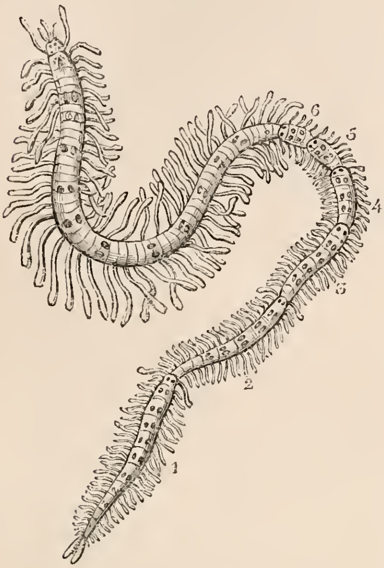
Times, vol. xx. p. 83, where he refers also to observations of Oersted in an Eulosoma, and of Schmidt in a tubicolar Annelide, called Filograna.

‡ Annal. des Scien. Nat. 1844, tom. i. p. 22. Otto F. Müller had also noticed the phenomenon in the same animal, and described it under the name of Nereis prolifera, in his Zoolog. Danica, vol. ii. p. 15.

§ Annal. des Scien. Nat. 1845, tom. iii. p. 170. See also Longet's Traité de Physiologie, tom. ii. part 3rd, p. 47.

arrived at maturity, and acquired the external configuration and structure (though of smaller size) of the parent, was found to be possessed of reproductive organs, while the original animal had not acquired any. The first

Fig. 29.



Myrianida fasciata. (*From Milne Edwards.*)

Twice the natural size. At the posterior part of the body are seen six young, produced between the caudal and the next joint in succession, from 1 to 6.

formed was situated farthest back, and remained for the time attached to the original caudal joint, and the others followed in succession before it, the last produced being attached to the terminal joint of the parent body; and each newer individual presented a less developed structure than the preceding one. In the animal observed by M. Edwards, the anterior or youngest individual had only ten rings, the second had fourteen, the third sixteen, the fourth eighteen, the fifth twenty-three, and the last, or caudal one, thirty rings. It would appear, therefore, that the new individuals take their origin from the last joint of the parent Annelide. The observations of M. Edwards farther make it appear that the process of development and multiplication of the segments in each of the new individuals is the same as in the young Annelide first formed from the ovum; that is, the embryo is at first without segments or rings, the head and caudal part existing alone, and the joints being gradually formed between them, and in succession, from the posterior of the segments previously produced.

These phenomena cannot fail to recal to our recollection the production of sexual individuals by a non-sexual process analogous to gemmation from imperfect parents or nursing stocks; and as Mr. Owen has remarked*, "Since the individuals so propagated alone acquire the generative organs, an alternation of generations may here be affirmed of such species; the oviparous individuals producing eggs from which the gemmiparous individuals come, and these, in their turn, reproducing the oviparous individuals."†

But it is to be observed, that in many others of the Annelida, the generation is of the ordinary kind, or consists in the production of sexual individuals, by their direct or metamorphic development from the ovum.

Insecta. Aphides. — A remarkable example of a similar modification of the reproductive

B. (*After Leydig.*) Enlarged view of the chambers of one of the ovarian oviducts of a viviparous Aphis. In the uppermost chambers are seen the fine nucleated cells, of which one in 1′ and 2′, larger than the rest, descends; and in 3, 4, and 5, are seen the changes of this and other granular and cellular blastema, from which the new individual is formed.

* Lectures, 1849, Med. Times, vol. xx. p. 83.

† At the same time it ought to be mentioned in connection with the above, that, according to some

process among animals higher in the scale, but in them of an exceptional character, has long been known to occur in the various species of the common plant-louse, or Aphis, first discovered by Reaumur * and Bonnet †, and confirmed and more fully illustrated by a variety of accurate entomologists in more recent times. In this animal, successive generations, amounting each to a considerable number, and in the Aphis lanigera ‡ averaging about a hundred, are produced for seven, nine, or eleven times, according to the species, from parents of no sex, or rather which seem to possess the structure of females imperfectly developed. The course of the generative process is the following: perfect male and female winged insects are observed only towards the autumn season: these fly about in great quantities, the impregnated females deposit their eggs covered with a protecting case of mucus in the axils and other recesses of plants, where they remain during the winter. In spring there are developed from these ova a brood of larvæ, or imperfect female Aphides, which soon produce, by an act of viviparous generation, and without any concurrence of the male sex, a progeny of a similar kind, and this is repeated, in successive generations, for nine or ten times in the common species, or for ten or twelve weeks during the summer, at the end of which time the last brood brings forth male and perfect female individuals, both of which die after having provided by the production of fecundated ova for the continued generation during the next season.

Upon the discovery of this very remarkable mode of reproduction, various theoretical conjectures were made in regard to its nature; but no satisfactory explanation presented itself, till the knowledge of the general nature of the process of non-sexual larvation came to be brought under a general principle or law. It is now obvious that the production of the successive generations of Aphis-larvæ may be regarded as an instance of the multiplication of individuals from the product of a single ovum, previous to the development of the true sexual organs and the exercise of the sexual functions. But this example of non-sexual larvation deserves attention, not only from its occurrence among animals placed so high in the zoological scale of organisation as insects, but also from the degree of perfection of the larvæ themselves, and from the circumstance that the new broods are formed, not as in the other examples of this process to which the attention of the reader has already been directed, by a division of the whole body, or by gemmation from its external or internal substance, but from germs arising within a determinate organ, corresponding in its general form and anatomical relation, though not entirely similar, to the generative organ of the perfect female.*

The genital organs of the viviparous or larval Aphides differ from those of the perfect or oviparous females, principally in the want of the receptaculum seminis, and the organ which secretes the mucous investment for the ova, and there is also some difference in the form of the ovarium, or germiparous part of the organs.†

The gradual development of the larva brood within the oviduct of the viviparous parent has been traced carefully by several observers. J. Victor Carus has attempted to show that this process is to be distinguished from the usual process of development from an ovum by the absence of cell multiplication, and by the formation of the embryo of the larva from a merely granular germ: but more recently Leydig ‡ has shown that though there may be differences in the structure and mode of development of the ovum and of the viviparous germ, the latter arises as truly as the former from cellular elements. The uppermost compartment of the oviduct contains, according to Leydig, from eight to twelve distinct nucleated cells, together with a quantity of finely granular substance. One of these cells appears to descend into the second compartment, in which an outer layer of cells exists, with finely granular substance internally: in the third compartment the cells of the outer layer have become still smaller and more numerous, and have formed, in fact, a covering to the germ, similar to that which proceeds from cleavage in the ovum. The rudiments of the internal organs now begin to be distinguishable, and the various external organs are successively developed out of the cellular mass. The cellular structure of the ovum of insects is at all times difficult to be traced in the earlier stages of development; and it seems to be established by these observations that the origin of the embryonic structures from cells is at least as obvious in the viviparous as in the oviparous germ (see *fig.* 30. B.).

General Remarks on Alternate Generations.—Having now shortly described the principal varieties of the reproductive process which may be brought under Steenstrup's law of "Alternate Generation," it may be proper to review very briefly their general nature.

recent observations, the parent or stock individuals of both Syllis prolifera and Nais proboscidea arrive ultimately at sexual perfection after having given off a number of sexual individuals by the caudal gemmation. See Leuckart on Metamorphosis, Non-sexual Reproduction and Alternate Generations, in Zeitsch. für Wissensch. Zool. 1851, in which he refers to Frey and Leuckart, in Beitrage zur Kenntniss Wirbellos. Thiere, p. 96; and to Schultze, in Archiv. für Naturgesch, 1849, p. 287, for observations proving this fact.

‡ See Owen's Lect. on the Invertebrate Animals, 1843, p. 235.

* It is conjectured by Von Siebold (Vergleich Anat. der Wirbellos. Thiere, p. 634), that the same mode of production may occur also in some kinds of Cynips and Psyche.

† See the interesting observations of Owen, in Parthenogenesis, p. 38., and elsewhere; V. Siebold Vergleich. Anat. and Froriep's Neue Notizen, vol xii. p. 308; and J. Victor Carus, Zür nähern Kenntniss des Generations-Wechsels, Leipzig, 1849.

‡ V. Siebold and Kölliker's Zeitsch. für Wissenschaftliche Zoologie, vol. ii. p. 53.

These phenomena are confined to the Invertebrated animals, and among them are to be regarded as occasional and exceptional rather than general. Among the Protozoa they may exist to a greater extent than is yet known; they occur more or less in all the divisions of the Radiata, but more constantly and obviously in the Polypina and Acalepha than in the Echinodermata: among the Mollusca they have been observed only in the comparatively limited classes of Bryozoa and Tunicata: they are almost universal in two divisions of the class Entozoa, viz. the Cestoidea and Trematoda, but they are altogether absent in the Nematoidea; they belong only to the lowest division of the Annelida, and among the Articulata proper the almost entirely exceptional examples are confined to the class of insects. Nor are the phenomena universal in those classes or orders of the animal kingdom in which they have been described. In some of these divisions, therefore, and in all the others of the animal kingdom, the manner of the reproductive process is ascertained to be *direct*, that is, by generation from sexual parents, and by development, or in some instances by metamorphosis, from ova to sexual individuals; to which may be added, in some animals, by the multiplication of like individuals, separate or aggregated, by gemmation. But although this general statement is applicable to the present state of our knowledge, we are still too imperfectly acquainted with many forms of the reproductive process to warrant us in affirming that there may not yet be discovered many other deviations from that which has long been familiar to our minds as the more common and direct connection between the ovum and the perfect or sexual individuals which produce it. In the mean time let us endeavour, according to our present information, to determine the true character of the seemingly exceptional phenomena, of which the more important have been noticed in the preceding section.

The views first suggested by Steenstrup, in 1842, in connection with these phenomena are unquestionably to be regarded in the light of a discovery, and the attempt to deprive them of their character of novelty and importance, or to refer them to other previously known general laws, has entirely failed.* It may be that the smaller portion only of the facts on which the views are founded may have been first observed by Steenstrup, and that parts also of these views may be in themselves premature, speculative, or erroneous; but all discoveries in science are the result of the successive and concurrent observations of a number of inquirers; and no one who has had an opportunity of studying the history of the progress of research into the reproductive function during the last twenty years, will deny that the view which has associated together the phenomena in question under a common principle, has had a most important influence in modifying the doctrines and in guiding and suggesting the researches of those physiologists who have devoted themselves to inquiries into the origin, early conditions, and zoological affinities of the lower animals; and it may truly be affirmed, that no one could at present enter upon the investigation of any obscure or doubtful department of animal or vegetable production among the lower series of these kingdoms of nature, without making especial reference to the views embodied in Steenstrup's generalisation.

The occurrence of non-sexual multiplication among some of the Invertebrated animals had long been known, as of Polypes, by budding, so admirably described by Trembley in his work published in 1744; and of the Aphides, by internal production, discovered by Reaumur and Bonnet; and of the Nais and Nereis, by external extension, described by Otto F. Müller, in 1800; the imperfect conditions of some of the Entozoa had been detected by Nitsch and V. Baer in 1818: the two forms of the Salpæ were known to Chamisso in 1819, who, more than any other observer, appears to have foreseen in these animals the discovery of alternate or dissimilar generations; but the first observations, from which the peculiar nature and general doctrine of the phenomena now under consideration may be regarded as having been deduced, are those of Sars, on the compound Polype stock of the Medusæ, in 1828, and of Rud. Wagner, on the production of Medusiform bodies from a polype (Coryne aculeata), in 1833. From that time, observations followed one another in rapid succession, and continue still to crowd upon us, so as to have changed almost entirely the aspect in which we have been accustomed to regard the development of the lower animals: and it is only necessary to mention collectively the names of some of those whose observations have contributed most to extend and to establish these discoveries in different classes of animals, to exhibit the importance attached to them by zoologists, comparative anatomists, and physiologists of the highest character in our time, such as Dalyell, Lister, Sars, Lovén, V. Siebold, Nordmann, Eschricht, Steenstrup, Van Bénéden, Kölliker, Owen, Dujardin, Milne Edwards, Blanchard, Quatrefages, J. Reid, J. Müller, E. Forbes, Désor, Vogt, Agassiz, Huxley.

The peculiar nature of these phenomena as compared with those of the better known and more common form of sexual generation, consists in this, that in some animals, in all of which, be it observed, the permanence of the species is secured by the sexual production of ova, the body or individual which is developed immediately from the ovum is not, in general, itself the bearer of the sexual organs, but, nevertheless, maintains for a time an independent existence, or presents the structural and functional characters of a separate or distinct individual; these characters often differing remarkably from those of the sexual

* See Ed. Forbes' Remarks, in Treatise on Naked-eyed Medusæ, 1848, p. 83., *et seq.*

individuals from which the ovum derived its origin: and that subsequently this individual, or one or other of its successors, has formed in connection with it, either internally or externally, and without sexual organs, a new progeny, which may consist of one or of many individuals, which have each of them more or less of the structure and properties of independent animals, and which, however variable their other organisation may be, present this in common, that they are sexually complete, and renew the true generative act by the formation of fecundated ova. In some animals it is the immediate offspring of the individual developed from the ovum which resumes the sexual function; in other animals this offspring bears a second brood, or a third, and even more successive generations, before the return is made to sexual reproduction. This process of non-sexual production is, in some instances, very analogous to external gemmation; in some it resembles transverse fission; and in others it proceeds from the interior of the parent body, in a manner which has been called internal gemmation, but which must be considered as different from a true budding process, and cannot, in a few words, be correctly characterised. These deviations, therefore, are peculiar in this, as compared with the mode of reproduction in other animals; viz. 1st, that the immediate product of development from the ovum is not usually itself the producer of ova, but that this function is delegated as it were to the sexual individuals, which are the products of its non-sexual generation; 2nd, that it frequently happens that in place of one individual only resulting from the development of an ovum, several, and even a great multitude of individuals are produced by the non-sexual multiplication of the product of sexual generation; and, 3rd, that while the several series of individuals proceeding from the various successive acts of production, may, in one sense, be regarded as different stages of an animal specifically the same, or are together necessary to make up the species, yet their form, organisation, and modes of life are often so different, that many of them have frequently been described as belonging to different species and genera, or even to different orders and classes of animals; and, but for the knowledge now possessed of their close affinity, as established by their common origin, would still continue to be dissociated from each other in the systems of the zoologist.

The doctrine of alternating generation has not, however, been admitted without reservation by some physiologists. In various parts of his recent admirable work on General and Comparative Physiology, and elsewhere*, Dr. Carpenter has expressed his dissent from the views of Steenstrup, both as regards the existence of an alternation of a true generative process and the alleged *nursing* function of one or more of the series of individuals so produced; and seems disposed in some measure to undervalue that author's researches, considered either as original observations, or as embodying a novel and important generalisation. Dr. Carpenter regards the phenomena in question as analogous to, if not identical with, those of metamorphosis rather than of generation; and we are left to suppose that he does not think the difference essential between such metamorphoses as occur in one and the same individual and those which result in the production of a multitude of dissimilar individuals. According to this view, the new animal produced by the non-sexual process is the result of a process of development or growth, and ought therefore to be regarded as formed by budding or gemmation, rather than by an act of generation properly so called. In a recent paper on the subject of Metamorphosis, Non-sexual Reproduction, and Alternate Generation (Zeitsch. für Wissensch. Zool. June, 1851, p. 170.), Leuckart has advocated somewhat similar views, endeavouring to refer all the instances of so-called alternate generations to metamorphosis; but this obviously requires that we should change the signification usually given to this term. But the restriction of the word generation to the sexual process of reproduction, though it might be convenient and proper, were we now to have to employ it for the first time, seems somewhat arbitrary in this case, as it is contrary to common practice, and physiologists have long been in the habit of making the distinction between sexual and non-sexual generation. No new term has been suggested applicable to, or descriptive of, all the phenomena in question; and I apprehend, that, however desirable the change may appear, we must continue to designate the process of non-sexual production as one of "Generation" in its physiological sense, and the series of new beings thus formed as so many "generations" of individuals in the common or vernacular sense of the term. As Professor E. Forbes remarks, the alternation of forms is admitted, but not the alternation of generations. The bodies produced by one individual, if they assume new forms and move about as separate and independent animals, must be regarded as so many distinct individuals; and if they are different, and if the one produces the other (even though it may be by a process of gemmation), we must admit that they belong to different generations.

The distinction between the formation of a new individual from an impregnated ovum, and that which takes place without the concurrence of sexual organs, is one which, unquestionably, all will feel disposed to regard as most important; but it still remains undemonstrated that all the animal beings which are of non-sexual origin are necessarily formed by a process of gemmation analogous to ordinary growth. It has already been pointed out that the mode of their origin is, so far as it has yet been ascertained, very various; and, at all events, in some of them, there is a wide departure from that which we have been accustomed to regard as an act of

* In the British and Foreign Medico-Chirurgical Review, vol. i. and vol. iv.

gemmation, or simple sprouting of the parent texture. We cannot be too cautious in making wide generalisations in regard to phenomena so various and so imperfectly known as those of alternate or intermediate generation are; and the only safe course in the progress of such inquiries is to apply terms to the phenomena which are no more than the exact expression of what is well ascertained regarding their nature. Now, who that has observed or studied the history of the two states of the Salpians, and the relation in which they stand to each other, can hesitate to admit that two dissimilar generations alternate, and that a different generative process has taken place for the production of each? or who, knowing the relation subsisting between the fixed marine polype and its free moving medusoid offspring, or that between the larger medusæ and their compound polype stocks, would deny to each of these series of beings the attributes of distinct individuals, or regard the productive acts by which they take their origin in any other light than as two dissimilar kinds of generation? But this seems scarcely more than a question of words. It is important rather to notice that while some of the polypes now alluded to multiply their like (that is polype-forms) by budding, their medusoid progeny also occasionally produce their like (or similar medusoids) by gemmation; and surely it is expedient to regard as somewhat different that production of distinct medusoid individuals from a polype stock, which is an advance in its stage of being, and which gives rise to an animal different in structure, mode of life, and functions, from its parent, from that kind of production which is no more than the repetition of the parental form or the extension of its parts.

The term *nurse*, applied by Steenstrup to the non-sexual producers, seems inappropriate, and may, in one part at least of his treatise*, have led him into purely speculative comparisons, such as that with the workers among the gregarious insects; but in other parts of his essay the author's speculative views are kept in strict subordination to the simple description of the facts. Due allowance ought also to be made by the English reader of this work, for the circumstance that, though an excellent translation, it comes to him through the German from its original language. Less objection would probably have been taken to his theory had the term "preparing stocks," or some one conveying a similar meaning, been substituted for that of "nursing individuals."

Professor Owen also, though admitting in the full extent the peculiar and important nature of the phenomena of alternate generation, objects to the term nurse or nursing animal, as calculated to mislead, and holds the views of Steenstrup, embodied in the phrase "Alternating Generation," to be defective, as not affording any real explanation of the nature of the phenomena, or rather, as being no more than a statement of the facts, without referring them to a sufficiently general law or connecting principle.

Professor Owen's attention had been, before 1843, attracted to the remarkable non-sexual multiplication of the summer Aphides, the structure of which he minutely examined, and had been led to the opinion* that the germs from which the offspring of this non-sexual generation arises are the remains of the original germ-substance of the yolk, which have not been applied to the formation of organised textures in the individual immediately developed from the ovum. Professor Owen has given the name of Parthenogenesis, or Virgin-production, to this mode of generation, and in the very able and ingenious Essay under that title, published in 1849, containing the substance of two lectures, introductory to a most instructive course of lectures on the Generation and Development of the Invertebrated Animals, and also in various parts of these lectures†, has communicated a more lengthened exposition of his views. "The progeny of the impregnated germ-cell," says he, "form the tissues, &c., but not all of them are so employed, some of the derivative germ-cells may remain unchanged, and become included in that body which has been composed of their metamorphosed and diversely combined or confluent brethren: so included, any derivative germ-cell, or the nucleus of such, may commence and repeat the same processes of growth by imbibition, and of propagation by spontaneous fission, as those to which itself owed its origin; followed by metamorphoses and combinations of the germ-masses so produced, which concur to the development of another individual; and this may be, or may not be, like that individual in which the secondary germ-cell or germ-mass was included."‡ He states farther, that the lower the animal in the scale of life, the number of derivative germ-cells and nuclei which retain their individuality and spermatic power is greater, and the number of those that are metamorphosed into tissues and organs, less. The simplest animals are nothing more than nucleated cells, or in the minute and microscopic ones, as Gregarina and Polygastria, one nucleated cell only; the middle layer of the wall of the Hydra he describes as consisting of nucleated cells. In Compound Polypes and Parenchymatous Entozoa a large quantity of derivative germ-cells is retained among their textures or other parts; and the same is the case at the caudal extremity of the Nais and young Annelida. Professor Owen informs us that he has observed the germs of the viviparous Aphides in the embryoes near the simple digestive sac before any organs have been formed for their reception, and that when these germs are afterwards included in the tubes which correspond to the ovaries and oviducts, he regards them as comparable to the germ mass in its mi-

† As published in the Medical Times, vols. xix. and xx.

‡ On Parthenogenesis, p. 5.

nutest state of division, and as differing from ova in the absence of the germinal cell.* Notwithstanding the attractive ingenuity of these views, and the great weight which all must be disposed to attach to the statements of so accomplished an anatomist, the theory they involve or expound, when fully considered, does not appear entirely to remove the veil from the mystery of alternate generations, nor to afford that satisfactory explanation or generalisation of its nature which might be desired: for it is to be feared that under the appellation of nucleated cells, as applied to the structure of the lowest animals, very various kinds of organised structures have been confounded by authors, and we are certainly very far from having had determined, by actual observation, the nature or source of the minutely granular masses from which what has been called internal gemmation proceeds; and though it may be admitted that most new structures take their origin in masses of blastema, more or less cellular and granular, the relation of these to the germ masses of the ovum are far from being ascertained. It may be granted, that in the case of the first brood of Aphides formed in the non-sexual way from the first individual immediately developed in the ovum, a residuum of germ-cells may have served as the original blastema of their germs; but when we consider the inconceivably minute portions of this that are to pass to the next and to the successive generations up to nine or eleven, we seem to have to deal rather with a theory of the original pre-existence and "encasement of germs" than with a matter that we can ever hope to decide by observation: and in the greater number of the other instances of alternate generation, there is no possibility of tracing the origin of the germs of the new individuals formed by gemmation to the yolk or germ-mass, of which they are regarded as the included remains.

Professor Owen has well remarked †, that "in the Vertebrated, and in the higher Invertebrated animals, only a single individual is propagated from each impregnated ovum. Organised beings might be divided into those in which the ovum is uniparous, and those in which it is multiparous. This is the first and widest or most general distinction which we have to consider in regard to generation, and in proportion as we may recognise its cause will be our insight into the true condition on which Parthenogenesis depends." But this distinction, notwithstanding its acknowledged importance, does not carry us any farther into the insight of the essential conditions of the phenomena by the theory of the residual germ-mass originating new germs; for when the greater part of this mass is converted into the textures and organs of the embryo directly developed from the ovum, there is still as great a difficulty as ever to understand what circumstances should determine a minute residuum, supposing it to exist, to form an entire new individual, or a prodigious multitude of individuals, in place of only an additional portion of texture, or an additional organ, which might more naturally be regarded as the correlative products of their brethern germ-cells; or why, in other numerous instances, in which, to all appearance, an equal quantity of residual germ-mass exists, no such formation of new individuals occurs.

It appears equally fair to suppose that the germs of the ova of all animals must have originated within the ovaries of the female parents from residual germ-cells included in the blastema of these organs; but no distinction has ever been established between that blastema in its primitive state and that of other organs of the body: and there does not appear to be better reason for considering the germs of individuals formed by gemmation, as derived more directly from residual and included germ-cells, than those of the ovarian ova.

I have not adopted the term Parthenogenesis, as applied to the alternate generations, because it implies that this kind of production occurs in female animals. Now, although the observations of Owen and V. Siebold have shown a remarkable similarity to the female structure in the case of the viviparous Aphides, this is altogether wanting in the other instances of alternate generations; and this process is strictly non-sexual rather than uni-sexual in its nature. Were it desirable to change the name for this process, the term "Metagenesis," suggested and sometimes employed by Professor Owen, seems well adapted to express exactly what occurs in alternate generations, without calling for the admission of any hypothesis beyond that of the new production being an act of generation; and it seems to me to be the most exact translation in scientific terminology that can be given of the German of Steenstrup in "Generations-Wechsel." In a convenient shape it is precisely descriptive of that change of form by generation, or by production of a new individual, which it has been my object to show has been accurately distinguished in the general law of Steenstrup, as different from a mere change of form by growth or by metamorphosis in the same individual.

At the same time it is deserving of notice, that, among the compound Polypina, the continuous multiplication of individuals proceeds to such an extent, and with such remarkable regularity, as to give rise to composite masses, often of very large size, the general arrangement of which bears a considerable resemblance to that of plants: and we are led still more to institute a comparison between these animals and plants by the circumstance of the similarity of their continuous growth by the addition of new sets of polype individuals to the extension of the leaves and branches of a tree or ramified plant, and by the correspondence of the occasional formation of sexual individuals on the polype stock

* On Parthenogenesis, p. 38.
† Loc. cit. p. 62.

with the development of flowers. It is not without considerable interest, that the same conditions as to temperature, season, supply of nourishment, &c., seem to determine the one or the other kind of production in both the animal and the vegetable bodies. Many botanists regard the plant as an assemblage of individuals; and zoologists are for the most part agreed as to the distinct individuality of the parts united in a compound polype. But the tendency to spontaneous separation of these individuals, especially in their sexual form, is very frequently exhibited in the animal kingdom, while it is rarely, if ever, met with among plants; and among the polype tribes, as well as in other examples of alternate generation, the striking difference of form, structure, mode of life, and functions, of some of the sexual individuals developed by non-sexual generation, seem to warn us against extending the comparison farther than the admission of the general analogy above adverted to, or, at all events, precludes us in the mean time from drawing any arguments as to the nature of animal production from that which is as yet only imperfectly understood in the vegetable kingdom.*

These considerations raise another question on which recent writers are at issue in regard to the theory of Alternate Generations, viz. whether the various animal bodies formed by the non-sexual process within one act of sexual generation are to be regarded as so many *individuals* composing the species, or whether they are to be considered only as the different states of one and the same individual. I have abstained from entering directly on the discussion of this question, from the desire to avoid the confusion which is apt to arise in it from the use of terms in other than their usual significations. In regard to connected animal forms, such as those which coexist in a Compound Polype, less difficulty might be felt than in those instances in which a complete separation of the progeny from its producer has taken place; but it seems to require a greater departure from the ordinary signification of a common term than is warranted by our present imperfect knowledge of the phenomena, arbitrarily to determine to regard as merely one individual all those bodies which may be formed by a non-sexual process from the product of a single ovum, notwithstanding the great variations in their structure and mode of life, and the complete separation and apparent independence to which they may attain. It is unquestionably important to acknowledge the integrity and permanence of the species as maintained in the midst of all these variations by generation from an ovum; but there does not seem to be any obvious impropriety in the instances in question in regarding the species as made up of individuals differently constituted among themselves, and produced one out of another by a non-sexual process. The term Zöoid suggested by Huxley, or Zöonite previously employed by Milne Edwards and some other French authors, or any such term agreed upon as implying a relation of affinity among the various bodies included in one act of true sexual generation, may perhaps remove some of the ambiguity; but I confess I do not think the present state of the inquiry warrants the total abnegation of individuality to the various animal bodies produced in the non-sexual manner.*

In reviewing, then, the whole subject of Alternate Generation, it seems to be equally premature to refer the whole of the phenomena included under this term, which may hereafter be discovered to be very various in their nature, to a simple process of gemmation or individual development, or to attribute them to the existence of certain powers, such as a germ-force or spermatic power, remaining in certain germ-cells, or to reject altogether the hypothesis of Steenstrup of Alternate Generations, which indeed is little more than the expression of the course of the observed phenomena; until we shall know more exactly the minute structure of the germ from which a bud arises, and the difference between that and the germ of an ovum, and until we shall be more fully acquainted with the whole structure and series of changes of the various animal forms that have been the subject of consideration in the preceding section.

We regard it, therefore, as more consistent with the actual state of our knowledge of the facts to describe the phenomena of Alternate Generation as a peculiar mode of existence belonging to some of the simplest kinds of various classes of Invertebrated animals, which seems to have especial reference to the preparation of the sexual organs; and of this nature, that the animal immediately developed from the fecundated ovum does not usually arrive at sexual completeness, but has formed from it, by a non-sexual process of production, another individual of a different form, or a succession of them, which finally attain to sexual completeness, and produce the fecundated ova that originate the generative cycle; and the effect of which is, to render two or more successive generations of dissimilar animals necessary to the completion of the species to which they belong.

* For farther remarks on this subject the reader is referred to an account of vegetable production, under the Article Vegetable Ovum.

* Some acute and interesting remarks by Mr. Huxley on this subject will be found appended to a sketch of J. Müller's discoveries on the Echinodermata, in the Annals of Natural History, 1851, vol. vii. p. 1. I would also refer at this place to the Lectures of M. Agassiz on Comparative Embryology, Boston, 1849, as presenting a most engaging view of the influence which the study of the metamorphosis of animals, along with the history of alternate generations, must exercise on the systematic views in Zoology and Comparative Anatomy, and I also take this opportunity of referring to some remarks by Mr. C. Spencer Bates in a paper on the Development of the Cirripedia, in the Ann. and Mag. of Nat. Hist. for 1851, vol. viii. p. 331. for a statement of the relations subsisting between the various forms of animals considered in their sedentary and free states, either in individual species or in different genera or families of the various classes of animals.

Additional Remarks. — Since the foregoing observations on alternate generation were printed in August, 1852, the knowledge of these peculiar phenomena and of the whole forms of reproduction in various classes of animals has been considerably augmented by several important contributions. A short reference to some of these researches seems necessary in this place, in order to complete our notice of the phenomena referred to.

The statements of Stein, referred to at p. 7 of this article, as to the encysted condition of the Vorticellæ previous to their undergoing multiplication, having been called in question by Ehrenberg*, the subject has been farther investigated by F. Cohn, with the result both of a full confirmation of Stein's statements, and of its being ascertained that a considerable number of other infusoria are subject to a similar change; among which he mentions species belonging to the genera Euglena, Prorodon, Chilodon, Notophyra, Trachelius, Trachelocera, and Stentor.† Stein holds it to be fully established that the nucleus of the Vorticella is its true reproductive organ. From this nucleus a progeny is formed in two modes, in both of which the parent animal becomes encysted. In one mode the encysted Vorticella is converted into an Acineta-form by the prolongation of narrow contractile processes of its substance from the external surface, and from the nucleus of this Acineta-like animal successive single ones are produced by gemmation. In the other form, the nucleus of the encysted Vorticella undergoing subdivision, becomes converted into the germs or spores of numerous new Vorticellæ. This process is probably in these Protozoa the equivalent of a sexual production of ova; and appears to correspond nearly with that which takes place in the production of the Navicella-like progeny from Gregarinæ, with this difference, that in the latter case two Gregarinæ are united or fused together into a sphere previous to the production of the new progeny or spores.

The view of Leydig, therefore‡, that the parasitic infusoria named Gregarinæ are only an imperfect or metamorphosed condition of a Filaria, does not appear to be confirmed.

In reference to the Entozoa, recent experiments have furnished ample confirmation of the views now adopted by almost all physiologists, that these animals are the product of a true sexual generation, and that their ova, or embryoes, or larvæ, are introduced from without into the bodies of those animals which they parasitically inhabit; while at the same time the knowledge of their migrations and remarkable transformations becomes more and more precise from additional and renewed investigation of their different forms.

Herbst, who had previously failed in some experiments to cause the transmission of the Trichinæ of the muscles by implantation in wounds of animals, at last succeeded in 1850–51 in causing the muscles of several young dogs to be infected with these parasites by giving them to eat the flesh of a badger which had lived with him for some time in confinement, and in which the Trichinæ existed in great quantity.* About the same time Kuchenmeister found that by causing young dogs to swallow along with their food a quantity of the Cysticercus pisiformis (of the hare and rabbit), the intestines of these animals were in a few weeks invariably occupied by a Tænia (T. serrata). Von Siebold, who, as has before been remarked, was the first to advance the opinion (in 1844), that the Cysticercus fasciolaris inhabiting the liver of the rat and mouse is only the early condition of the Tænia crassicolis of the intestine of the cat, has with the assistance of Lewald performed a series of experiments of a nature similar to those of Kuchenmeister, which have established beyond doubt that various kinds of Cysticerci, and also the Cænurus of the sheep's brain, and the Echinococcus veterinorum, are always converted into Tæniæ or Cestoid Worms within a short time after they have been transferred, as by feeding, into the alimentary canal of suitable animals. These experiments have also afforded to V. Siebold the means of observing in a most interesting manner the process of development and gradual conversion of the cystic into the cestoid entozoon.†

Since the publication of V. Siebold's experiments, farther researches on the same subject have been laid before the Academy of Sciences of Paris by Van Beneden and by Kuchenmeister, in Memoirs presented by them in competition for the grand prize offered by the Academy in 1853 for the scientific investigation of the Development and Transmission of Intestinal Worms.‡

The observations and experiments communicated by Van Beneden in this prize essay, and those contained in his highly interesting Memoir on the Cestoid Entozoa, published in the Mémoires de l'Académie Royale de Belgique for 1850, have also established in the most satisfactory manner the relation between the encysted or scolex condition and the cestoid form of the Tetrarhynchi; facts which have also been in part confirmed by R. Wagner.§ Van Beneden has observed the first development of the ova of the Tænia dispar of the Rana temporaria ‖ into the small embryo provided with its three pairs of boring hooklets, and has watched with care the active motions of these instruments, by which

the minute embryoes, scarcely larger than the blood-discs of the frog, penetrate into the tissues or organs in which they afterwards become encysted; thus affording the most direct proof from observation of the manner in which the young of these parasites become established in the internal parts of animals. The head, with the circle of hooklets and the four suckers, is then formed at the anterior part of the embryo, constituting now the scolex of Van Beneden; and this author proposes to give the name of proscolex to the previous embryonic stage. In connection with the formation of the head of the encysted animal, it may also be noticed that Stein has observed the three pairs of embryo hooklets remaining for a time irregularly scattered over the enlarged vesicular part of the body.* When the encysted animal (Cysticercus) has been introduced into the stomach and intestine of a suitable animal, generally a carnivorous one, it resists the digestive action of these organs, but speedily loses its caudal vesicle, and gradually acquires the new joints which are formed from the head. It is thus brought to the condition of the strobila, if we choose to liken the jointed state of the tape-worm to the multiple or divided polype stock from which medusæ are thrown off; and lastly, as the sexual organs become fully developed in each of these joints, beginning in the posterior ones, which are first formed, these are detached one by one, and constitute in the separate condition the bodies named proglottis by Dujardin and Van Beneden. The latter author regards these as alone the perfect animals of the Cestoid, the jointed strobila being only a preparing stock; and he adheres to the view, previously referred to in this article, that each proglottis approaches in some degree to the organisation of a Trematode animal. According to the views of Van Beneden, therefore, the different stages of a Cestoid worm are the following:—1st, the ovum; 2nd, the first embryo or proscolex; 3rd, the cysticercus, or encysted vesicular body, or scolex; 4th, the jointed stock, tape-worm, or strobila; and 5th, the separate sexual individuals, or proglottides.

Among the Trematode animals the production of a succession of new progenies by a process of internal non-sexual generation has received full confirmation. Van Beneden has added the important fact, however, that some of the Trematoda are not subject to any process of alternate generation or metagenesis. He has traced the whole process of direct development of the animal from the ovum of Udonella caligorum, a viviparous Trematode with large ova. The alternating generation belongs, according to him, to the Oviparous Trematoda, in which the ova are of small size.

In reference to the Compound Medusoid Animals, Siphonophora and Physsophorida, it appears from the researches of Leuckart, Kölliker, Gegenbaur and others*, that the several joints of the connected chains of these animals, as previously conjectured by Milne, Edwards, and others, may fairly be regarded as distinct, though imperfect individuals, some of which are destined for the sexual production of ova, while the free or floating polypine stock remains destitute of sexual organs. The free polypine stock is first developed from the fecundated ovum, and acquires its one or two swimming vesicles: from it there is afterwards formed the long chain of smaller bodies connected together by an extension of the digestive cavity and external substance of the animal. Some of these form swimming bells or vesicles with prehensile and stinging filaments; others are digesting cavities or stomachs, and others, most frequently those last formed in the chain, contain one or other of the sexual products, either male and female among the individuals of the same stock, or distinct sexes on separate stocks. But there is sometimes a combination of the motor and nutritive with the reproductive organs in the same individuals of the chain, which warrants fully their being regarded as something more than the mere repetition of organs belonging to one animal. They are, in fact, the same as the sexual individuals of a compound polype; and in some rare instances indeed they have been observed to become detached and to swim about in the separate condition.

In connection with the alternating generation of the Salpæ, in the discovery of which the whole series of facts now under review may be said to have originated, some doubts were in the previous part of the article stated to prevail as to the relation of the sexes in the animals of the aggregated chain. These doubts have now been in a great measure removed, and the knowledge of the whole phenomena of the reproductive processes in these remarkable animals greatly extended by the researches of C. Vogt† and of H. Müller.‡ From these researches it appears that while, as was previously known, the Solitary Salpæ are entirely non-sexual, the animals united together in the aggregated chain, formed by successive gemmations from one spot of each solitary individual, are hermaphrodite, or possess both male and female sexual products. The ova, however, according to Vogt are developed at a much earlier period than the spermatic substance: indeed, they are advanced to the condition in which they are ready for fecundation, while their producers are still attached as a chain to their solitary gemmiparous parent. The spermigerous organs only advance to perfection after separation; and the process of fecundation must therefore be effected in the animals of the attached chain by the

spermatic matter derived from detached chains which are frequently floating near them. To this result, no doubt, the currents of water in the respiratory cavity will materially contribute.

Since the publication of the first part of this article, the general aspect also of the questions involved in the facts referred to has undergone revision by several authors. The whole doctrine of alternate generation has, it appears, been called in question by Reichert, in a programme entitled Unisexual Reproduction*, which I have not had an opportunity of seeing. In his recent very able and instructive treatise on Reproduction in the Handwörterbuch der Physiologie, Rud. Leuckart†, though he retains the name of alternate generation as designating the phenomena referred to, gives the doctrine little place, and seems still inclined to regard this mode of production rather as a peculiar modification of growth than as a true generation. He is perhaps right in his remark‡, that physiologists have been too much disposed to separate the phenomena of alternate generation from other forms of production of a non-sexual kind, of which he considers them as only a variety; the alternation of different forms being, according to him, only a subordinate and not an essential phenomenon. In his recent very interesting work on Animal Morphology, Victor Carus§ has allowed more importance to the views of Steenstrup, adopting at the same time Owen's term Metagenesis, as most suitable for the designation of this kind of production. This author appears to me to have made the nearest approach to a correct appreciation of the nature of this process in its relation to the whole phenomena of animal reproduction as at present known.

Reviewing therefore finally the whole of the facts and opinions on this subject, I am inclined to adhere to the views expressed in a previous part of this article, that the phenomena of alternate generation or metagenesis ought to be grouped together, and to retain their place as constituting one of the general forms of reproduction among animals; consisting, as they constantly do in a certain number of animals, in the combination, alternation, or succession of the sexual and non-sexual production of individuals all proceeding originally from the development of one ovum. At the same time it is to be noted, that this mode of production does not exist in all the species or genera of those tribes of the lower animals among which it has been observed to occur, and that in some it passes by gradual transitions into other forms of the generative process. It is not on that account the same as them. Metamorphosis and Metagenesis, also, as V. Carus remarks, may be combined, but they are different. "Larvæ, the subjects of metamorphosis, arrive at the state of perfection by throwing off provisional structures which belong to their larval condition, but nurses, the subjects of metagenesis, are themselves entirely provisional structures."

Generation, therefore, or the production of new individuals belonging to a species, may be either of the sexual or of the non-sexual kind. It is only in the Protozoa that the distinction of sex has not yet been discovered. In all other animals the production of new individuals of the species is the result of the development of ova fecundated by spermatic matter. In all the Vertebrate animals and in the majority of the Invertebrate, the development of the ovum gives rise to a single new individual; in most of them by a continuous process of formative growth, in some by successive stages, or by metamorphosis. In a few Invertebrate animals the development of the ovum gives rise directly to more than one individual by what may be named primary division of the ovum. In a considerable number of Invertebrate animals the production of new individuals sexually perfect is not immediate from the fecundated ovum, but secondary or intermediate by non-sexual formation from a preparing stock which is the product of development from the ovum. In such animals an alternation of sexual and non-sexual formation of individuals is necessary for the completion of the act of generation or the reproduction of the species. In a few of these animals only one new individual is formed; but in by far the greater number the product is multiple, thus leading to a great increase in the number of individuals, either in the distinct or in the aggregate form, which have all derived their origin from a single ovum. It is to be observed however, that in some instances the alternating generation may co-exist either with the non-sexual mode of multiplication or with direct sexual reproduction.

In conformity with these views of the relation of the product of generation to the ovum and its progenitors, there might thus be established the following modes of reproduction among animals—viz.

I. Monogenesis, reproduction without known sexual distinction.

II. Digenesis, bisexual reproduction.

III. Metagenesis, alternation of sexual and non-sexual reproduction.

In each of these main forms of the reproductive process the following varieties might also be distinguished—viz.

1. With single progeny.
2. With multiple progeny.
3. By consecutive development.
4. By metamorphic or interrupted development.

PART SECOND.

Of the Ovum previous to the Commencement of Fœtal Development.

I. Anatomical Structure, Chemical Composition, Origin and Formation of the Ovum in Man and Animals.

§ I. Preliminary and General Comparison of the Ova of Animals.

At a time when the analogy and difference in the structure and functions of the ova of various animals were less known than at present, and especially before the discovery of the true mammiferous ovum, the phenomena of development were almost exclusively observed in the eggs of birds; and consequently in the progress of investigations on this subject, and their extension to other animals, the nomenclature of parts of the egg, and the interpretation of the phenomena of development, came naturally to be founded on those which had previously been adopted in the study of the egg of the common fowl. In more recent times it has been found that the egg of birds presents in some measure exceptional characters, as compared with that of the greater number of animals; and it has thus become apparent that the close limitation of our observations to the class of birds, fruitful as they are universally acknowledged to have been in most important and interesting information on our subject, might tend even to retard in some degree the establishment of the more general laws of typical structure and formative change, which constitute so remarkable a feature of the result of modern embryological researches.

Still, the convenience of being able to obtain the egg of the bird without trouble in all stages of advancement, the familiar knowledge that has so long been possessed of the phenomena of incubation, the proportionally large size of the embryo, the difficulty, on the other hand, of making serial examinations of the ova of mammalia, and, though numerous and important, the comparatively fragmentary nature of the observations in this class, and especially in the human subject, make it desirable that we should not too soon depart from the practice, which has so long prevailed, of making the bird's egg the main foundation of our description of the ovum and formative process in general. But, at the same time, the exceptional structure of the fowl's egg alluded to renders it proper for me to present here, in a connected form, some account of the principal differences among the ova of various animals; so that we may, in some measure, avoid drawing false analogies, or deducing supposed general laws, which may be premature, or may be rendered inadmissible by the existence of ascertained individual peculiarities, or more extensive differences among various classes of animals.

In the commencement of this treatise (p. 3.), the ovum of animals has been described as consisting in general of two sets of parts, of which the one is formed in the ovary of the female, and the other is superadded to the first after it has left the place of its formation. The first, constituting the ovarian ovum (or ovulum of some authors), consists essentially of, 1, the external vesicular covering, or vitelline membrane, 2, the yolk or vitelline substance, and 3, the germinal vesicle, with, 4, its nucleus or macula. As being the most constant in their structure and relations, and the more immediate seat and agents of the formation of the embryo, these parts may be regarded as the essential and most important structures of the egg. The other set of parts, which are subject to great variation in different animals, and are only remotely connected with the formative process, consist chiefly of external coverings of more or less density, either membranous or calcareous, within which often is enclosed some portion of albumen or albuminous fluid along with the ovarian ovum. They serve the purpose, in oviparous animals, of protecting the ovarian egg from the hurtful influences of external agents, and, in rarer instances, of supplying additional nourishment to the embryo; in viviparous animals these parts (as in the chorion of mammalia) serve more important ends, being the more immediate means of establishing that intimate organic connection between the parent and embryo, by which a continual supply of materials for the growth of the latter, is transmitted into its body. From analogy, the outermost covering of the ovum of all animals has generally been termed the chorion.

In thus stating the general structure of the ovum of animals, a certain amount of uniformity, analogy, or correspondence in their several parts has in the meantime been assumed; and the best ascertained facts seemed for long, indeed, to have warranted such an assumption. It will be for after consideration to determine how far the comparison of the several parts of the ova of different animals proves their uniformity of structure and relation. In some instances it may appear difficult or impossible to discover the correspondence; and we must therefore be careful not to be led by the attractive nature of a great generalization, to confound a merely functional or physiological analogy, with an anatomical, a structural and relational identity.

Without entering at present into a detail of the observations bearing upon the foregoing view of the general analogy in structure and function of the ova of animals (which in truth would involve the history of almost all the more recent researches on the subject), it seems proper at this place to call the attention of the reader to the most prominent modern discoveries which have laid the foundation of a more accurate acquaintance with the structure of the ovum, and have also led to the application of improved histological views to the study of ovology.*

* It is not intended at this place to refer to the history of discovery in the department of our subject which includes embryological development, in which

The first modern discovery, which introduced a far greater accuracy into the study of ovology than existed previously, was unquestionably that of the germinal vesicle in the ovarian ovum of birds, by Purkinje, of Breslau, in 1825 *, an observation which led directly to the ascertainment of the general fact that such a vesicle exists invariably in the ovarian ovum of all animals. The extension of this discovery to a variety of oviparous animals, we may consider as due, in the first instance, to Von Baer and R. Wagner.

The next important discovery in chronological order, which contributed, in an eminent degree, to remove one of the greatest difficulties in our subject, was that made by Von Baer, in 1827, of the minute ovum of mammalia, or true viviparous animals. † The discovery of the nature of the mammiferous ovum was rendered complete in 1834, by the observation of the germinal vesicle first by Coste and somewhat later but independently by T. Wharton Jones ‡; and the knowledge of the mammiferous ovum was greatly extended and confirmed by the observations of G. Valentin and Bernardt, of Breslau. §

The nature of the germinal vesicle itself next attracted the attention of ovologists, and a farther addition to the knowledge of its structure was made by Rudolph Wagner, of Göttingen, in 1835, by the discovery in it of a minute particle or mass of fine granules, to which he gave the name of macula germinativa, or germinal spot.* The subsequent researches which that author instituted on the earliest condition of the ovula in the whole series of animals, contributed, more than any others of the same period, to establish the doctrine of a general uniformity in the structure and mode of origin of the ova of animals.† Although it appeared, from the researches of R. Wagner, and has been made still more apparent from late observations, that in several classes of animals the germinal macula loses its determinate form and is subdivided and diffused, as it were, in the germinal vesicle, yet the more circumscribed form of this body, in its earliest condition, and its general prevalence, as a constituent part of the vesicle in almost all animals, seem to indicate the analogy of that vesicle with the true nucleated cell of other parts of the animal body.

After the general nature and structure of the ovum had been ascertained by the several discoveries now mentioned, numerous and important researches followed one another in rapid succession, giving greater extent, minuteness, and accuracy to, and in some instances modifying and correcting, the knowledge previously acquired. Among the authors of these researches, besides those already mentioned, the names of Rathke, J. Müller, Prevost and Dumas, Barry, Reichert, Bischoff, Kölliker, and Vogt, occupy the most prominent place. Of these, and others, more special mention will be made in the progress of our history of the ovum and its development. But, as my present object is to place before the reader only the principal discoveries which may be regarded as the groundwork of the scientific knowledge of our subject, I will only farther call attention at this place, to the influence which the ob-

Malpighi, Wolff, Döllinger, Von Baer and Pander took a prominent part, but only that which belongs to the structure of the ovum itself.

* This discovery was first announced in a small work, entitled Symbolæ ad Ovi Historiam ante Incubationem, Auct. Joann. Evang. Purkinje; printed at Leipzig in 1825, on the occasion of the celebration of Blumenbach's Semisecular Jubilee. A second edition in 4to, with two lithog. plates, appeared in 1830. Purkinje is also the author of the Article *Ei* in the Berliner Encyclopædisches Wörterbuch, in 1834.

† See the Epistola de Ovi Mammalium et Hominis Genesi, Auct. Car. Ern. De Baer, published in 4to., at Leipzig, in 1827; and the interesting Commentary on or Supplement to the same in Heusinger's Journal; and the translation of both of these writings in Breschet's Répertoire d'Anatomie et de Physiologie. 4to. Paris, 1829. As I shall have occasion to return to the history of this discovery, I will not enter on farther details here; but it is right to state that Messrs. Prevost and Dumas may in some measure be considered to have shared in the merit of the discovery; as, in an extended and highly illustrative series of experiments, instituted by them as early as 1824, they were led to the conclusion that the ovules of mammiferous animals, of extremely minute size, were really contained in the Graafian follicles previous to conception; and they even appear to have twice seen in the contents of very advanced follicles, a small spherical body which could be no other than the ovule. See Annal. des Scien. Nat., tom. iii., 1824, p. 135. But Von Baer first demonstrated this body with precision, and explained its relations to the follicle, &c.

‡ Coste's discovery of the germinal vesicle in the rabbit, was communicated to the public in the Comptes rendus for 1833; it is fully described in his Recherches sur la Génération des Mammifères, &c.; 4to. Paris, 1834. In 1835, Thomas Wharton Jones read a paper to the Royal Society of London, containing an account of his observations on this vesicle in the mammiferous ovum, made without a knowledge of those of Coste in the autumn of 1834; but this paper was not printed in the Transactions of that year. It was afterwards published in the Lond. Med. Gazette, in 1838, p. 680. This discovery was confirmed and extended by Valentin and Bernardt, whose observations are recorded by the latter in his work, Symb. ad Ovi Mammal. Hist. ante Prægnationem, Vratislaviæ, 1834.

§ See G. Valentin's Handbuch der Entwickelungsgeschichte des Menschen, &c.; 8vo. Berlin, 1835, at p. 14. The part of this work relating to the structure and formation of the ovum, was translated and published by Dr. M. Barry, in the Edin. Med. and Surg. Journal, No. 127.

* The observations of R. Wagner on this subject, were made towards the end of 1834. This discovery was first published in the 1st Edit. of his Lehrbuch der Vergleich. Anat. 8vo., Leipzig, 1834 — 35, pp. 320 and 352, and in Müller's Archiv. for the latter year, p. 373.

† His more extended researches are described in the work entitled, Prodromus Historiæ Generationis Hominis atque Animalium; folio, Leipzig, 1836. With two copper-plates and very numerous figures. These and the researches of Valentin, are, with reference to the ovum, peculiarly interesting and important as the immediate precursors of the Microscopic Researches of Schwann. See also, the Beiträge zur Geschichte der Zeugung und Entwickelung, by R. Wagner; published in the Trans. of the Roy. Bavar. Acad. of Sciences, 4to., Munich, 1837.

R. Wagner is also the author of the Article *Ei* in Ersch and Grüber's Encyclopædie.

servations and doctrines of Schwann, as to the cellular origin and constitution of the textures of plants and animals, published in 1838, have exerted on the progress of ovology and embryology. In accordance with his general views, Schwann regarded the ovarian ovum as constituting an organised cell, of which the vitelline membrane is the outer cell-wall, the yolk substance the contents, the germinal vesicle the nucleus, and the macula or maculæ the nucleolus or nucleoli.* While the observations of Schwann do not present us with any very important new facts as to the structure of the ovum in particular, and although it may be necessary even to modify, in some degree, the view we should now, with our increased knowledge, be disposed to take of its relation to other organised cells of the economy, still it cannot be doubted that the great generalisation matured by this author has exerted, and still continues to exert, upon the progress of discovery and the scientific aspect of our subject, a no less remarkable influence than that which has been apparent since its first promulgation, on almost the whole range of physiological anatomy; furnishing the key to the structure of the ovum itself, laying the foundation of the histological laws of development, bringing a vast amount of observed facts under a consistent doctrine, and stimulating and guiding the embryologist in new paths of research.†

The most important general facts that have been ascertained in regard to the ova of animals may now be stated shortly as follows: —

1. The ova of animals begin to be formed in the ovary of the female parent at an early period of life, and are produced more commonly in vesicular, more rarely in tubular, cavities or ovisacs of these organs.

2. In those instances, in which it has been possible to detect the earliest stages of formation, the ovum appears very generally to take its origin in the form of a minute spherule or vesicle. This soon enlarges, and is converted into a nucleated cell, which forms the germinal vesicle, and this remains as a constituent part of the ovulum, till the latter is about to leave the ovary, or till the first formative changes commence.

3. The vitellus, or yolk substance, begins to be formed a little later. It is gradually accumulated, either in the vicinity of or round the germinal vesicle, in some rarer instances being produced in a separate organ; it consists of an albuminous fluid in which are suspended a large quantity of granules and oil spherules, or of larger corpuscles, having the form of non-nucleated simple cells. The structure of the yolk substance is subject to considerable variety.

4. The yolk substance and germinal vesicle are together enclosed, in the mature state of the ovarian ovum, by an almost structureless vesicular vitelline membrane, which in most animals is formed later than the other parts, in some at an early period, in others comparatively late, and which is not, therefore, to be invariably regarded as a true cell-wall, or as an original part of the ovum.

5. The germinal vesicle presents several of the characteristics of a true organised cell: the macula, or germinal spot, has in many animals the form and relation of a nucleus; but in some, the subdivided structure of this macula, which succeeds in the progress of formation of the ovum, causes it to lose its simple nuclear character.

6. When the ovulum, or ovarian ovum, attains maturity, it generally leaves the place of its formation in the ovary, and about the same time — in some animals before, in others after it — the germinal vesicle disappears, bursts, or dissolves. In the greater number of ani-

* Schwann, after hesitating somewhat whether to regard the entire ovum or the germinal vesicle as a true cell, gave the preference to the above view, chiefly from a consideration of the manner in which the ovum was believed to be formed, and its correspondence, as he conceived, with the invariable and necessary mode of formation of cells in general. These latter views have themselves undergone some modification since the publication of Schwann's Researches, and we shall probably find (as will afterwards be more fully stated) that a study of the structure and mode of production of the ova in a variety of animals, may render it necessary to modify also the comparison of the parts of the ovum to the organic cell, adopting rather the view of R. Wagner and Henle, according to which the germinal vesicle is regarded as the true cell, and the other parts of the ovum as of the nature of superadded structures.

† Mikroskop. Untersuch. über die Ubereinstimmung in der Struktur und dem Wachsthum der Thiere und Pflanzen, von Dr. Thomas Schwann. Berlin, 1839. The interesting Researches of M. J. Schleiden, on the cellular structure of Plants, entitled Beiträge zur Phytogenesis, published in Müller's Archiv. for 1838, immediately preceded those of Schwann; and they may be considered as forming in some measure, along with his, the basis of modern histology: the researches of the latter author were independently made, and an extract of them published in the beginning of 1838, in Froriep's Notizen; and the two first parts of his fuller treatise were sent to the French Academy, in August and December of 1838. An interesting analysis of both these works in the British and Foreign Medical Review, vol. ix. for 1840, made their contents generally known in this country; and an excellent translation of them both by Mr. H. Smith has since been published (1847) under the auspices of the Sydenham Society. It may be observed, however, that the great and important generalisations which Schleiden and Schwann have, with so much merit, established, may in some measure be regarded as the fulfilment or amplification of, and true deduction from, a variety of detached observations, which had been accumulating, in regard to both kingdoms of nature, for some years, more especially after the improvement of the achromatic microscope had given increased facility and precision to the minute examination of the tissues; such as the discovery of the nucleus of the vegetable cell by Robert Brown, in 1831; the discovery of the cellular structure of the chorda dorsalis by J. Müller; the observations of Henle on epithelium, of Valentin on several similar subjects, and of Turpin and Mirbel on plants, together with the observations previously referred to on the ovum of animals itself. But these detached observations had not led to any important general views before the publication of the Researches of Schleiden and Schwann.

mals, it is uncertain what becomes of its substance.

7. In the greater number of animals the ovum acquires some additional parts, such as albumen, external coverings (shell, chorion &c.), in its descent through the passages of the female parent after leaving the ovary; in some animals an external covering corresponding with the chorion is already formed in the ovary.

8. When the spermatic substance of the male parent has come in contact with the ovum, so as to exert its peculiar fecundating influence upon its germinal part — an action which in a few animals occurs before, but in the greater number shortly after it has left the ovary — the first of the series of changes which follows, and is preparatory to laying the foundation of the new being, consists, in almost all animals, in a peculiar process of division, cleavage, or segmentation, which affects either the whole yolk, or a part of it, or that portion only in the vicinity of which the germinal vesicle has before been situated, and in which the rudiments of the embryo afterwards make their appearance. This subdivision proceeds continuously, till the whole germinal part of the yolk is reduced by it to a nearly uniform mass of corpuscles, or structural elements of microscopic size, which generally occupy or are spread over more or less of the surface of the yolk mass within the vitelline membrane.

9. The rudiments of the embryo, and its accompanying organised structures in the ovum, when such exist, are first formed in the centre of a layer of nucleated organised cells, named by Pander *Blastoderm* or germinal membrane, the formation of which results more or less directly from the process of segmentation above referred to. The disappearance of the germinal vesicle when the ovarian ovum arrives at maturity, the influence of fecundation acting about the same time, the process of yolk-segmentation which immediately follows the latter change, and only occurs as a consequence of fecundation, and the formation of the germinal membrane or blastodermic layer of cells, in which the segmentation results, are successive phenomena of change in a fruitful ovum, which undoubtedly stand in some very immediate and close relation to each other; but the exact nature of that relation is still involved in some degree of obscurity. In some animals the process of yolk-segmentation seems either in itself to be a process of rapid cell-formation, or to be accompanied by it; while in other animals (chiefly those highest in the scale), the segmentation is only the immediate prelude to the generation of the true nucleated cells, which afterwards constitute the blastoderm.

10. The centre of fœtal development is coincident with the place of the germinal vesicle in the mature egg, and with the centre of the blastodermic layer of cells; and it would appear, also, that the principal axis of the embryo is coincident with the line of first division of the germinal part of the yolk in the commencement of segmentation: but it is yet undecided what part the germinal vesicle or its nucleus or macula more immediately take in the segmenting process, or in the origination of the true embryo-cells; and in the higher animals, at least, it is still uncertain whether or not these embryo-cells are the direct progeny or descendants of the germinal vesicle, or its nucleus. The germ spot, the centre of the first segmentation, and the centre of embryonic formation, constitute, therefore, a constant point in all animals, which may be termed the germinal centre of the ovum.

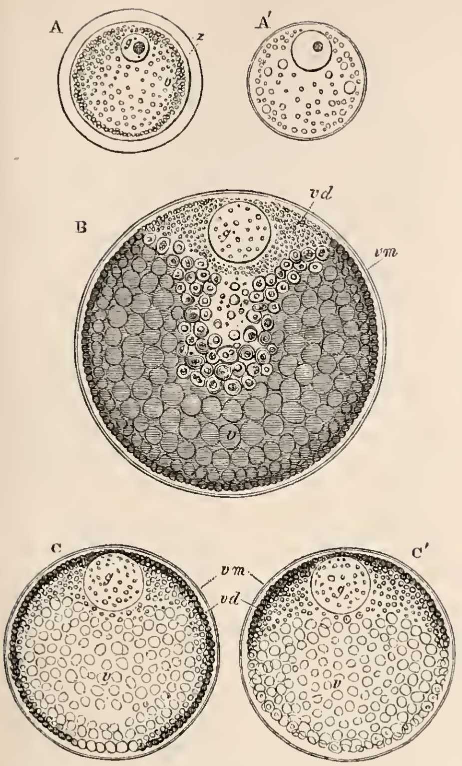
Division of the Ova of Animals into Groups. — Although the researches of modern ovologists thus enable us to assert with confidence the general similarity of structure in the ova of animals, and to point out general features of correspondence in the phenomena which they exhibit in their first origin, progress to perfection, and conversion into the rudiments of the new being; yet it must be admitted that very important differences are also to be observed among various ova, more especially when they have reached a state of maturity. In what has previously been affirmed, therefore, of the similarity of animal ova, it is to be understood that uniformity of a general kind only is implied; and even that correspondence is demonstrated not so immediately, in many instances, by the examination of the fully formed ova, as by their careful comparison, at different stages of their growth, and more especially in their earlier conditions.

The more important of these differences are those which are related to the nature of the germinal portion of the ovum, as compared with the rest of its parts; and a consideration of these differences, in so far as they have yet been observed, appears to lead to a division of the ova of animals into three principal groups, as follows: —

First group. — In a certain number of animals, some of which are viviparous, others oviparous, the ovum is for the most part of proportionally small size, sometimes very minute, as compared with the full-grown parents, and of very simple structure; the yolk substance is entirely composed of elementary granules, or minute and simple spherules; the process of segmentation affects the whole mass of the yolk, and the germinal or blastodermic layer, resulting from that segmentation extends from the first over the whole surface of the ovum; the whole of this layer contributes at once to the formation of the rudiments of the embryo and its accompanying organised structures; the whole yolk, or ovulum, in fact, is germinal, or is converted into the parts of the future embryo. Such is the nature of the ovum in mammalia, and among the Invertebrata, in most Mollusca, Entozoa, Echinodermata, Acalephæ, Polypes, and a considerable number of other tribes.

Second group. — In another set of animals, the great majority of which are oviparous, the ova are proportionally of the largest size; the yolk substance consists very obviously of

Fig. 31.



Diagrammatic representation of the three principal kinds of ovarian ova, in sections (the relation of size not, however, being maintained).

A. Mammiferous ovarian ovum; *z.* zona pellucida or vitelline membrane of some authors; *v.* granular yolk substance; *g.* germinal vesicle, with its nucleus or germinal spot; A′. young ovum of a molluscous animal.

B. Young ovarian ovum of a bird; *v. m.* vitelline membrane; *v.* large yolk corpuscles of two kinds—viz. those of the yellow external part, and those of the cavity; *g.* germinal vesicle without spot or nucleus, but granular diffused maculæ; *v. d.* small granular yolk substance forming the vitelline disc.

C. Ovarian ovum of a batrachian reptile; *v. m.* vitelline membrane; *v. d.* vitelline disc, or formative yolk-substance deeply coloured, and surrounding the large granular yolk substance, in one nearly entirely, in the other, C′, only half round the ovum; *g.* germinal vesicle.

two kinds of organised particles, — viz., of smaller granules nearly similar to those which form the whole yolk in the last group, and of larger cells, usually non-nucleated, and fat vesicles, which constitute the greater part of the mass. The first or granular part of the yolk constitutes a thin disc, limited to one region of the surface, — viz., the upper side in the vicinity of the place occupied by the germinal vesicle, while the cellular substance of the yolk forms the larger spherical mass of the egg. Besides these two, there are also various intermediate forms, which seem to be stages of transition between the other kinds of structural elements. The germinal vesicle in the ripe ovarian ovulum, is situated in the centre of the granular disc, and after its disappearance, the process of segmentation is limited to that disc. The germinal or blastodermic membrane, or layer of cells, extends, therefore, at first, no farther than this granular disc, and consequently it is only a very small part of the ovum which directly contributes to lay the first foundations of the embryo, or its accessory parts; while the larger mass of cellular yolk comes only secondarily to take a part in the process of embryo nourishment. Hence, in such ova, the distinction may be broadly drawn between the germinal or formative, and the nutritive parts of the yolk. Such is the invariable relation of the parts of the ovum to development in the whole class of birds, with some differences in scaly reptiles, in cartilaginous fishes, and perhaps also in cephalopodous mollusca, and a few other invertebrata.

Third group. — In another group of animals the structure and relations of the parts of the ovum are different from, but in some degree also intermediate between, those of the two groups previously described. In this one the yolk, or ovulum, may be stated to be of middle size; its structural elements appear to be of two kinds, — viz., the smaller germinal or formative granules, and the larger, or nutritive corpuscles; but these last are in less quantity, are subject to considerable variety, and exhibit less of the cellular structure which characterises the ova of the previous group. The germinal layer occupies a larger portion of the surface of the yolk than in the large-yolked ova (second group), but in general less than in the small-yolked ova (first group), and its extent is subject to considerable variety; in some, covering not more than a half, in others, extending nearly over the whole surface of the yolk. The segmentation is co-extensive with the germinal part, and more or less of the yolk, therefore, contributes at the first to form the primitive parts of the embryo. Such is the condition of the ovum in the Scaleless Reptiles or Amphibia, and Osseous Fishes. The ova of the higher Crustacea, Arachnida, Insecta, and some other Invertebrata may perhaps be included in the same group.

It will be perceived that in the three groups now mentioned, a distinction has been drawn between a part of the yolk, which is immediately employed in the formation of the embryo, and another, which is only remotely connected with that process. In the bird's egg, it has been stated that the latter part of the yolk is in large quantity, and that in the minute mammiferous ovum the first part only exists, and that in batrachia the two kinds of yolk substance are more nearly equally balanced. This difference among the ova of animals has been long known to physiologists in a general way; but its true nature, as connected with a difference of structure of the two kinds of yolk substance, and their relation to the earliest development of the embryo, has of late attracted considerable attention, and appears to have been first clearly stated by Reichert in 1840, and afterwards in 1843 *; and in accordance with the views of that author, we may with propriety distinguish the formative (or germinal) from the nutritive parts of the yolk. In the fowl's egg, for example (in which it must be admitted these two parts were long confounded together), the cicatricula, together with its so called nucleus, and a part, perhaps, of the lighter-coloured substance which occupies the centre of the yolk and the canal extending from it to the cicatricula, constitutes the formative or germinal part ; and the larger mass of the more deeply-coloured portion of the yolk forms the nutritive vitelline substance. In the mammiferous ovum, on the other hand, the latter part is either entirely absent, or is in small quantity, and the whole of the yolk substance may be looked upon as directly formative, or as analogous to that which forms only the cicatricula of the fowl's egg. Among more recent writers the distinction of these parts has been particularly insisted upon, and illustrated by M. Coste †, and also by Messrs. Prevost and Lebert.‡

The difference in the relative amount of the formative and nutritive yolk substance, as well as in the size of the whole ovum, in birds and mammalia, is manifestly to be regarded as more immediately connected with the different manner in which the embryo is to be supplied with the materials necessary for its growth in the two cases ; in the oviparous mode of development, the whole amount of nourishment required being provided in the egg itself, and detached along with it from the parent ; in the truly viviparous mode, a continual addition of new materials for growth, being made by transmission from the maternal parent in the placenta, or in some analogous structure, which accompanies utero-gestation.

The smaller proportional size of the nutritive part in Batrachia and Osseous Fishes (though most of these animals are truly oviparous), may be attributed to the very early period of development, and consequent small size of the embryo at the time when in these aquatic animals it leaves the egg, and, taking upon itself an independent life, gathers nourishment in the same manner as the adult animal.§

The above arrangement is by no means offered as exhausting the divisions which might be formed of the ova of animals, but rather as bringing forward prominently the most remarkable characteristics of those of vertebrata. It is not improbable that a more accurate acquaintance with the structure of the ova in the animals thus grouped, and more especially of the Invertebrata, may lead to some considerable modifications of the divisions here adopted; but the main distinction upon which they are founded is so important, that even with our present incomplete acquaintance with them, it seems advisable to call attention to it at this place. As I shall have occasion to refer frequently to these groups in the subsequent description of the ova of various animals, in the absence of more appropriate appellations, I will, for the sake of brevity, designate them severally, as follows,—viz., 1st group, *Small-yolked ova*, as in Mammalia ; 2nd group, *Large-yolked ova*, as in Birds, Scaly Reptiles, and Cartilaginous Fishes; 3rd group, *Middle-sized yolked ova*, as in Batrachia, Osseous Fishes, &c.

§ 2. Further comparison of the ova of animals in general, as respects their size, number, form, and the relation of their parts.

Size of ova. — In addition to what has been said on this subject in the previous section, it may farther be remarked that, in the second and third groups, the size of the ova of different genera and species is to a certain extent proportional to that of the adult animal, or of the fully-developed fœtus; but in the first group, or at least in Mammalia, in which the nutritive part of the yolk may be considered as wholly or nearly entirely absent, there is a much greater uniformity in the size of the ova; and, accordingly, the largest mammiferous animal may take origin from an ovum which, when mature, is even smaller than those of species of animals many hundred times less in bulk ; while in the class of Birds we observe the nearly regular increase of the size of the ovum in proportion to that of the parent animal, from the smallest humming bird up to the ostrich, or the still larger egg of the Æpyornis, an extinct bird, of which some of the bones, along with the eggs, have recently been discovered in Madagascar.*

† Cours d'Embryogénie Comparée, tom. i. Paris, 1837; and Histoire gén. et partic. du Developpement de l'Homme et des Animaux, Paris, tom. i. 4to., 1848.

‡ In Annal. des Scien. Nat. for 1844. 3rd Ser. tom. i. p. 193 and 265.

§ At the same time it is to be kept in mind that there are exceptions to these relations, which make it extremely difficult to state any general law of connection between the structure of the ovum and the mode of gestation and place of development of the embryo; as in the case of a few of the lizards and serpents, and some cartilaginous fishes, in which although the egg agrees in general structure with that of animals which are generally oviparous, it is retained in the oviduct or uterus of the female during a part or even the whole of the time of fœtal development; and there are also exceptions in the third group—viz. that of batrachia and osseous fishes as in the Land Salamander and Viviparous Blenny. To this mode of gestation the name of Ovoviviparous has been given. There are many varieties of a similar kind among the Invertebrata, and on the whole it may be stated that there is no constant correspondence between the size of the ovum and the mode of gestation. The Marsupiata also, and the Monotremata among the Mammalia, exhibit interesting modifications, in the first a partial, and in the second, probably a complete residence of the ovum in the uterus of the female parent during development; while the ovum in these animals approaches, in some respects, the type which is more commonly oviparous.

* The circumference of this extraordinary egg

In illustration of the most striking of these differences of size in the ova of animals, the following examples may be referred to: — The human ovum is a body not more than $\frac{1}{200}$ of an inch in diameter; so minute, in fact, that we can scarcely form any estimate of its weight or quantity of matter. Let us assume, what seems probable, that it weighs about $\frac{1}{1000}$ of a grain. Now, if we take the weight of a full-grown fœtus as between six and seven pounds, or 45,000 grains, and the adult human body as about 120 or 130 lbs., or 900,000 grains, it appears that while the full-grown fœtus bears the proportion of one-twentieth of the weight of the adult, the ovum is scarcely a thousand-millionth part. In the fowl, the entire egg, when newly laid, weighs about 2 ounces, or 900 grains, and is nearly one twenty-second part of the weight of the adult body, supposing it to be somewhat under 3 lbs. The chick, produced by incubation, is about 600 grains in weight, or about two-thirds of the egg, and is, therefore, somewhat less than a thirtieth part of the weight of the adult. Again, let us take the weight of an osseous fish (as in a female cyclopterus lumpus recently measured by myself), at 9 lbs. 8 ounces, or 66,500 grains; one of the ova, which were fully developed and filled two enormous ovaries, weighed one-seventh of a grain; and the fœtus of such a fish, when it first leaves the egg, might probably weigh not more than one-tenth of a grain; so that the egg would be in the proportion of 1 to 500,000, as compared with the body of the fish.

It is to be observed, however, that this great disparity of size belongs principally to the nutritive part of the egg, and that there is a nearer approach to uniformity in the size of the germinal vesicle; but in this, too, we shall afterwards see that the size is greatest in the ova of the second group, in which the whole ovum attains the greatest magnitude. In the mammiferous ovum, the germinal vesicle is about $\frac{1}{600}$ or $\frac{1}{800}$ of an inch in diameter; but in the fowl's egg it is of a diameter about ten times greater, and in cartilaginous fishes it is even of a somewhat larger size; but still in no egg does this vesicle depart altogether from that small and almost microscopic magnitude which may be regarded as characteristic of the elementary organic structures.

The size of the ovary, when full of developed ova, is also deserving of notice, as giving some indication of the relative amount of reproductive power in the three groups before distinguished. Thus, in the human species, the two ovaries weigh about 500 grains; in the fowl, when developed at the breeding season, the ovary, with its yolks, may weigh 1,500 grains; and in the lump fish, above mentioned, the ovaries weighed together 3 lbs. and 3 ounces, or 22,300 grains. Thus the ovaries were to the body, in the first, as 1 to 1,800; in the second, as 1 to 13; and in the third, as 1 to 3.*

The following table may serve to exhibit these proportions in a general way: —

Weight in Grains of the —

	Ovum.	Ovaries.	Fœtus.	Adult.
Mammifer -	0·001	500	45,000·0	900,000.
Fowl - -	900·000	1500	600·0	20,000.
Osseous fish -	0·135	22,300	0·1	66,500.

Number of ova. — The number or quantity of the ova which the females of different animals are capable of producing in a given time, or during the whole of their lives, is so various, that only a very vague statement can be made in regard to it. The very great productiveness or fecundity of osseous fishes, and of many of the invertebrata, is well known. The ovary of the herring has been found to contain 25,000 ova. In the Cyclopterus lumpus, before referred to, the number of ova estimated as being contained in the ripe ovaries together was about 155,000; and in the ovaries of a Holibut or Hippoglossus, of 156 lbs. weight, I found about three and a half millions. The queen ant of the African termites is said to lay 80,000 eggs in 24 hours; and the common hair worm, or Gordius, as many as 8,000,000 in less than a day. The Entozoa appear to produce the greatest number of all animals — a fact which is somewhat surprising, when we consider how few of these animals comparatively reach their adult condition. In many of the above animals this enormous production is not a single act, but is repeated again and again in successive seasons.

In birds and those animals belonging to the second group, in which the eggs are proportionally of large size, comparatively few of the ova, of which the germs are visible in the ovaries, come to maturity; and in the natural state only a small number are productive. But it is well known that great variations may be caused in this respect by the condition of the animal; and that in a state of domesticity, and under high feeding, a much greater number of eggs may, in some birds, come to maturity, as in the common fowl, in some kinds of which, indeed, an egg is laid daily for two-thirds of the year — a production which would amount to upwards of 30 lbs. or ten times the weight of the whole animal; and, if

over its long diameter, is stated to have been nearly three feet, and over its short diameter two feet four inches; its greatest length nearly thirteen inches. M. Isidore Geoffroy estimates that it must have contained 10½ quarts of substance, or nearly six times as much as an ostrich's egg, 148 times as much as an ordinary hen's egg, and 50,000 times as much as that of a humming bird. Notwithstanding, however, that in the class of birds there is a general correspondence between the size of the egg and the stature of the adult, this correspondence is not regular or constant, and Prof. Owen has illustrated this fact in a striking manner by reference to the Apteryx of New Zealand, which produces a proportionally very large egg.

* The Article "Zeugung" by Leuckart, contained in two parts of R. Wagner's Handwörterbuch der Physiologie, and which I have only received since the above was written, may be consulted as containing fuller information on the same and the following subject.

the product of different successive years be taken together, a fowl may, at the most, bring forth about 1,200 eggs. I have attempted to count and estimate the whole number of ovula in the undeveloped state to be seen in the ovary of the common fowl, and I find it to amount to 30,000 or 40,000. A great many of these ovula must, therefore, be unproductive in the higher oviparous animals, their germs either remaining undeveloped or being absorbed in the ovaries.

In mammalia, and in the human species, although only a few ovula approach to maturity at a time, and a small number only of the ova, as compared with the whole of those contained in the ovaries, serve for production of the offspring, it is known that a considerable number is discharged from the Graafian vesicles of the ovaries in the unimpregnated state. Thus, in the human female (as will be more fully stated hereafter), one or more ovula are discharged from the ovarian vesicles at every successive four-weekly menstrual period during about 30 years of life, and thus not less than 400 ovula may be excluded from the ovaries; but this number is probably greatly below that of the whole ovula or their germs, which the human ovaries contain; and the ovaries of many quadrupeds present, undoubtedly, a greater number.

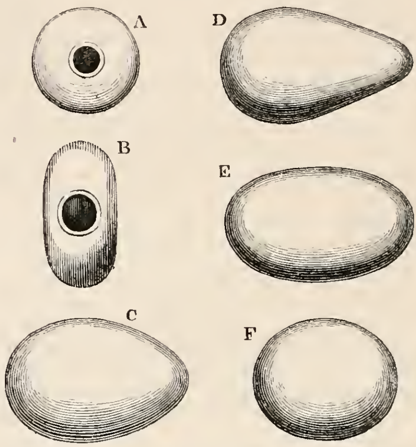
External form and relation of the parts.— The ovum, being composed of cellular, granular, and fluid substance, and being enclosed by an entire vesicular membrane, has generally, at least in its early condition, a spherical form. In the mature state, this form is in many instances retained; but there is also not unfrequently a departure from it, in consequence of the addition of the external parts unequally deposited on the surface of the more globular yolk within them. This spherical form of the ovarian ovum points to its isolated mode of production, and its destination for a separate existence, and is characteristic of the elementary nature of its organic structure.

In the class of birds, the egg is always covered in by an external hard calcareous shell; and in the greater number the external form given by this is somewhat elongated, and not unfrequently, as in the common fowl, with a difference of the size and curvatures at the opposite ends, caused by the manner of the descent through the female passages. There are, however, considerable differences among the different families of birds, as in the nearly globular form of the predaceous, the more elongated form with nearly equal ends in some of the ducks, the well-known shape of the gallinæ and others allied to them, and the greater disparity at the opposite ends, as in the seafowl.*

In those of the scaly reptiles which are oviparous, there is also a firm external covering; but only in some of them, as in most chelonia and in the crocodiles, is there a hard calcareous shell. In the greater number of the sauria and ophidia, the external covering is of a tough membranous or parchment-like consistence, formed of several layers of condensed fibro-albuminous substance, in which either no calcareous matter, or only a small quantity of it, is contained. In those serpents and lizards, again, which are ovoviviparous, the egg, when it descends into the oviduct, is not covered there with the firm external envelope, but with a thinner and softer membrane, similar somewhat to the membrane lining the shell in birds.

* See on this subject the works of Hewetson and others.

Fig. 32



External forms of different eggs of Birds and Reptiles.

A. Batrachian reptile, frog or toad; spherical shape, the dark yolk within, the gelatinous albumen externally; swollen by imbibition of water.

B. Triton or Salamander; elongated external membrane, coloured spherical yolk within.

C. Oval of unequal curves at the two ends, as in gallinaceous, passerine, and many other birds.

D. Very unequal size of the two ends, as common among sea-fowl.

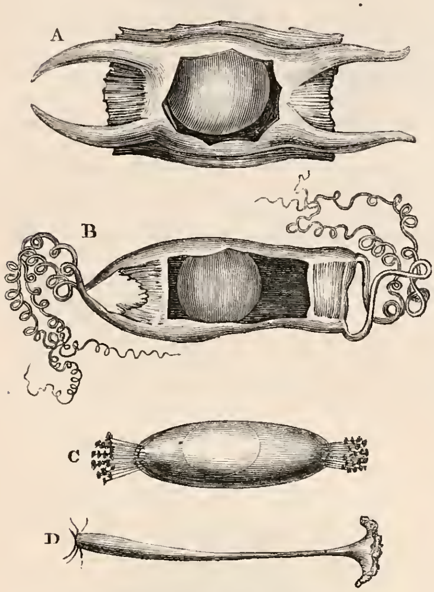
E. Equal oval, as among some ducks, the crocodile, lizard, &c.

F. Short oval or nearly spherical, as in predaceous birds, chelonia, &c.

In the oviparous cartilaginous fishes, a peculiar horny capsule is formed round the yolk and albumen, as they pass through the oviduct at a place where a particular gland is provided for its formation. These capsules are of a fibrous structure, of an oblong, somewhat quadrilateral shape, as in the skate and shark, and, at each angle, are prolonged into tubular processes or filaments, of great length in some sharks, which when short and open, may allow of the passage of water to the embryo contained for a long time within the ovum; and serve also the purpose, when long and convoluted, of entangling and attaching the egg capsule among seaweed and floating bodies.

I have found that in the Myxine glutinosa the globular yolk is enclosed in a horny capsule of similar consistence and structure, but of a simple elongated ellypsoidal shape, and in place of four terminal angular tubes, a number of trumpet-shaped tubular processes projecting from the middle of the two ends, which probably serve the same purposes as the differently shaped appendages of the ova of the shark and skate.

Fig. 33.



External form of ova of Oviparous Cartilaginous Fishes.

B. Ovum of the shark, squalus catulus, also opened: half the natural size.

C. Ovum of the Myxine glutinosa, entire: natural size.

D. Enlarged view of one of the 25—30 tubular funnel-shaped processes from the same ovum; the attached end is at D.

In birds, it is well known that the yolk and germ, with their enclosing vitelline membrane, are produced in the ovary, while the albumen, chalazæ, membrane, and shell are more rapidly formed and are added during the passage of the egg through the oviduct. It is by an entirely similar process that these accessory parts are formed in the scaly reptiles, the eggs of which agree with those of birds in the most essential points. The albumen, however, is generally in less quantity and softer, and the twisted chalazæ have not been observed. The membrane which immediately covers the albumen has the same structure as that of the bird's egg; and the calcareous shell, when it exists, as in turtles and crocodiles, is more porous and thinner.

In cartilaginous fishes there is also a glairy albumen investing the yolk, and secreted from the oviduct. In most animals of the second group, or with the large-yolked ova, the vitelline substance consists almost entirely of oily and albuminous matter enclosed in organised cells, the nature of which differs, as previously explained, in the vicinity of the germ and in the other parts of the yolk; this substance contains, besides, the peculiar colouring matter which has given the name to this part of the egg. In all of them a cicatricula exists, which is the seat of the germinal vesicle, and of the first formation of the rudiments of the embryo.

The ovum of the frog, when newly expelled from the oviduct of the parent, consists of the yolk-ball, closely surrounded by a tough layer of peculiar albuminous matter deposited on it in the course of its passage through the oviduct. This substance has the property of imbibing a large, but yet a limited, quantity of water whenever it is immersed in it; and thus, within a short time after the expulsion of the egg from the female, the external substance has assumed a gelatinous consistence, and has enlarged to such an extent as to be on every side equal in thickness to the diameter of the dark-coloured yolk within. I shall have occasion afterwards to state more particularly the important relation which subsists between this process of imbibition and the action of the spermatic substance in fecundation. In the common frog, the ova are thus united in large masses, floating in the water of stagnant pools or rivulets: in the common toad, they are united in long cords, which become entangled among aquatic plants.

In the newts, the external covering of the ovum is membranous, homogeneous and transparent, and of an elongated oval shape, and there is merely fluid intervening between it and the spherical yolk and its membrane; but when the ova are deposited by the parent in the folded leaves of water-plants or other situations, a small quantity of a peculiar glutinous matter, not readily acted on by water, is excreted along with the ova, which serves to fix the ova in a suitable place during the development of the young.* Various examples of a similar kind occur among the oviparous animals of the invertebrata, more especially among insects and mollusca, when the ova are destined to remain exposed, and require protection during a considerable time before development takes place.

In batrachia the yolk is variously coloured in different species: thus, in the common frog, toad, and some others, the surface or germinal part of the yolk is of a black or dark-brown colour, owing to a deposit of pigment granules in the cells of the germinal layer, while the remainder of the yolk internally is grey. In some other batrachia the colour is light brown. In the larger water-newt, or triton, the yolk is of a brilliant light yellow; while in the smaller one, or lissotriton, it is

* See the interesting description of this process by Rusconi, in Amours des Salamandres Aquatiques; Milan, 4to. 1821. I have often confirmed his observations on this process in ponds, and with animals kept in vessels in the house.

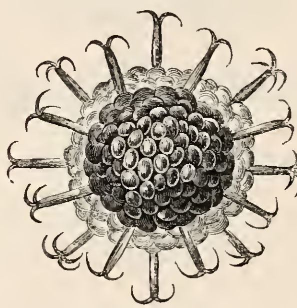
ash-coloured. In the land-newt, which is ovo-viviparous, the yolk is of considerable size, and of a dark yellow, approaching to orange.

In osseous fishes, which are almost all oviparous, the ovule receives, apparently in the ovarian capsule itself, before leaving that cavity, an external covering (or chorion) of considerable firmness. This membrane appears to consist of a substance deposited on the external surface of the vitelline membrane, and becomes coagulated under the action of water; so that its density increases greatly after the ova are deposited, while it is separated at the same time from the yolk by the imbibition of water. The ova are in spawning either deposited separately, or are united in chains or bundles, and in some less common examples* in peculiar nidamental structures, more after the manner of some of the mollusca. The structure of the ovarian ovule, or yolk, and its relation to the germ, differs somewhat from that of the batrachia; for while in the latter animals the yolk substance consists of granules and cells of nearly uniform size, and the germinal layer covers the greater part of the surface, in osseous fishes this layer is more circumscribed, not extending at first over more than a third, or, at most, a half of the yolk, and the remainder of the yolk, which contains a much greater quantity of transparent fluid than in most other vertebrate animals, presents almost invariably a peculiar heap or mass of large oil globules, which float to the upper part of the fluid below the germinal layer.†

The minute ovula of mammalia, when they have reached maturity in the Graafian capsules of the ovary, are nearly spherical bodies, of from $\frac{1}{120}$ to $\frac{1}{300}$ of an inch in diameter, and consist of a mass of finely granular yolk substance, more loose in the interior and more dense towards the surface, and enclosed in a thick firm and transparent vesicular envelope, the vitelline membrane, or so-called zona pellucida. While still within the Graafian capsules, they occupy a situation near the most projecting part of the capsule, or towards the external surface of the ovary, being there imbedded in a layer of granular cells, the *discus proligerus* of Von Baer, which lines the ovicapsule, and lies on the exterior of the clear coagulable fluid with which this capsule is filled. A portion of this lining membrane of granular cells, remains adherent to the ovum after it leaves theGraafian capsule, and has passed into the Fallopian tube; but as it descends towards the uterus, these cells gradually loosen and fall away from the surface of the ovum, the zona pellucida or vitelline membrane of which is thus finally left free. In the farther progress of its descent, there is formed, in some mammalia at least (rabbit), on the surface of the zona by a new deposit, in others, perhaps, by conversion of the zona itself, the external membrane of the ovum, which at a later stage constitutes the chorion. But, in accordance with the destination of the ovum in this tribe of animals for true utero-gestation, this external membrane has then no longer the character of mere inactive limitation of the exterior of the ovum, or defence from injury, which belongs to it in the lower animals; but it becomes an organised and growing texture of active functions, which is the more immediate means of uniting organically the blood-vessels of the mother and fœtus, in such a manner as to allow of the transmission of nourishment from the one to the other.

Varieties of form of the ova among the invertebrata are too numerous to allow of their being described in this place. In the greater number, an external envelope, besides the vitelline membrane, exists; but it must be admitted, that there are some in which these two coverings cannot be distinguished. In some, as in insects, arachnida, polypes, &c., the chorion, or outer surface, presents peculiar markings, ridges, tubercles, or long spines, and is strong and opaque; in others, it is

Fig. 34.



Ovum of Cristatella mucedo.

smooth, delicate, and transparent, so as to allow the whole internal structure of the ovum to be seen through it, and thus to afford most favourable opportunities of witnessing the early changes of development. In most of the invertebrata the germinal part of the yolk covers the whole, or a considerable part, of its surface; they present, however, great varieties of colour and structure, and may, probably, belong to various modifications of the second and third groups before distinguished.

It does not appear that any essential difference has yet been observed in the structure of the ova of those animals which are subject to alternate generation, and those of animals in which the adult form is directly developed from the ovum.

§ 3. Of the ovary in general as the formative organ for the ova of animals.

* As Gobius. See Prof. Owen's Lectures on the Compar. Anat. and Physiol. of Vertebrated Animals, part i. p. 304. A. Hancock on the Nidification of the Gasterosteus aculeatus, &c., in Annals of Natural History, Oct. 1852.

† See a paper by Dr. Davy on the chemical properties of the vitellus of Osseous fishes in Trans. Roy. Soc. for 1851.

The name of ovary is in all animals applied to the organ, however varied in its structure and relations, in which the ova are formed. As already indicated, however, it is to be observed, that in the higher animals, it is only the ovule, or yolk, with its germinal vesicle and enclosing membrane that is formed in the ovary, while the external or cortical parts of the ovum are added to these in their descent through the female passages after leaving the ovary. There are some examples in which it would appear that the whole

Fig. 35.

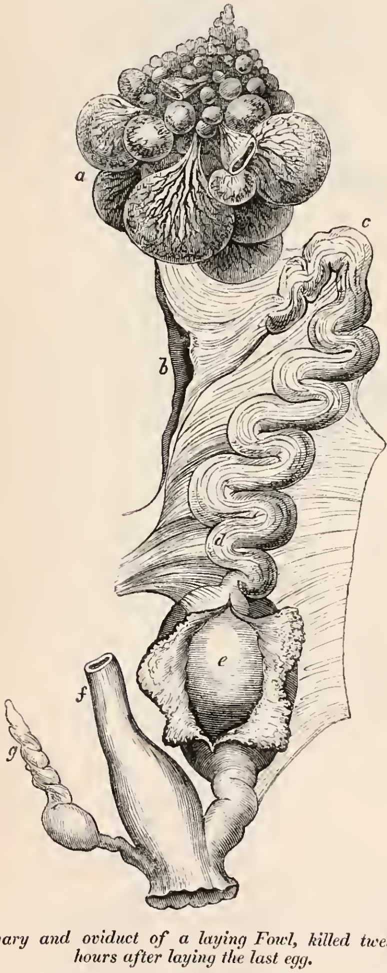
formative process of the ovum, including the addition of the external coverings, is completed within the ovary; and, on the other hand, there are a few instances in which, as in the trematoda and cestoid entozoa, the germinal vesicle and yolk substance of the ovule are formed in separate organs, instead of in the usual manner entirely in the ovary.

The varieties of the ovaries in different animals may be considered under two heads —viz., 1st. Their relation to the passages or outlets as influencing the mode of discharge of the ova from them; and 2nd, their internal structure as related to the form of the ovum produced.

Fig. 36



Ovary and oviduct of a laying Fowl, killed twelve hours after laying the last egg.

a. Left ovary; *b*, opening of the infundibulum of the oviduct; *c, d*, glandular portion of the oviduct; at *d*, the isthmus; *e*, an egg in the uterine portion of the oviduct, in which the shell is begun to be deposited; *f*, the rectum, ending in the cloaca; *g*, the undeveloped right oviduct occasionally met with.

a. Relations of the form of the ovaries to the discharge of ova.—In the majority of vertebrated animals the ovary or ovaries are quite detached from the conducting tube or oviduct; the ovules are formed in close capsules of the ovary, by the bursting or fissure of the wall of which they escape; the oviduct opens at its upper end into the abdominal cavity, and there receives the ovum which has been discharged from the ovary. This is the general arrangement in mammalia, birds, reptiles, amphibia, and cartilaginous fishes. There is some difference in the form of the ovary in the higher and lower of these animals. In mammalia and birds, in chelonia and the crocodiles among the reptiles, and in cartilaginous fishes the ovary is more or less solid, and the ovules are developed in capsules which project towards the external surface; but in the lizards

Fig 37.

(*From Carus and Otto.*)

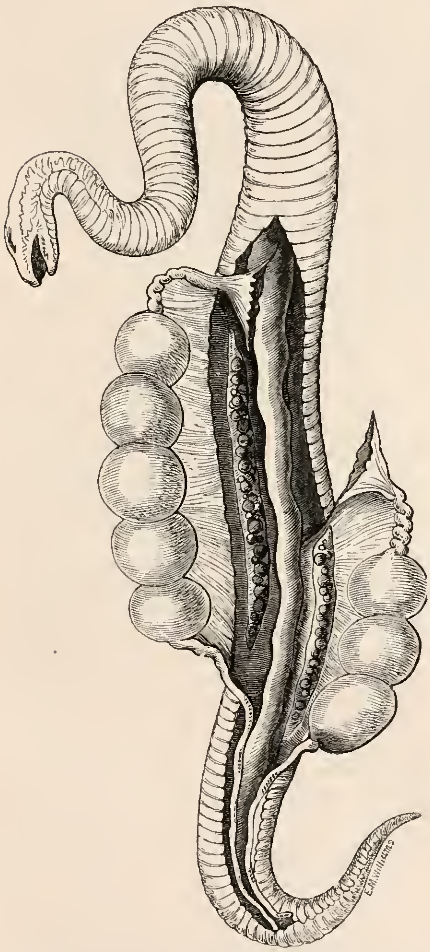
and serpents, and in the batrachia, this organ is hollow, and the capsules in which the ovules are formed burst in dehiscence into an internal cavity, whence the ovules escape into the abdomen by the rupture or opening of the sack of the oviduct, generally at one, but sometimes, as in the frog, at a greater number of places. In the higher animals, in which the ovules escape from the external surface of the ovary, their entrance into the oviduct is in general secured by the temporary apposition of the dilated upper end or infundibulum of the oviduct to the ovary, or the capsule containing a ripe ovule; in the other animals, in which the ova come from the interior of the hollow ovary, the apposition of the oviduct does not appear to be so direct, and there are various other means by which the ova, when they have escaped into the abdominal cavity, reach the open extremity of the oviduct.

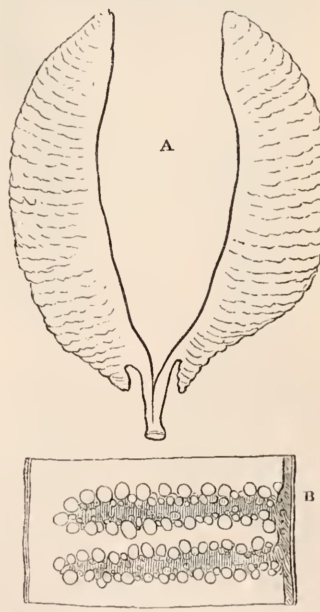
Fig. 38.



Common adder, in which the ova have descended to occupy both oviducts, five in the right, and three in the left: the infundibulum is shown in each oviduct; *a′ a*, the right and left ovaries, each forming a sac, opening anteriorly near the infundibulum for the discharge of the ova, which, when ripe, fall into the interior of the sac, and thence pass into the oviduct.

It is in the class of fishes that the transition occurs from the higher to the lower type of organisation of the ovaries and oviducts. In all of them the ovules are formed in ovarian follicles, and escape by dehiscence from these follicles; but there are several modifications of the relation between the oviduct and ovary among them. 1st. In the sharks and rays, as already stated, the arrangement is nearly similar to that existing in higher animals. The ova, which are of large size, come to maturity singly, or in small numbers at once: on being discharged externally from the ovarian capsules, they pass into the oviduct, and there receive a considerable addition from this organ. The majority of them, as previously stated, are oviparous, and in them a hard covering is formed by a peculiar glandular organ connected with the oviduct; in a few which are ovoviviparous, as the common dogfish, torpedo, &c., the external covering of the ovum is membranous and soft. 2nd. In the sturgeon and in the lamprey the oviduct is very short; still, as it opens superiorly into the abdominal cavity, the relation may be considered the same as in the previous examples. 3rd. In the genus salmo and in

Fig. 39.



Ovaries and oviduct of an osseous Fish.

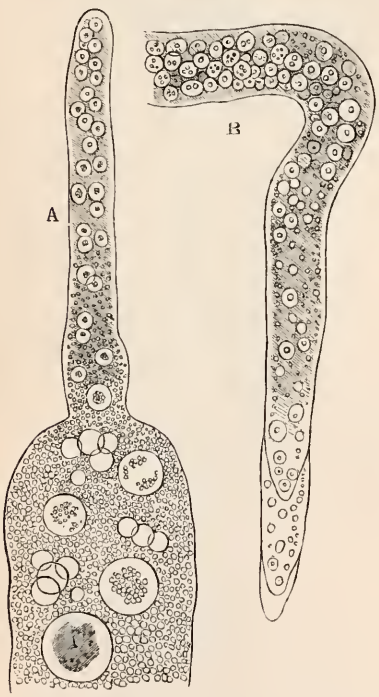
B. Diagrammatic section of a portion of the ovarian sac, showing two of the ovarian plates, from which the developed ova hang in small pediculated vesicles or ovisacs.

the eel among the osseous fishes, the oviduct is entirely wanting, and the numerous ova, which are discharged by external dehiscence from the ovary into the cavity of the abdomen, escape from that cavity by an orifice (porus abdominalis) situated on each side close to the anus. 4th. In other osseous fishes, the ovary and oviduct are united, or the ovary forms a saccular organ, in the interior of the wall of which the ovicapsules are situated, occupying a variable extent of it in different genera ; and the wall of the oviduct, usually very short, is continued from that of the ovary to the outlet from the animal's body. The ova, therefore, which drop by internal dehiscence into the cavity of the ovary, pass directly out by the short oviduct in the laying of the spawn. Most osseous fishes are oviparous; but in a few, as the viviparous blenny, the anableps, paecilia, and some siluroids, the ova, on escaping from their capsules into the cavity of the ovary, remain there during the development of the embryo.

In the invertebrate animals there are very many varieties in the form and relations of the productive and conducting parts of the female generative organs. Three principal varieties may be distinguished among them 1st. A form similar to that just now described as generally prevalent among osseous fishes, in which the ovary and oviduct are continuous, but in which the ova, being formed in ovarian capsules, are dropped by dehiscence into the upper part of the oviducts. Such is still the structure in cephalopoda and some other mollusca. 2nd. A form in which the oviduct may be said to be, as in the last, continuous with the ovary, but in which there is no true dehiscence of the ovules from ovarian capsules, as they are formed at once in the internal cavities of the ovary, which directly open into, or are mere prolongations of, the oviducal tubes. In this form the oviducts may be considered to stand in the relation of excretory ducts to the ovarian glands. In many of this class the ovaries present very various forms ; in some the continuity of the ovarian and oviducal tubes is very obvious and simple, as in the nematoid entozoa, insects, &c. ; while in others, the ovary is more complex and racemose, and the oviducal tubes comparatively simple. 3rd. That form in which the ovaries are variously disseminated over the body of the animals, and in which there are no true oviducts, but the ova escape on various parts of the internal or external surface of the body.*

Fig. 40.



Oviduct and ovary in a continuous tube in Insects and Entozoa.

A. (*From R. Wagner*). Upper part of the oviduct or ovary of the Acheta campestris.

B. (*From H. Nelson.*) Upper part of the oviduct or ovary of the Ascaris mystax. In both of these figures the germ-cells and germinal vesicles, with their nuclei, are seen surrounded by the granular matter which afterwards collects round them as vitelline or yolk substance.

b. Structure of the ovaries themselves, as related to the production of the ovula.—In mammalia these organs consist of a pair of solid oval flattened bodies, attached by intervening fibrous tissue to the posterior surface of the broad ligaments of the uterus, and are covered completely, excepting at this attached part, by peritoneum. Below this serous covering there is also a layer of firm fibrous tissue, or *tunica albuginea.* The internal substance, or parenchyma, or stroma, as it has been called, consists of a firm basis of fibrocellular texture, of considerable vascularity. The fibres, as well as the blood-vessels of this substance, radiate principally from the attached border of the organ towards the opposite, or free side, and the rest of the surface. The ovicapsules, or so-called vesicles or follicles of De Graaf, in the human ovary, are situated in this stroma; and at or after the period of puberty are found of some size ; a variable number, from twelve to thirty, or more, being of from $\frac{1}{20}$ to $\frac{1}{6}$ of an inch, and a few even a little larger. These membranous vesicles, filled with fluid, are situated chiefly towards the surface of the free side of the ovary. A larger number of undeveloped capsules, of minute size, also exist in the

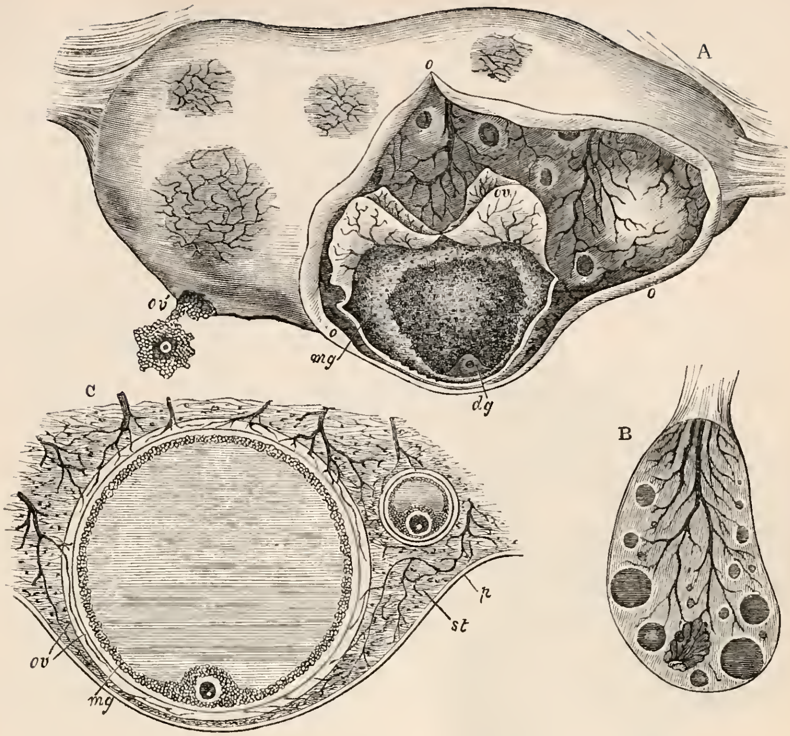
Fig. 41.



Relation of the ova and ovaries in Mammalia.

A. (*From Coste, as reduced by Longet.*) Human ovary, enlarged four diameters, partially dissected at *o o o*, to show the Graafian follicles in the ovarian stroma: one of these, more advanced, has had its double tunic, *o v*, cut into and reflected; the granular membrane, *m g*, has also been partially opened, showing the thickened portion or granular disc, *dg*, in which the ovum is imbedded near the most projecting part. At *o v'*, another Graafian follicle has been burst, and the ovum in its granular disc is seen expelled from it.

B. Transverse section of human ovary, to show the general arrangement of the developed Graafian follicles towards the surface; twice the natural size.

C. Diagrammatic representation, in section, of two Graafian follicles, in different stages of advancement in the ovary of a mammifer, enlarged about ten diameters. *p*. Peritoneal covering of the ovary, *s t*, ovarian stroma; *o v*, the two layers of the ovisac; *m g*, membrana granulosa, near which is the discus granulosus, with the ovum imbedded.

stroma; and it has been observed, that these are present from a very early period in the ovaries, as first noticed by Carus, and since by myself and others in the child at birth.

The more developed of these ovi-capsules are enclosed by a strong theca or membrane, consisting of two layers; the external thinner and firmer, of a fibrous and vascular structure, the internal thicker and softer, of a fibro-cellular structure and also of considerable vascularity. The capsules are filled with a fluid nearly transparent, which coagulates under the action of heat; and inside the theca, or lining it and covering the fluid, there is a layer of nucleated cells united together in the form of a soft, easily-lacerated membrane, somewhat like an epithelial lining of the capsule. It is in this cellular layer (*tunica granulosa* of Von Baer) that the ovum is placed, being situated in the thicker portion of it (*cumulus proligerus*), directed towards the surface of the ovary.

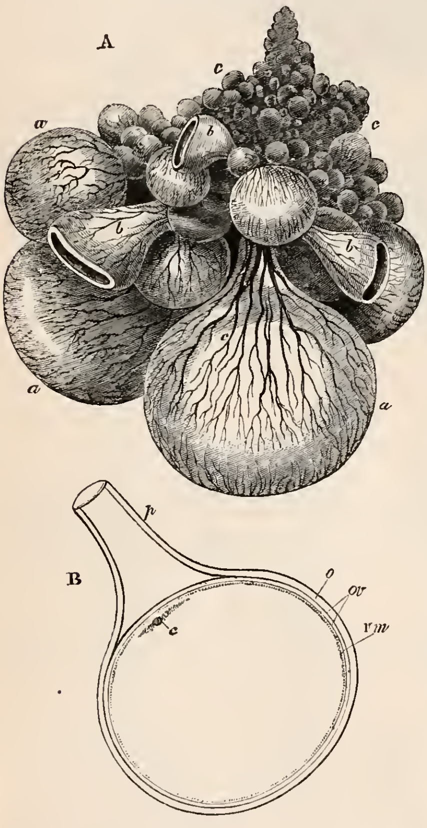
When one of the ovicapsules and its contained ovule has reached maturity, which takes place in one or more of them at regularly recurrent periods, besides the swelling of the ovicapsule itself from the increase of its fluid and other causes, the stroma of the ovary between the capsule and the surface undergoes considerable thinning, and the ovicapsule comes thus to project more immediately from the surface of the ovary. An increased vascularity is also apparent in the same situation; and finally a small circumscribed fissure near the middle of the most projecting part occurs, allowing the escape of the ovule and the granular layer and fluid from the ovicapsule.

The ovule, surrounded by a portion of the cellular layer in which it was embedded, is received by the open fimbriated extremity of the Fallopian tube.

The empty ovicapsule now undergoes a remarkable change by the deposit in its interior of the substance termed corpus luteum, the quantity and nature of which vary greatly according as the escape of the ovule is followed or not by pregnancy. Of this change more will be said hereafter. The result in both cases is the ultimate closure and obliteration of the ovicapsules.

In birds, scaly reptiles, and cartilaginous fishes, the greater size of the ovules when in a state of maturity is connected with a modification of the structure of the ovary and the ovicapsules.

Fig. 42.



Relation of the ova to the ovary in Birds.

A. Ovary of a fowl, showing at *a a a* the most developed ova hanging from the ovary in their pediculated capsules; the non-vascular bands are seen on their most projecting sides; at *b b*, the empty capsules or calyces of ova that have been previously discharged; at *c c*, the more compact part near the root of the ovary, where the ova are less developed.

B. Diagrammatic section of one of the most advanced of the capsules; *o*, the extended ovarian substance forming the capsule; *p*, its pedicle; *c*, indicates in this and the preceding figure the most common position of the cicatricula or germ-disc and vesicle; *o v*, the two layers of the ovicapsule or ovisac, into which the blood-vessels penetrate: the dotted line *v m*, marks the vitelline membrane.

Previous to the age for breeding, the ovary of birds — in which animals only one ovary and oviduct is usually developed or attains to functional activity — is a solid organ of a less firm texture than that of mammalia, and is adherent to the vertebral column in the middle of the dorsal region. It contains at an earlier period a much greater number of ovicapsules of a considerable size than are perceptible in mammalia. The stroma or ovarian substance is in less proportion, therefore, to the ovicapsules and ova.

As the ovules become more developed, they increase rapidly in size; and we then perceive that they bear a different relation to the ovicapsules from that which has previously been described in mammalia, as they fill completely the ovicapsules, and there is no fluid or loose cellular layer between the outer surface of the vitelline membrane and the lining membrane of the theca.* As some of the yolks approach maturity their increase in size is proportionally much greater, and the theca or ovicapsule, and along with it the ovarian substance, is distended in like proportion; and in this manner the ovary of the fowl at the breeding season has lost its appearance of compactness or solidity, and seems to be composed almost entirely of a larger number of pediculated ovarian capsules of the most various sizes, filled with the yolks or ovules in all stages of development. Nevertheless, a little attention shows the solid part of the ovary still remaining at the part attached to the vertebral column, forming the ground, as it were, from which the pedicles of the enlarged capsules spring, and containing still a very large number of minute undeveloped ovules in their correspondingly small ovicapsules.

The large ovicapsules of the developed ovary of the bird consist of two layers, which are loosely united together by blood-vessels and binding tissue towards the pedicle and over the greater part of the capsule, but are more firmly knit together at the free border. At the latter place the blood-vessels of the theca, which are on all the other parts distributed in wide or comparatively large channels very thickly set, suddenly become so small and delicate as to give, at first sight, the appearance of an absence of vascularity in the course of a band of about $\frac{1}{6}$th of an inch in breadth, and extending across a large portion of the free circumference of the capsule.† This is the so-called stigma, at which, when the ovule is to escape from the ovary and to be transferred into the oviduct, the rupture of the theca occurs.

* There may probably be an epithelial lining of this membrane. See H. Meckel's paper, afterwards referred to, Zeitsch. für Wissensch. Zool. vol. iii., 1852, p. 420.

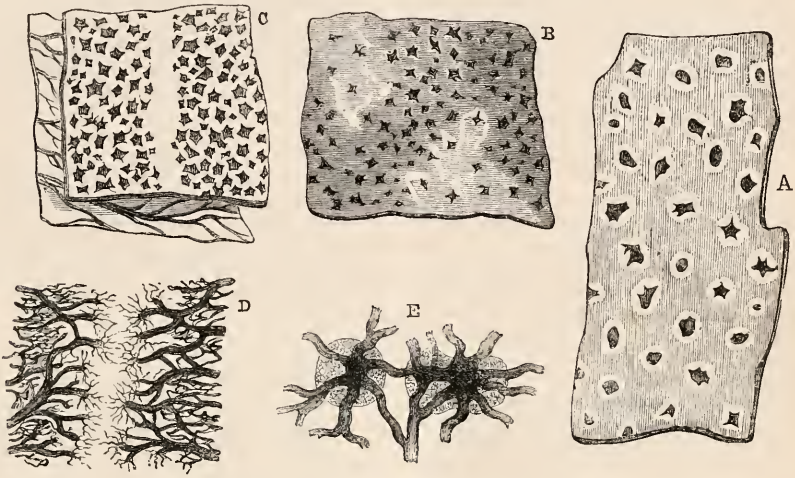
† The length of this band or stigma is about equal to the long diameter, or a third of the circumference of the capsule at its widest part. It is sometimes crossed by a second band of the same kind.

Each developed ovule, therefore, in these oviparous animals, comes to be contained in a pediculated capsule, which is formed by the extension of the substance of the ovary; but from the great extent to which the dilatation of the capsule occurs, the true ovarian stroma is reduced to a very small amount, and scarcely more remaining than the theca of the capsule itself and the ovarian coverings.

In the other animals possessing the large yolked ova, nearly the same structure of the ovary prevails. In chelonia and crocodiles, it is indeed almost identical with that in birds. In lizards and serpents, the hollow state of the ovary produces some difference in the general form; and in cartilaginous fishes (sharks and rays) other differences in the structure of the ovary may exist; but in all these animals the essential points of relation between the ovarian substance and capsules, and the large ovules, are the same as that now described in birds.

The lining membrane of the ovicapsule of birds is thick and tough, and on its inner sur-

Fig. 43.



Structure of the ovisac in the Fowl's ovary.

A. Inner surface of a portion of the ovisac of a fully-developed ovarian capsule, magnified about six diameters, showing an appearance which might be mistaken for glandular depressions produced by the peculiar disposition of the veins.

B. The same, from a calyx from which the ovum has been discharged some days before; a whitish flaky membrane is deposited on portions of the surface.

C. The same, from an undeveloped capsule of a quarter of an inch in diameter, across the stigmatic band.

D. The disposition of the blood-vessels near the stigmatic band, which seems at first sight non-vascular, but is in reality traversed by ramifying small vessels proceeding from the neighbouring larger veins, and crossing the stigmatic band.

E. Two of the large mouths of the veins, which give the semblance of follicular pits represented in A and C, but which are quite closed, with the smaller vessels ending in them, as seen from the inner surface of the ovisac.

face presents a soft appearance somewhat similar to that of a mucous membrane. In examining the inner surface of this membrane, Dr. Sharpey and the author had their attention arrested by an appearance such as might, on first sight, be attributed to a number of follicular or glandular pits. This appearance, as we first observed it, is represented in *fig.* 43. (A, B, C) as it was seen in a fully-developed capsule—in one a third of an inch in diameter—and in a calyx from which the yolk had been discharged some days previously. We supposed, indeed, at first that the appearance depended on the presence of the orifices of follicular depressions or glands on the inner surface of the membrane. A more attentive examination of this membrane by Dr. Sharpey has shown that the appearance is not due to depressions of the inner surface of the membrane or to the mouths of follicles opening upon it, but is caused by a peculiar form of the blood-vessels seen through the entire and smooth inner surface of the membrane. The apparent depressions are in fact the sudden terminations or beginnings of veins of considerable size seen through a delicate and transparent portion of the membrane which closes them towards the inner surface. They may be made very obvious by merely coarsely brushing the smooth blunt edge of any instrument over the membrane, and thus causing the blood to flow from the vessels in other parts in these sinuses or dilated veins.

It would appear that the smaller capillary vessels in which the arteries terminate, in approaching the inner surface of the capsule, ramify with considerable minuteness, and at each of the marks or apparent depressions referred to suddenly fall into or end in the comparatively large veins which constitute the hollow spaces. The ends of these veins, then, look towards the inner surface of the membrane; and the appearance of a divided cavity in some of the supposed follicles is merely caused by two or more veins meeting in a common dilatation at this place. The capillary vessels, in passing into these large commencements of the veins seem to converge from its circumference to its centre.

In the enlarged ovarian capsules of the turtle, a somewhat similar arrangement may be observed; but I have not had an opportunity of tracing its relation to the blood-vessels; nor have I had the means of ascertaining whether anything of the same kind exists in other reptiles with large yolks. In the skate I have not been able to perceive any similar arrangement; and in the Graafian vesicle of mammalia the lining membrane presents internally a smooth surface destitute of any appearance of depressions or of peculiar venous sinuses.

The appearance which I have just now described had not escaped the notice of Von Baer; for at p. 23 of his work on development, he mentions the existence of clearer points in the inner membrane of the theca, and states his opinion that they may be open mouths of blood-vessels, by means of which the yolk may be nourished by the direct access of blood to it.

In the naked amphibia and osseous fishes, the ovaries (of which the general form has been previously noticed) present a still greater decrease in the proportion of the stroma to the ovicapsules and ova. These capsules are themselves also of much more delicate structure than in the higher animals; but the relation of the ovules to the ovicapsules in their formation, and the mode of their escape by the rupture of the theca, are essentially analogous to those of birds and reptiles. In the earliest condition, it is true, the ovary may present a greater amount of solidity in some of these animals; but from the prodigious number of the germs of the ovules and the small quantity of the ovarian stroma, as soon as the ovary has made some progress in development, it acquires the appearance rather of a mere mass of ova connected together by a membrane and fine thread-like pedicles, than of a solid or consistent organ containing them. The delicate ovicapsules containing the ovules embrace them closely as in the large-yolked group of animals, there being little or no fluid between the capsules and the vitelline membrane.

The structure of the ovaries in the invertebrate animals presents so many varieties that it would occupy too much space to allude to them here. I refer the reader for information regarding them to the article ORGANS OF GENERATION, and others on particular classes and orders of animals in different parts of this work. For our present purpose the structure of these organs has been sufficiently indicated in the previous section.

In conclusion, it may be right to recapitulate the general nature of the ovary or formative organ in its relation to the production of ova. A comparison of the forms previously indicated leads to the general view that the ovary is to be regarded as analogous to the glandular organs. In the great majority of animals highest in the scale, the ovisacs are close follicles from which the product of formation (or secretion) escapes by the bursting of the wall of the follicle — in the highest animals, on the external surface of the organ, in those coming next in the series, towards an internal cavity. In other instances, principally among the lower animals, the structure is more analogous to that we are accustomed to consider as characteristic of the true glands, in which the secreted cellular product is formed within the same or a continuation of the tubular ducts themselves by which they make their escape. The more complex structure of the capsules in which the large-yolked ovules are produced in birds constitutes a special apparatus, which, though without follicular complication, may be looked upon as a modification or higher degree of development of the glandular structure of the ovary, provided for the rapid formation of the larger mass of nutritive substance which is present in these ova.

§ 4. *More detailed description of the ovum of birds as the type of the* 1*st group.*

Having in the previous section given a sketch of the general resemblances and differences observed among the ova of various animals, I now proceed to describe more in detail an example from each of the three groups previously distinguished, and more particularly those of Birds and Mammalia, which demand the greatest share of our attention in the study of development; and first as to the ovum of the common fowl.

Quantity of matter, composition, &c. — The average dimensions of the fowl's egg in this country are the following: The long diameter 2¼ inches, short diameter 1¾ inch. The average weight of eggs of this size is a little more than 2 oz. avoird., or 920 grains.*

The extremes in weight which I have observed among eggs of the fowl naturally formed are 750 and 1060 grains. Double-yolked eggs are, as might be expected, much larger, reaching often a weight of 1400 grains, or 3¼ oz.

The yolk weighs about a third of the whole; the albumen, membrane, and shell forming the remaining two thirds. These parts of the egg are in the following proportions to each other in 100 parts; the albu-

* The following is a comparative view of the average size and weight of the eggs of the common fowl, duck, turkey, and goose.

	Length (in inches).	Breadth (in inches).	Weight (in grains).	
Fowl -	2·25	1·7	920 nearly	2 oz.
Duck -	2·5	1·75	1100	2½ oz.
Turkey	2·7	1·9	1300	3 oz.
Goose -	3·3	2·4	2600	6 oz.

men 58, the yolk $31\frac{1}{2}$, and the shell with its lining membrane, $10\frac{1}{2}$.

When eggs are kept exposed, they gradually sustain a small loss, due chiefly to the evaporation of water, and amounting to about one grain per day. When putrefaction ensues, an additional loss from chemical changes occurs.

During incubation, the loss of weight is more considerable, amounting in twenty-one days to 16 or 17 per cent., or nearly one sixth of their entire substance.* The loss by an egg during incubation, therefore, is eight times as great as that which occurs in an egg kept at the usual atmospheric temperature for the same period — a circumstance which depends partly on the higher temperature, but principally on the evolution of carbon from the oily matters of the incubated egg, in combination with the oxygen of the air, or as carbonic acid, &c.

Of the 17 parts per cent. lost during incubation, not more than $5\frac{1}{2}$ or 6 consist of water, and the remaining two thirds, that is 10 or 11 parts, are derived from the oily and other substances of the egg which undergo chemical changes attendant upon the process of organisation and respiration of the embryo.

By evaporation to dryness of the whole egg without the shell and membrane, about 27 per cent. of the substance are left; the oily ingredients of this residue, amounting to about $10\frac{3}{4}$, are almost all contained in the yolk, and the remaining $16\frac{1}{4}$ parts of solid matter are nearly equally divided between the yolk and the white. The yolk, therefore, is much richer in the fixed and solid parts than the white; but its specific gravity, as will afterwards be seen, is considerably reduced by the larger quantity of oily matter it contains: the per-centage of solid matter (independently of the oleaginous substance) contained in the yolk and albumen, is in the proportion of 32 in the first to 14 in the second.†

The solid residue obtained by evaporation of the white at a low temperature, amounting to nearly one seventh of the whole, consists chiefly of albumen; along with which there is also some animal matter which has hitherto been named by chemists as extractive, and a small amount of salts, which are principally alkaline sulphates, muriates and phosphates, with phosphate of lime, some free soda and sulphur.

The yolk contains little more than half its weight of water, or 54 per cent. The remaining 46 parts consist of about 17 of albumen, or analogous principles, 28 of oily matter, and $1\frac{1}{4}$ of salts. These last are chiefly alkaline muriates and sulphates, phosphate of lime and magnesia, and traces of iron, sulphur, and phosphorus. The albumen has an alkaline, the yolk a neutral, reaction.*

The membrane lining the shell consists apparently of a protein compound, analogous somewhat to that of the elastic yellow tissue.

The shell consists of earthy salts deposited in a delicate matrix of animal matter, which last constitutes not more than 3 per cent. of the whole. The earthy ingredients are in great part carbonate of lime, together with a little carbonate of magnesia, and phosphate of lime and magnesia.

Of the ingredients of the egg before mentioned, the albumen and other animal principles, together with the sulphur and salts, are no doubt more immediately employed in the growth of the embryo; while the oily matter, besides contributing, as it appears, in some part, to the same purpose, serves more directly and in greater quantity for the respiratory process, in which it is consumed largely during incubation.

The alkalinity of the white of egg appears to depend on the presence of caustic soda, which albumen has the property of separating from its carbonate.

The following tabular view exhibits in a general way the change in the relative proportion of the ingredients of the egg resulting from incubation†: —

	Fresh egg.	Incubated egg.
Shell and membrane - -	10·67	10·
Albumen, &c. - - - -	17·8	19·4
Oily matter, &c. - - -	18·83	6·5
Water - - - - - -	52·7	47·1
Loss { Water - 5·6; Oily matt., &c. 11·4 }		17·
	100·00	100·00

When an egg is examined immediately on being laid and while yet warm, or still better when taken from the egg-bag of the fowl previous to laying, the yolk and white fill completely the interior; but immediately on cooling, a small space or vacuity appears generally towards the obtuse end of the egg, and this air-space increases gradually in size as the eggs are longer kept and the natural evaporation of water proceeds. This space is formed by the separation of the two principal layers of the lining membrane of the shell. During incubation the air-space increases much more rapidly; and indeed towards the end of this

These salts are the following — viz., chloride of sodium and potassium, sulphate of potassa, muriate of ammonia, phosphates of lime and magnesia, lactic acid, colouring matter, iron.

† From Sacc, loc. citat.

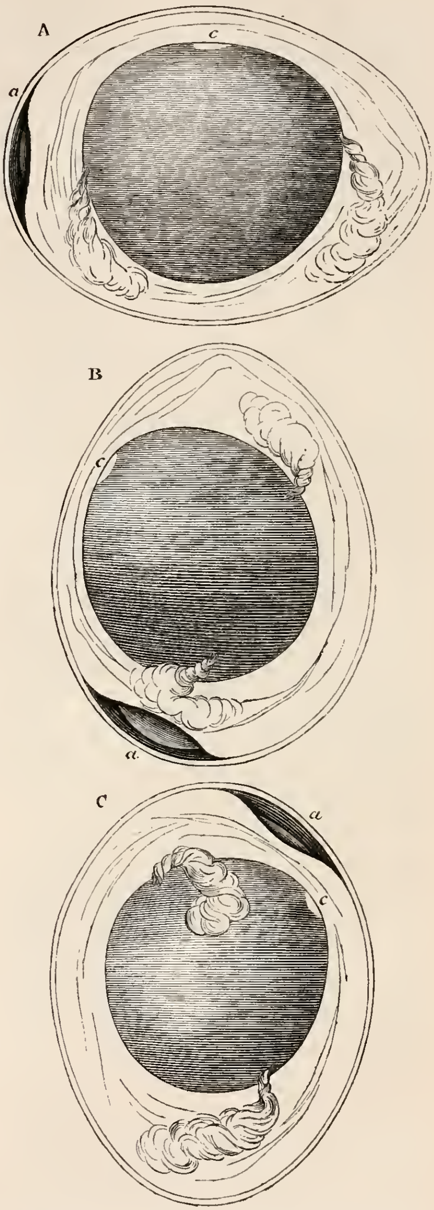
process, and in eggs that have been long kept, the space has extended over the whole width of the egg, and the quantity of gas contained in this space is sufficient to cause the eggs to float in water. The extent of the air-space may be ascertained in some degree by the greater or less feeling of coldness of the shell of the egg near the obtuse end, when it is applied to the skin of a delicate part, such as the eyelid, in consequence of the heat being less rapidly carried off by that part of the shell within which the air-space has been formed, than at others with which the albumen is in contact.

Dr. Paris found this air, amounting to about half a cubic inch, to be nearly pure atmospheric air, with a small quantity of carbonic acid towards the end of the period of incubation. MM. Baudrimont and St. Ange find it to contain in general more oxygen than atmospheric air, and no carbonic acid; whence they conclude that the shell has a peculiar power of passing outwards the carbonic acid formed during incubation and taking in oxygen.* The formation of the air-space is manifestly a compensation for the loss of substance in whatever way occasioned, that may take place from the egg. We shall have occasion afterwards to consider in how far it may be important in connection with the phenomena of incubation.

The specific gravity of the whole egg, when newly laid, and before evaporation has taken place, is generally as high as 1090, being raised considerably above the common specific gravity of the fluids and soft parts of animals by the superior density of the shell; but as the air space increases, the whole specific gravity will be lowered.

The specific gravity of the albumen and yolk differ in a considerable degree; that of the yolk, though containing the largest amount of solid matter, being lowest in consequence of the large quantity of oily matter belonging to it; and thus when the albumen becomes more fluid during incubation, the yolk naturally rises towards its upper part, or displaces some of the albumen which lay above it in the newly laid egg. It is also an interesting circumstance, that the specific gravity of the lower and upper parts of the yolk differs perceptibly; that of the upper part being reduced by the greater quantity of oily matter contained in the cells situated in the vicinity of the cicatricula. The upturning of the side of the yolk bearing the cicatricula, which is familiarly known, has long excited attention; and several explanations have been suggested of its cause; and, among others, the chalazæ have been supposed to balance the yolk in such a manner as to secure this position. But Von Baer showed that this view was erroneous, and that the less specific gravity of the upper part, or of that portion of the yolk in which the cicatricula is placed, is the true cause of the phenomenon. The measurements of the specific gravity of different parts of the egg by Messrs.

Fig. 44.



Position, form, and attachment of the chalazæ, yolk, and cicatricula, as shown by sections of fowls' eggs boiled in different positions.

A. Section of an egg, boiled on its side: B, with the narrow end up: C, with the wide end up These figures show the tendency of the lighter part of the yolk, on the surface of which the cicatricula, *c*, is situated, to be buoyed up and to expand in the white, at the same time that the movements of the yolk are to a certain extent limited by the attachment of the chalazæ; *a*, air-space.

* Recherches Anat. et Physiol. sur l'Œuf des Vertebrés, Mém. Couronn.; published in Mém. des Savans Etrangers de l'Acad. Fran. 1850.

Baudrimont and St. Ange* are quite confirmatory of this view. They are as follows: —

Sp. gr. of the	External albumen	1041·
„	Internal albumen	1042·5
„	Whole yolk	1029·5
„	Upper part of yolk	1027·
„	Lower part of yolk	1031·5†

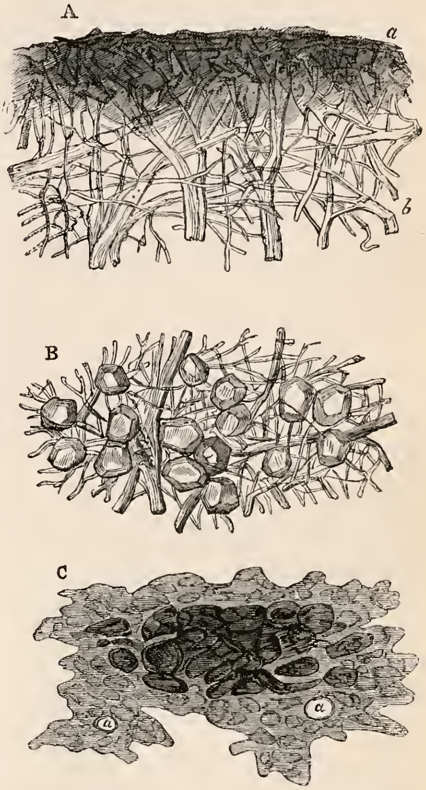
The chalazæ, being of greater specific gravity than even the inner layer of white, always float lowest; but, being attached to the yolk near its poles, they hang down from these points. All these circumstances may be illustrated very clearly by sections of eggs that have been boiled in different fixed positions, as on the side, on the large and small end; in which it will be found that, while the chalazæ exercise a certain control over the position of the yolk, that portion of its surface containing the cicatricula rises higher and expands more fully within the white than the opposite portion, while the chalazæ gravitate towards the lower side. (*See fig.* 44.)

Structure of the external parts of the egg.— The shell of the bird's egg is composed of a delicate basis of organised animal matter impregnated with the calcareous and earthy particles, the arrangement of which approaches to a crystalline appearance, but is probably of a different nature. This substance is porous, like concreted gypsum-plaster, and allows of evaporation and the mutual diffusion of gases through it in the same manner as that substance; while, by its strength and rigidity, it affords protection and support to the softer parts of the egg during incubation. The pores of the egg-shell may be easily stopped by any greasy or oily matter, or by melted wax or varnish; and then all passage of moisture or air through the shell being prevented, the development of the embryo becomes impossible. Eggs that have been oiled cannot, it is well known, be hatched; but eggs may be kept for a considerable time — weeks, or even for months — by immersion in lime-water, which impedes the evaporation and the access of air, which might favour putrefaction, while the natural condition of the contents is thus preserved.

The shell in most eggs is slightly dimpled externally, with small depressions visible to the naked eye; but these are not the openings of the pores through which evaporation or exchange of gases takes place — these being much more minute and numerous—but merely the indication of depressions caused by the largely villous structure of that part of the oviduct (uterus) in which the calcareous shell is deposited.

On removing the earthy matter by means of a dilute acid, the animal basis remains as a slightly coherent, cellular, organised structure, the form of the small compartments in which corresponds with that of the calcareous particles of the shell (see *fig.* 45. c). The in-

Fig. 45.



Structure of the shell and shell-membrane in the Fowl's egg.

A. Lining membrane of the shell; *a*, thick matted or felty portion; *b*, thin shred of the torn margin, showing the peculiar fibrous tissue of which the various layers are composed.

B. Outermost layer of the same, which is incorporated with the shell; some of the angular corpuscles of the shell lying upon the fibrous substance and firmly united with it.

C. Small portion of the calcareous shell, which has been steeped in dilute hydrochloric acid, showing the remains of opaque calcareous substance in the centre, some portions of it exhibiting a granular aspect, and round the margins the animal basis or matrix from which the calcareous matter has been dissolved, presenting an irregular granular or almost amorphous aspect. Here and there clear oval cells are seen, as at *a a*.

ternal surface is irregular and flocculent, and adheres very closely to a different kind of membrane which lines the shell.

In those instances in which the shell of eggs is coloured, the pigment substance, of various hues, is generally deposited in cells, which are strewed uniformly or in patches over the external surface of the calcareous shell. In some other instances, however, the

* Op. cit.

† Dr. Wm. Aitken has, at my request, repeated these experiments, and has obtained results in accordance with the above statement. He found the unboiled yolk to float indifferently in any part of a saline fluid of specific gravity 1035. By boiling, the specific gravity was reduced to 1031, and in both cases the side with the cicatricula floated uppermost. The upper half, containing the cicatricula, had a specific gravity of 1030; the lower half, 1032.

colour seems to be merely a uniform tinge of the outermost layer of calcareous matter.*

The lining membrane of the shell is a peculiar fibrous, interwoven structure, deposited in laminæ of some thickness and toughness, which is readily divided by tearing into two layers over the whole surface of the egg — an outer, thicker, and denser, adhering firmly to the inner surface of the shell; and an inner, thinner, smoother, and of finer texture, which may be easily withdrawn from the outer one, and which naturally separates from it at the air-space; but both the outer and inner layers of this membrane may be torn into a number of thinner laminæ, all agreeing in their minute structure.

By microscopic examination, this membrane is found to consist of a closely-interwoven network of peculiar fibres, which are of various sizes, generally between $\frac{1}{8000}$th and $\frac{1}{3000}$th of an inch in diameter; the larger frequently branching into or giving off smaller fibres at acute angles, the sides rendered uneven by minute projections or knots upon them (not represented in the figure); the larger fibres are of a somewhat flattened or ribband-like form. The external layer of the membrane contains the largest fibres. These fibres appear to be analogous in their chemical nature to those of the elastic yellow texture, not being soluble in strong acetic acid; but they do not coil up in the manner of the elastic tissue (see *fig.* 45. A).

The parchment-like coverings of the eggs of serpents and lizards, which have no calcareous shell, seem to be composed of a greater number of layers of the fibro-laminar texture now described.

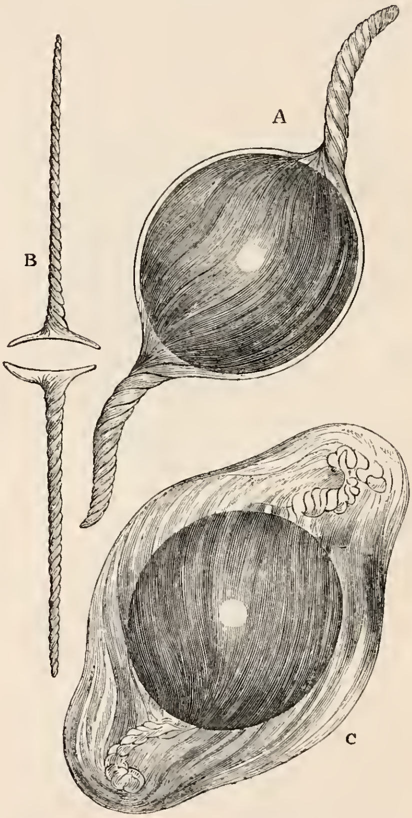
The albumen, or white of the egg, comprehends several layers of glairy, albuminous, semifluid substance deposited round the yolk, the chalazæ, or grandines, or twisted cords, and the condensed layer of albumen, forming a thin membranous investment immediately over the yolk membrane. In a perfectly-fresh egg, or in an egg taken from the oviduct previously to its being laid, the whole albumen has the consistence of a moderately-firm jelly; but very soon the outer part becomes fluid, and allows of the freer motion of the parts within the shell. This solution of the albumen proceeds to a greater extent after some hours' incubation, especially over the cicatricula.

The deeper part of the albumen, or that next the yolk, is more dense in consistence. No part of it, when unchanged by reagents, presents any sensible structure either to the naked eye or when viewed microscopically. If, however, the soft contents of a fresh egg, or one removed from the oviduct, be taken from within the shell, and thrown into water either pure or with a little acetic acid mixed with it, a slight turbidity or coagulation of the albumen takes place on the surface, which brings out the appearance of a spiral arrangement of laminæ; and in a boiled egg these laminæ may be torn in great numbers in succession from off it, the direction of the spiral being from left to right, from the large towards the small end of the egg. With a little care, almost the whole of the albumen may thus be wound off the egg in spiral strips, the deeper ones enclosing the twisted chalazæ (see *fig.* 46. D).

The coagulated albumen presents, in the microscope, a minute but indefinite granular structure.

The *chalazæ* (*grandines*) are two irregularly-twisted cords of albumen, harder than the rest,

Fig. 46.



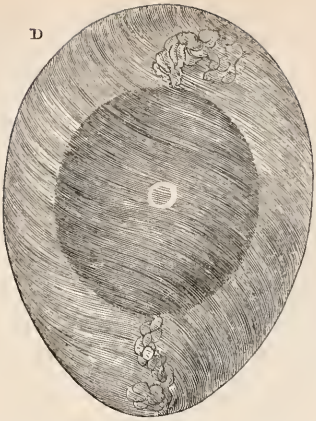
Manner in which the chalazæ, albumen, &c., are deposited round the ovarian ovum of the Fowl.

A. Yolk from the upper part of the oviduct soon after it has entered it, showing a thin covering of albumen on the yolk, forming the chalaziferous membrane, and the twisted chalazæ extending from the opposite poles of the yolk The twisting in these is represented more strongly than it can be seen at this period.

B. Sketch of the fully formed chalazæ from opposite sides of the yolk, stretched to their full length, and showing the opposite direction of the spiral in each.

C. Egg from above the middle of the oviduct; the first layers of albumen deposited round the yolk and chalazæ.

* See the works of Hewetson and others on the Eggs of Birds. Carus and Otto, Erlauterungstafeln der Vergleich. Anat. part v.



D. Egg from the lower part of the glandular oviduct near the isthmus, when the deposit of albumen is complete; the spiral arrangement of the albumen made manifest by slight coagulation.

attached to the opposite ends or poles of the yolk by means of a membrane which looks exactly like a continuation of the twisted part of these bodies opening or expanded over the surface of the vitelline membrane. These bodies attracted considerable notice from the earlier observers of the structure of the egg, and have had various uses attributed to them; but, if we may judge from the varieties they are subject to in the fowl and other birds, and their absence in the ova of scaly reptiles (otherwise very similar to those of birds), it would appear that they are only of secondary importance.

One of the chalazæ is directed towards the larger, and the other to the smaller end of the egg, and the latter usually adheres with some firmness to the inside of the shell-membrane, while that of the large end floats more freely. In this manner the yolk moves more freely at the large than at the small end of the egg. The spiral twist is in opposite directions in the two chalazæ; a circumstance depending on the manner of their production, by the gradual deposit of albumen and the spiral motion of the yolk during its descent in the oviduct. The membrane which proceeds from the chalazæ over the surface of the yolk has been called chalaziferous; and the funnel-shaped dilatation of the chalazæ where they join the membrane, has been supposed to be the opening of a tube passing through these bodies, and serving as a conduit from the white to the yolk; but entirely without reason. The chalaziferous membrane and innermost twisted part of the chalazæ are, in fact, nothing more than the first-deposited and densest parts of the albumen; nor is any importance to be attributed to a curved line or fold of the membrane which is often seen stretching over the yolk between the adhering parts of the opposite chalazæ.

The fact of the upturning of the side of the yolk which bears the cicatricula has already been adverted to, as well as the supposition that the chalazæ may be the means of securing this position; but, although it is well ascertained that these bodies control, in various directions, the motions of the yolk, they cannot be the cause of the upturning of the cicatricula; as this is secured by the difference of specific gravity in the upper and lower parts of the yolk. The true action of the chalazæ is to limit the motions of the yolk in the long axis of the egg, and control the rotation during a certain time; but in incubation the relations of the chalazæ, white, and yolk are very soon changed; and, in the progress of these changes, the remains of the denser white are collected at the lower part of the egg. If a fresh egg be turned round on its long axis, the cicatricula will keep its position upwards for one turn or a little more, and then, by the twisting of the chalazæ, the yolk is carried completely round, and balances itself again with the cicatricula uppermost in its new position.

The accessory parts of the egg, now described, are formed round the yolk or ovarian egg during its descent through the oviduct; and as they may be regarded as only indirectly connected with the functions of the true ovulum in their relation to embryonic development, it may be best to complete their history at this place by stating what has been observed as to their formation, referring for this to the researches of Purkinje, Coste, and others, which I have confirmed in most particulars by the examination of a considerable number of fowls during the process.

Formation of the external or accessory parts of the bird's egg.—These parts are produced with much greater rapidity than those of the ovulum. Many fowls lay an egg every twenty-four hours for a part of the season, while others lay only every second day, or two or three days in succession, generally at a later hour on each successive day, and then intermit for a day; other fowls lay regularly nearly every thirty-six hours. There is probably some difference in the rapidity of the descent of the egg, or at least in the length of time it remains in particular parts of the oviduct, in these various cases; but in general the whole passage of the egg, from the time of the reception of the yolk by the infundibulum to its being laid, occupies about twenty-four hours.

If a fowl which is laying only every second day, be killed and opened from seventeen to twenty hours, or if one which is laying daily be opened from three to six hours after the last egg was deposited, one of the ovarian capsules will sometimes be found completely enveloped by the infundibulum of the oviduct, which is thus in the act of receiving the ovulum or yolk about to be discharged by the cleaving of the capsule along the stigmatic band.* The infundibulum is contracted round the neck or pedicle of the ovarian capsule, so that the whole is embraced by it with moderate firmness, and the yolk thus usually passes securely into the

* See a later section for an account of the circumstances which influence the discharge of the ovarian ovula.

oviduct; but it occasionally happens that capsules burst without being so embraced, or that the process is disturbed, and the substance of the yolk falling into the abdominal cavity of the fowl either produces serious injury by peritoneal inflammation, or may be gradually removed by absorption.

The yolk enters the infundibulum, with its long axis corresponding to that of the oviduct, consequently with the cicatricula on its side, which we shall find to be its position also in the completed egg.

The passage of the yolk through the first two-thirds of the length of the oviduct, in which part the albumen is deposited, is very rapid, scarcely occupying more than three hours, according to Coste*, before it arrives in the narrow or constricted part of a more limited extent (isthmus), in which the membrane of the shell is formed. About three hours more suffice for this process, and the ovum then enters the dilated portion, which has been called uterus, in which the substance of the shell is deposited and gradually consolidated on its surface.

The albumen begins to be deposited round the yolk, immediately upon the entrance of the latter into the oviduct; at first in a thin layer, immediately investing the yolk, which subsequently becomes condensed into the chalaziferous membrane, and in two long narrow portions extending before and behind the yolk from its poles, which portions of albumen are at first straight and simple, but afterwards become twisted and form the chalazæ. (See *fig.* 46, A.)

In the next part of the albuminiferous part of the oviduct, in which the glandular structure is most fully developed, the albumen is deposited in much greater quantity round the yolk and chalazæ, not following the form of the latter, and thus soon gives to the whole the oval shape which belongs to the egg; and we then recognise, previous to the formation of the shell or its lining membrane, that the narrower end of the oval is placed downwards, or advances first in the oviduct.

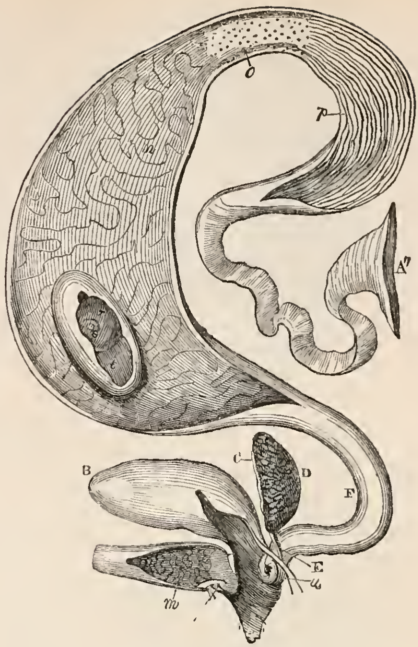
During the passage of the egg, and the formation of the albumen, membrane, and shell, a greatly increased determination of blood is observed in the vessels of the several parts of the oviduct. (See *fig.* 47.)

The formation of the accessory parts of the egg appears to proceed nearly in the same manner in the scaly reptiles as in birds. The accompanying figure, borrowed from the article Reptilia, is illustrative of the main features of the process.

The advancing motion of the egg of the fowl is caused by the peristaltic action of the muscular coat of the oviduct, which may be easily seen in any laying fowl opened immediately after death. The egg does not descend, however, in a straight line, but in a spiral direction, corresponding with that of the ridges of glands with which the mucous membrane of the oviduct is beset. Two peculiarities in the structure of the albuminous part of the egg result from this spiral motion—viz.,

* Hist. gén. et partic. du Dével. &c.

Fig. 47.



Descent of the egg in the oviduct of the Tortoise (after Bojanus).

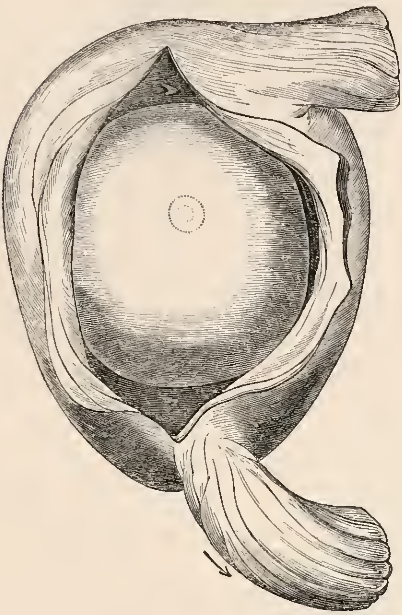
A. Infundibular opening of the oviduct; *n, o, p*, canal of the oviduct laid open; *s, t*, ovum opened, showing the yolk, albumen and shell; B, allantoid bladder; F, oviduct; C, D, kidney; E, ureter; *m*, termination of the opposite oviduct.

the spiral laminated form of the outer layers of albumen, and the marked tortuosity of the chalazæ. It is easy to understand how the spiral form is given to the deposit of the layers of albumen. The cause of the peculiar manner in which the chalazæ are twisted is not so immediately apparent ; it may be explained as follows. As already remarked, the spiral twist is in an opposite direction in the two chalazæ; one end of each of these cords must, therefore, have remained in a state of rest as compared with the other. Either, it may be supposed, the farther ends of the two chalazæ extending into the oviduct before and behind the descending yolk, remain comparatively at rest, while that body with the albumen forming round it being closely embraced by the oviduct has the rotary motion impressed upon it; or, as is more probable, when the chalazæ become attached to and involved in the deposited albumen, their outer ends move with it, while the yolk within, to which the inner ends of the chalazæ are fixed, does not rotate in the same degree; a circumstance to which it is possible the disposition of the side on which the cicatricula is placed to remain uppermost may in some degree contribute; and thus the yolk not turning so rapidly, or so often as the white, the chalazæ are twisted upon their roots attached to the surface of the yolk.*

* It ought to be observed, however, that according to Coste, the yolk does not at first rotate freely

Although it can scarcely be doubted that the chalazæ are produced during the descent of the egg, while the albumen is being deposited, it is worthy of remark, that the twisted structure of these bodies is usually not to be seen till after the shell has begun to be formed*; but it is very probable that

Fig. 48.



Position of the egg in the oviduct as it descends.

A portion of the oviduct near the lower end opened, taken from a fowl killed three and a half hours after the last egg was laid. The greater part of the albumen has been deposited, and the egg has assumed its peculiar form, the small end of the oval advancing first; the cicatricula placed on the side of the yolk.

this may depend on their not having previously acquired sufficient opacity or condensation to render their tortuous structure obvious. Indeed, Von Baer has observed them to make their appearance by increase of their opacity from exposure while under actual observation.

It has been ascertained by experimental observation that the membrane of the shell is formed in the narrow part of the oviduct, termed the isthmus, which intervenes between the albuminiferous part and the uterine dilatation. It consists, no doubt, in the fibrillation of consolidated albumen, or some analogous substance, which must take place with great rapidity; but we are not yet sufficiently acquainted with the nature of this process, for the phenomena of the solidification and fibrillar organisation have not been minutely examined, nor has any difference yet been ascertained between the substance secreted in the isthmus, which undergoes the fibrillation without calcification, and that of the uterine dilatation, which seems to have no such tendency, remaining amorphous or cellular, and having very soon a deposit of calcareous matter formed in it.

By the time the egg arrives in the uterus, it has acquired its peculiar oval form, the small end pointing downwards in the oviduct. The cause of this form, which is already apparent in the white previous to the formation of the shell, is somewhat obscure, on account of the complexity of the mechanical conditions influencing the egg in its passage. It may probably depend on the circumstance that the soft mass dilates the oviduct more gradually as it insinuates itself between its coats, in being propelled onwards, while the part of the duct through which it has passed contracts more abruptly and firmly in consequence of the stimulus of distension to which it has been subjected. But the variety of forms which occurs in the eggs of different birds and other animals must not be forgotten, as indicating that the peculiarity of a lesser and greater end is not essential, and may depend on very slight or transient circumstances. Perhaps, the greater density of the albumen, secreted over the end which advances first in the oviduct, may also have some effect in giving this part the smaller volume. It certainly seems remarkable that the ends of the egg should be moulded into so smooth and rounded a surface as that of the membrane and shell by a tubular organ. In some rare instances, however, I have observed irregularities of form at the extremities of the egg, indicating an imperfect contraction of the oviduct during the passage.

The egg remains a much longer time (from twelve to eighteen or more hours) in the uterine dilatation of the oviduct during the formation of the shell. The mucous membrane of this part differs in structure considerably from the rest: it presents over its whole extent large villous-like processes, or short folds, of a flattened form, containing small follicular glands, from which the substance of the shell is secreted. As soon as the egg enters this part of the passage a thickish white fluid is poured out from the membrane, which speedily coagulates on the surface of the membrane lining the shell, and very soon we can perceive with the microscope small heaps or united groups of particles somewhat of a crystalline appearance, but in reality calcified blastema studded over the whole surface. These are the calcareous particles of the shell, which are deposited in a delicate matrix of animal tissue of a large cellular structure. The deposit goes on rapidly increasing: at first the shell is soft, it remains friable for a considerable time, and, subsequently, it

within the white, and that it is only towards the end of the period of its passing through the oviduct that a liquefaction of the albumen, which then occurs, permits this rotation: but I think it doubtful that the adhesion between the surface of the yolk and deeper albumen is so great as to prevent the degree of rotation above referred to.

* Von Baer, Uber Entwick. p. 31.

gradually acquires the peculiar dry hardness which characterises it after the egg is laid.* The view of H. Meckel that the animal basis of the shell is formed by the separation of a layer of the mucous membrane of the uterine part of the oviduct does not appear to be established.

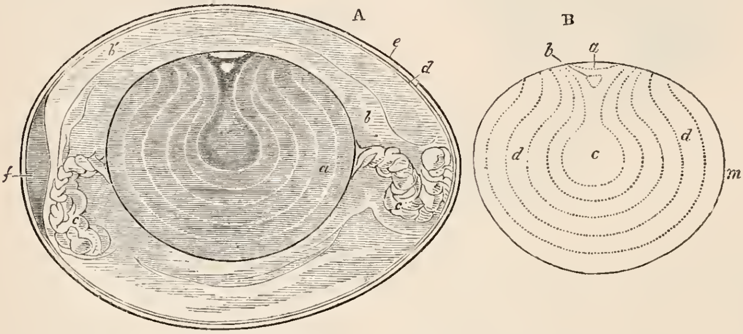
During the time that the shell is forming, the distinction between the softer and thinner external albumen, and the more dense and deeper part, becomes more obvious, and, at the same time, according to M. Coste, a certain degree of liquefaction occurs in a layer of albumen immediately surrounding the yolk, which allows the latter body to float more freely within the superincumbent albumen.

The egg remains in the uterine dilatation till it is about to be laid. The expulsion of it from this cavity through the narrow part of the tube, leading into the cloaca, requires very strong muscular contraction for its accomplishment; and, although the egg always descends in the oviduct, and usually lies in the uterus, with its narrow end downwards, both Purkinje and Von Baer state that they have sometimes seen its position inverted towards the end of the time of its residence there in consequence of the force of the muscular contractions of the wall of the oviduct.

Ovarian ovum of birds; ovulum; yolk and its contents.—The yolk, yelk, or vitellus (*Jaune*, Fr. *Dotter*, Germ.) consists in the newly laid egg of the external enclosing vitelline membrane, of the yolk substance, a mass of vesicular, cellular, and granular matter of various structure, to which as a whole the membrane gives a subglobular form, and on the surface of this mass, below or within the vitelline membrane, and on that side of the yolk which naturally turns uppermost in the complete egg, the cicatricula, or embryo spot, a thin disc of organised cellular structure, in which, under the influence of heat and air, as during ordinary incubation, the embryo, and its accompanying fœtal membranes, &c., are first formed.

The cicatricula of the laid egg, as has already been remarked, however, has, during its descent through the oviduct, undergone some part of those changes which belong to the

Fig. 49.



Form of the Fowl's egg and structure of the yolk as exhibited by a section.

fecundated condition, and by which the foundation is laid of that structure in which the future embryo is more immediately developed; for it has now lost its germinal vesicle, and from being formed, as at first, of mere granules or simple spherules, it has acquired a true organised cellular structure. It now consists, in fact, of the delicate discoid collection of cells, which has been called *blastoderma*. It may be proper, therefore, to consider the mass of the yolk and the germ, in their unfecundated state, while still within the ovarian capsule, next, after the ovulum has entered the oviduct, and, subsequently, when it is laid; reserving, however, for a latter part of the article the account of the process by which the change in the cicatricula referred to takes place.

In the newly laid egg the yolk forms an ellipsoidal mass, somewhat flattened on the upper or cicatricular surface, and with its long axis corresponding to that of the egg. Its largest diameter is about one inch and a quarter, its shortest about an inch: it floats within the white, capable of a certain degree of motion, which is controlled, as before explained, by its own specific gravity, and by the attachment of the chalazæ.

The yolk substance is not of the same nature throughout, there being a part of a lighter colour in the centre, about one fourth of the diameter of the whole; from this, a narrower prolongation extends upwards

* It is to be remarked that the animal basis of the calcareous shell is of quite a different structure from the fibrous lining membrane of the shell; and the calcareous deposit is not to be regarded as taking place in that fibrous membrane. The outermost layer of the lining membrane adheres very firmly to the shell, which may have misled some on this point, who describe the animal basis of the calcareous shell as of the same structure with the fibrous lining membrane.

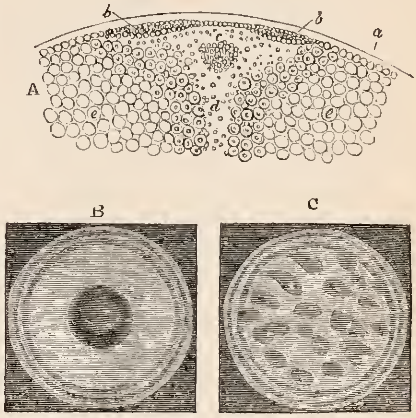
towards the cicatricula, near which it again widens and spreads out like a shallow cone. This whiter internal substance constitutes what has been called the central cavity (or latebra) of the yolk: the whole of this inner part has something of the shape of a flask, with a narrowing neck and a wider mouth at the top, which is, as it were, surmounted or closed in by the cicatricula. (See *fig.* 49.)

The shape of the yolk, I have said, is not that of a regular ellipsoid; the less density of the upper part, which is towards the cicatricula, giving rise to a widening of the yolk on that side, as may be seen in *fig.* 44, A, which represents a vertical section of an egg boiled while lying on its side. This does not depend simply on the rising of oil globules in greater quantity to the upper side of the yolk, but, as has already been noticed, on the fixed predominance of globules containing oil in the neighbourhood of the cicatricula.

Neither is the outer deeper-coloured portion of the yolk altogether uniform in structure or appearance; for it will be seen, both in the raw and boiled egg, but most easily in the latter, that several concentric layers surround the central cavity and canal of the yolk, as well as the funnel-shaped dilatation which lies below the cicatricula. These layers are marked by a slight variation in colour, and are attended by a difference in the minute structure of the corpuscles composing the alternate layers. They probably depend upon the growth of the coloured part of the yolk being more or less rapid at different successive periods.

The cicatricula of the newly laid egg is a spot of an opaque yellowish white, easily distinguished by its difference of colour from the rest of the yolk, about one sixth of an inch in diameter, and lying immediately within the vitelline membrane, in connection at its margins with the most superficial layer of the yolk substance. Examined in a favourable light* it will be found, that in the laid egg, when fecundated, the cicatricula consists of a central clearer and thinner part, and of an external more opaque annular portion. The central part is about one third the diameter of the whole, and seems as if it perforated the remainder of the disc with a circular aperture, something after the manner of the pupil of the iris. There is not, however, any perforation in reality, but only a greater thinness and transparency of the central part of the disc. Neither is this central part entirely clear; for there is placed below its middle a round heap of whitish granules, described by Pander as the *nucleus cicatriculæ* (see the figure in section), which gives greater opacity to that part when viewed directly from above. The central part of the cicatricula, already obvious when the egg is first laid, is the same which, after some hours of incubation, expands, changes its figure, and becoming still

Fig. 50.



Structure of the cicatricula in a laid Fowl's egg.

A. Diagrammatic section of the yolk near the cicatricula, enlarged; *a*, vitelline membrane; *b*, cicatricula; *c*, nucleus; *d*, canal leading to the cavity; *e*, *e*, large yolk corpuscles of the coloured part: the corpuscles are not represented of their real proportional sizes, but more with a view to show their general difference.

B. Enlarged view of the cicatricula, as seen from above on the surface of the yolk in an impregnated egg: the dark central space or transparent area surrounded by an opaque zone and one or two delicate haloes.

C. Cicatricula of an unfecundated laid egg: instead of the central transparent area a number of rather irregular transparent spots are seen.

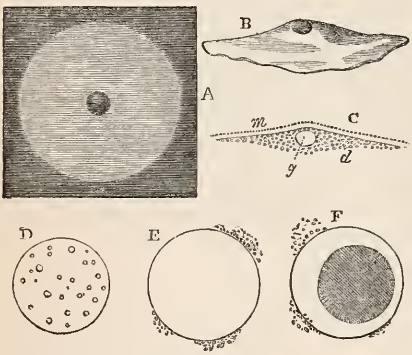
more clear, receives the name of transparent area, in the centre of which the embryo begins to be formed; while the outer more opaque part retains its greater thickness, and is converted afterwards into the vascular and peripheral part of the germinal membrane which spreads over the yolk. Round the margin of the cicatricula the deeper-coloured yolk substance is seen even in a perfectly fresh or newly laid egg to be intersected by one or more fine circles of a lighter colour. These seem to be the same which afterwards, expanding and widening, constitute the *haloes* which precede and accompany the extension of the germinal membrane over the yolk. These circles are the terminations at the surface of the concentric layers of lighter substance, which, as already mentioned, may be seen surrounding the central cavity and canal of the yolk (see *fig.* 49). It seems not improbable that, the difference in the structure of the central and peripheral parts of the cicatricula just stated proceeds from, or is connected with, the peculiar process of fissuring or segmentation which follows the disappearance of the germinal vesicle from its central part in the fecundated egg; but the description of this process belongs to a later section of the present chapter.

* It may be here mentioned, that by far the best mode of examining the natural appearances of the parts as they lie in the opened egg, is to allow a ray of strong or of direct sunlight to fall upon the part which it is wished to investigate, through an aperture in a screen, which places the rest of the egg and the observer in comparative darkness.

The cicatricula of the unfecundated egg, such as is laid by fowls secluded from the cock, differs from that now described principally in the absence of the marked distinction between the central clear and the peripheral opaque part. The germinal vesicle, which to all appearance remains the same in the ovary till the yolk leaves the ovarian capsule, is now no longer to be seen; and the cicatricula is often marked irregularly throughout, but more especially towards the circumference, with clearer intervals, or small irregular circular or oval spaces, mingled with the opaque substance of the disc. I have, not, however, had the means in more recent times of making a sufficiently careful examination of the cicatricula in this condition to enable me to state more minutely in what respects it differs from that of the fecundated egg.

In the ovarian yolk, while still within its capsule, a white spot corresponding to the cicatricula also exists, and occupies the same place in relation to the yolk cavity and canal. Its structure and appearance, however, are somewhat different from that of the true cicatricula of the egg which has passed through the oviduct; it is covered by a layer of closely set nucleated cells which lie below the vitelline membrane; it contains the germinal vesicle in its centre, and, instead of being thinnest towards the middle, the mass of its granular substance is accumulated in greater quantity in that part round and below the germinal vesicle, and thins gradually off towards the margin. Nevertheless, its much lighter colour than the surrounding part of the yolk makes it always easy to distinguish it. Its margin, however, is not so well marked as that of the true cicatricula; for the opaque whitish substance seems there gradually to pass into or be continuous with the most superficial layer of cells covering the yolk. To this ovarian representative of the cicatricula, Von Baer has given the name of *stratum proligerum*. It is also somewhat smaller than that of the laid egg. It is usually to be found on that part of the yolk which is next the ovary, which, as the yolk hangs within its capsule in the usual attitude of the bird, will be uppermost, and for the most part is situated close to the pedicle of the ovarian capsule. This position is not, however, a constant one; for sometimes the cicatricula is seen on the sides of the yolk, or towards the stigmatic band of the capsule, but rarely, it would appear, towards the ends or poles of the yolk.

Fig. 51.



Cicatricula, and its contents, in the ovarian egg of the Fowl.

A. A square portion of the surface of the ripe ovarian yolk, showing the vitelline disc or cicatricula, with the germinal vesicle in the centre, magnified about six diameters.

B. Lateral view of the same, to show the convexity produced by the thickness of the disc round the germinal vesicle.

C. Vertical diagrammatic section of the same; *m*, vitelline membrane; *d*, granular disc; *g*, germinal vesicle.

D, E, F. Germinal vesicles more highly magnified; D, from a yolk of about one tenth of an inch diameter, showing scattered globules or germinal spots; E, from a nearly ripe yolk, quite clear; F, from another of the same period, exhibiting a turbid or minutely granular mass from the action of water.

The cicatricula may generally be perceived on the surface of the yolk when the outermost layers of the capsule have been removed, and the germinal vesicle can be distinguished in it shining through the inner layer of the capsule and the vitelline membrane. It is placed close below the nucleated cells which line the latter, and adheres along with them somewhat to its inner surface; so that in general, it is easiest to remove this disc along with a portion of the vitelline membrane, when it is desired to obtain it for separate and more minute observation by transmitted light. The vitelline membrane being cut round with scissors at a short distance from the margin of the disc, the parts are floated off in water or serum, and then may readily be separated with a little careful manipulation.

The germinal vesicle, or vesicle of Purkinje, may always be seen with the unassisted eye, with a good light, in the centre of the ovarian cicatricula, or proligerous disc, in all ripe ovula, and in most of those which are above a tenth of an inch in diameter. It constitutes there a well-defined shaded circular spot, from $\frac{1}{80}$ to $\frac{1}{60}$ of an inch in diameter. When the proligerous disc alone has been removed for observation and laid on a flat surface, and viewed somewhat from the side, or when the granules are torn asunder with needles, so as to make a partial section of it without removing or bursting the germinal vesicle, it is easy to perceive that the middle part, containing the vesicle, is more elevated than the rest; and that, although the substance of the disc seems to pass quite smoothly or evenly from the sides over the germinal vesicle, the granules of the disc envelope the vesicle only slightly, and none cover its middle part: the vesicle, therefore, is set, as it were, in a depression of the disc, which fits round and overlaps its margins, and a considerable thickness of granular substance is continued in the disc below the vesicle. (See *fig.* 51, in section).

If we select for examination the most advanced yolk of the ovary, which, in a hen laying daily, or almost daily, would probably have been discharged from the capsule in a few hours, we may find some difficulty in isolating the vesicle of Purkinje from the granular disc; for, by this time, the vesicle has become flaccid, weak, and flattened down, and has begun to be softened and dissolved, preparatory to its complete disappearance, which generally occurs about the time when the stigma of the capsule opens to allow of the escape of the yolk into the infundibulum which embraces it. But, in all the other yolks down to those of $\frac{1}{10}$ of an inch in diameter, it is quite easy to break up the granular disc with needle points, and to preserve the vesicle uninjured. We may then free it entirely from adhering granules, and cause it to roll along in the fluid in which it is immersed, or on a plate of glass; and we may perceive that it is a simple membranous vesicle filled with fluid, and without any very obvious granules or nuclei. In the perfectly fresh state, the contents of the vesicle are almost limpid, exhibiting only a slight turbidity scarcely amounting to a granular deposit, provided it has been placed in a medium which does not change its appearance; but, if it is allowed to remain a short time in water, and still more if it is immersed in fluids which coagulate albumen, its interior speedily assumes a minutely granular aspect. The external wall of the vesicle then separates somewhat from the spherical granular mass within; and I have sometimes seen (as represented in *fig.* 51, F) a considerable condensation of the granular mass, so as to leave a large clear space between it and the external vesicle, and give it very much the appearance of the yolk mass in the ova of some small animals within the vitelline membrane. This change seems to be a combined effect of the condensation of the granular mass and the imbibition of fluid by the external vesicle. In the earlier ovula this rounded molecular mass is of proportionately smaller size; and although it differs very much from the smaller nucleus or macula contained in the germinal vesicle of the ova of many other animals, there can be little doubt that it is derived from this structure, as will appear from what is hereafter said of the progress of its development.

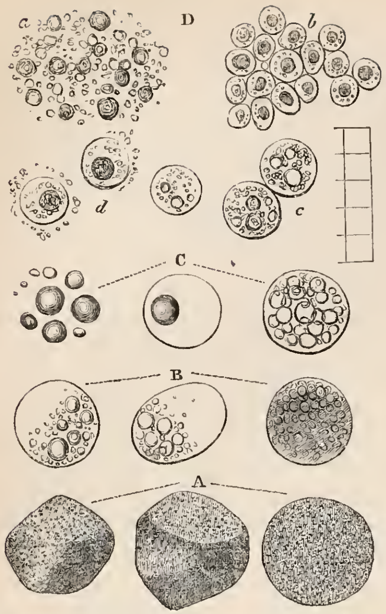
When the yolk has passed into the oviduct, and, in most instances, probably even sooner, or when it has entered the infundibulum, the germinal vesicle has entirely disappeared. Sometimes it is already gone before the opening of the ovarian capsule. The cicatricula then presents an irregularly broken appearance in consequence of the want of support from the wall of the vesicle, and the diffusion of the contents of the vesicle over the surface of the proligerous disc. The solution of the wall of the vesicle is probably a gradual process connected with the state of complete maturation of the ovule. It occurs, as is well known, in the unfecundated as well as in the fecundated egg, and cannot, therefore, in itself, be dependent on the action of the spermatozoa; neither is it altogether caused by the mechanical pressure to which the yolk is subjected in issuing from the ovarian capsule, nor by the pressure of the oviduct itself; for it usually begins, and is sometimes completed before these causes can operate.

The diffusion of the germinal substance from the vesicle (which in the fowl must have already received the spermatic influence in the ovary) has the effect thus of mingling with the remainder of the cicatricula, a material which, it can scarcely be doubted, exerts some immediate influence in inducing the change of segmentation and subsequent process of organisation by which the blastoderm is produced.

Microscopic structure of the ovum. — The investigation of the microscopic structure of the yolk is attended with considerable difficulty, in consequence both of the variety and the delicacy of the organised elements of which it consists. The following parts require our separate attention — viz., 1st. The yellow or external yolk substance; 2nd, the substance of the cavity and canal; 3rd, that of the cicatricula and cumulus; 4th, the vitelline membrane. We shall consider these both in the laid egg and in the ovarian capsule.

1. From the effect of boiling the yolk, every one is familiar with the fact that its yellow substance is coarsely granular; but the exact nature of the small bodies giving this granular structure has not been equally well understood. The examination of this substance with a microscope of moderate magnifying power in a newly laid egg, shows that almost all of the deeply coloured part of the yolk consists of spherical corpuscles of considerable size, so closely set together that they are mutually compressed; and thus, when the yolk has been hardened by boiling, the substance of the corpuscles being coagulated by heat, they present polyhedral forms; but when diffused in fluid in the unboiled state, they are all nearly or quite spherical. The size of these corpuscles varies between $\frac{1}{150}$ and $\frac{1}{500}$ of an inch; but the greater number of them are more near $\frac{1}{200}$ or $\frac{1}{250}$. Some have described the yolk corpuscles as floating in a fluid; and no doubt in the earlier condition of the yolk, a considerable quantity of fluid exists, but in the more advanced condition the amount of mutual compression they exert when coagulated is sufficient to show that its quantity must be very small indeed. Those who have described the yolk substance as mainly consisting of a fluid holding in suspension a quantity of extremely minute granules or molecules, together with some larger corpuscles, have probably been misled, by making an examination of the yolk when not perfectly fresh, and when the larger corpuscles have been in part broken up, and thus resolved into the granular fluid of which they consist. There is no doubt that in birds, and in all the large-yolked animals, the deeply coloured vitelline substance, which, in fact, forms the great mass af these ova, consists almost entirely of the large and usually spherical corpuscles just now noticed. In some animals the form is not

Fig. 52.



Microscopic structure of the elements of the yolk and ovarian ovum of the Fowl.

A. Large granular corpuscles of the yellow part of the vitellus; one of them quite spherical, as they are seen when free; two others angular from mutual compression, from a boiled yolk.

B. Various corpuscles found on the confines of the yellow yolk and the cavity and canal, showing transition forms to the next set.

C. Clear vesicles containing oil globules and detached oil globules of various sizes from the cavity and canal.

D. From the cicatricula; *a*, various-sized granules and globules forming the vitelline disc of the yolk before its discharge from the ovary; *b*, the organised nucleated cells forming the upper layer of the cicatricula in a laid egg; *c*, larger cells of the lower layer; *d*, cells of the cicatricula from an egg in its descent through the oviduct in process of formation. A scale with divisions of $\frac{1}{1000}$ of an inch is appended.

spherical; as, for example, in the cartilaginous fishes, in which a remarkable variety occurs of a cubical form, and sometimes these mixed with tetrahedral forms, as in the skate.*

When free, these corpuscles in the yolk of the bird's egg roll easily on the surface of a plate of glass as perfectly distinct spherical bodies. They present (see *fig.* 52, A) a minutely molecular or granular aspect, but with quite a smooth outline or margin to the whole corpuscle. If subjected to pressure, or cautiously ruptured with needle points, they break readily at one or more places, and allow the escape from their interior of the thick granular fluid, which flows slowly out of them in a stream. The granules are in large quantity, as compared with the fluid in which they are suspended, and are most of them of an extremely minute size, probably below $\frac{1}{30000}$ of an inch in diameter.

* See Müller's Physiology, vol. ii.

Although the yolk corpuscles present the distinct external margin now mentioned, and thus constitute capsules containing the granular fluid, yet we cannot, in most instances, detect any vesicular membranous envelope surrounding them. One may sometimes observe a delicate limiting line; but it has been impossible for me to determine whether it consisted really of a membrane or of a thin condensed layer of the granular substance or plasma containing it. At an earlier period it is probable that these corpuscles have membranous envelopes, but when fully formed the greater number are certainly destitute of them; for occasionally a larger corpuscle may be observed to divide into smaller ones, the outlines of which are nearly as distinct as that of the larger corpuscles.

Nor is any nucleus in general to be perceived in these corpuscles. I have occasionally seen in those from which the granular matter was escaping, and which had thus become less opaque than usual, a slight appearance of a clear hyaline circular space, but it scarcely deserved the name of nucleus; and if these spherical bodies are to be regarded as cells, which I think they ought, it must be in a somewhat different acceptation from that in which the term cell has hitherto been generally applied to vesicular organised structures. But recent researches on the early condition of cells seem to have rendered it necessary that we should include under this denomination several simple spherical minute forms of organised or organising matter, which were not at first regarded as true cells by the authors of the cellular view of organic structure; and when we consider the mode of their formation, it is more than probable that the vitelline corpuscles now under consideration may be included among the number.*

They probably constitute, at all events, as Schwann has first shown, one stage of development of a cellular structure; and, in the meantime, they may with propriety be styled the larger granular yolk corpuscles.

There is considerable uniformity in the appearance and structure of these corpuscles in nearly the whole of the deeper-coloured portion of the yolk; but immediately below the vitelline membrane, several layers of them are of a smaller size, and the outermost layer of all consists of cells which are much smaller and more compressed, distinctly nucleated and of a short cylindrical or prismatic shape. In some places also, corresponding to the concentric lighter lines which run through the yellow yolk, some approach is seen to the next kind of yolk cells or corpuscles, which I shall have to describe—viz., those of the cavity.

The substance of the yolk-cavity and canal, which in the unboiled egg may be distinguished from the other part by its lighter

* The above observation has a general application to such minute spherical masses of matter as are destitute of external envelope or nucleus: but in reference to the corpuscles of the yolk, I ought to observe that Schwann regarded them as cells in various stages of growth.

colour, and in the boiled egg by its softer consistence and less granular appearance, is found by microscopic examination to consist of organised corpuscles floating in a larger portion of fluid, and different from those of the external part of the yolk. The transition from the one kind of corpuscles to the other in these two portions of the yolk, is not sudden; but many gradations of intermediate forms are to be met with on the confines of the two regions.

In the central part of the cavity or latebra, which, when boiled, appears like a thick milky fluid, corpuscles very different from those of the external part are to be found (see *fig.* 52, c). They are almost all of a very regular spherical form with a delicate and clear, but distinct vesicular wall; the interior of the vesicle is occupied by a perfectly limpid fluid, and by one or several highly refracting globules of various sizes, not exactly similar to nuclei, but rather like oil globules, floating within the cell and moving with freedom from one part of it to another. The diameter of the clear vesicles varies from $\frac{1}{700}$ to $\frac{1}{400}$ of an inch, the most being about $\frac{1}{500}$; therefore about half the size of the granular corpuscles of the yellow yolk. The internal oil globules are of very various sizes, the largest being generally about a third or a fourth of the diameter of the enclosing vesicle. Mingled with these vesicles, there are also floating in the fluid of the yolk cavity in considerable numbers, but in less quantity than the vesicles themselves, a set of simple highly refracting globules, exactly similar to those contained within the vesicles from which we may suppose they have been set free. These oil-like globules are of every variety of size, from the minutest point up to $\frac{1}{1200}$ or $\frac{1}{1000}$ of an inch. Towards the surface of the yolk cavity and canal, and extending below the cicatricula, where the vitelline substance gradually passes into the darker yellow yolk, the microscope shows some mixture of and transitions between the several cells or corpuscles before described, those of the intermediate structure being in greatest numbers; these exhibit very various gradations of deposit within them, from the finest granular particles in some, to larger and fewer oil-like globules in others. In most of these transition corpuscles a delicate vesicular wall is perceptible. In the more advanced of these transition forms, as the minute granules are in the process of uniting into larger and larger oil globules, and at last coalesce into a very few or into a single one, the condensation of the exterior layer increases to form a vesicular wall, and a separation of an albuminous fluid from the oil globules takes place within (see *fig.* 52, B). It is these vesicular globules of the cavity which, according to Reichert, are the more immediate source of additions to the germinal membrane in the course of development; for the cavity and canal expand, as it were, at the expense of the yellow yolk, and as these inner globules increase the extension of the haloes and change of colour of the yolk in the first days of incubation spreads rapidly over its surface below the germinal vesicle.

3. *Cicatricula or proligerous disc.* — There does not appear to be any marked difference as to the minute structure of the mass of the yolk and its cavity in the newly laid egg and in the mature ovarian ovulum; but the cicatricula undergoes a great change during the passage of the ovum through the oviduct, which is indicated in a marked manner by the difference in its microscopic structure. During this period, besides the loss of the germinal vesicle, the cicatricula has undergone the peculiar process of segmentation and cell formation, upon the details of which it is my intention to return in connection with the special history of that process in the ovum of mammalia, batrachia, and other animals. The cicatricula of the laid egg is, in fact, after having undergone this process, the organised blastoderm or germinal membrane in which, under the influence of the heat of incubation, the rudiments of the embryo take their origin. It already consists, before incubation, of two layers of organised cells, which are the indication or earliest condition of the upper or serous, and lower or mucous layers, which were described by Pander and Von Baer as taking their origin only after incubation for some hours.* (See *fig.* 52, D.)

The cells of the upper layer are about $\frac{1}{1500}$ of an inch in diameter. They are closely set and very slightly connected together in a continuous layer one cell thick, presenting a smoother upper surface next the vitelline membrane. Each cell consists of an external vesicular wall, a distinct nucleus, and some granular deposit. The nucleus is highly refracting. The cells of the lower layer are nearly double the size of the upper ones, more regularly spherical and less closely connected together. They do not in general present any single nucleus, but rather a small mass of granules and oil-like spherules within them, giving them much of the appearance, though smaller in size, of the corpuscles found between the cavity and rest of the yolk.

In the cicatricula or proligerous disc of the ovarian yolk, on the other hand, containing the germinal vesicle set in its centre, the microscope shows no truly organised cells, but only a mass of simple spherules of very various sizes, but the largest of which for the most part are less than half the diameter of the cells in the upper layer of the blastoderm of the laid egg. They are without any nucleus, and have all the appearance of simple solid spherules from $\frac{1}{3000}$ to $\frac{1}{2000}$ of an inch in diameter, of considerable refracting power, and, indeed, very similar to the nuclei of the cells in the upper blastodermic layer.

Vitelline membrane. — The condensed layer of structureless membrane which has gene-

* The most exact descriptions of the minute structure of the cicatricula are those of Schwann in his Microscopic Researches; of Reichert, in his Beiträge zur heutige Entwickelungsgeschichte, &c.; and Remak, in his Beiträge zur Entwick. des Hühnchens, &c., 1850.

rally received this name in the fowl's egg, and which I have hitherto regarded as corresponding with the immediate membranous investment of the yolk (zona pellucida) in mammalia, and in all animals, constitutes, both in the mature ovarian yolk and in the laid egg, an entire thin transparent covering of the yolk substance, without any aperture that has been discovered in it at any time; delicate and easily torn, but yet of such consistence that under water any portion of it may easily be removed and examined. In the egg which has passed through the oviduct, the vitelline membrane floats free from the cicatricula and surface of the yolk substance; but, so long as it remains in the ovarian capsule, these parts cohere somewhat together; so that, in general, on removing a part of the yolk membrane, a more or less complete lining of the nucleated or outermost layer of yolk cells comes away with it. The microscopic examination of this membrane in the fully formed yolk does not, as already stated, show any very distinct structure beyond an obscure fibrillar and molecular marking, of such fineness, indeed, as to require a high magnifying power (500 to 600 diameters) to bring it into view; and in many parts the membrane appears perfectly homogeneous. In the earlier stages of the yolk's growth, however, we shall see that this membrane is not to be distinguished from the layer of closely set nucleated cells, the outermost part of which appears to become fused together into the membrane as the yolks advance to maturity (see *fig.* 53, K *vm*). We shall presently see that the vesicular envelope which is generally termed the yolk membrane in the bird's egg, and in the ova of all animals possessing the large yolks, is probably a different *structure* from the perfectly homogeneous vesicle which in many other animals arises at a much earlier period of the growth of the ovule, and remains in them as the external covering of the yolk to the end.

Early condition and first formation of the ovarian ovum in birds.—It has already been stated that the ovula exist at a very early period of life in the female bird; constituting in their earliest undeveloped condition minute cells closely surrounded by the simple vesicular capsules and the solid substance of the ovary, which at this period has not lost its primitive compact form. As the bird approaches maturity, a considerable number of the ovula situated nearest the surface increasing in size make an advance in their structure by undergoing certain changes which will immediately be more particularly adverted to. Having attained various sizes from $\frac{1}{20}$ to $\frac{1}{6}$ of an inch, they project slightly as rounded bodies from the surface of the ovary, and remain in this condition till the approach of the breeding season, when some of them destined to reach their full state of development, are at last discharged from their ovarian capsules. A much greater number, however, must remain in the undeveloped condition, awaiting future seasons of evolution; and a very considerable proportion of the whole germs of the ovary rather pass through a retrograde process and gradually disappear without having attained to any considerable size.

Of the smaller or undeveloped ova, such as those of less than $\frac{1}{10}$ of an inch in diameter, some are of a dull whitish or milky colour, the deeper-coloured external yolk substance not having been yet formed, and the yolk substance consisting almost entirely of small spherules or globules, not of true cells or of the granular corpuscles which appear at a later stage. Those between $\frac{1}{10}$ and $\frac{1}{4}$ of an inch are for the most part of a lighter yellow than the larger ovula; but above the latter size the colour has attained nearly its full intensity from the deposit externally of the deep-coloured yolk substance.

In all the ovula above $\frac{1}{10}$ of an inch it is easy to see the germinal vesicle situated on the surface of the yolk, when the capsule is opened, embedded in a more opaque and compact layer of substance which represents the discus proligerus, extending at this period nearly over the whole surface of the yolk. But in those less than $\frac{1}{15}$ or $\frac{1}{20}$ of an inch, the vesicle is not to be seen on the surface. On carefully opening or breaking up the substance of the yolk, the vesicle is easily found in the softer internal substance which flows out from the centre. From the central part of the small ovule, the vesicle appears gradually to pass outwards towards a determinate part of the surface, making its way through the proligerous layer or primitive yolk granules; and thus, in examining ovula at this stage, I have been able to perceive occasionally that the vesicle was situated in a more or less deep depression on the inner surface of that layer, which therefore must be perforated, as it were, by the vesicle in its passage towards the surface. The substance of the disc afterwards collects round the vesicle internally, and is accumulated in greater quantity (cumulus) in that situation. This change of place of the germinal vesicle from the centre or interior to the surface of the yolk in the progress of development of the ovula occurs in some degree throughout the animal kingdom; but it is especially remarkable in the eggs of birds and other animals with large yolks, in consequence of the peculiar connection of the vesicle with the proligerous disc. In the batrachia also, the change is very obvious, and the progress of the vesicle outwards has been well described by Von Baer and others. In this latter class of animals the proligerous layer covers a much greater part, or indeed in most of them nearly the whole of the yolk; but the germinal vesicle occupies always a determinate place in the centre of the layer; showing that the development of the various parts of the ovum proceeds from the first with a fixed relation of position between the germinal vesicle and other parts.

In birds, as in all other animals, the germinal vesicle, which we shall see is the fundamental part of the ovum, is proportionally large in the earlier stage of growth of the ovule, being at the first from a fourth to a half of the diameter of the whole ovule. In the progress of growth, it enlarges somewhat, but only in the earlier periods, and in less proportion than the yolk, and undergoes no farther increase during the greater part of the time that the yolk acquires the greatest addition of new matter. It is worthy of remark, however, that the germinal vesicle is originally of a large size in the eggs of birds and other large-yolked ova; that it is also of very considerable size, even proportionally larger, in the batrachia; and that in mammalia, and other animals with the smaller and granular yolk, its size bears in general a proportion to that of the yolk.

The substance of the yolk appears, in the first place, to be simply granular, or to be composed entirely of minute molecules such as those which always form the yolk in mammalia. These are united together by a somewhat glairy fluid; larger spherules gradually appear among them; and next the distinction between the substance of the proligerous disc and of the yolk cavity becomes apparent. Lastly, the deep-coloured yolk corpuscles are produced, layer after layer being deposited from the exterior, so that the outermost are the last formed. Externally a closer-set layer of nucleated cells covers the surface, in connection with which the vitelline membrane is formed.

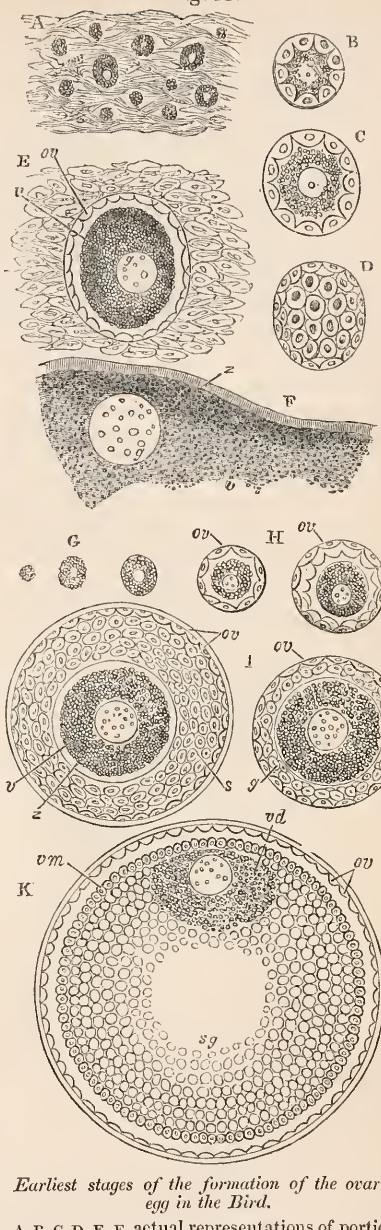
The vitelline membrane is not formed at an early period in the bird's egg: it cannot indeed be perceived in ovula of a tenth of an inch in diameter. We shall presently see that its relations and mode of formation are peculiar in the bird's egg.

Morphology of the bird's egg as ascertained from its first origin and development. — The ovaries of the common fowl, and indeed of most large birds, are less favourable for the investigation of the first origin and earliest condition of the ovule, than those of the smaller tribes; this arises, not so much from the dense structure of the ovary in the undeveloped state, as from the great opacity produced in the ovules themselves, almost from the first, by the deposit of thick-set yolk granules. In some of the smaller singing birds, the thrush, yellow-hammer, or chaffinch, the parts are clearer and more transparent; and it will be found that the phenomena of earliest formation are most easily investigated in them.

According to Dr. Martin Barry's observations, in birds as well as in other animals, the germinal vesicle is the part of the ovum which is first formed. In the pigeon and common fowl, he has observed these vesicles in the ovarian substance at a very early period*; and he believes their origin as simple cells to precede that of the ovarian vesicles, or follicles, or, as he has termed them, ovisacs, which surround them at a somewhat later period, but still in the earliest stages of the formative process. By other observers the ovarian vesicles have

* See Philos. Trans. for 1838, p. 309. In this, coinciding with the opinion previously expressed by Von Baer.

Fig. 53.



Earliest stages of the formation of the ovarian egg in the Bird.

A, B, C, D, E, F, actual representations of portions of the ovarian stroma and ovisacs of the thrush; G, H, I, K, diagrammatic sections of the same. A. In the ovarian stroma are seen the earliest state of the ova and ovisacs that can be perceived, consisting, first, of minute granular spots; next, of clear points within a minute granular mass; and third, of small germinal vesicles, surrounded with the minutely granular dark yolk substance. Compare with G, in the diagrammatic figure.

B and C. Different stages of formation of the ovisac round the small ova: the epithelium is seen to line the sac: the germinal vesicle with occasionally a single macula is now apparent. D. The epithelium of the ovisac shown in focus over the whole surface: in the other figures it is only shown in focus at the margin. E. The ovisac and ovum more advanced; *o, v*, ovisac, with epithelial lining; *v*, minutely granular yolk; *g*, germinal vesicle.

F. Part of an ovule of $\frac{1}{40}$ of an inch in diameter highly magnified: *v*, minutely granular or primitive yolk substance; *g*, germinal vesicle; *z*, thick consolidated membranous layer which formed a vesicular covering for the primitive ovule, and which corresponds to the zona pellucida of the mammiferous ovule.

I and K are intended to illustrate, diagrammatically, the view, that after the disappearance of the zona, and the formation of larger granular yolk cells, the outer layer of the cells of this substance forms the permanent vitelline membrane of the bird's egg; *v, d*, remains of minutely granular yolk, forming the vitelline disc round the germinal vesicle; *s, g*, large corpuscles of the yolk; *v, m*, outer layer of the cells of the same, on which the vitelline membrane is afterwards formed.

been looked upon as the primitive or first-formed structures connected with the origin of the ova, the germinal vesicles subsequently making their appearance within them. We shall return to this point hereafter in connection with the history of the mammiferous ovum. My own observations agree with those of Barry, as I have sometimes observed very small germ-vesicles or cells in the ovarian stroma without any follicular covering. But it must be admitted, at the same time, that in birds the ovisac or ovarian vesicle is formed so early that it is observed almost always coexisting with the germinal vesicle or rudiments of the ovule; so that, if the latter takes the precedence of the ovisac, it must be by a very short period.

According to Barry, there is seen almost from the first, in the clear germinal vesicle, a minute distinct granule or round spot, which constitutes the first state of the macula germinativa. Very soon the vesicle is surrounded by a small quantity of a clear fluid in which are rapidly deposited globules or granules constituting the first rudiments of yolk substance. There is no vitelline membrane, however, in birds, at the first; nor are the larger cells which at a later period intervene between the ovisac and the primitive yolk, formed in the earliest stage. The smallest ovisacs which Barry observed, and which consisted of perfectly simple vesicular linings of the cavities containing the rudimentary ova, in the pigeon and common fowl, were from $\frac{1}{600}$ to $\frac{1}{300}$ of an inch in diameter.* At a somewhat later period, the number of maculæ (nuclei) in the vesicle, and of the yolk granules externally, had increased, and a delicate membrane, which he describes as vitelline membrane, and believed apparently to be the same which afterwards surrounds the large yolk in the fully-developed ovum, has made its appearance. At this period also there begin to be formed within the ovisac a set of larger nucleated corpuscles or cells, which are external to the true ovum, and which may be considered as corresponding with the so-called granular contents (substantia and tunica granulosa) of the Graafian follicle in mammalia.

The early structure and development of the ovum of birds have more recently been described, with considerable detail, from observations on the chaffinch and common fowl by Dr. H. Meckel*; and as the observations of this author have led him to take a somewhat different view of the relations of some of the parts of the ova of birds and other animals from that which has hitherto been generally adopted, it will be proper to give a particular account of them in this place. Many physiologists have felt the incongruity of the comparison generally made between the minute and simple ovum of the mammifer, and the large and more complex yolk of the bird, and most are disposed to acknowledge the necessity of making some more marked distinction between the granular and the cellular yolk substance in the two great groups to which these ova respectively belong. It has before been stated, that Von Baer on his discovery of the mammiferous ovum, regarded it as corresponding, not to the whole ovum of birds, but to the vesicle of Purkinje. The discovery, in 1834, of the germinal vesicle in the mammiferous ovum, of the existence of which Von Baer had no distinct knowledge, induced Valentin and others to maintain that the essential parts of the ovum are the same in the bird and the mammifer. But it may be doubted whether physiologists may not have proceeded further than they were warranted by observation in regarding the vitelline membrane and large corpuscles of the yellow yolk of birds as essentially corresponding parts with the zona pellucida and the smaller granular yolk of the mammifer. For the membrana vitelli of the bird's egg may, perhaps, be more analogous to the outermost layer of the membrana granulosa of the Graafian follicle, and the large cellular yolk to a part of the same substance or the fluid of the Graafian follicle; while the minutely granular yolk in which the cicatricula originates and the germinal vesicle together are the true representatives of the small ovum of the mammifer. It seems undoubted, that what we term the yolk membrane in the fowl's egg does not exist in the early stages, and is formed indeed only as the ovarian egg approaches maturity, and it is admitted that no large cells similar to those of the bird's yolk exist within the cavity of the zona pellucida of the mammiferous ovum. If this view is correct, we may expect to find a representative in the egg of the bird and of other animals having similar ova, of the very marked enclosing vesicle, which has received the name of zona pellucida

* Vide loc. cit. Plate v., figs. 18, 19, and 22 of pigeon; figs. 23 and 24 of common fowl. The membrane which Barry described as vitelline in the earliest stages of growth of the bird's egg was probably not so, but the outline merely of the albuminous substance in which the primitive yolk granules are deposited. This will be made more apparent in our description of the formation of the ova of Batrachia.

* See his paper, Die Bildung der fur partielle Fürchung bestimmten Eier der Vögel, &c., in Siebold and Kölliker's Zeitsch. für Wissenschaft. Zool. vol. iii. p. 420, 1852.

in the mammiferous ovum. Now, according to H. Meckel there is, not from the very first, but in the earlier stages of formation of the yolk of the fowl and of other birds, a homogeneous vesicular membrane enclosing the primitive or granular yolk, or what he terms the true egg substance. As the cellular yolk is formed, this membrane, to which he thinks himself warranted in giving the name of zona pellucida, disappears, and already in ova above $\frac{1}{10}$ of an inch there is no trace of it left.

The observations of H. Meckel on this subject appear to be both novel and important; but he has not been equally successful in the theoretical deductions made from them. In the commencement of the paper before referred to, he thus announces his view of the morphology of the bird's egg: "For a right and consistent nomenclature and definition, we must designate the corresponding parts according to their analogy with those of the human body. I believe, therefore, that that alone ought to be regarded as the true egg which exists in Man, Mammalia, Naked Amphibia, and Osseous Fishes; and that in the remaining Vertebrata the ovum consists only of the so-called vesicle of Purkinje, and that all the other parts are accessory, superimposed, and unessential. In particular, that the yellow yolk of the bird and scaly reptile is analogous to the corpus luteum of the human ovary, the albumen ovi to the uterine secretion, and the calcareous shell to the decidual mucous membrane of the uterus." Von Baer, at p. 32. of his Epistola, uses the following words, which have been much controverted by some of those coming after him, but which show that he was aware of the difference in the relation of parts in the birds and mammiferous ovum: "Vesicula ergo Graafiana cum ad ovarium generatimque ad corpus maternum respiciamus, ovum sane est Mammalium, sed evolutionem quod attinet, vehementer discrepat a reliquorum ovo animalium," &c. And again, "In mammalibus vesicula innata vitellum magis excultum continet, et ratione ad fetum geniturum habita verum sese probat ovum. Ovum fetale dici potest in ovo materno. Mammalia ergo habent ovum in ovo; aut, si hac dicendi formula uti licet, ovum in secunda potentia." Both in the Epistola, and the Commentary upon it, Von Baer insists strongly on the analogy between the cellular substance of the Graafian follicle and the yellow yolk; and he seems to have erred chiefly in limiting his comparison of the mammiferous ovum (within the zona) to the vesicle of Purkinje of the bird's egg. If, therefore, we modify Von Baer's view so much as to regard the vesicle of Purkinje along with the granular cicatricula of the bird's egg, as corresponding to the whole of the mammiferous ovum, and the granular cells (tunica granulosa, &c.) of the Graafian vesicle as corresponding to the yellow yolk (the zona pellucida having disappeared in the bird's egg), we shall establish a more correct relation of the parts than that suggested by H. Meckel. I am not aware of any animal in which the germinal vesicle alone, without some yolk substance and an external inclosing membrane (zona, or vitelline membrane) forms the entire ovum.

I will now state the result of my own observations on this subject, by which I conceive is proved the correctness of H. Meckel's view, that in birds there is a primitive ovum, enclosed within a zona, distinct from the large mass of cellular yolk, which is formed at a later period.

As soon as the membranous wall of the ovisac or ovarian follicle has become distinct in the ovary of the fowl, we can perceive at the same time a layer of larger cells lining it which form a clearer ring round the opaque ovule. The ovule itself consists then merely of the germinal vesicle and a small quantity of the primitive yolk substance. The latter becomes opaque at so early a period that it in general hides completely the germinal vesicle. It seems to arise by the deposit of very fine granules, probably of an oily nature, in a dense albuminous fluid or blastema which collects round the germinal vesicle very soon after the latter is invested by the ovarian follicle. In follicles of $\frac{1}{100}$ of an inch in diameter the primitive ovule, the membrane of the enclosing follicle, and between them the layer of larger clearer cells, are all perceived with facility. There is not yet, however, any investment of the ovule comparable either to a zona pellucida or vitelline membrane.

In ovarian follicles of $\frac{1}{30}$ or $\frac{1}{40}$ of an inch in diameter, a farther progress is to be perceived. On bursting any such follicle with fine needle points, the ovum is ruptured, and the germinal vesicle usually first escapes along with the more fluid internal part of the yolk, in which it is freely suspended. This vesicle is about $\frac{1}{130}$ of an inch in diameter, presenting externally a smooth, thin and delicate vesicular membrane of a spherical form, of which the double outline is just discernible with a magnifying power of 300 diameters. The vesicle is partly filled with fluid and partly with a finely granular spherical mass of no great opacity, which corresponds to the macula germinativa. In most instances this mass occupies about two thirds of the diameter of the vesicle. The yolk substance, which has scarcely altered from its primitive opaque finely granular condition, now consists of a more fluid internal part containing fewer granules, and in which the germinal vesicle floats, and of a more consistent external part. In the latter a manifest change has occurred in this respect, that towards the outer surface there is separated a much clearer ring of substance contrasting strongly with the more opaque part. This may with correctness, it is true, be described as a membrane, as H. Meckel has done in comparing it with and giving it the designation of the zona pellucida. But the very remarkable structure, which the author now mentioned has had the merit of first pointing out, is one deserving of the greatest attention. It has appeared to me to be gradually formed in ovula of about $\frac{1}{80}$ or $\frac{1}{60}$ of an inch in diameter, by the clearing and partial consolidation of the outermost part of the albuminous basis or blastema in which the granules of the primitive yolk substance are deposited. It is at first comparatively thin: it is most apparent by its greater clearness and consistence in ovules of $\frac{1}{40}$ or $\frac{1}{30}$ of an inch in diameter, in none of which have I ever failed to observe it. In those of $\frac{1}{20}$ it becomes broader, but less clear and somewhat softer in its consistence, and is uneven and as if softening away or breaking up on the external edge; and in ovules of $\frac{1}{10}$ of an inch it has in general disappeared. At no period have I observed it to assume the glassy transparency, nor has it the distinct outline and membranous appearance represented by H. Meckel; but it seemed rather like a portion of the albuminous basis of the yolk substance, nearly but not quite deprived of the granules, which are thickly deposited in the rest.

While these differences are stated, however, it appears to me warrantable to coincide in so far with the view of H. Meckel as to regard this structure as a temporary representation in the fowl's egg of the zona pellucida, which in the mammiferous ovum assumes greater consistence, passes into the membranous form, and constitutes the only ovarium covering of the ovule.

In ovules of $\frac{1}{30}$ to $\frac{1}{20}$ of an inch in diameter, the layer of nucleated cells placed between the primitive ovule and the membrane of the follicle, and which may be looked upon either as a cellular lining of the follicle or a peculiar investment of the ovule, has become more distinct and consistent, and the cells of the outermost layer have assumed the form of short compressed prisms. They have finely granular contents and clear nuclei, with one or sometimes two nucleoli, like the cells of the tunica granulosa of the mammalian follicle. It appears that these cells come afterwards to form the external part of the yolk of the bird's ovum, the cellular part of the yolk being formed within them, and the vitelline membrane being produced on their outer surface.

The bird's ovule, it is well known, usually fills completely the ovarian follicle; but in several instances I have observed, from imbibition of water or some other cause, the ovule to occupy not more than half the diameter of the follicle, the remainder being filled with a clear fluid; and in these instances the prismatic layer of cells adhered closely to the surface of the zona and primitive granular yolk.

In ovules of from $\frac{1}{20}$ to $\frac{1}{10}$ of an inch the formation of the vitelline membrane appears to commence. The external nucleated cell covering has increased in quantity, and adheres more closely to the granular yolk, with which it generally comes away when the follicle is opened. The external edge of the layer of prismatic cells, the length of which is considerably increased, is now surrounded by a narrow pellucid space enclosed by a double line, presenting the appearance as if a small part of the bases of these cells had been fused together in a homogenous film. This is the commencement of the formation of the true vitelline membrane, which in the latest period of ovarian growth of the ovum becomes nearly quite structureless, but which throughout the greater part of the process retains somewhat of the hexagonal marking from the close adhesion of the cells by the amalgamation of a part of which the membrane has been produced.

In follicles of about $\frac{1}{10}$ of an inch or larger the true cellular elements of the yolk have begun to be formed. The manner in which these originate I have not as yet had the means of determining with precision. They appear, as H. Meckel has suggested, to be produced as a secretion from the interior of the ovarian follicle; but they are more immediately formed within the layer of prismatic cells which envelope the whole ovule. Nor have I been able to determine their precise relation to the zona and primitive fine granular yolk. When the zona has disappeared, as is usually the case in ovules of $\frac{1}{10}$ of an inch, the cellular elements of the yolk seem to begin to mingle with the finely granular substance. At first, cells and larger oil globules, similar to those of the yolk cavity, are produced. So long as these alone exist, the yolks have a dull milky-white aspect. Later, or in those of $\frac{1}{6}$ of an inch, or even somewhat smaller, the yellow tinge appears, and this very soon becomes more decided, at the same time that the peculiar large granular corpuscles or cells are formed in which the vitelline colouring matter principally resides. These corpuscles are produced in successive layers within the layer of prismatic cells of the external tunic; and it is probable that there is some periodical variation in the rapidity of their formation from the alternation of concentric layers of deep yellow corpuscles with those of a lighter colour which may be observed in the section of a boiled yolk. The corpuscles of the yellow yolk are not, however, formed in equal quantity in every part: indeed they are quite deficient at that side on which the remains of the primitive granular yolk with the imbedded germinal vesicle are situated.

With regard to the germinal vesicle, it is to be observed that it is at first quite free in the more fluid internal part of the primitive yolk; in the next stage, before the formation of the cellular yolk, the germinal vesicle comes to be imbedded in the more consistent external part of the primitive granular yolk; and it is, no doubt, chiefly the remains of this which form the germinal or vitelline disc: but further observations are still required to determine the precise manner in which this arrangement of the primitive yolk in the discoid shape takes place.

It appears, further, that in the formation of the elements of the more advanced yolk, the earliest produced, or innermost, remain the softest; the latest formed, or outermost, acquire the greatest consistence. The external layer of prismatic cells next the vitelline membrane passes with it completely round the whole yolk and over the vitelline disc; the next layer, less prismatic and more rounded in their form, but still distinctly nucleated cells, covers the whole surface of the yolk, with the exception of the part occupied by the vitelline disc, with the margin of which this layer is continuous. The next layers passing inwards consist of granular corpuscles, which do not in general present the appearance of nucleated cells.*

In conclusion, therefore, the ovarian ovum of the bird being formed in an ovarian capsule, is at first very similar to the Graafian vesicle of the mammalia, and differs chiefly in the earliest stages from the mammiferous ovum in the proportionally large size of the germinal vesicle, and in the absence from this vesicle of the more distinct and persistent nucleus which exists in animals having the smaller yolk. This germinal vesicle may be looked upon as the fundamental part of the ovum in both kinds of animals. Along with it there exists, from a very early period in birds, a granular opaque yolk substance. This substance by itself constitutes the whole yolk of mammalia; but in birds it probably remains as a part, if not the whole, of the proligerous disc (afterwards cicatricula). The mammiferous ovum is closely surrounded at an early period with a dense transparent membrane (the zona pellucida) formed by a condensation of the outermost layer of the albuminous part of the yolk; and a similar envelope, but less dense, exists in the earlier stages of formation of the fowl's egg, surrounding the finely granular primitive yolk substance along with the germinal vesicle. In both birds and mammalia the ovarian follicle, besides being lined with a layer of epithelial cells, secretes, or has formed immediately within it, a quantity of nucleated granular cells more loosely united together, known in mammalia by the somewhat inappropriate names of tunica granulosa and substantia granulosa of the ovarian follicle. But in birds, although this substance is at first somewhat similar in structure and relations, cells afterwards increase within it in very large quantity, and acquire a peculiar structure and colour, constituting the yellow part of the yolk substance. The outer covering of the yolk, or vitelline membrane, is only produced when the ovule has attained considerable advancement, by a new deposit upon the external surface, or by the condensation of a part of the external layer of these cells, which covers the whole yolk, together with the cicatricula. The germinal vesicle is fixed in the bird's yolk, towards the surface, in the proligerous disc. In the mammiferous ovum the germinal vesicle is, for the most part, near the surface of the yolk substance, but not so far as is known in a determinate situation, and the whole ovum in its zona pellucida is fixed in the tunica granulosa towards that part of the follicle which is next the surface of the ovary.

The germinal vesicle bursts or is dissolved in both. In mammalia it is probably diffused through or over the whole granular yolk: in birds it probably overspreads only the proligerous disc. The whole yolk is segmented in mammalia, while in birds this process is confined to the proligerous disc, out of which the blastoderma is produced.

The full description now given of the structure of the bird's egg will enable me to treat comparatively briefly of that of other animals. In regard to most of them, indeed, it will scarcely be necessary to do more than to notice their most important peculiarities.

Before leaving the ova of the first group, it may be noticed on the authority of Leuckart*, that in the scaly reptiles there is not the same difference between an external coloured yolk and the lighter cavity as in birds, but that the whole yolk substance is of a paler colour, and of a more clear and uniform appearance. Still from a preponderance of oily matter in the vicinity of the cicatricula, there is the same tendency to that part of the ovum floating uppermost. The germinal vesicle in the ovarian ovum of these animals presents at an early period a very subdivided condition of the macula; and it is placed in a granular disc, which does not appear to differ essentially from that of birds. The vitelline membrane is equally structureless. Leuckart has traced the development of the ovum in Lacerta crocea and Coluber lævis, and has ascertained that in them, as in birds, the primitive yolk substance is destitute of cellular elements, and has at first no special covering. The true or external vitelline membrane is probably formed, precisely as in birds, on the exterior of the outermost layer of the cellular part of the yolk.

In the cartilaginous fishes there is a greater departure from the type of structure now described. The external vitelline membrane is of

* While the above was passing through the press, I received the 27th and 28th parts of R. Wagner's Handwörterbuch der Physiologie, containing the Article "Zeugung," by Professor Leuckart of Giessen. I regret that I have not previously had the advantage of perusing the very luminous and comprehensive sketch, by that author, of the structure and morphology of the ovum of different animals. As, however, Professor Leuckart has stated that his observations do not confirm the statements of H. Meckel in regard to the zona pellucida of the bird's ovule, I have thought it right, notwithstanding the unfavourable period of the year (October), to repeat carefully my examination of this matter; and I have here to state that, in the common fowl and thrush, the description given above has received the fullest confirmation. While, therefore, I am inclined to differ, as above stated, from the views of H. Meckel as to the morphological analogy of parts of the ovum in different animals, I must admit the existence, at a certain stage, of the very peculiar structure pointed out by him, as corresponding with the zona pellucida, with the differences as to details which I have there mentioned. The primitive ovule of the bird therefore consists of the germinal vesicle, granular yolk, and this so-called zona; and the cellular substance of the bird's yolk, is the product of secretion, or is a modification of epithelial formation from the interior of the ovarian follicle.

* Art. *Zeugung.*

great delicacy, and is perceived only with difficulty. The yolk substance is in great part composed of peculiar angular corpuscles, sometimes flat and tabular, at other times cubical, octahedral, and of other forms. It has been stated by Leydig * that in the plagiostomatous fishes there is no vitelline disc or cicatricula ; but this does not agree with my observations in the common skate fish, in the ova of which I have always observed a very distinct flat disc about three-eighths of an inch in diameter, of a lighter colour than the surrounding part of the yolk, and situated on the surface which naturally floats uppermost. The germinal vesicle, which is larger than that of birds, sometimes $\frac{1}{40}$ of an inch in diameter, is extremely delicate and very easily ruptured. Its nucleus or macula is originally single, but becomes afterwards subdivided or multiple and diffused.

The ova of the cephalopoda, which may, according to most embryologists, be included in this group, are of considerable size. They possess a germinal disc, and the segmentation of the yolk is partial or is confined to that disc, as in the animals previously mentioned.† The large yolk corpuscles are spherical masses of united oil granules, and like the most of those of the bird's egg without any true enclosing vesicle. The germinal vesicle is of considerable size, and has subdivided maculæ. The whole are enveloped by a fine structureless vitelline membrane. In the course of the formation of the ovum, the external part of it undergoes a remarkable change in being folded inwards in numerous deep grooves, which almost reach the centre of the yolk. This folded structure is in the smaller species again effaced before the ova reach maturity, but in the larger species it appears to remain, and to be the cause of a peculiar reticulated marking over the surface of the ova.

In regard to other classes of the invertebrate animals of which the ova may appear to belong to this group, I shall have occasion hereafter to state some additional facts, in explanation of the manner in which in some of them the granular and cellular elements of the yolk are occasionally combined.

From the foregoing considerations, then, it appears that in ova of the first group as distinguished in this treatise, the germinal vesicle is at once the first formed and the fundamental part of the ovum around which the rest of the parts are deposited. It alone, therefore, is strictly to be regarded as a simple or primary cell. It may aptly be called the *Germ-cell.* In birds its nucleus or macula is originally simple, but at a very early period it undergoes subdivision into nucleoli or maculæ, so numerous and minute as at last scarcely to be recognisable, and thus the germinal vesicle loses in such animals somewhat the characteristic cellular structure which it presents in many others. Next, by aggregation of the primitive yolk substance round the germ-cell, and by the gradual consolidation of a clear film on the outermost part of the albuminous matrix of this substance into the form of an enclosing vesicle, there is produced the *primitive ovum*, a secondary cell, in which the zona pellucida constitutes the cell wall, the oil granules and albuminous fluid of the yolk substance the contents, and of which the germinal vesicle is now the nucleus. And lastly, if it is considered desirable to extend the application of the term cell also to the mature state of the ovarian egg of the bird, we may perhaps still regard that organism as a tertiary cell (in the ascending series) formed by the superposition of new parts, some of which are themselves cellular in their origin, round the primitive ovum, the whole being at last enclosed and moulded in the vesicular form by the external vitelline membrane ; a peculiarity of this formation being that in the meantime the wall of the secondary cell or primitive ovum has disappeared. But, notwithstanding the spherical form, the isolated position, and the simple structure of the parts which compose the completed ovarian ovum of birds, doubts may fairly be entertained as to the propriety of bringing such complex organisms under the designation of cell as now generally employed.

§ 5. More detailed description of ova belonging to the second group, or with small granular yolk and complete segmentation.

If the foregoing views are correct, it appears that, while the ova of birds and other animals of the first group contain within the vitelline membrane the whole product of formation which belongs to the ovarian capsule, the ova of mammalia and animals of the second group comprehend only those parts of the contents of the Graafian follicle which are formed within it at the earliest period — viz., the germinal vesicle and the primitive yolk substance with its limiting zona. In the Graafian follicle of mammalia, there is likewise produced a large proportional quantity of cellular elements and albuminous fluid, the tunica and substantia granulosa, &c., in a part of which (cumulus proligerus), the ovum comes to be imbedded in the progress of their formation ; and these superadded contents of the Graafian follicle escape along with the ovum when it leaves the ovary, but do not apparently maintain any long or constant connection with it.

In the ova of those invertebrate animals which belong to this group, the conditions of formation do not admit of their comparison with those of mammalia ; but they agree with them in so far that the first germ-cell is enclosed by a finely granular yolk, and that the vesicular envelope of the ovum generally corresponds to the zona formed by consolidation on the surface of the primitive yolk.

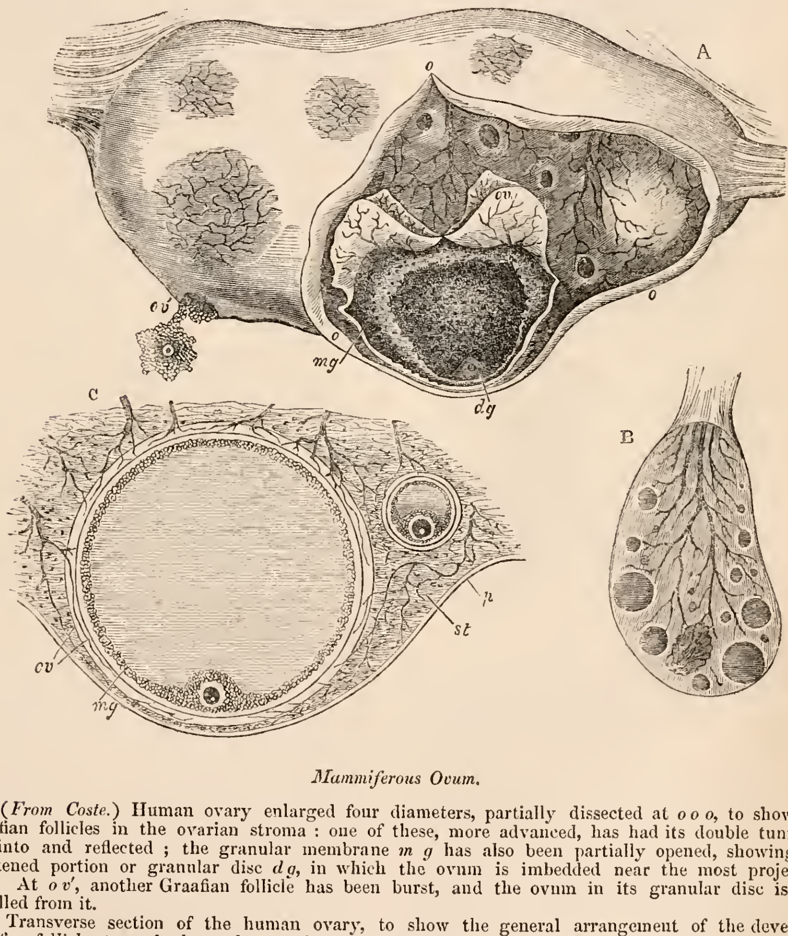
* Beitrage zur Mikroskop. Anat. der Rochen und Haïen, p. 87., a work which I quote only from Leuckart.

† We owe this interesting discovery to Kölliker. See his work on the Development of the Cephalopoda. Zürich, 1844.

Ovum of Mammalia and of the Human Species.— There is a remarkable uniformity in the size, structure, and relations of the ovarian ovum in the whole class of Mammalia, with the exception of the families of Marsupiata and Monotremata; in the last of which especially there is an approach to the oviparous type. We shall first consider the more common form of the mammiferous ovum. Of this the most marked characteristics are, as has already been stated, the very small size in proportion to the ovarian follicle, the finely granular yolk-substance, and the dense, clear, and firm external covering or zona pellucida.

The Graafian follicles, or ovarian vesicles, in which the ova are situated, attain, when mature, a size of from $\frac{1}{50}$ to $\frac{1}{4}$ or even $\frac{1}{2}$ an inch, varying in size in some measure with, but not in exact proportion to, the stature of the animals. In the human ovary these follicles are firm spheroidal sacs, which attain when mature an average size of about $\frac{1}{8}$ of an inch. In the ovaries of women, during the child-bearing period, a number of smaller follicles lie throughout the greater part of the substance of the ovary; the more developed follicles being usually placed towards the free surface, but at some little distance from it. As they enlarge and approach maturity, the ovarian substance appears to give way to them, or to become gradually thinner between the follicles and the outer surface of the ovary, so as at last to leave almost nothing but the covering membranes of the ovary at the most projecting part. Even when of their full size, however, the Graafian follicles of the human subject and of most animals do not project much beyond the general surface of the ovary;

Fig. 54.*



Mammiferous Ovum.

A. (*From Coste.*) Human ovary enlarged four diameters, partially dissected at *o o o*, to show the Graafian follicles in the ovarian stroma: one of these, more advanced, has had its double tunic *o v* cut into and reflected; the granular membrane *m g* has also been partially opened, showing the thickened portion or granular disc *d g*, in which the ovum is imbedded near the most projecting part. At *o v'*, another Graafian follicle has been burst, and the ovum in its granular disc is seen expelled from it.

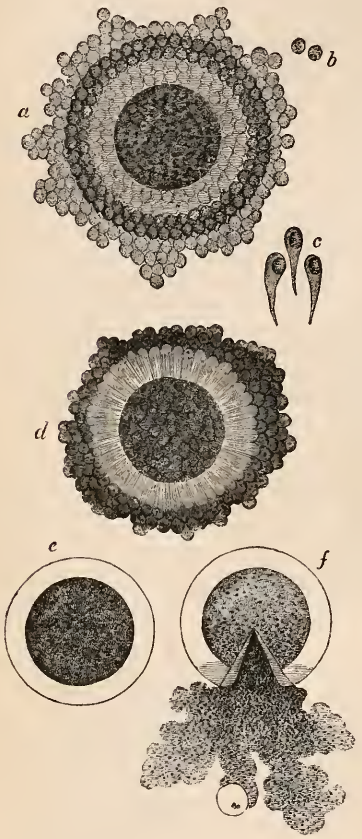
B. Transverse section of the human ovary, to show the general arrangement of the developed Graafian follicles towards the surface; twice the natural size.

C. Diagrammatic representation on an enlarged scale, in section, of two Graafian follicles, in different stages of advancement in the ovary of a mammifer. *p*, peritoneal covering of the ovary; *st*, ovarian stroma; *o v*, the two layers of the ovisac; *m g*, membrana granulosa, near which is the discus granulosus, with the ovum imbedded.

but in some animals, in which the vesicles are proportionately more expanded, they extend beyond the general line of the surface in various places, and even sometimes give the ovary somewhat of the mammillated or grape-like appearance more common among oviparous animals.

The follicle is filled to distension with a clear albuminous fluid, which escapes with force when an incision is made through the

Fig. 55*.



Ovarian ovum of the Dog. (*From Bischoff.*)

a, magnified representation of the ovarian ovum of the dog, nearly mature, situated in the discus proligerus and part of the cells of the granular membrane; *b*, several detached granular cells.

d, another ovarian ovum of the same animal perfectly ripe, immediately previous to the rupture of the Graafian follicle; the cells of the proligerous disc have become of a pediculated shape; *c*, some of these cells detached.

e, the ovum from the same specimen as in *fig. a*, freed artificially from the granular cells of the disc, showing externally the thick clear zona or external membrane, and internally the opaque yolk substance: in the latter the germinal vesicle is obscured by the opacity of the substance surrounding it.

f, the same ovum burst by pressure, showing the contents of the ovum which have escaped, viz. the finely granular yolk substance and the germinal vesicle with its macula.

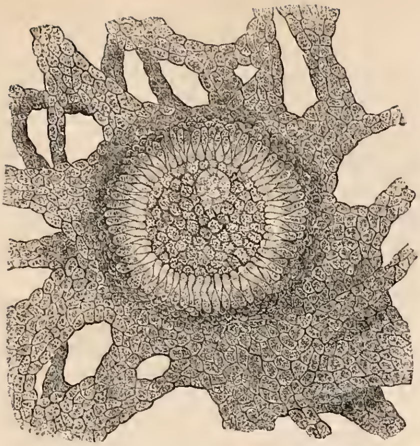
membrane. Close to the inner surface of the follicle, and surrounding the fluid, is situated the layer of nucleated granular cells which has been termed *tunica* or *membrana granulosa*, from the opaque granular appearance of the cells composing it. These cells form a complete vesicular lining of the follicle; but throughout the greater part they cohere with only a moderate degree of firmness, so that the membrane readily tears when the follicle is opened. The minute ovum is imbedded in a thicker portion of this layer, the *cumulus* or *discus proligerus* of Von Baer, and is almost invariably situated close to the inner surface of the most projecting part of the Graafian follicle (see *fig*. 54*. A. and C., *mg*.) where in some animals, but not in the human ovary, the ovum may be detected in the undissected follicle through its coats and the ovarian coverings.

The cells of the membrana granulosa are in general about $\frac{1}{2400}''$ in diameter. They adhere with considerable firmness to the surface of the zona; so that when the follicle is opened and its contents are allowed to run upon a plate of glass for examination, the ovum is always found placed in its disc in a circumscribed attached portion of the membrana granulosa of about twice its own diameter. The ovum is itself of a nearly perfect spherical form when freed from pressure; but as it lies thus imbedded in the membrana granulosa, and moistened on a plate of glass, it gives rise to a slight rounded elevation in that membrane, which may easily be detected with the naked eye when the specimen is viewed sideways.

When the contents of the Graafian follicle are discharged naturally during life, a small aperture occurs nearly in the centre of the most projecting part of the wall of the follicle; and as the ovum lies near this place in the membrana granulosa, it is liable to be evacuated first, along with a portion of that membrane, which is soon torn away from the rest by the pressure of the fluid behind it, impelled by the contraction of the walls of the follicle and surrounding ovarian substance. During the descent of the ovum through the Fallopian tube the cells of the proligerous disc immediately surrounding the ovum alter their form, and are subsequently detached from the zona, so as to leave its external surface quite free and smooth. I have not, any more than Bischoff, been able to observe the four retaining straps or retinacula described by Martin Barry in his first series of Researches, as portions of the membrana granulosa naturally thicker than the rest, and which, radiating nearly at right angles from the proligerous disc, serve, as it were, to guide the ovum and its disc towards the aperture by which it escapes on the bursting of the follicle. The accompanying figure from Coste (56*.) gives that author's view of a structure somewhat similar to the retinacula of Barry.

The size of the mammiferous ovum itself is much more uniform among the different families of Mammalia than that of the Graafian follicle,

Fig. 56*.



Ovum of the Rabbit in the tunica granulosa. (*From Coste.*)

The middle part of one of M. Coste's figures has been here copied to show the peculiar arrangement of the granular cells round the disc and ovum, which according to him are of the same nature with those described by Dr. Martin Barry as *retinacula*. It may be doubtful whether this structure is constant.

and bears no regular proportion in different families of animals to the stature of the whole body. In the mature state this variation extends from $\frac{1}{140}$ to $\frac{1}{260}$ or $\frac{1}{300}''$. The following are the results of a few measurements made by myself and others of the external diameter of the mature ovarian ovum, viz., man $\frac{1}{180}$, dog $\frac{1}{160}$, cat $\frac{1}{180}$, rabbit $\frac{1}{150}$, rat $\frac{1}{200}$, mouse $\frac{1}{220}$, pig $\frac{1}{200}$, cow $\frac{1}{250}$, guinea-pig $\frac{1}{240}''$.

The external tunic, or zona pellucida (a term founded on the description of Von Baer*, from its presenting the appearance of a transparent ring between the opaque granular yolk-mass within and the granular cells externally), is of great proportional thickness; viz., from $\frac{1}{1500}$ to $\frac{1}{2500}''$, or from $\frac{1}{8}$ to $\frac{1}{12}$ of the whole diameter of the ovum. When entirely freed from the granular cells, its external surface appears smooth; and the inner surface, which is exactly parallel to the outer, is also remarkably smooth. The substance of this tunic is very tough, and possesses considerable elasticity; so that the ovum and its zona may be flattened by external pressure to a great extent; and yet it regains its nearly spherical form when the pressure is removed. It is of glassy transparency and homogeneous; neither any laminated, nor fibrous, nor other structure being perceptible under the highest magnifying power. It is easy to obtain evidence that it is one thick membrane, and not composed of two layers with intervening fluid, as some have held, by cleaving it with fine needle-points, when the cut edge becomes fully apparent. It has recently been stated by Remak*, that in the mature ovarian ovum of the rabbit, when freed from the granular cells, radiated lines may be perceived running quite through the zona pellucida; these linear radiations, he conceives, indicate a peculiar structure of the zona, somewhat similar to the perforated condition of the outer membrane of the ovum in osseous fishes. I have perceived some of this radiated appearance; but I am inclined to believe that it depends not on any structure of the zona itself, but rather on the marking produced by the adhesion of parts of the cells of the tunica granulosa, which become pediculated in very ripe ova, and have then a radiated appearance on the zona under pressure; as represented by Bischoff in his view of the ovum of the dog, of which *fig.* 55 D. is a copy. I shall have occasion afterwards to state the nature of the fine canals which have been observed in the outer tunic of fishes' eggs.

It has been customary among ovologists, till very recently, to look upon the zona as corresponding to the external membrane of the yolk in the bird's egg. But from what has been already said in connection with that subject, the propriety of drawing a distinction between these two envelopes has been fully shown. I prefer, therefore, to retain the name of zona pellucida, though it may not be perhaps the best designation, as it prevents all confusion which might be introduced by views of its analogies. It will hereafter be more fully demonstrated that it not only differs in its mode of origin from the true vitelline membrane of birds, but that it also has a different destination in connection with embryonic development, inasmuch as, though formed in the ovary, it remains and constitutes the basis of, or becomes incorporated with, the important structure which at a later period becomes the chorion.

In the foregoing description of the membrane of the mammiferous ovum, I have adopted the view first advocated by Coste†, and by Thomas Wharton Jones‡; and more fully brought out and established by the researches of Bischoff in his admirable works on the development of the Rabbit and the Dog.§ It may be proper to remark farther, that though the name of zona pellucida has been employed to designate the thick single tough membrane by which, as is now well ascertained, the yolk of the mammiferous ovum is invariably enclosed from an early period of its formation in the ovary, this term is used synonymously with that of vitelline membrane, and as applied to

the only covering with which the ovarian ovum is provided at the time of its leaving the Graafian vesicle, excepting that which it retains for a time derived from the cells of the tunica granulosa in the proligerous disc. Von Baer indeed, from whose description the term pellucid area or zone has been borrowed, was not fully aware of its consisting only of one thick membrane; and more than once, both in the Epistola and in the Commentary upon it, expresses himself doubtfully as to whether this pellucid space or halo* might not be formed of an external envelope which he terms the cortical membrane, and of another situated within it.

It is well known that when the mammiferous ovum has been fecundated, and arrives in the cavity of the uterus, and begins then rapidly to expand, it is covered by a membrane which soon undergoes great extension, and acquires a villous structure on its external surface, by which it may always be easily recognised. This villous envelope of the uterine ovum, universally now known as the chorion, is the product no doubt of changes which only occur in their completeness after fecundation, and as an accompaniment of embryonic development; but still as it appears probable that the zona pellucida is intimately connected with the first condition of the chorion, and as the first formation of the latter membrane is by many believed to take place independently of fecundation or fœtal development, it is necessary for me to make some remarks in this place on the relations of the zona pellucida to the external covering which the ovum obtains in the first periods of its residence within the female passages. This is a subject on which embryological writers are by no means agreed, and several of them indeed have themselves changed their opinions in regard to it in the progress of their researches.

Von Baer, the correctness of whose general views on the phenomena of development we have occasion to admire in almost every part of the subject of which he has treated, was at first of opinion that the chorion might arise in Mammalia from the outer of the two layers of which he at that time (though also doubtingly) conceived the external covering of the ovarian ovum to consist, and he looked upon this as a great difference or departure from analogy between the bird's egg and the ovum of the mammifer: but in his work on Development†, published eight years later than the Epistola and Commentary, he states his conviction from his observations, that in some mammiferous animals at least, such as the pig and sheep, the chorion is formed by external deposit on the surface of the ovarian ovum during its descent into the uterus, and therefore takes its origin more in analogy with the external covering of the bird's egg. At the same time he confesses that he was not able to reconcile this view with what he had seen in the dog and rabbit.

Valentin, in his Manual of the History of Development*, regarded it as most probable that the chorion is formed by the deposition and consolidation of an albuminous matter on the surface of the ovum during its descent through the first part of the Fallopian tubes; but though taking, as it appears, a perfectly correct view of this subject, he did not bring forward observations sufficient to establish the opinion which he had founded chiefly on analogical considerations.

We owe to Thomas Wharton Jones the first direct observation of the actual deposit of a layer of albuminous matter round the surface of the zona pellucida. But although Mr. Jones, in the observation which he made on the ovum of the rabbit within the Fallopian tubes on the third day after conception, was quite assured that a new structure had made its appearance in considerable thickness on the surface of the zona, yet he at first supposed that this might proceed from some change in the remains of the granular tunic which adhered to that membrane after it had left the Graafian follicle.† He afterwards, however, became aware of the source of this fallacy, and adopted the view that the mammiferous ovum receives a superadded structure, contributing to the formation of the chorion, in its descent through the tubes.

In the first series of his Embryological Researches, Martin Barry described not only the zona pellucida as recognised by other observers, but also a distinct vitelline membrane within it; and he conceived that the zona became afterwards the chorion. But in his second series he became aware, both from the statements of Wharton Jones and from his own observations, that a new deposit occurs in the rabbit's ovum; and this new deposit he now regarded as "the true chorion." He retained, however, for a time his view of the separate existence of a vitelline membrane; and thus described articulately three membranes as belonging to the mammiferous ovum, viz., vitelline membrane, zona pellucida, and chorion.‡ The first membrane he believed to disappear previous to the period of full maturity: the two last he regarded as together the source of the chorion of a later stage.

Bischoff also had not been aware from his earliest observations that any new deposit occurred round the ovum of the rabbit in the tubes; and even after he had become acquainted with this fact, and had observed it himself, as he did not detect a similar deposit on the ovum of the dog, he adhered to the

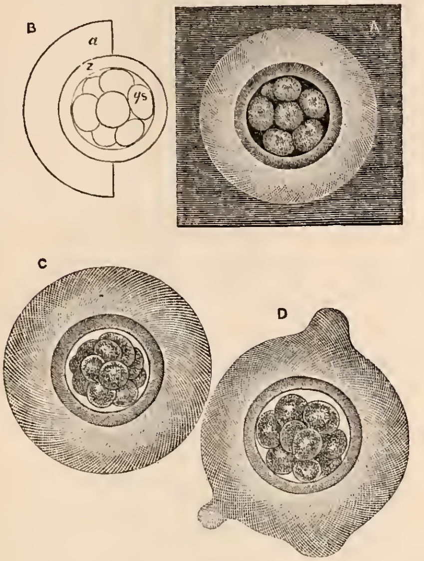
view which he had previously taken, that the zona becomes the chorion, or at least that a new deposit is not in all Mammalia necessary for the formation of that membrane.

Fig. 57*.



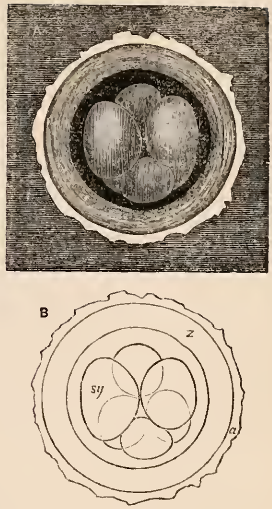
Ova of the Rabbit from the Fallopian tube three days after impregnation.

A, shows on a dark ground one of these ova, of which B is an explanatory outline. *y, s*, are the yolk segments of which there were eight; *z*, the zona; *a*, the thick layer of albumen which in this animal is always deposited on the exterior of the zona after the granular cells have been removed from it.

C and D. Other ova from the same animal; in D, are shown three projections of the albuminous covering which have been taken for villi of the chorion; but which according to Bischoff are not so. This ovum was farthest down in the Fallopian tube.

In a series of observations made by myself on the ovum of the dog and rabbit during their descent from the ovary to the uterus, in the summer of 1840, I was induced to adopt the opinion that a new deposit does really occur on the surface of the ovum in both of these animals. I repeatedly observed the large gelatinous or firm thick albuminous covering on the rabbit's ovum when it had just entered the cavity of the uterus; and in several instances I thought I could perceive the first formation of the villi of the chorion by sprouting or budding from the surface of the newly deposited substance, which, as in Wharton Jones' and Barry's observations, it was quite easy to distinguish from the membrane of the zona. In the ovum of the dog I admit, with Bischoff, the appearance is very different; but yet my observations appeared to me to demonstrate that in that animal also a substance is superadded to the surface of the zona, for that membrane, which presents at an earlier period a

Fig. 58*.



Ovum of the Dog from the Fallopian tube ten days after impregnation.

A. The yolk has undergone division into eight segments, and there is a thin irregular deposit of albumen on the outer surface of the zona. (This is represented too light in the figure.)

B. Explanatory outline of the same; *y, s*, yolk segments; *z*, zona pellucida; *a*, layer of albumen, from which in connection with the zona the chorion takes its origin.

perfectly distinct and smooth outline on its external surface, becomes in the course of the descent through the Fallopian tubes and by the time of its first arrival in the uterus, not only irregularly flocculent on its surface, but also thickened; in fact, presents all the appearance of a granulo-mucous substance having been deposited upon it.

It may be proper to explain here, that it has now been fully shown by Bischoff's excellent observations, that in both the animals mentioned, and also in the guinea-pig, the cells of the tunica granulosa, which adhere to the surface of the zona when it leaves the Graafian follicle, are completely separated from it within the first two or three days of the residence of the ovum within the tube, so as to leave the external surface of the zona perfectly smooth. Bischoff has shown, indeed, as I have also repeatedly observed, that a change has occurred in the cells of the proligerous disc, adherent to the ovum while it is still within the ovary, which indicates its approaching maturity. This change consists, as already stated, in these cells becoming somewhat spindle-shaped or pyriform, their narrow or pointed ends being attached to and radiating from the surface of the zona. (See as before *fig.* 55. D.) It is quite easy, therefore, after this separation takes place, to distinguish any change by addition of new matter or otherwise which the surface of the zona may undergo. No one can fail to perceive the addition to the ovum of the rabbit, the diameter of which is thus increased between two and three times, so as to give it somewhat the aspect of the ovum of a Batrachian in miniature; and in the dog it has appeared to me that the increased thickness and more opaque and flocculent roughness of the surface of the zona were sufficient proofs of a new deposit having taken place. This deposit, no doubt, becomes very completely incorporated with the substance of the zona, and is not easily to be distinguished from it; but in one or two instances I have thought that I was able to perceive a line of demarcation between them. Several of Bischoff's very faithful figures seem to me even to represent this deposit as it has occurred on the ova of the dog. But his statements in his work on the Development of the Guinea-Pig * are so precise against the occurrence of such a deposit, that further observations will be required fully to determine the question whether it is of constant occurrence or essential to the formation of the chorion.

Later observations lead me to think that I may have been in error in supposing that the villi of the chorion grow directly from the albuminous deposit. These villi, which, as I have said, form a most characteristic feature of the external covering of the mammiferous ovum in the course of development, begin to be formed only when the ovum has reached the cavity of the uterus. The time of the formation of these villi, as well as their size, varies, however, considerably in different animals, and probably also to some extent in the same animal.† They are developed from the external surface, and their structure is at first nearly homogeneous, or at least only slightly granular; they afterwards acquire a cellular structure, and in the course of fœtal development become at an early period the seat of a complicated vascular growth, by which the relations of the maternal parent and offspring are maintained through utero-gestation. But the fuller description of this part of the growth of the chorion belongs rather to the history of development after fecundation. My present object has been only to show the relation of this membrane to the zona or ovarian coverings of the ovum.

The contents of the ovum or parts within the zona consist of the yolk-mass or yolk-substance, and the germinal vesicle. The first of these constitutes a spherical mass of variable consistence, in which granules, or molecules and globules of various sizes, from the most minute up to about $\frac{1}{6000}$ or $\frac{1}{4000}''$, are suspended in a fluid. The proportion of the granules to the fluid varies to a considerable extent in different animals, the ovum being much more opaque, and usually of a dull-yellow colour when the granules are in large quantity, as is the case in most Carnivora, and may be easily seen in the dog or cat. The clear fluid in

a, ovarian ovum extracted from a nearly ripe Graafian follicle, and freed from the adherent granular cells; the close set granules of the yolk substance, among which the germinal vesicle is perceived with a slightly oval macula or nucleus, are well represented.

b, the same burst by pressure; the yolk granules adhering together by a viscid clearer fluid substance are seen escaping from the large aperture in the zona along with the germinal vesicle.

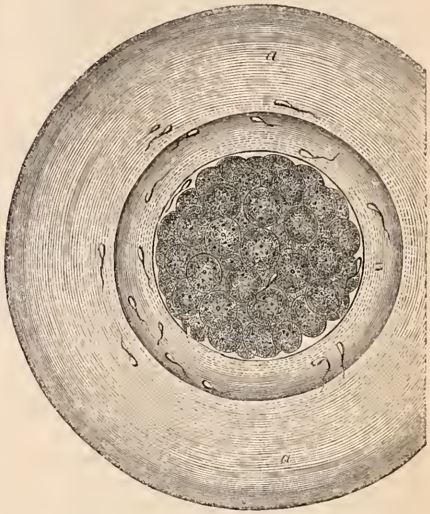
which the granules are suspended varies also in its consistence, being of a marked viscid quality in some instances, and thin and limpid in others; so that in some animals, when the zona is punctured, the yolk-substance flows freely out, while in others, and this is the case in the human ovum, the yolk-substance holds together as one consistent mass. The yolk-substance does not adhere in the slightest to the interior of the the zona, but on the contrary is readily detached from it; and in some instances, in the entire unimpregnated ovum, a space is seen between the yolk-substance and the zona, formed apparently by the imbibition of water between them. This separation between the yolk-substance and zona appears to be, at a later period, a constant and probably important change in connection with fecundation and development.

The granules of the yolk-substance are generally rather more densely set together and more firmly united towards the external surface. This circumstance has given rise to the belief among some observers in the existence of an additional delicate membrane enclosing the yolk-mass; but the most attentive observation by Bischoff, Wharton Jones, myself, and others has failed to detect such a membrane; and there is reason to think that the confident belief in its existence has had its origin in part at least in a desire to establish a more complete analogy between the ovum of birds and Mammalia, and to find accordingly a vitelline membrane as well as a chorion present in the ova of the latter.

The germinal vesicle is usually about a sixth of the diameter of the whole ovum; but it is sometimes larger, or between a fifth and a fourth. It possesses a delicate membranous wall of a spherical or spheroidal form and homogeneous structure: it is barely possible to observe the double line of the thickness of this wall with the quarter of an inch lens in the microscope. In most animals the germinal vesicle is readily distinguishable from the rest of the ovum by its superior clearness, excepting in those instances in which it is hidden by the great opacity of the yolk-substance; but then it may generally be made manifest by flattening the ovum by compression between plates of glass. The fluid which fills its cavity, which is generally very clear, contains some minute granules in suspension; and besides these there is apparent within it the macula germinativa or germinal nucleus. This last, which is in general well defined in the mammiferous ovum, varies slightly in different animals: in some presenting the appearance of a round globule, with a delicate circumscribing line almost amounting to a vesicular covering; but more frequently it consists only of a small spherical or discoid mass of fine granules. In a germinal vesicle of $\frac{1}{600}''$ in diameter, such as that of the rabbit, the diameter of the macula is about one-fourth of that of the vesicle, or $\frac{1}{2400}''$.

In the earlier stages of formation of the ovum the germinal vesicle is of smaller size; but it is then proportionally larger than the other parts. It is the part of the ovum first formed; the yolk-substance, which is subsequently deposited in gradually increasing quantity round it, together with the zona, grow at a more rapid rate than the vesicle, and thus the latter remains in the mature state proportionally smaller. As the yolk-substance is at first deposited nearly in equal quantity on every side of the vesicle, it for a time contains the vesicle in its centre; but as the formation of the ovum proceeds the vesicle is found in general to have approached the surface at one side of the yolk-substance; and in the mature ovum the vesicle seems to be imbedded in the most compact and superficial layer of fine granules of the yolk-substance. This place no doubt corresponds in Mammalia, as has been ascertained in Batrachia, to the point from which after fecundation the first cleavage of the yolk proceeds; but this fact has not yet been determined by observation in the Mammalia, nor has any one as yet succeeded in observing a canal or pore leading from the surface of the yolk-substance towards the germinal vesicle in the mammiferous ovum.

Fig. 60*.



Ovum of the Rabbit from the Fallopian tube with spermatozoa.

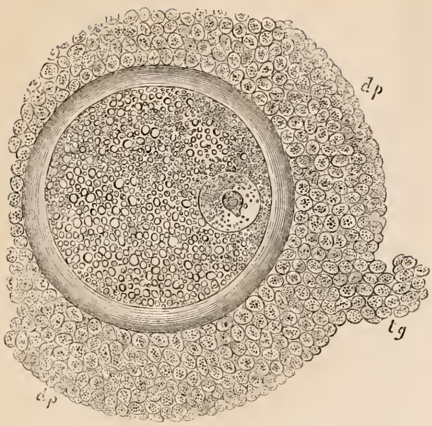
The accompanying figure is introduced to show the usual position of the spermatozoa in relation to the zona and albuminous layer in the ovum of Mammalia during and after impregnation. This ovum is magnified 250 diameters. It was taken along with five others from the lower part of the Fallopian tube 68 or 70 hours after impregnation. The segmentation appears to have proceeded to the fifth stage. There is a thick covering of albumen over the zona, and a number of spermatozoa are represented involved in the albuminous substance; some were also seen on the surface of the zona, and some, varying in number in the different ova observed from five to seven or nine, were clearly ascertained to be situated within the zona on the surface of and in the grooves between the yolk segments. The position of these last is not sufficiently clearly represented in the figure.

In the situation now described the germinal vesicle, though not by any means firmly fixed, is yet sufficiently embraced by the yolk-substance to prevent it from changing place when the ovum is moved in different directions. In the instances of the more fluid condition of the yolk it flows freely out from within the zona when this has been broken; but in those ova in which the yolk-substance is more viscid, as in the human ovum, we generally fail to isolate the vesicle from the rest of the substance.

The macula or nucleus appears to be attached to the inner surface of the membrane of the germinal vesicle. This is especially seen to be the case in the Pig, in which the macula seems to be somewhat pyriform or pediculated (see *fig.* 61*).

No important changes have been observed

Fig. 61 *.



Ovarian ovum of the Sow.

This ovum is represented in order to show the peculiar pyriform shape of the macula in the germinal vesicle, to the wall of which the macula appears to be attached. This ovum was taken from a Graafian follicle of $\frac{1}{12}''$ in diameter. The following are the dimensions of its several parts which are magnified 250 diameters in the figure. The ovum across the exterior of the zona $\frac{1}{175}''$; the vitellus $\frac{1}{200}''$; the germinal vesicle $\frac{1}{750}''$; the macula $\frac{1}{2100}''$; thickness of the zona $\frac{1}{2400}''$. The ovum is surrounded by the thick layer of cells which form the granular disc, *dp*. A few cells of the thinner membrana granulosa are represented at *tg*.

to occur in the germinal vesicle during the ovarian existence of the ovum. It usually disappears in Mammalia previous to the escape of the ovum from the Graafian follicle; but in this class of animals the phenomena attending the disappearance have not yet been fully investigated. There are some grounds for believing that immediately previous to the bursting of the vesicle there may be changes of the macula and other contents of the vesicle of a corresponding nature with those which have been more clearly observed in Batrachia and Fishes. Dr. Martin Barry seems to have observed something of this kind, and M. Coste has figured, but not so far as I am aware described, the development of cells in the germinal vesicle of a ripe ovarian human ovum.*

R. Wagner states, that occasionally a double macula may be seen in the germinal vesicle.† I have on one occasion observed two germinal vesicles within the same ovum in the dog.

Bischoff has on three occasions observed two ovules in the same Graafian follicle of the rabbit.‡ This had been previously noticed by Von Baer in the dog and pig. And Bidder § detected two ovules embedded in the same granular membrane of one Graafian vesicle of the cow. Upon the question how far these varieties in the structure of the ovum may be supposed to be related to the origin of Double-monsters and Twins, I must refer to Professor Vrolik's interesting article Teratology.*

For the assistance of those who may wish to engage in researches of the same nature as those by which the above facts have been ascertained, I will state shortly the manner in which the ova of Mammalia may be procured either from the ovary or after they have left that organ. 1st. For the examination of the earlier ovarian ova and follicles, thin sections of the ovarian substance are to be made, especially towards the surface of the ovary; and some of these are to be teased out with needle points, and examined with the aid of compression, &c. 2nd. For the more mature ovarian ovum, &c., the outer covering of the ovary is to be removed from the surface of one or more of the prominent follicles; and the latter may then, if large, be carefully dissected out of the ovary, and laid on a glass plate, where it is to be opened with a sharp-pointed knife, and its contents are to be gently pressed out on the glass. The ovum may in general be easily detected in a part of the tunica granulosa with a low magnifying lens, or even sometimes with the naked eye. In the ovary of the dog the ovum may sometimes be seen without any dissection towards the most prominent part of the surface of the mature follicles.† 3rd. To procure the ova after they have left the ovary, or while they are in the tubes, two methods may be pursued: either the whole length of the tube may be opened with very finely-pointed and sharp scissors, and the surface then spread out and examined carefully with a low magnifying power under a good elumination, but this must not be done under water; or another plan may be followed according to the recommendation of Martin Barry, founded on a suggestion thrown out by Cruickshank, as follows: The Fallopian tubes being divided into several portions, the contents of each portion are to be separately pressed out by passing a blunt instrument firmly along the outside of the tube, and, being placed on suitable plates of glass, are to be subjected to the necessary examination. The latter method is particularly convenient in small animals: in the larger I have followed both plans. The method of Barry certainly saves much time and trouble, and is on the whole sure enough.‡ 4th. Of the plan for obtaining the ova from the uterus, when of considerable size, as it belongs rather to the history of development, I will only say here that the greatest caution is necessary in cutting through the walls of the uterus in different layers so as to

avoid injuring the ova, and that the examination must be made at first in the dry state.

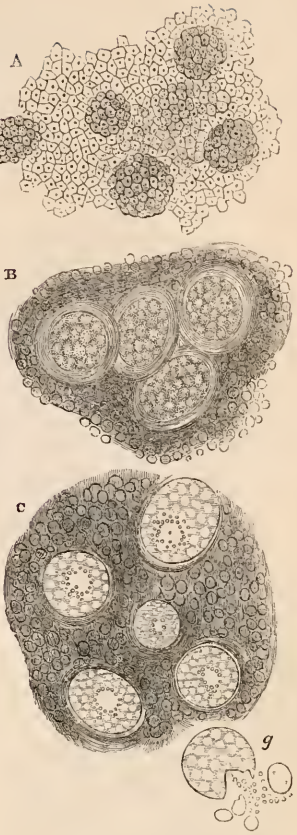
Origin and Formation of the Mammiferous Ovum.—This subject has already been adverted to in the previous section in connection with the history of the formation of the bird's egg. Dr. Martin Barry was led, by his numerous observations, to form the conclusion, that the germinal vesicle is the first part which makes its appearance in the ovarian stroma at the commencement of the formation of the ova. All observers seem now to be agreed, that of the parts belonging strictly to the ovum itself, the germinal vesicle is the first formed; but the observations of Valentin, Bischoff and others appear rather to support the view, which is opposed to that of Barry, that the Graafian follicles may be detected in the ovarian stroma before any part of the ovule is distinguishable.

The ovules are formed at a comparatively early period in the ovary. Carus was the first to point out * that in the ovary of the human female child the follicles containing distinct ovules are perceptible at birth. Vallisnieri had long previously, it appears, made a similar observation. Bischoff has, with more precision, pointed out, that there is considerable variation in different children of the same age as to the degree of advancement of the germs of ova within the ovarium; in some nothing more than a perfectly uniform ovarian stroma is perceptible at birth, while in others the follicles are distinctly formed, even at an earlier period. By the age of ten or eleven years a number of the vesicles are found to be approaching maturity, and almost all have left their earliest condition. Both Barry and Bischoff, however, are of opinion that new sets of Graafian follicles and ova may continue to arise within the ovaries during the whole child-bearing period of the human female; and there can be little doubt that this takes place in most of the lower animals.

Bischoff describes the Graafian follicles as taking their origin from minute heaps of granules in the ovarian stroma; but he has not been able to confirm the statement of Valentin that the earliest follicles proceed from primitive gland tubes stretching from the attached border towards the surface of the ovary.† In various animals the follicles and ova begin to be formed at an earlier period than in the human female: according to Bischoff, they arise very early both in the cow and pig.

When the primary follicle can be perceived, it consists of a small vesicle scarcely more than $\frac{1}{1000}''$ in diameter. To this primary vesicle Martin Barry has given the appropriate name of Ovisac. Soon afterwards, when the vesicle has expanded somewhat, it is found to contain the rudiment of the ovum; first in the shape of the very small germinal vesicle, generally surrounded by a small quantity of granular fluid. Soon afterwards the outer follicle is lined with a few extremely delicate or hyaline hemispherical cells, which have somewhat the appearance of those of epithelium, and which thus give rise to a clear space between

Fig. 62*.



Development of the Ovarian ovum of Mammalia. (*From Bischoff.*)

A represents a very small portion of the ovary of a fœtal dog. The commencing Graafian follicles are visible in the granular or cellular stroma of the ovary, constituting dark heaps of more opaque granules or small cells.

B, fragment of the ovary of a dog three weeks after birth. The Graafian follicles are now seen in the fibro-granular ovarian stroma, each surrounded by a homogeneous and fibrous covering, and filled with granules.

C, fragment of the ovary of a pig three weeks old. The Graafian follicles are now seen to be formed of a fine transparent vesicular membrane, and round the larger ones fibres are beginning to be deposited. The wall of the follicles are lined internally with delicate epithelial cells. The germinal vesicles now visible within consist of a fine clear cell with a nucleus or dot, and a few vitelline granules have begun to be deposited round the germinal vesicles.

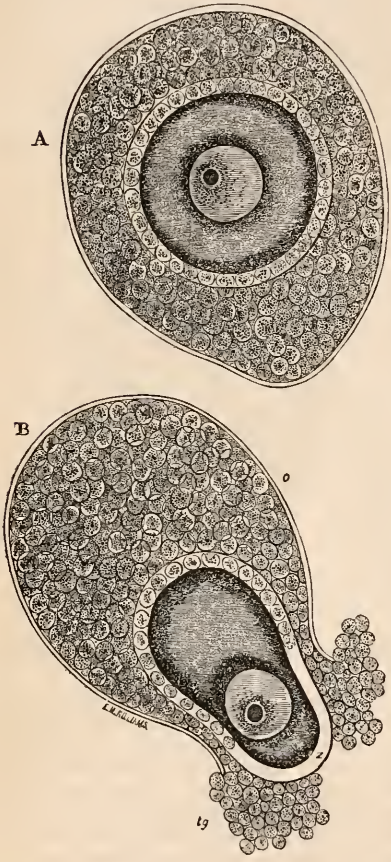
g, one of these Graafian follicles burst with a needle, showing the contents of the follicle; there being as yet no zona or vitelline membrane.

* Müller's Archiv. for 1832, p. 379.

† Handbuch der Entwickelungsgeschichte, 1835, p. 389.; and Müller's Archiv for 1838, p. 529.

the membrane or wall of the follicle, and all that yet exists of the ovule. Next, the yolk substance is formed round the germinal vesicle; first of all, as has been shown by Leuckart†, by the deposit of a clear viscid fluid, and next by the formation of dark or opaque small granules in this fluid adjacent to the germinal vesicle. Somewhat later the zona pellucida,

Fig. 63*.



Ovarian follicle and ovum of the Rabbit at an early stage.

The follicle here represented was about $\frac{1}{100}$'' in diameter: in the figure it is shown as it appears under slight pressure. All the parts of the ovum are distinct, and its large size in proportion to the follicle and tunica granulosa is apparent. In the lower of the two figures the follicle is represented as having been burst by pressure and the ovum with the tunica granulosa in the act of escaping from within: the yielding character and elasticity of the zona is shown by the change of form during the escape, and the ovum afterwards regaining its spherical shape. *o*, the wall of the follicle; *t g*, the tunica granulosa; *z*, the zona partially freed from the cell covering. The macula with the germinal vesicle is remarkably distinct, and is surrounded by a quantity of fine molecular substance.

† Article Zeugung in Wagner's Handworterbuch der Physiologie, 1853.

which cannot be said to have existed from the first, comes to be apparent outside the opaque granular substance of the yolk, and close to the epithelial cells which line the follicle: it seems as if it owed its origin to the condensation of the outermost layer of the clear basement matter from which the yolk-substance is formed.

The membrana granulosa consists for a time of a single layer of nucleated epithelial cells situated between the ovule and the Graafian follicle. The latter not being yet expanded by fluid, is at this period completely filled by the ovum. Such is the state of the parts, now all present, in follicles of from $\frac{1}{100}$ to $\frac{1}{200}$'' in diameter. Subsequently the follicle increases in size much more rapidly than the ovum; the membrana granulosa follows closely the wall of the follicle in its rapid expansion by the increasing accumulation of fluid within; and the ovum is now found to be imbedded in a particular portion of the layer of granular cells constituting the *cumulus*.

According to the best observations, then, as to the formation of the mammiferous ovum, it appears that the ovarian follicle, which we may look upon as the primary gland cell, is first produced; that within it at a very early period the germinal vesicle with its nucleus next arises, and that very soon after the origin of this primary part the yolk-substance commences by a deposit of fluid and granules round the germinal vesicle; that the Graafian follicle is lined by a layer of nucleated cells resembling epithelium, which constitute the commencement of the tunica granulosa; that the zona pellucida, which forms the outermost covering of the ovum when it leaves the ovary, is formed at an early period, but somewhat later than the commencement of the other parts of the ovum; and that it probably owes its origin to a membranous condensation of the outermost part of the clear primitive yolk-substance; and that, finally, the tunica granulosa increases in quantity and extent, is expanded along with the follicle by the fluid within it, and being deposited at its thickened cumulus round the ovum encloses it in a part of its substance.

The structure of the ovum is, on the whole, very similar throughout all the families of the class Mammalia in which it has been examined, excepting one, viz., the Monotremata. In Marsupialia, in which, from the remarkable deviation from the more common mode of gestation, it has been supposed that the ovum might present some peculiarities, it does not appear, from the observations of Professor Owen, that any remarkable difference is to be detected. In the ovisac there was observed a somewhat larger quantity of granular substance than usual; but the diameter of one of the largest ova in the *Macropus Parryi* or Kangaroo was not greater than $\frac{1}{120}$'', and the germinal vesicle was only $\frac{1}{1680}$'', which is proportionally small; so that it cannot be held that in this animal there was apparent any approach to the oviparous type.

In the Monotremata, however, the ovum is of much larger size, and appears to occupy the whole or the greater part of the ovarian follicle or capsule; more in the manner of that in birds and scaly reptiles. According to Professor Owen*, the ovaries of the Ornithorhynchus present numerous elevations on their surface caused by the projection of ovisacs of different sizes and in different stages of development. The largest of these sacs have a diameter of two lines; and, as in birds, though in a less marked manner, the right oviduct and ovary are less developed than the left. The unimpregnated ovum nearly completely fills the ovisac or ovarian capsule. The germinal vesicle is of a comparatively large size, being about $\frac{1}{250}''$ in diameter. The vitelline substance is rich in nucleated (?) cells or granules, intermixed with clear colourless oil globules. The vitelline membrane is moderately thick and smooth, and refracts light strongly. The ovum is separated from the inner surface of the ovarian capsule by a very small quantity of fluid, and by a stratum of granules or cells.

The ova found in the uterus of the Ornithorhynchus were of a deep-yellow colour, with a smooth polished surface, and had no adhesion to the inner uterine membrane. In one animal the yolks were found enclosed in a more transparent mass, which was surrounded by a cortical membrane of some tenacity, presenting in fact some resemblance to the albumen and shell membrane of a bird's egg. Leuckart † thinks it probable that Owen may have been misled as to the size of the ova by the examination of specimens which had been preserved in alcohol; but Professor Owen informs me, that he was fully on his guard against such an error, and was quite satisfied of the approach in the structure of these ova to the oviparous type of birds and reptiles.

I have examined the ovaries in a specimen of *Echidna hystrix*, which has been preserved in alcohol; and although the somewhat deteriorated state of the specimen, and the circumstance of the ovaries not being in the fully developed condition, were not the most favourable for minute observation, I was convinced that the ovarian ova of this animal, like those of its congener the Ornithorhynchus, belong rather to the oviparous than to the usual mammiferous type. The yolks, which quite filled the ovisacs, were some of them about $\frac{1}{20}''$ in diameter: they contained a large quantity of granular globules similar to the yolk corpuscles of birds; the yolk, in fact, consisted of the nutritive as well as the formative substance; and the whole aspect of the ovary, as well as of the individual yolks, recalled to my mind that of an oviparous animal in a somewhat undeveloped state.

* See Prof. Owen's Article Monotremata in this Cyclopædia, and his Memoirs in the Philos. Trans. for 1832 and 1835. See in particular figures 191, 192, and 194 of the article Monotremata, Cylopæd. of Anat. vol. iii. p. 393, et seq.

† Article Zeugung, p. 783.

The ova of a considerable number of the Invertebrate animals belong to the same group under which I have placed that of Mammalia; that is, they consist principally of formative or granular yolk-substance, undergo complete segmentation, and have a simple zona or structureless covering; but yet the varieties in structure, relations, and mode of production among these ova themselves, and their differences from the ova of Mammalia are so great, that I think it will conduce to greater clearness and prevent repetition, to defer treating of the ova of Invertebrata till after I shall have given the description of the remaining ova of the Vertebrate animals, to which we shall now proceed.

Third Group of the Ova of Vertebrate Animals.—Under this head I have now to state some details as to the structure, relations, and mode of formation of the ova of amphibious reptiles or chiefly the Batrachia, and of osseous fishes. The ova of both of these tribes of animals appear to occupy an intermediate place between the very small and granular-yolked ova of the Mammalia and the large cellular-yolked ova of birds and scaly reptiles. They agree in both possessing a yolk of moderate size, in the substance of the yolk being principally or largely of the formative kind, and in the possession of a proportionally large germinal vesicle, in which the macula is not a single nucleus, but rather a large collection of nuclei or maculæ. In both of them the segmentation is partial or not complete, affecting chiefly the superficial part of the yolk, in which the formative or germinal portion of the yolk is placed, but varying considerably in the depth and the extent of the surface which it involves in different species and genera, more especially among the Amphibia. In the predominance of the formative yolk and in its relations to the process of segmentation, therefore, they approach the Mammalia, while in the large size and structure of the germinal vesicle in all, and in the considerable amount of nutritive yolk in some, they more nearly resemble the group of large-yolked ova. It will be proper, on account of the differences between them, to describe separately the ova of Amphibia and those of Osseous fishes.

Amphibia.—Batrachia.—The ripe ovarian ovum of the common frog or toad is a nearly spherical body of from $\frac{1}{15}$ to $\frac{1}{12}$ of an inch in diameter, of a dark colour, contained within and closely embraced by a thin vascular sac formed by the dilatation of the ovisacs which hang into the general ovarian cavity.

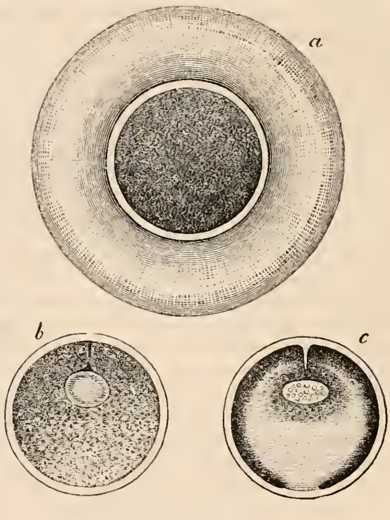
This capsule or ovisac is attached to the rest of the ovarian substance by a broad band rather than by a narrow pedicle; and when the yolk or ovarian ovum is mature, it escapes from the ovisac by the formation of an aperture in the remote or free side of this capsule, somewhat in the same manner as occurs in the calyces of the bird, but with a wider aperture. Through the apertures of the general ovarian capsule the numerous ova pass into the abdominal cavity, during the first period of sexual union, and they are thence taken up singly by the open upper extremities of the two oviducts ; through the whole of which canals they descend, and in their passage receive an additional covering of a peculiar gelatinous or albuminous substance, which adheres closely to the surface of the yolk membrane, and is firm and of comparatively little bulk while the ova are still within the oviduct, but which after exclusion rapidly swells by the imbibition of a large quantity of water, so as to become several times its original thickness, and to assume a soft gelatinous consistence.

The ova which have passed through the oviducts remain for a time accumulated in large numbers in a dilated part of the canals near their lower end, until the whole or greater part of those which are ready to descend from the ovary have passed down ; and then, while the male still continues united with the female, the ova are rapidly excluded, and the male sheds the spermatic fluid in abundance, partly on the ova as they pass into the water, and partly after separating from the female, upon the spawn as it floats in the water. The importance of the imbibition of water by the gelatinous covering immediately on the exclusion of the ova and just at the time when the spermatic fluid has been placed upon them, in securing the access of the spermatozoa to the surface of the vitelline membrane through the stiff jelly, and in thus promoting fecundation, will be afterwards more particularly adverted to.

In the tailed Amphibia, such as the different kinds of Newt (Salamandra, Triton, and Lissotriton) there is not the same union of the male and female as in the tailless or Anurous Batrachia ; and impregnation takes place by the entrance of the spermatic fluid, shed in the water by the male while placed near the female, into the oviducts of the latter. In these animals the external covering consists of an elliptical membranous capsule filled with a clear fluid and containing the coloured spherical yolk ; but there is also externally a small quantity of gelatinous substance which in some of them serves to attach the ova to leaves of plants or other objects. In the common larger and smaller newts the ova are in smaller number than in the frog or toad, and are excluded one by one by the female, which deposits them singly in a folded leaf or other place of security.*

The yolk of the ripe ovarian ovum in Amphibia consists of a thick opaque mass of vitelline substance, within which and towards one side the large germinal vesicle is placed. The vitelline substance is usually of a darker colour on the exterior and lighter in the centre. In the common toad the superficial part is almost black ; in the common frog, *Rana temporaria*, it is of a very dark brown ; and it is in different other species of various hues, as stated in a former part of this article. The dark superficial part does not in general cover the whole surface of the yolk, but is deficient on one side ; and its extent as compared with the inner paler part, which appears where the dark part terminates, varies in different species and is greater in proportion to the degree of advancement of the ova. In some species, as in the *Alytes obstetricans*, of which C. Vogt has given an excellent description†, it does not, when the ovum is mature, occupy more than a half of the surface ; but in the common frog and toad it covers so much of the surface of the yolk when it is about to leave the ovary, that the gray internal part is only seen as a defined round spot on the opposite side. In the undeveloped ovarian ova, however, the dark part is much more limited in its extent, thus allowing a greater part of the lighter-coloured internal part to be seen.

Fig. 64 *.



Ovum of the Frog.

a. (*From Newport.*) An ovum of the frog half an hour after impregnation, covered with its gelatinous mass. The dark part of the egg or yolk is seen to be surrounded by a vitelline membrane. Spermatozoa were seen everywhere in the gelatinous envelope, but are not represented in the figure.

b. Vertical section of the yolk or ovarian ovum of the frog which has been hardened in alcohol, showing the germinal vesicle within and the canal of the yolk which leads down to it from the upper or germinal pole. The external line indicates the vitelline membrane.

c. Diagrammatic representation of the same section, showing, according to the views of Ransom, the relation of the canal or depression of the yolk to the germinal vesicle. The micropyle, if it exists in these ova, may be situated in the vitelline membrane immediately above this canal. This figure also shows the relations of the dark and light coloured parts of the yolk substance.

* I have frequently observed this process, which has been beautifully described and figured by Mauro Rusconi in his work, "Amours des Salamandres Aquatiques, Milan, 1821."

† Entwickelungsg. der Geburtshoelferkröte, Solothurn, 1842.

It is towards the centre of the dark superficial part of the yolk that the first changes of embryonic development always take place; and it is apparent that this dark part corresponds more immediately to the germinal part of the yolk. It is beneath the central part of this dark covering that the germinal vesicle is situated in the ripe ovum. When taken from the ovary previous to impregnation, the ova float in water indifferently as regards the position of their parts; but after impregnation, when the imbibition of water allows of the free rotation of the yolk within its coverings, it is invariably found that the dark or germinal part of the yolk is directed upwards, and the whiter or grey spot downwards; — a circumstance by which the difference between the fecundated and the unfecundated ova may readily be detected. We may distinguish therefore, as the upper, dorsal, or germinal pole of the ovum, the central point of the dark part, and name the opposite point in the centre of the light-coloured space the lower or ventral pole.

The thickness of the dark layer of substance which covers the upper part of the ovum is throughout its greater part considerable; viz. about one-eighth to one-tenth of the whole diameter of the yolk. It thins off somewhat at its edges below. Within this darkest layer the colour of the yolk-substance is slightly shaded off into the grey substance of the interior: the consistence of the inner substance is less than that of the superficial layer, and it contains a cavity situated considerably nearer the upper than the lower surface of the yolk, in which the germinal vesicle is situated. This vesicle is not perfectly spherical in its form, but somewhat flattened from above downwards, and it is surrounded by a peculiar mass of fine granules.

The yolk-substance contains no cells nor large corpuscles; the greater part of it consists in the mature state of peculiar flat or tabular corpuscles, the largest of which are about $\frac{1}{2500}''$ in diameter. Most of these are quadrangular in shape, but somewhat rounded on the edges and at their angles. There are also numerous smaller particles of the same kind of every dimension from that already stated down to the smallest granules, and with some variation of shape, together with a considerable amount of molecules of very minute size, of which those in the darker part have the appearance of pigment granules. These last are accumulated in greatest quantity towards the surface; but they do not constitute a separate layer, being rather interspersed with the tabular corpuscles. There are also to be seen in the upper or germinal part a few rounded corpuscles, somewhat larger than the tabular particles, which seem to be formed by the aggregation of smaller molecules; but these have no external envelope nor clear nucleus, and only bear a distant resemblance to the cells which, after impregnation, are formed in the germinal part of the yolk-substance.

The peculiar quadrilateral tabular corpuscles refract light strongly, so as to present distinct outlines; they have also considerable firmness, resisting pressure, but by force may be broken up somewhat in the same manner as would occur in small plates of wax. From this circumstance they have generally been regarded as of a fatty nature, and were described by Vogt as stearine tables; but Virchow*, from a careful investigation of their reaction with different substances, throws a doubt upon this view, and is more inclined to regard these corpuscles, both in Batrachia and in the ovum of the carp-fish, as composed of some albuminous or protein principle, the exact nature of which he has been unable to determine. He admits that they may also contain some oil. They are probably very analogous to the larger firm angular particles which were first described by J. Müller as forming the greater part of the yolk-substance in the Sharks and Rays, and which also exist in the ova of Cephalopodous Mollusca.†

The germinal vesicle of the Batrachian ovum is of very large proportionate size. According to Vogt, in the *Alytes obstetricans* its diameter is nearly equal to one-third of that of the entire yolk mass. In the common frog and toad it is somewhat less, but nearly $\frac{1}{40}$ of an inch. This vesicle may be obtained separate for examination by breaking open the yolk carefully under water; but it is much easier to observe its position, form, and structure in the ovum which has been hardened by some re-agent,—a plan which has been successfully adopted by a variety of observers. Cramer‡ recommends for this purpose alcohol, or more particularly dilute chromic acid; Newport§ employed alcohol, as I also have done with success; more recently Remak|| states that he has found a mixture of a solution of sulphate of copper with alcohol, to which a few drops of rectified wood spirit are added, peculiarly fitted to give the proper consistence to the various parts, without inducing any destructive change in their structure or appearance. All observers agree that there is scarcely any other animal in which the relations of the germinal vesicle to the other parts of the yolk can be more favourably investigated.

The enclosing wall of the vesicle is of extreme tenuity, so thin, indeed, that some have doubted its existence. I have been able, however, to distinguish the double outline of its thickness with a good magnifying power of 350 diameters. The outer surface of the vesicle is not always of a regular circular or spherical form, but often presents within the yolk, both at earlier and more advanced stages, a notched

|| Untersuch. über die Entwickel. der Wirbelthiere, Berlin, 1855, p. 127.

appearance: when, however, the vesicle has been extracted from the yolk, I have generally found this appearance to be removed and perfect sphericity restored. It would appear also, from Vogt's observations in Alytes, that this appearance is not constant: it may depend on the viscidity of the contents, and the extreme softness and thinness of the enclosing membrane of the vesicle.

It is only in the earliest stages of ovarian formation that any appearance of distinct maculæ, such as they have been described in other animals, is to be perceived; for from a very early period these spots or nuclei are already very numerous. As the ova approach maturity the contents of the germinal vesicle undergo very considerable and rapid changes, by which a number of corpuscles, some loose, others aggregated, and subsequently delicate cells, are formed, and completely fill the whole cavity of the vesicle.

The germinal vesicle is situated, in the ripe ovarian ovum, nearer the upper than the lower part of the yolk. When the egg has been hardened by the re-agents already referred to, there can be perceived in the middle of the upper surface, or exactly in the upper or germinal pole of the yolk, a minute depression, which was first noticed by Prevost and Dumas *, and which they, erroneously, according to most of the observers who have followed them, conceived to be connected with an aperture or pore in the external membranes of the ovum. Von Baer showed that this depression leads into a canal which extends from the upper pole of the yolk, through the yolk-substance, to the surface of the germinal vesicle. The existence of this canal has been fully established, and its situation well represented by Newport. The interval between the upper surface of the yolk and the germinal vesicle appears to become less as the ovum approaches maturity.

The vitelline membrane of the mature ovarian ovum in the frog is thin and homogeneous. In the ova which have escaped from the ovary into the abdominal cavity it is still so thin, that they are very liable to be broken by the slightest force applied unequally on their surface; but in their descent through the oviduct considerable consistence is given by the addition of the layers of albumen to the vitelline membrane. Besides the simple vitelline membrane, there appears to be a second envelope formed within the albuminous deposit. Remak †, indeed, describes the vitelline membrane itself as consisting of two layers, besides the superadded membrane within the albumen.

Formation of the Ovum, and Changes in its Progress. — The ovary of the Batrachia is peculiarly well adapted for making observations on the development of the ova, as the stroma is in small quantity and transparent, and as it contains at most seasons a considerable number of ova in different stages of their formation and progress. If examined in the autumn or in spring before pairing, there are generally found three sets of ova; one uniformly large and dark-coloured, obviously belonging to those which are about to be brought forth in the ensuing breeding season; another set, also of uniform size, but less than the first, and in which only a partial deposit of colouring matter has taken place, probably constitute the ova for the next season after the first; and, third, a number of ova of inferior magnitude to either of the other sets, and of most various sizes, down to the most minute, which we may suppose to comprise those destined for succeeding breeding seasons. It seems probable that three seasons are necessary for the full development of the ova in the common frog and toad.

The earliest ova are seen within the ovicapsules or ovisacs, in the delicate ovarian stroma; the more advanced are enclosed in their pediculated capsules or calyces.

The germinal vesicle is the part of the ovum first distinctly recognisable; but so soon as it, or any part of the ovum can be distinguished, the delicate membrane of the ovisac or ovarian follicle is also seen surrounding it. Leuckart * was never able to perceive a follicle without there being already also an ovum within it. It would appear, therefore, either that the follicle and germinal vesicle arise together, or that observations have not yet determined which of them has the priority. It has been stated by some, that in the very earliest periods a single macula or nucleus may be observed in the germinal vesicle †; but it is rare to find the germinal vesicle in this state, and I have generally observed the macula, even in the earliest stages, to be multiple, or to consist of several maculæ. Still it is undoubted that, in the earliest period, there are fewer maculæ than at more advanced periods, and that their number gradually increases. About the time of maturation of the ovum the contents of the germinal vesicle undergo further changes, to which reference will hereafter be made.

From a very early period, though perhaps not from the first, the germinal vesicle is surrounded by a thick viscid substance, which closely adheres to its surface. This substance is at first remarkably clear, especially at its outer part, where it has a hyaline appearance: a little later it becomes gradually more and more opaque, as if by the deposit in or mixture with its clearer substance of fine molecules or granules. This appears to be the primitive yolk-substance; which in these animals therefore, as in most others, is ascertained to consist of a clear basis or matrix, in which the granular part is suspended. The out-

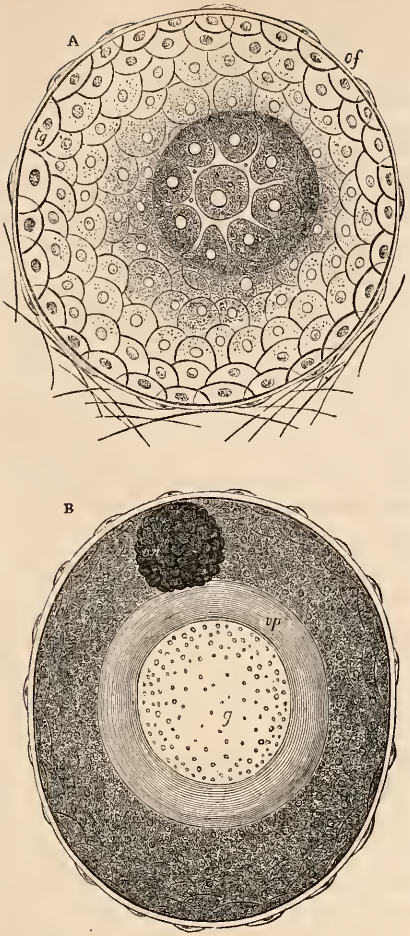
† Loc. cit. p. 127.

* Loc. cit.

† Mr. Newport describes the germinal vesicle of the frog's ovum as nucleated, even when half-grown. He also speaks of the corpuscles of the yolk substance as "nucleated cells" (1st Series, p. 176.); but this is quite inconsistent with the statements of most other observers.

Fig. 65 *.



Formation of the ovarian ovum in the Frog.

A, and B. Magnified representations of an ovarian follicle and its contents in an early stage of the formation of the ovum. The follicle is $\frac{1}{100}''$ in diameter: in A the follicular membrane and its epithelial lining are chiefly brought into focus; in B the parts of the ovum within are represented when the microscope was adjusted so as to place them in focus. The wall of the ovarian follicle consists of a structureless membrane or ovicapsule, and an external covering of thin flattened cells; the epithelial cells of the follicle within are seen in profile towards the margin, and full towards the centre (in A) where their granular contents and nuclei are distinct. In the centre of B the large germinal vesicle with numerous maculæ is seen; around it a clear space which is a part of the basement substance of the primitive yolk, and between this and the wall of the follicle there is seen superiorly the dark granular mass which has been called yolk nucleus. The clear primitive yolk is also surrounded by a finely granular vitelline substance which has begun to be deposited.

line of the clear part remains remarkably smooth and well-defined for a time, and there appears to be some fluid or different substance interposed between it and the inner surface of the ovicapsule. The homogeneous membrane of the latter is found at an early period to be lined by a single layer of very distinct largely nucleated cells, which lie flatly applied against its inner surface, but bulge or project roundly on their other sides towards the ovum. This layer of cells no doubt corresponds to the tunica granulosa of the ovisac in other animals, and has a similar destination.

There is as yet, neither in the earlier ova nor in those half-grown, any zona or other proper vitelline membrane; and it is obvious that what some authors* have described as such could be nothing more than the distinct surface of the primitive yolk. Whether this surface becomes condensed into a membrane, or at what time this may occur, has not yet been determined by observation.

Besides these parts in the early Batrachian ovum, there is another which has frequently been seen by various observers from Von Baer downwards, and which, as it is different from anything that has been observed in the ova of other Vertebrata, deserves some attention; I refer to a dark mass of granules situated excentrically or towards the side of the clear primitive yolk-substance, and between it and the tunica granulosa of the ovisac, and which, from its supposed connection with the formation of the yolk-substance, has been called the *yolk-nucleus*. This mass may easily be seen in ovisacs of the common frog of from $\frac{1}{150}$ to $\frac{1}{100}$ of an inch in diameter. It is then about one-tenth of the diameter of the ovisac. It is very opaque as compared with the other parts, being composed of aggregated heaps or small balls of finer granules. The opaque granules of the yolk have been supposed to be derived from this body, and it has been alleged that, as the yolk-substance increases, this yolk-nucleus gradually disappears or spreads itself round the germinal vesicle.† Leuckart, however, states that this body is not invariably present, and that it is subject to considerable varieties, and he is not inclined to attribute to it any important function in connection with the formation of parts of the ovum. I have in general found it present, and think it more probable that it may be destined to form the external and larger corpuscles of the yolk, while the clearer part immediately surrounding the germinal vesicle may contribute to the production both of these and of the finer substance in which the germinal vesicle is found imbedded. But farther observations will be required for the determination of these points.

As the growth of the ovarian ova proceeds, the deposit of fine granules in and around the primitive albuminous yolk-mass increases rapidly; and the yolk-nucleus, becoming less distinct, finally disappears at an early but somewhat variable period. The yolk-sub-

* As Cramer, loc. cit. p. 21.

‡ See V. Carus in Zeitsch. für Wissen. Zool. vol. ii. p. 103.; and Ecker in his new edition of R. Wagner's Icones Physiolog. descript. of Tab. xxiii.

stance contains at first only fine granules; but in the second season of development there are found mixed with these, especially towards the surface, corpuscles of a somewhat larger size, and these are gradually converted into the quadrilateral tabular particles. The distinction of colour between the surface and the deeper parts, and between the upper and lower portions of the yolk, also now appears; but it is not till the third season of development that, along with a proportional enlargement of the yolk, the darkest kind of pigment is deposited among the corpuscles on the upper surface. The gradual extension of this coloured layer over a greater portion of the surface of the yolk from the upper towards the lower part has already been stated. The extent of the coloured portion marks in fact, in a great measure, the proportion which the immediately germinal part of the yolk bears to that not concerned in the first process of embryonic development; or it indicates at least the extent of the yolk which is immediately involved in the process of segmentation.

The vitelline membrane, I have already said, is absent during the early stages of development of the ovum; it appears to be present in the third season, but I have not been able to determine precisely its mode of origin. Farther observations are still necessary to ascertain whether, as in Mammalia and some other animals, a zona is formed by the condensation of the outer part of the primitive yolk-substance, or whether this membrane proceeds from another source. From the gradual flattening and disappearance of the inner cells of the ovarian follicle, and the close adhesion of their remains to the vitelline membrane in the later stages, I am led to believe, that the covering with which the yolk leaves the ovary may owe its origin to the amalgamation of one or more layers of fused or united cells of the tunica granulosa, or to the union of these with the zona or primitive vitelline membrane, should such exist.

There is no true cellular yolk, but the granular yolk is of proportionally large size; and if we are disposed to regard the yolk as containing both a formative and nutritive part, these are united or combined in a more close manner than in the larger ova of ovipara. The ova of Batrachia differ, on the other hand, greatly from those of Mammalia in their relation to the Graafian follicle; more especially in the fact of the ovum completely filling the follicle, and the entire absence, excepting in the epithelial lining, of fluid or other deposit between that layer and the surface of the ovum. The history of development shows that the peculiar structure of the ovum of Batrachia, as well as that of osseous fishes, has some connection with the large proportion of the yolk which becomes immediately germinal, and with the comparatively early period of advancement at which the young leave the egg and assume an independent mode of life.

Before concluding this account of the ovum of the Amphibia, it will be proper to notice the changes that have been observed in the germinal vesicle near the time of the discharge of the ova, and in its descent through the tubes till its exclusion. All observers are agreed that the germinal vesicle is no longer visible in the excluded ovum, whether fecundation shall have occurred or not; and the solution or disappearance of this vesicle is now looked upon, in these as well as in other animals, as a natural concomitant of the maturation of the ovum independently of fecundation. The recent and very precise observations of Newport * have shown, that in a considerable number of the ova about to leave the ovary but still situated within that organ, the germinal vesicle has disappeared, and that it is invariably gone in all those which have passed into the abdominal cavity.

Very shortly before disappearing, and when the ovum is approaching maturity, a remarkable change has been observed in the contents of the germinal vesicle; which is of great interest, in consequence of its probable intimate relation to the process of segmentation and cell-formation, which follow fecundation and are the precursors of true embryonic development. These changes have been described first by Cramer, and afterwards by Newport; the latter author, apparently, not having been aware of the observations of the former.

In early spring (February) Cramer † found the fine granules into which the maculæ of the germinal vesicle had previously been resolved by multiplication, beginning to unite together into heaps or small masses; and somewhat later he found these masses to become surrounded by a fine membrane or envelope, giving them all the appearance of small cells with a granular nucleus. There are often several hundred such cells at this period in the germinal vesicle of the brown frog, varying slightly in size and shape. At a still later period the greater part of the granular nuclei or contents of these cells become dissolved, leaving only a few remaining in each; and finally these also disappear, so as to render the cells entirely clear.

Now, all observers are agreed, that in the yolk-substance of the ovarian ovum, previous to the rupture of the germinal vesicle, there are not to be perceived any other solid particles excepting those already mentioned, viz., granules or heaps of granules, and the peculiar quadrangular tables; but many observers have perceived that immediately after the disappearance of the germinal vesicle, and during the whole time previous to fecundation, as well as after that change, the yolk-substance contains, mixed with the darker corpuscles, other clearer and spherical vesicular globules, somewhat larger than the tabular corpuscles. Vogt described them as scattered through the whole of the superficial yolk-substance in the *Alytes obstetricans*, and Cramer pointed out that these vesicular corpuscles are identical with the cells which he had observed to be formed in the germinal vesicle immediately before its

* Researches, &c., 1st Series, p. 177.

† Müller's Archiv. 1848, p. 23.

disappearance. He attributed their origin, therefore, to this source; and regarded it as probable that these cells, which may perhaps be descendants of the original maculæ of the germinal vesicle (but this is a point which he leaves undetermined), constitute afterwards the nuclei round which the tabular and granular substance of the yolk group themselves; and thus probably form, subsequent to segmentation, the nuclei or foundation of the cells which are the seat of true embryonic development.

Newport's description of these changes differs somewhat from that of Cramer, but is not altogether at variance with the view now suggested as to the nature of the process with which they are connected. He states *, that towards the period of maturity he found the germinal vesicle filled with secondary cells, and that each of these contained other or tertiary cells within them, and in the interior of these last were granules which he called quaternary. "In the midst of these numerous cells, and in the centre of the germinal vesicle, I was able to distinguish," says he, "in some specimens, one or two cells of larger size than the rest, and which I regarded as the remains of the germinal spot or central nucleus." He further states †, that these internal cells were, he conceived, afterwards thrown loose by the solution of the parent cells.

As to the mode of disappearance of the germinal vesicle, Von Baer had stated ‡ that, it gradually rises from its deeper situation, towards the surface of the yolk, and that, finally bursting or being dissolved there, its contents are allowed to flow over the surface of the yolk. This process he also described in several other animals as proceeding in a similar manner; and he supposed that the germinal substance from the vesicle was thus diffused over that part of the ovum which is most closely related to the subsequent changes of development. He regarded the canal of the yolk as the remains of a passage through which the vesicle had been carried to the surface. Newport, on the other hand, is quite confident that no such passage of the vesicle to the surface occurs in the ova of Batrachia, and that the vesicle most probably dissolves or disappears in its situation below the germinal part of the yolk. From the facts he has pointed out, Newport infers that the germinal vesicle is burst or destroyed by the development of the progeny of cells within it, and that the cells thus set free are mingled with the rest of the yolk. It belongs rather to the history of the changes which the ovum undergoes after fecundation, than to our present subject, to trace the relation between the cell progeny of the germinal vesicle now described, and the cells of embryonic formation afterwards developed; but it may be proper here merely to mention that from the concurrent testimony of several observers, it seems probable that the origin of the blastodermic cells is closely connected with a combination of the vesicles or cells from the germinal vesicle with the other solid elements of the yolk-substance. To this process of cell formation the change of segmentation seems, in the Batrachia, as in all other animals, to be the necessary prelude.

It may be proper here also to state, in conclusion, that Newport has shown that the process of segmentation begins by a fissure which passes in a determinate direction through the canal of the yolk.

Although the statement of Prevost and Dumas as to the existence of an aperture in the membranes of the ovum, through which they supposed the spermatozoa might be introduced in fecundation, has not yet been confirmed by subsequent observers, but has on the contrary, met with an explicit denial from Von Baer, Newport, and Remak, after a very careful examination by these authors; and although it would appear, from Newport's statement, that the spermatozoa penetrate the vitelline membrane of the frog's egg over a considerable portion of its surface, yet the discoveries which have in the last few years been made as to the existence of the micropyle in fishes and some other animals, are of so unexpected a kind, that we must not regard this point as altogether settled. Dr. Ransom, indeed, in some observations communicated to me, has stated his belief that a micropyle may still be discovered in the membrane of the Batrachian ovum. The statement of Prevost and Dumas on this subject is so precise that it deserves to be recorded in their own words. — "On remarque ensuite qu'il existe au centre de l'hémisphère brun une tache circulaire très regulière, jaune, et marquée d'un point opaque dans son milieu. Celuici provient d'un petit trou dont les deux membranes sont percées, ce qui met à découvert la bouillie brune que renferme l'ovule. Pour s'en assurer il suffit de vider l'œuf et d'examiner à la loupe les membranes transparentes qui sont restées intactes dans toutes leurs parties, sauf l'endroit qu'on a piqué pour évacuer la pulpe qu'elles contenaient." *

The observations of Von Baer, Rusconi, Newport, and myself have shown that with certain differences in the form and structure of the external membranes, the colour of the yolk-substance, &c., previously referred to, the structure of the ovum, and the phenomena of change at the time of its discharge, are essentially the same in the Newts as in the common Frog.

A few observations which I have made on the Menobranchus lateralis and Siredon mexicanum, show that the Perennibranchiate Amphibia agree very closely with the

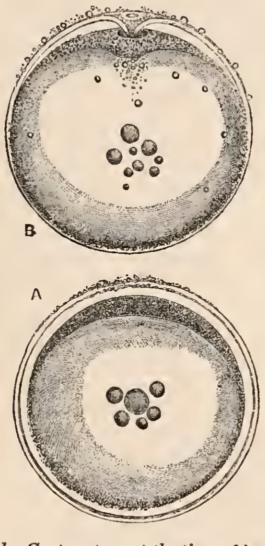
Salamandrina in regard to the structure and formation of their ova.

Osseous Fishes.—The ovarian ova of Osseous Fishes, while they bear a general resemblance to those of Vertebrata, among which they come nearest to those of Batrachia, are distinguished by several marked peculiarities. They are of middle size, and possess a strong external covering formed within the ovary. The yolk-substance contains several kinds of elements ; and the germinal vesicle is of considerable size. The external membrane is thick, strong, and elastic, and of a peculiar porous structure. The yolk-substance contains a large quantity of clear fluid, in which the albuminous granules and yolk corpuscles and the oil globules are suspended, the latter usually of large size and few in number ; the germinal layer or disc is limited to a part of the yolk, varying in size from about a sixth to a half of the circumference, and the process of segmentation in this part after fecundation is consequently more limited than in Mammalia and most Batrachia ; but more extended than in birds or scaly reptiles. The germinal vesicle contains subdivided or multiple maculæ. I now proceed to give a few details with respect to these several parts of the ovum.

Fig. 66 *.



Ovum of the Gasterosteus at the time of impregnation. (*From Ransom.*)

A. An ovum of the Stickleback eight or ten minutes after impregnation, showing the clear respiratory space formed immediately upon the access of spermatozoa between the external membrane and the surface of the yolk. Towards the upper part of the figure the situation of the micropyle is indicated by the small projections in the external membrane ; towards the same or upper part of the yolk the germinal disc or layer is easily distinguished from the clearer part of the yolk ; and in the middle a few large coloured oil globules.

B. The same ovum about three minutes after impregnation, showing somewhat in profile the funnel of the micropyle descending into a depression on the upper surface of the germinal part of the egg. In consequence of impregnation, however, the funnel of the micropyle has begun to rise out of the hollow, and the respiratory space to be formed by the separation of the external membrane from the surface of the yolk.

The yolk-mass or yolk-substance consists, in the more mature ovarian ova, of three parts : viz., the clear fluid, which is in great abundance and occupies chiefly the centre and the lower part of the ovum; the superficial layer of fine granules, with the vesicular corpuscles; and the large oily globules, which from their less specific gravity are usually situated towards the surface and on the upper side. In a number of fishes the clear fluid, which has an acid reaction, becomes immediately turbid or quite thick by the deposit of granular substance when water is added to it. This change is very apparent in the ova of the trout or salmon, which, when placed in water, retain their natural clearness and colour so long only as the coverings are entire ; but immediately on their being divided so as to allow of the action of water on the contents, the whole yolk is suddenly precipitated as a thick and somewhat tenacious granular mass. The albuminous matter which surrounds ova that have been spawned has an alkaline reaction. It is an interesting fact, that in these ova, when imbibition of water takes place as a consequence of fecundation, no precipitate follows ; but that in unfecundated ova left for some time in the same circumstances without fecundation, though unbroken, turbidity ensues ; so that by the difference of internal appearance the fertile ova soon come to be easily distinguished from those which have not been fecundated.* The solid elements of the yolk-substance appear to be in general of three kinds for some time before the ovum has arrived at maturity : viz., 1st, a quantity of small granules comparable to the granular yolk-substance of the primitive ovum ; 2nd, collections of clearer vesicles and globules interspersed with the first, and in general partly mixed with them and partly situated in a deeper layer ; and, 3rd, the large oil globules. These last are usually somewhat coloured ; they are comparatively large, and in some fishes are very few in number, and even reduced at last to only one, which is then of proportionally large size. In all fishes, the number of oil globules appears from the observations of Retzius gradually to diminish as the ova approach maturity.† The large oil globules float quite freely in the fluid of the yolk ; so that from their greater lightness they always rise towards the side of the ovum which is turned uppermost ; but the other elements of the yolk-substance, and especially the small granules of the germ-disc, come in the mature ovarian ovum to occupy one side of the yolk, and, as they form a coherent layer, do not move readily from this place. The smaller granular par-

* See a paper by Dr. Davy in the Proceed. of Roy. Soc. of Lond. 1852, p. 149.

† See Retzius in Müller's Archiv. for 1855, p. 34.

ticles become more and more circumscribed in a layer on one side of the egg as it approaches maturity, so as to form a germinal disc; and this occurs independently of fecundation.

The germinal vesicle is not easily perceived in the ovarian ovum when it has attained some size. This proceeds in part from its extreme delicacy and transparency, and also from the opacity of the granules of the yolk within which it is situated. But it is to be observed also, that it disappears proportionally sooner than in other vertebrate animals. It is of considerable size in proportion to the rest of the ovum, having a diameter not unfrequently of $\frac{1}{50}$ or $\frac{1}{60}''$ in ova of $\frac{1}{20}''$. It is never to be found in ova that have left their capsules in the ovary; and according to Lereboullet's* observations in the pike and perch, it has already disappeared for a considerable time before it attains complete maturity. In the earlier stages of the growth of the ovum the germinal vesicle contains numerous distinct maculæ; but in the progress of development these multiply to a great degree, so that the vesicle is at last completely filled with fine clear cells, or brilliant vesicles, and extremely minute granules. When the vesicle bursts, its contents are dispersed over the yolk, and very probably are mingled or combined with the layer of germinal granules; but it is not probable, as Lereboullet supposes, that the whole of the formative layer of the germ (afterwards undergoing segmentation) is produced from the effused contents of the germinal vesicle. This multiplication of the maculæ and filling of the germinal vesicle with fine cells appears to be of an analogous kind to that which has been described by Vogt and Newport in the Batrachia; and it seems not improbable that in both classes of animals the dispersed maculæ may in some way or other, not yet fully ascertained, contribute to the origin and development of the blastodermic cells in the formation of which the process of segmentation results. It appears certain at least that, after the disappearance of the germinal vesicle and the dispersion of its contents, a marked change takes place in the disposition of the germinal part of the egg by its granular disc or layer becoming more circumscribed and distinct; and, as Lereboullet supposes, it may then be mingled with the brilliant points which proceed from the contents of the germinal vesicle.

The process of segmentation, into the description of which it is not intended at present to enter, is co-extensive with the granular layer or germinal disc of the ovum. The larger yolk globules and the fat cells are not immediately concerned in this process.†

* Resumé d'un Travail sur l'Embryogénie du Brochet, de la Perche, et de l'Ecrevisse, in Annal. des Scien. Nat. 1854, tom. i. p. 237. *et seq.*

† M. Coste (Comptes rendus, 1850, vol. xxx. p. 692.) has described the germinal disc as being formed only after fecundation; but from the observations of Vogt, Aubert, Lereboullet, and Ransom, it is ascertained that it exists previously.

The membranes of the ripe ovarian ovum of osseous fishes have been described by most recent observers as two in number; viz. 1st, the external tough membrane which some have called chorion or shell-membrane, and others vitelline membrane, which possesses a peculiar structure, hereafter to be described more particularly; and, 2nd, an extremely delicate film of membrane lying close to the yolk-substance and destitute of visible structure. The latter of these membranes is just discernible in the ovarian egg at the later periods of its growth; but in ova of two thirds their full size I have failed to perceive it. Dr. Ransom has observed, that in the Stickleback, Gasterosteus aculeatus, this membrane becomes more distinctly marked off from the substance of the yolk subsequent to impregnation, and that it follows the inflections of the surface of that substance during segmentation; from which he infers, that it is not to be compared with the vitelline membrane as heretofore described by authors in the ova of other animals. The observations which have been obligingly communicated to me by Dr. Ransom leave no doubt as to the existence of this inner membrane, and have shown the new and interesting fact that it is possessed of some vital contractile power. It seems probable that it proceeds from a consolidation of the outermost layer of the basement or clear substance of the yolk, in a manner somewhat analogous to the zona pellucida. But I refrain from saying more of it at present, as Dr. Ransom will ere long probably communicate his observations to the public in detail.

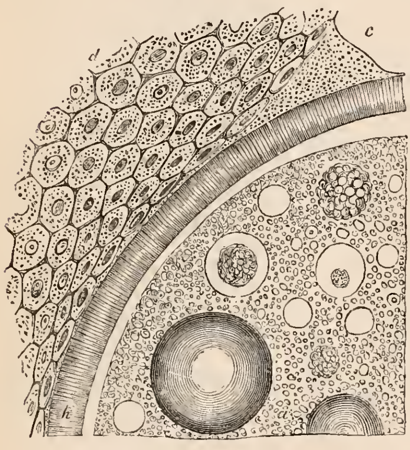
The external membrane of the Fish's egg which has been deposited in spawning or has been extracted from the ovary when approaching maturity, presents a remarkably well defined line internally, and is also generally smooth on its outer surface. In some fishes, however, as the perch, it is covered externally with villous, reticular, or other appendages, which serve to connect the ova in masses or strings, in the same manner as occurs with the albuminous matter added to the ova of some Batrachia, but in a less degree. In other instances, as the Stickleback, these villi or projecting processes are limited to one portion of the exterior. This membrane possesses considerable thickness and tenacity, and usually gives the ovum a nearly regular spherical form when imbibition is complete, as is the case after impregnation. Previous to that change, however, the outer covering of the Fish's egg is more yielding, and possesses so little elasticity, that it usually retains dimples or impressions made upon it from without. Two peculiarities of structure have been observed in this membrane which both merit farther attention, and one of which is of great interest.

The first of these to which I will refer is the dotted or porous structure of the external membrane. Von Baer* had remarked that the external membrane of the ova of the Cyprinus

* Entwickelungsgesch. der Fische, Leipzig, 1835.

genus was not entirely homogeneous, but was marked through its thickness with fine lines set perpendicularly to the surface. Vogt observed a similar structure, and described it more fully in the Salmonidæ.* More recently attention has been particularly called to it by the fuller description of the structure of the egg coverings in the Perca fluviatilis by Professor Müller of Berlin. In this fish Müller described the radiated lines as produced by fine tubes which pierce the whole thickness of the external membrane, beginning with cup or funnel-shaped dilatations on the exterior, preserving a nearly equal diameter throughout, and terminating on the inner surface.† The tubes have a slight spiral winding as they pass through. That they are really hollow tubes Müller ascertained by finding that he was able to press portions of the coloured oily contents of the yolk through them. Müller farther observed, that in the perch each tube is set in a small prism, which terminates by a hexagonal end on the outer surface. According to Dr.

Fig. 67 *.



Part of the ovarian ovum of the Salmon.

Semi-diagrammatic view of the section of a portion of the yolk, porous membrane and external layer of cells in an ovarian ovum of the salmon of $\frac{1}{40}''$ in diameter. *a*, portion of the yolk substance showing the various granules, granular and nucleated corpuscles, and oil globules composing it; *h*, section of the porous or dotted external membrane; *c*, portion of the outer surface of the same turned towards the observer so as to show the punctated or dotted marking produced by the external apertures of the fine canals which run through the membrane; *d*, the flat surfaces of the nucleated cells (epithelial or granular) which line the ovicapsule, between which and *h* they are seen edgeways lying close along the outer surface of the dotted membrane; a granular or dotted appearance in the contents of these cells seems to indicate their conversion into the dotted membrane, which is probably formed in successive layers from the exterior. The diameter of these cells is $\frac{1}{1250}''$, that of their nuclei $\frac{1}{3300}''$.

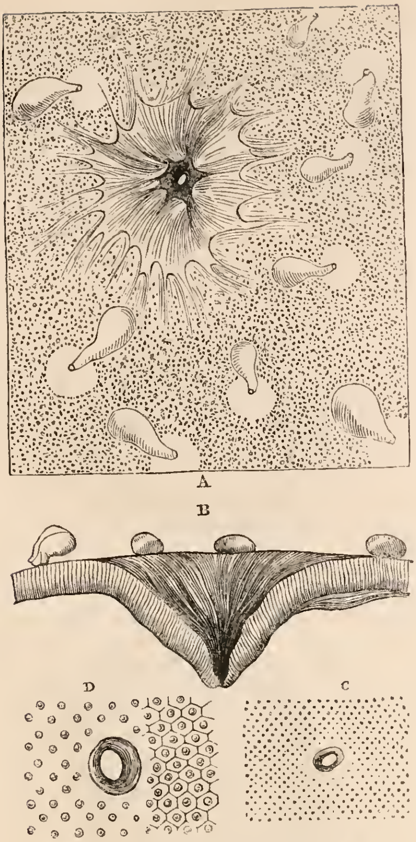
* Embryogénie des Saumons, Neufchatel, 1842.
† Müller's Archiv. for 1854, p. 186.

Ransom's observations, however, it appears that the structure described by Müller in the perch is peculiar to that fish, and belongs only to an outer covering superadded to the surface of the dotted membrane, which last resembles in all respects that of other fishes. This outer covering appears to be of cellular origin; and Dr. Ransom thinks it may be due to the separation of the tunica granulosa along with the ovum. The diameter of these tubes in the perch is about $\frac{1}{10000}''$. In most other fishes the fine lines which appear to be tubular are much smaller. I have observed them in several fishes, and have rarely found more than ten of these tubes in the breadth of $\frac{1}{1000}''$, and the tubes themselves or double lines bounding them were not more than $\frac{1}{25000}''$ or $\frac{1}{30000}''$ in breadth. In looking at the flat surface of the membrane the ends of these tubes give the appearance of a finely dotted structure to the membrane. It is quite possible, however, even where they are finest, to perceive the circle or lumen of the tube by using a high magnifying power; and I have thought that I could also in the salmon perceive a hexagonal marking of the intervals between the pores (see *fig.* 68 * D); but in this fish the size of the pores is only a third of that of the tubes in the perch as described by Müller, and the structure must be of a different kind according to Ransom's observation. All recent observers have recognised this structure in the external membrane of the fish's ovum. Müller conceived that the tubes he had observed in the perch might be connected with the introduction of the spermatozoa into the ovum; but Dr. Ransom does not find these tubes to pass entirely through the outer membrane of the perch's ovum, and has observed that the part of the true vitelline or dotted membrane which admits the spermatozoa is destitute of the additional layer; and it will immediately be shown that in all fishes a special and more direct passage for the admission of these bodies through the dense membrane is provided, constituting the second peculiarity of structure in the covering of the Fish's ovum before referred to.

The interesting discovery of an aperture in the external membrane of the ovum of osseous fishes is due to Dr. Ransom of Nottingham, who observed it first in two species of Stickleback or Gasterosteus, and afterwards in other fishes. This author made the farther interesting observation in the first-mentioned fish, that in impregnation the spermatozoa entered the ovum only through this aperture or micropyle. As this is the first instance in which the existence of this aperture and its relation to the process of fecundation have been ascertained by direct observation in a vertebrate animal, I will describe it more fully from Dr. Ransom's paper to the Royal Society of London*, and from farther information which he has obligingly furnished to me in private. I may also mention that I have fully confirmed Ransom's observations as to

* Proceedings of Roy. Soc. 1854, Nov. 23rd.

Fig. 68*.



Micropyle of the ovum in Osseous Fishes.

A. Enlarged view of a quadrangular portion of the surface of the mature ovarian egg of the Stickleback containing the micropyle from above. In the outer part of this figure the general dotted appearance of the membrane is seen, and here and there the pediculated flask-like processes attached to the membrane in this fish in the vicinity of the micropyle; the radiated shading represents the appearance of the funnel-shaped depression leading to the aperture of the micropyle, which is seen in the centre of the space it encloses.

B. Transverse section of the dotted membrane and funnel of the micropyle of the same egg somewhat more enlarged, seen in profile; the aperture of the micropyle is seen towards the point of the funnel. This view is semidiagrammatic, and the fine canals passing through the membrane are represented fewer and wider than they are in nature.

The diameter of the whole ovum was about $\frac{1}{20}''$; the thickness of the external membrane $\frac{1}{1000}''$; the width of the base of the funnel about $\frac{1}{150}''$; the depth of the funnel $\frac{1}{200}''$; the diameter of the micropyle aperture at the apex $\frac{1}{3300}''$.

C. Small portion of the membrane at the apex of the funnel containing the aperture of the micropyle pressed flat, magnified 500 diameters; from the trout's egg.

D. A similar portion of the membrane magnified 1000 diameters. The lumen of the canals is seen, and an indication of hexagonal division of the spaces between them, represented somewhat too distinctly in the figure.

the existence of the micropyle in the ova of several fishes; and though I have not yet been so fortunate as to perceive the spermatozoa actually passing into the ovum through this aperture, the accuracy of Ransom's observations on this as well as on other points leave little doubt as to the fact stated by him.

The micropyle in the Gasterosteus, as described by Ransom and observed by myself, is a considerable funnel-shaped depression in the outer membrane, which projects inwards on the granular substance of the yolk, so as to indent this layer to some depth, and probably to reach near to the germinal vesicle, which lies imbedded within the germinal layer. The inner narrow end of the funnel terminates in a distinct rounded or elliptical mark, with a fine but distinct line bounding it, which has all the appearance of a foramen, and which is either an open passage or one which is closed only by an extremely delicate structure. The funnel-shaped depression leading to the micropyle may be easily seen on the surface of the egg of the salmon or trout when slightly dried of the adhering moisture, and is of such a size that it may be perceived with the naked eye or with a lens of low magnifying power. In order to perceive the micropyle itself, however, or pore in the point of the funnel, it is necessary to remove from the egg that portion of the dotted shell membrane containing the funnel; and having freed it from the adherent granules of the yolk-substance by careful washing, for which Ransom has recommended a solution of acetate of potash, this part of it may be viewed under pressure with great ease with a magnifying power of 200 or 300 diameters. The porous structure of the membrane is then seen to continue very nearly up to the margin of the micropyle. This last has a diameter of from $\frac{1}{3000}''$ to $\frac{1}{6000}''$. The appearance of a double outline surrounding the micropyle proceeds from the circumstance that, in looking through the funnel we see at once two portions of the narrowing wall of the passage of different widths.

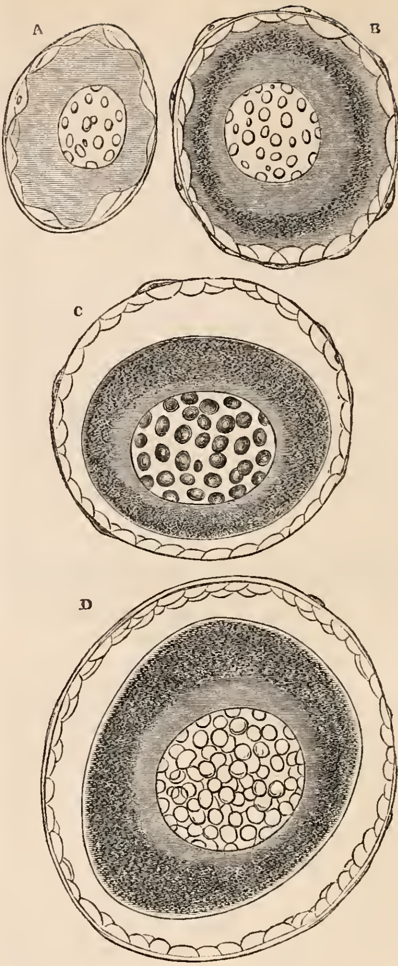
In Ransom's experiments, very soon after spermatic fluid was placed in the water round the ovum of the Stickleback, several of the spermatozoa were perceived to pass in at the micropyle; and immediately upon this water was imbibed, and the space named the respiratory chamber was formed between the yolk surface and the external membrane; a change which in this fish did not take place in the unfecundated ova, but which in some others occurs without impregnation. It is from this fact apparently that Ransom is inclined to the opinion that the micropyle may be closed by a very delicate membrane, which in fecundation is removed or broken through by the entrance of the spermatozoa; but with regard to this point there is still some uncertainty. The germinal vesicle previous to its disappearance is imbedded below the superficial layer of yolk-substance in a stratum of granular matter; and Ransom conceives that at the time of the rupture of the vesicle, this granular matter being mingled with the contents of the vesicle, the more immediately germinal part of the egg is formed from the mixture of the two. However this may be, it seems not improbable, from the observations now referred to, that the spermatozoa are conveyed directly to the germinal part of the egg by the funnel of the micropyle. I shall afterwards have to state the more numerous instances in which, following its first discovery by J. Müller in the Holothuria, a micropyle has been detected in the ova of Invertebrate animals; and I may attempt to show the great importance of this aperture in connection with fecundation in ova with thick external coverings to which the spermatic substance does not gain access till the later periods of their formation. The accompanying figures of the micropyle in the Stickleback will give a sufficiently clear view of this remarkable structure. At present it may be permitted to remark that, if we consider the size of this aperture, and the ease with which it may be found in the ova of fishes by an observer whose attention has been called to its existence, together with the fact of its having been so long overlooked previously, there is much ground for caution as to negative statements as to the existence of a similar aperture in the ova of other animals. I have already made allusion to this subject in the previous sections, in which I have stated that Dr. Ransom has expressed to me his firm conviction, founded on observations, that the micropyle exists also in the ova of Batrachia. At the same time it is quite probable that such an aperture may only exist or be required for the admission of the spermatozoa when fecundation is of late occurrence, and when the covering membrane of the ovum is so dense as to resist the penetration of the spermatozoa through its solid substance.

It is right also to mention that the existence of this aperture, or rather the funnel leading to it, did not entirely escape the observation of preceding physiologists. The accurate Von Baer, in his work on the development of Fishes*, has described in the Bream (Cyprinus blicca) a funnel-shaped depression of the external membrane, which reached nearly to the surface of the germ; and he observed that this funnel was effaced as soon as the imbibition of water took place. He considered this aperture as most probably owing to the escape of the germinal vesicle from the surface of the yolk and through the coverings of the ovum, in the same manner as he had described in the frog†, and did not therefore conceive it to serve any immediate purpose in connection with the introduction of the spermatozoa. Dr. Ransom has observed that the effacement of the funnel which he had seen in the Stickleback is not invariably the consequence of fecundation in the Fish's ovum; for in the salmon and trout

* Entwickelungsgeschichte der Fische, Leipzig, 1835, p. 9. figs. 1. and 2.

† De Ovi Mammal. &c., pl. xxv.

Fig. 69.*



Development of the ova of Gasterosteus.

A. B. C. D. Four ova of the Stickleback in the earlier stages of their development within their ovisacs.

In that figured at A, which is the earliest, $\frac{1}{400}''$ in diam., the germinal vesicle placed near the centre has scarcely any perceptible membrane or wall, but resembles a gelatinous mass in which the small number of maculæ are developed: there is as yet no yolk, but only a slightly turbid fluid substance filling the space between the ovisac and the germinal vesicle: delicate epithelial cells project from the inner surface of the ovisac.

In B. $\frac{1}{250}''$ the maculæ have increased in number, the germinal vesicle, as well as all the other parts, has increased in size, the fine granules of the yolk substance have begun to be deposited towards the periphery, but there is as yet no vitelline membrane. The wall of the ovisac is now more distinct, and besides the internal cells, there are seen on the exterior the nuclei of external flattened cells.

In C. $\frac{1}{180}''$ the maculæ have become more numerous and distinct; the yolk granules are more opaque and in greater quantity, and the mass of the yolk more circumscribed, a clear space now intervening between it and the wall of the ovisac.

In D. $\frac{1}{140}''$, although the number of maculæ has greatly increased by endogenous multiplication, the germinal vesicle has not now undergone an enlargement proportional to that of other parts of the egg and ovisac: the granules of the yolk, especially towards the surface, are much increased, and a narrow clear marginal space on the surface now indicates the commencement of the formation of a zona or vitelline membrane. This appearance is also slightly perceptible in *fig.* C.

The dimensions of the several parts in these different specimens were as follows:

	A.	B.	C.	D.
Ovisac - -	·0025	·004	·0056	·007
Yolk - -	—	—	·0042	·005
Germinal vesicle -	·001	·0016	·0025	·0026
Maculæ - -	·00015	·00018	·00025	·0003

he found the funnel-shaped aperture to remain for some time after the completion of fecundation, and in none of the fishes he has observed does he conceive the aperture of the micropyle to be closed.

The ova of osseous fishes appear to take their origin within the rudimentary follicles or ovisacs of the ovary much in the same manner as those of the Batrachia. The earliest part of the ovum that can be distinctly seen within the follicle is a vesicle of about half the diameter of the primitive follicle itself. A little later this vesicle is seen to be surrounded with a clear, jelly-like substance, in which some small dark granules are deposited chiefly towards the surface of the vesicle. There is as yet no enclosing membrane, but the follicle is seen to be lined by a layer of extremely delicate hyaline cells, often difficultly perceptible. The earliest recognisable part of the ovum, therefore, is the germinal vesicle; which, as in other animals, has soon deposited round it the clear gelatinous basement-substance of the yolk, in which the opaque yolk granules soon make their appearance. There is not at first any vitelline or other membrane enclosing the primitive parts of the egg, and indeed it is a considerable time before any such membranes are formed. The deposit of vitelline granules increases rapidly, so as to give the yolk considerable opacity; afterwards larger globules appear, and seem to increase by endogenous multiplication.* The oil globules are at first small, and equally diffused through the whole yolk; it is only in the later stages of formation that they unite into fewer and larger globules.† The granular or primitive yolk-substance continues to surround more immediately the germinal vesicle till the period when this vesicle is ruptured, and is probably spread over the germinal disc of the egg. Similar granules also occupy, however, in a layer the surface of this part of the egg previous to the rupture of the germinal vesicle; so that it is not probable that the germinal disc owes its origin, as Coste states ‡, entirely to the effusion of the contents of the germinal vesicle.

* Lereboullet, loc. cit.

† Retzius, loc. cit.

‡ Hist. gén. et part. du Développ. des Corps orgau. tom. i.

The ovum receives its firm porous membrane while within the ovarian capsule, but only in the latter part of the time of its formation. This membrane lies very close to the inside of the ovisac, is at first comparatively thin and destitute of apparent structure, and gradually increases in thickness towards the time of its approach to maturity. At the same time a remarkably thin pellicle may be distinguished close to the surface of the granular yolk-substance, scarcely meriting the name of membrane. As already remarked, it is difficult to determine what is the true homological signification of these membranes. The inner one might by some be regarded as a representative of the zona pellucida, or a consolidated pellicle on the surface of the yolk, though it must be admitted that Ransom's observation, that it follows the segmentation, is opposed to this view, and makes it more probable that it is only a part of the yolk itself. The origin of the external porous membrane I am inclined to connect rather with the interior of the ovarian follicle; but whether by exudation from it, or by amalgamation of the innermost layer of epithelial cells of the follicle, I have not yet been able to determine. I am inclined to regard the latter as most probable, and that this is the true vitelline membrane.

The manner in which the micropyle takes its origin has not yet been ascertained. It will afterwards be shown, that in a considerable proportion of those invertebrate animals in which this aperture in the egg coverings is found, it has existed from a very early period, and proceeds from the remains of the pedicle by which the ovum is originally connected with the ovarian substance. Such a pediculated connection has certainly not yet been observed by most of those who have investigated the ovarian ovum of fishes.* Rathke, indeed, observed the appearance of the remains of a pedicle in the detached ova of the Blennius viviparus †; according to Ransom the micropyle in the Pike is not a depression, but projects from the surface like a trumpet-shaped process; and in the earliest stage of development of the ovarian ovum of Trigla hirundo, according to Leydig ‡, the shape is somewhat pyriform or pediculated, in the same manner as in some of the invertebrate animals.

On the other hand, Ransom expressly states that he has never been able to observe the slightest connection in Gasterosteus between the pedicle of the ovum by which it is attached to the ovary, and the micropyle. This aperture he says is always situated at that side of the ovum towards which the germinal vesicle and the germinal disc are placed; but these parts have no regular connection with the pedicle. The pe-

* The pedicle here spoken of is not that of the ovarian capsule containing the ovum, but of the ovum itself within the capsule.

† Abhandlung. zur Entwick. part. ii. p. 4.

‡ Müller's Archiv. for 1854, p. 376. fig. 6.

dicle, he affirms consists only of the ovarian structure, and of no part of the membranes of the ovum. From his observations on Gasterosteus, in which the projecting bodies from the porous or outer membrane in the vicinity of the micropyle enable this part to be easily recognised, he feels confident that if any pediculated connection had existed it could hardly have escaped notice.

When the ovarian ovum has attained maturity it falls into the cavity of the ovary, or that which may be regarded as ovary and oviduct united, by the rupture of the ovarian capsule in which it is contained. The walls of the ovi-capsules have by this time become extremely thin; but according to Von Baer a small stigma or non-vascular mark may be distinguished where the rupture takes place. After the ova have fallen into the common cavity they are surrounded by a considerable amount of secreted albuminous matter, by which in some fishes the ova are covered when excluded. In some this albuminous secretion serves to unite the spawn in chains or networks. In other fishes the ova are covered externally with villous projections; but the manner in which these are formed has not yet, so far as I am aware, been observed.

One of the most remarkable, but as yet quite unexplained, varieties in the external coverings of the ovum in one of the osseous fishes, is that discovered and recently described by Ernst Hackel, as occurring in the family of Scomberesoces.* This consists in the formation, in the space between the surface of the yolk and the vitelline membrane (that is, the porous membrane), of a layer of long and very distinct fibres, which are wound somewhat spirally, but irregularly, over the surface of the yolk. Hackel has traced the gradual formation of these in fresh specimens of Belone from points on the surface of the yolk-substance; and in other genera he has observed several varieties in the forms of the fibres. They are on an average about $\frac{1}{3500}''$ thick, and long enough to surround the egg several times; and they appear to resemble the fibres of the elastic yellow tissue more than any other animal substance, but do not entirely agree with them. In the meantime we must suspend our judgment as to this very extraordinary addition to the surface of the ovum until farther observations shall have been made as to their distribution in various fishes or other animals, and as to their relation to the development of the embryo. †

Invertebrate Animals.—The ova of Invertebrata may be considered under two principal divisions, according as they present more of the large-celled or of the finely granular yolk-substance. The ova of the first kind are usually of a larger size; they possess a larger germinal vesicle, and often a divided or multiple macula; and the process of segmentation in them is either partial, that is, limited to one part of the surface of the yolk, or it occurs in a different manner on the upper and lower sides of the ovum. In these there is, in fact, nutritive as well as formative yolk. In the other division of animals the yolk is finally molecular, or is mainly composed of smaller granules, and is chiefly of the formative kind; segmentation usually involves the whole yolk, or if not so, is very nearly complete: the germinal vesicle is generally clear, and the macula most frequently single, and well marked. It is true that the form and structure of the ova of Invertebrata presents many and considerable varieties, as might indeed be expected among animals of such diversity of organisation as belongs to the great divisions of the Radiata, Articulata, and Mollusca; but still it is to be observed that as a greater degree of simplicity exists in the form and structure of the primordial elements than in the more developed textures and organs of animals, so also we find that much closer analogies may be traced among these elements in the lowest classes of the animal kingdom. We meet, therefore, with little difficulty, even in the most diverse tribes of the Invertebrate animals in tracing the correspondence of the essential parts of the ovum; and we are enabled also to trace a more close analogy between these and the corresponding parts in the Vertebrata than might have been expected. We are therefore warranted in applying to them similar designations; and we have daily increasing reason to trust to observations made on the ovology of the lower animals as the means of extending the knowledge of the reproductive functions in Vertebrata and in Man. Thus the recent discovery of the micropyle aperture in some animals, and the certain and clear observation of the penetration of the sperma-

* Müller's Archiv. 1855, p. 23. See plates IV. and V.

† Some time after the above was in the hands of the printer, I received the first and second parts of the seventh volume of the Zeitsch. für Wissen. Zool., containing a notice of the discovery of the micropyle in the Salmo salar, and S. fario, by Professor Bruch of Basle. The observations leading to this discovery were made in the winter of 1854-5; and it is right to state here, that Dr. Ransom's discovery of the micropyle in the gasterosteus, which was communicated to the Royal Society on the 23rd of November, 1854, was made in the months of June and July previous; and these observations had been communicated to Professor Sharpey and myself in August and September. In the beginning of January, 1855, Dr. Ransom informed me by letter of his having found the micropyle also in the Trout, and a few days later in the Salmon. I then saw the micropyle in the ova of both of these fishes; and I have since examined it minutely in the Stickleback, and have confirmed in every particular Dr. Ransom's statements. The existence of the micropyle in these Vertebrate animals has thus been established by several independent observations; and I believe that no one who uses the proper means can fail to detect it in these and other fishes. Professor Bruch's observations were chiefly made on the ova after impregnation, which may explain the reason of his having failed to perceive the connection pointed out between this aperture and the depression in the centre of the germ disc. Bruch was like myself unsuccessful in perceiving the entrance of spermatozoa by the micropyle. His measurement of the micropyle in the Salmon and Trout does not agree with mine, making it much smaller.

tozoa into the ovum in others, suggest novel and more general and extended views of the process of fecundation, and while they add certainty to the more limited observations of the same kind made upon animals higher in the scale, tend to prevent the adoption of partial views in regard to these functions of the animal economy.

It is principally among the more highly organised Invertebrata that we meet with that form of ovum in which the nutritive is combined in considerable quantity with the formative yolk, and in which segmentation is partial, such as the Cephalopoda, Insecta, Arachnida, Myriapoda, Crustacea, and some of the Articulate Worms. In by far the greater number of the Mollusca, such as Gasteropoda and Acephala, the ova belong to the smaller kind with more or less complete segmentation, as also in most of the Annelida, as Hirudinea and Lumbricina, the Nematoid, Cestoid and Trematode worms, with the Planariæ, the Rotifera, Echinodermata, Bryozoa, Acalephæ and Polypina.

I now proceed to give a short statement of the principal facts that have been ascertained as to the structure of the ovum in these animals, and to state some details with regard to some of those which are either best known or which present phenomena of the greatest interest.

1st. *Large-yolked Ova with partial Cleavage. Cephalopoda.*—The ova of this class of animals have already been referred to in connection with those of birds, scaly reptiles, and cartilaginous fishes, to which they present in some respects a greater analogy than to those of almost any of the Invertebrata. The considerable size of the germinal vesicle with its multiple maculæ, the large mass of the coloured yolk (nutritive), composed of conglomerated masses of yolk corpuscles, and the very limited extent of the process of segmentation, which affects only a round disc of the germinal part of the egg, are all characters in which the ova of the Cephalopoda, at least the Sepia and Loligo, which have been fully examined, are ascertained to be similar to those of the large-yolked group. We owe the most of our knowledge of the ova of this class and their development to Kölliker's interesting treatise, published in 1844.* The ova of the Sepia are deposited singly, but are attached in numbers close together by pedicles to the stalks of Algæ and other marine productions. Those of Loligo are arranged in small masses, in which a number are enclosed in a general bag or covering of gelatinous matter, which is attached along with others of the same kind by means of pedicles. I have found those of Sepiola also thus enclosed in small pyriform capsules.

The ovum of Cephalopoda possesses a firm laminated external covering or chorion, which in some is darkened on the surface by the colouring matter or ink, in others is transparent and colourless. Immediately within this outer membrane is situated a structureless vitelline membrane, containing the mass of yolk-substance, which is separated from the membrane by a slight interval. It appears to be ascertained that the chorion is formed by superposition on the surface of the ovum during its descent through the oviduct.

In the ovary the ova are contained in slender capsules, attached to the rest of the ovary by narrow pedicles. When ripe the ova escape from the capsules, in some species by an irregular laceration, in others by a more regular and defined opening, and, falling into the cavity of the ovary, pass thence into the oviduct, through which they are finally excluded. Fecundation is believed to occur soon after the escape of the ova from their ovicapsules or in the earlier part of their descent through the oviduct; but this process has not, so far as I am aware, been directly observed.

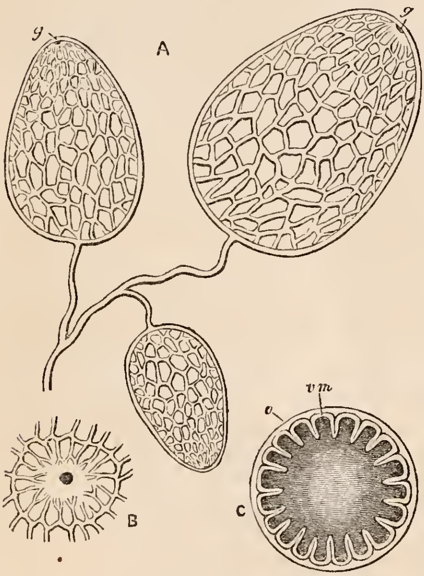
The ova of the common Sepia officinalis have an oval form, one end being much narrower than the other. It is at this the pointed extremity or narrow pole of the egg that the germinal vesicle is situated, while the egg is in the ovary, close under the vitelline membrane; and it is at this part also that, at a subsequent period, the process of segmentation and the first formation of the embryo take place. The narrow end is therefore the germinal pole. This extremity of the egg is always turned to the opposite side from the pedicle of the capsule, which is attached to the middle of the blunt or wider end.

One of the most remarkable peculiarities in these ova, is the extraordinary change which the outer part of the yolk and the vitelline membrane undergo during the greater part of the time occupied by the growth of the ovum in the ovary. This change, of which the appearance had been known to some previous observers, was first accurately described and explained by Kölliker. From his observations it appears that at first the ovarian ova are quite smooth on the surface, and that at the time of complete maturity of the ovum, or after its escape from the ovary, the vitelline membrane and surface of the yolk are also quite smooth; but that in the intervening time, that is, during the greater part of the period of its growth, the surface of the yolk is indented or marked with peculiar grooves, into which folds of the vitelline membrane pass so as to line them to the bottom, somewhat after the manner in which the pia mater descends into the sulci of the brain, but without the same convoluted form. This has been represented by Kölliker in the Sepia, and I have observed it in this genus, and have confirmed in every particular that author's statements as to this change. It appears that at first these inflections of the yolk and membrane begin as longitudinal folds, extending between the wide and narrow poles of the ovum, and, gradually increasing, become at last so deep as almost to meet each other in the interior of the yolk. Subsequently they are traversed by more numerous depressions.

* Entwickelungs-gesch. der Cephalopoden, 4to. Zurich, 1844.

which subdivide them; and as these cross folds are formed the longitudinal ones beome gradually shallower. The surface of the egg then presents the reticulated appearance which is shown in *fig.* 70.* On making a section through such an egg, hardened in alcohol or any other suitable reagent, it is easy to perceive that the ovicapsule takes no part in the inflections, but that they consist entirely in the grooving of the yolk, and the corresponding bending into the grooves of the vitelline membrane. This state is maintained till the ovum is approaching maturity, when the depth of the grooves or folds speedily diminishes; and these come at last to be completely effaced in those ova which have left the ovicapsule. In Loligo, it is stated by Kölliker, there are only the longitudinal folds. No satisfactory opinion has been offered as to the cause of this peculiar structure.

Fig. 70*.



Ova of the Sepia. (*From Kölliker.*)

A. Three ovarian ova of the Sepia in somewhat different stages of advancement attached by their pedicles to the ovary, and represented several times magnified. They all show the reticulated markings on the surface produced by the folding in of the vitelline membrane; *g*, the place of the germinal vesicle and possibly also of a micropyle at the small pole of the egg, in which segmentation afterwards occurs.

B. Direct view of this germinal pole of one of the ova, showing the absence of the folds towards the centre in which the germinal vesicle is situated.

C. Cross section of one of the ova, showing at *o* the unfolded or smooth ovarian capsule, and at *v m* the folded vitelline membrane.

Towards the narrow pole of the ovum, the folds now described become less marked; and they are entirely absent just at the pole itself, so that the germinal vesicle may be seen in the smooth space which is left between them. At this place I had some expectation to find an aperture of the nature of a micropyle; and I accordingly sought for it in some specimens of the ovarian ova of Sepia which I had preserved in alcohol, but without success, perhaps on account of the opacity produced in the membranes by the alcohol, and the adhesion of the yolk substance to them. Professor Kölliker has since informed me that he believes the micropyle to exist in these ova, which I think extremely probable.

The germinal vesicle, according to this observer, remains entire and visible till the ova are mature, as may be seen by the examination of specimens hardened in alcohol. It disappears just about the time of the ova leaving the ovarian capsule; but in several instances he found it still remaining in ova that were already free. It was always gone in those ova which had regained the smoothness of their exterior.

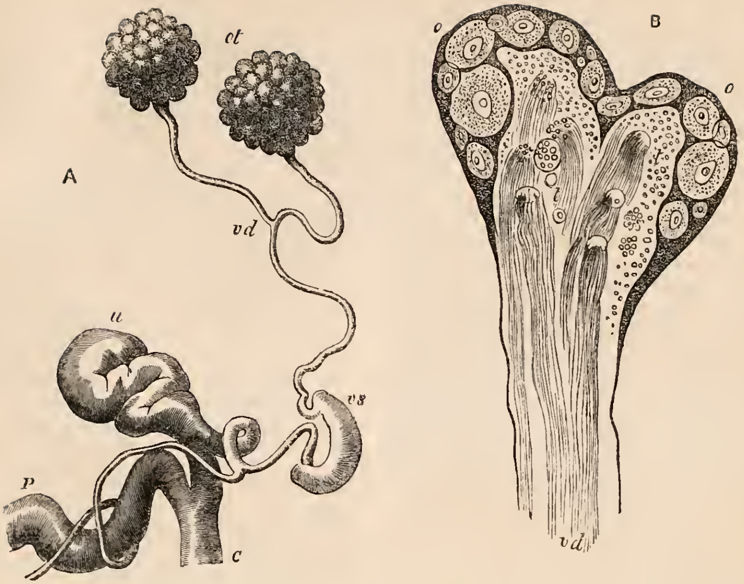
The yolk-substance of the mature ova consists entirely, excepting immediately at the seat of the germinal disc, of corpuscles somewhat similar to the vitelline tablets of the Frog's egg. At an earlier period there are heaps of fine granules of the same size, from which the corpuscles are therefore probably formed. In the earliest stage the vitelline substance is entirely composed of fine molecules — the primitive yolk — which appear to be formed in the same manner as in other animals.

The Cephalopoda furnish a remarkable example among the Invertebrata of a very limited or partial segmentation. This process, upon the detailed description of which I will not enter here, usually commences in a spot either in or more frequently near to the germinal pole, by the formation of the primitive groove which extends across the disc. The formation of the second groove, which crosses the first, the production of other radiating grooves, the separation of annular sets of segments from the periphery, and the successive steps of the process which follow, are probably determined by the same circumstances which have been referred to as related to this phenomenon in the cicatricula of the Bird's egg.

Gasteropoda.—In the greater number, if not almost all, of the remaining Mollusca, the ova differ greatly from those of the Cephalopoda, and approach more nearly to those I have classed under the groups possessing the small or middle sized yolk, which is principally or entirely formative, and which undergoes a more or less complete segmentation.* In the Pteropoda and in those of gasteropodous Mollusca, which have the male and female organs in the same individual, there is a remarkable combination of the ovary and testis in a single hermaphrodite organ, usually

* The genus Sagitta, among the Pteropoda, is, however, probably an exception to this statement, as in it, according to Darwin, the embryonal part of the yolk is distinct from the rest, or rather covers it like a ring.

Fig. 71 *.



Genital Organs of Phyllirhoe bucephalum, one of the Hermaphrodite Gasteropoda. (From H. Müller and Gegenbaur.)

A. The compound or hermaphrodite organs dissected out and represented several times magnified; *o t*, the two productive organs each composed of ovigerous and seminiferous parts; *v d*, the common excretory ducts for both kinds of organ; *v s*, the seminal vesicle; *u*, the uterus; *p*, a part of the penis; *c*, the common external vent.

B. One of the lobes of the common productive organ laid open and more highly magnified. Towards the surface *o o*, the ova are seen in different stages of development in the ovarian stroma; in the interior *t t*, the substance of the testis with spermatic cells and spermatozoa in various degrees of advancement; some of the filaments being very long; *v d*, the common excretory duct for ova and spermatozoa.

enclosed in the liver, the nature of which was for a long time involved in obscurity, and occasioned much doubt and difficulty to naturalists. The explanation of this peculiar structure we owe first to H. Meckel*, and Leuckart†; and more recently H. Meckel and Gegenbaur have described this organ particularly in one of the heteropodous Mollusca, viz. Phyllirrhoe bucephalum.‡ The outer part of this curious organ constitutes the ovary, the inner the testis; and the products of these respective organs, in leaving the seat of their first formation, pass together into an inner common cavity, and thence downwards in the excretory duct. There is, therefore, a common outlet for both. The ova and spermatozoa most frequently pass out at different times; but occasionally both these reproductive elements are seen together in the passages. It seems probable therefore that they in general meet for impregnation only in the lower part of the passages; but this apparently is not yet fully determined, and the modes of union may be

* Müller's Archiv. for 1844, p. 483., see plates xiv. and xv.

† Zur Morphologie und Anatomie der Geschlechts Organ. 1847, p. 128.

‡ Zeitsch. für Wissen. Zool. vol. v. p. 355. pl. xix.

various in different genera or families. At all events, the primitive ova and spermatozoa seem to come into contact with each other previous to the addition of the enveloping membrane.*

The ova of the Mollusca are in general of small size. The yolk consists of a viscid albuminous substance, containing suspended in it minute granules, and a variable quantity of coloured oil globules. The germinal vesicle is proportionally of considerable size; and the macula is distinct and granular. Leuckart† states that he and Nordmann have ascertained that in Lymneus, the first part of the ovum which is formed is the germinal vesicle, that the yolk-substance begins as a clear transparent albuminous matter surrounding the germinal vesicle, and, as we have seen in various other animals, the granular yolk matter is gradually deposited in this clearer part of the vitelline substance, occupying at first princi-

* The hermaphrodite gland exists in the Pteropoda, Apneusta, Nudibranchia, Infero-branchia, Tectibranchia, and Pulmonata. The Mollusca which have separate sexual organs belong chiefly to the orders Cyclobranchia, Scutibranchia, Tubulibranchia, and Cirribranchia, some Heteropoda, Pectinibranchia, and operculate Pulmonata or Cyclostoma.

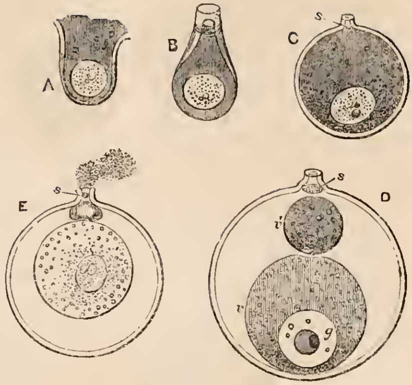
† Article Zeugung, p. 800.

pally its outer part. The vitelline membrane does not exist at first, but seems to be formed at a later period by the consolidation of an external layer of the primitive yolk substance.

The time of the disappearance of the germinal vesicle has not been determined in many of these Mollusca. Previous to segmentation a phenomenon occurs, which has now been observed in a large number of animals, but which first attracted special attention in the gasteropodous Mollusca; viz., the separation of one or more clear hyaline liquid globules of considerable size from the surface of the yolk substance, into the space between it and the vitelline membrane. This was first observed by Dumortier*, and described by Pouchet†, by Van Beneden in the Aplysia ‡, by Nordmann in Tergipes Edwardsii §, by C. Vogt in Actæon ||, and by various others. A precisely similar phenomenon has also been observed in some of the Vertebrata, as in Mammalia by Wharton Jones, Barry, and Bischoff, and in Batrachia by Newport. But though this separation of one or more hyaline globules from the yolk-substance at the time of segmentation appears to be a very general accompaniment of that process, it must be confessed that its import, either in connection with fecundation or development, has not yet been ascertained.

Acephala. — In Acephalous Mollusca the ova are generally of small size, the yolk-substance principally finely granular, the germinal vesicle clear, with a distinct macula, which last not unfrequently presents the form of a double or elongated biscuit-shaped particle. The vitelline membrane is distinct and possesses considerable strength; and there is generally a considerable space occupied by clear fluid between it and the surface of the yolk. The most interesting feature of the ova of these Mollusca is the funnel-shaped aperture which most of them possess, leading through the vitelline or external membrane into the space occupied by the yolk. This aperture, styled micropyle by J. Müller in the Holothuria, the first instance in which it was discovered, in 1850 ¶, was observed in the ova of Unio and Anodonta by Leuckart ** and Keber. †† The latter author supposed that he had observed the penetration of a spermatozoon into the ovum through this aperture, and has described with great formality and minuteness all the phenomena which he conceived were related to that process. Although Keber was correct in asserting the existence of the micropyle in these Mollusks,

Fig. 72 *.



Ova of Unio in different stages of development.

(A. B. C. and D., *from Hossling;* E. *from Keber.*)

A. The early stage of the ovum, when the germinal vesicle alone is distinguishable lying in a bulging part of the ovarian substance.

B. The same somewhat more advanced; the ovicapsule and vitelline membrane have assumed the pediculated form, and the yolk granules surround the germinal vesicle.

C. The ovum now enlarged and spherical in form, the yolk granules increased in quantity, and the pedicle narrowed so as to form a short micropyle tube; *s*, the small body taken by Keber for a spermatozoon, existing long previous to the occurrence of fecundation.

D. The ovum, &c. at a later stage; *g*, the germinal vesicle; *v*, the yolk; *v'*, the separated portion of the yolk; *s*, as in C. now enlarged.

E. A nearly similar stage of the ovum as figured by Keber. Some of the contents of the separated portion of the yolk are escaping through the micropyle aperture; *s*, Keber's alleged spermatozoon.

it appears that the body described by him as spermatozoon cannot have been of that nature, seeing that it has been proved by other observers that the appearance on which Keber's supposition was founded existed long before fecundation, and remained long after the commencement of embryonic formation in the same condition.*

The existence of a similar aperture or micropyle in several other Acephalous Mollusca has been ascertained by the recent investigations of various authors; but the actual entrance of the spermatozoa by the aperture, has not, so far as I aware, been satisfactorily observed. There seem, however, to be sufficient grounds for believing that in the Acephala, as in other animals in which it is found, the micropyle is immediately related to the process of impregnation, by affording a ready access of the spermatozoa to the yolk through the more resistent membranes of the ovum. The accompanying figures from Keber and his critic Hessling give a sufficiently clear view of

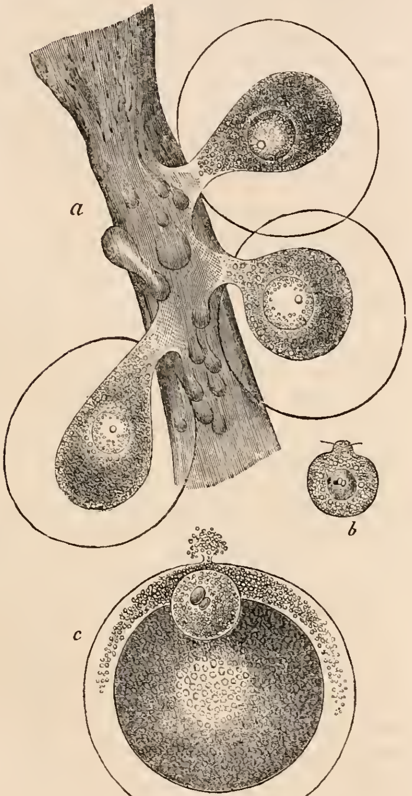
* Hessling, in Zeitsch. für Wissensch. Zool., 1854, vol. v. p. 380.; and Bischoff, Wiederlegung des von Dr. Keber bei den Naiaden, &c. Giessen, 4to. 1854.

the nature of this structure in the mature ovum of Anodonta.

In this family of Mollusca the micropyle forms a small but very apparent funnel-shaped projection from the surface of the outer membrane; and its hollow nature may easily be ascertained by the fact that the fluid and granular yolk-substance may be forced through it from within. The yolk ball is placed excentrically within the vitelline membrane, the inner surface of which it touches just at the place where the micropyle is situated.

From a variety of observations, it has been shown that the micropyle of the Acephalous Mollusca owes its origin to the early pediculated attachment of the ovum. This has been fully brought out by the observations of Hessling in Unio and Anodonta, of Leydig in Venus, and of Lecaze Duthiers in Cardium and some other genera.* From these observations it appears that the ova first arise in the ovarian stroma by the formation of the germinal vesicles, as in most other animals, each vesicle possessing a distinct single macula. These vesicles come very soon to be surrounded by some of the primitive or finely granular yolk, which gradually increases in quantity. These parts are from a very early period enclosed by a membrane which may be regarded as vitelline, but which is differently disposed from that in any of the animals previously referred to; for, instead of having a regular and complete spheroidal or vesicular form, this membrane is elongated at one part into a pedicle, so as to give the whole of the early ova a pyriform shape, and so as to attach them to the ovarian substance by the pediculated parts of the vitelline membrane. In Venus de-

Fig. 73*.



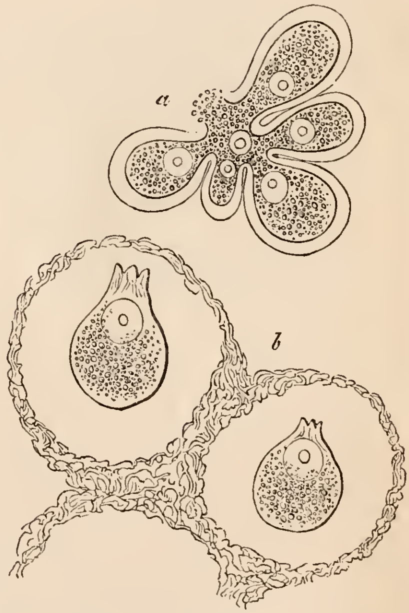
Structure and Formation of Ova in Acephala. (*From Lecaze Duthiers.*)

a. Portion of the ovary with three pediculated ovicapsules and contained ova from Cardium rusticum, magnified 400 diameters; the micropyle is afterwards formed at the place where the pedicles are detached from the secreting cœca of the ovary.

b. Unripe ovum of Spondylus gæderopus magnified 170 diameters, showing the remains of the capsule at the upper part, and the projection of the vitelline membrane at the same place where the micropyle is situated.

c. Ripe ovum of the same burst by pressure, showing the escape of some yolk granules through the micropyle and into the space between the yolk and the outer membrane. In this and the previous figure the double state of the macula is represented.

Fig. 74*.



Ovarian ova of Venus decussata. (*From Leydig.*)

a. A group of five ova in their earliest stage projecting from the ovary in their pediculated capsules: the germinal vesicles with single macula, the vitelline granules, vitelline membrane, and ovicapsule are all distinct.

b. Two ovicapsules within which at a more advanced stage the ova have become detached from their pedicles, the remains of which at the upper ends of the ova form the micropyle. A considerable amount of albumen has been deposited between the ovum and the ovicapsule.

* Annal. des Scien. Nat. 1854, ii. p. 155.

cussata, according to Leydig*, the ova are arranged in aggregated pediculated groups, from which it seems probable that they are originally produced in numbers by the multiplication or division of multiple germs, somewhat in the same manner as will afterwards be stated to have been observed by Meissner among the Gordian Nematoid Worms. An albuminous layer is afterwards formed externally, and may be instrumental at last, from its increasing thickness, in separating the ovum from its pediculated attachment to the ovary. There seems therefore to be little doubt that in these Mollusca, and in a certain number of other Invertebrate animals in which the micropyle has been observed, this apparatus is produced by the remains of an original or early ovarian pedicle. In the Unio and Anodonta it is certainly not formed by the peculiar process of development from within the ovum, which has been elaborately described by Keber.† It will afterwards be shown, however, as indeed may be concluded from what has already been stated in regard to osseous fishes, that in other animals the micropyle may arise in other modes and without the early existence of the pedicle now described.

When the ova are detached by the rupture of the pedicle in the Acephala, they lie, in different stages of advancement, but all provided with the micropyle, in the general ovarian cavity. The coverings of the Acephalous ovum appear to be composed at least of two layers, of which the inner may perhaps be looked upon as the vitelline membrane, the outer as a chorion; but sufficient data have not yet been furnished to determine the homological rank of these membranes. The early connection, in a pediculated form, with the ovarian stroma might point to a different view of their nature. Leydig states that while in Unio and Anodonta the albumen is deposited within the membranes, in Venus it is added externally. The micropyle appears to be closed previous to the commencement of embryonic development.

Arthropoda.—The ova of Articulate animals might with most propriety be classed with the large-yolked group, at least as regards the ova of Insecta, Arachnida, and the higher Crustacea. In addition to the germinal vesicle and finely granular yolk-substance, they all contain a large proportion of clear or oil globules of considerable size; and the process of segmentation is generally limited to a small portion of the yolk surface. The ova of these three classes present, however, many subordinate differences in their structure and mode of production, which renders it necessary to give a short separate account of them in this place.

Insecta.—The ova of insects are more especially distinguished by the extraordinary varieties of their external form and appearance. These varieties affect, however, principally, or depend upon modifications of the external covering, chorion or shell-membrane, as it has been called. They differ also from those of most other animals in a frequent departure from the regular symmetrical form. Some are nearly hemispherical, others more oval; many are somewhat bent in an antero-posterior direction*; many present the most curious elevations and irregularities on their external surface—reticulated ridges or fringes, and depressions, tubercles, hairs or spines, or other long processes, sometimes single, at other times in numbers. These modifications of the external coverings of the eggs of Insects appear to have reference chiefly to the protection of the ova from the effects of external injury, and to serve various mechanical purposes connected with their deposition and attachment; but they are not, in most at least, attended with any important varieties in the internal structure, which, on the whole, presents considerable uniformity throughout the whole class. The ova of all insects, we shall afterwards see, are provided with one or more apertures corresponding to the micropyle.

All recent observers agree that, in the ova of Insects, in addition to the external shell-covering, there is a delicate transparent vitelline membrane. The germinal vesicle is of proportionately large size. Its macula is at first single; but in the course of the growth of the ovum it becomes multiple, or diffused as a finely granular or molecular substance throughout the vesicle.† The germinal vesicle is situated in a vitelline or germinal area composed of fine granules, in which without doubt the limited process of segmentation afterwards takes place; but fuller observations are still much required in regard to the segmentation of the yolk in insects, which has as yet been very rarely seen. The germinal vesicle appears to be burst and diffused at a comparatively early stage of the growth of the egg.

The external membrane consists in general of more than one layer of substance. The outer and inner are described as being generally more clear, dense, and homogeneous; the middle one, in some insects at least, presenting greater varieties of structure, and not unfrequently being composed of united nucleated cells. It is in these several layers of the outer membrane that the micropyle apparatus, recently discovered, is situated. The existence of a micropyle in the ova of Insects was first published by Meissner, in September, 1854‡; but the discovery appears to have been made simultaneously by Leuckart, who has given a most interesting and elaborate description of this apparatus, and of the minute structure of the membranes, in a great variety of insects, in a memoir recently published by him.§

Meissner described several varieties of the

a. A portion of the upper pole of the ovum of Musca vomitoria from the Vagina. There are shown in succession the vitelline membrane, chorion and outer envelope, and at the upper part in profile the micropyle aperture situated in the middle of a nipple-like projection of the chorion, and with a number of spermatozoa involved in it.

b. Direct view of the upper pole of the ovum of an insect belonging to the Pyralida. The micropyle aperture is seen in the centre of the radiated markings of the chorion.

micropyle apparatus in the ova of Insects belonging to the following genera, viz., Musca, Tipula, Culex, Lampyris, Elater, Teleophorus, Adela, Pyralida, Tortrix, Euprepia, Liparis, Pieris, Panorpa, and in more than one species of several of these genera. The same author also observed and described in Musca vomitoria a number of spermatic filaments entangled in the micropyle.

Leuckart's observations, which are fuller and more minute than those of Meissner, and differ in some of their results from those obtained by that author, were extended over a very large number of Insects. Among nearly a thousand different kinds, he succeeded in detecting the existence of the micropyle in not less than two hundred; and his detailed observations on this apparatus, and the structure of the membranes, extend to one hundred and

Fig. 76*.

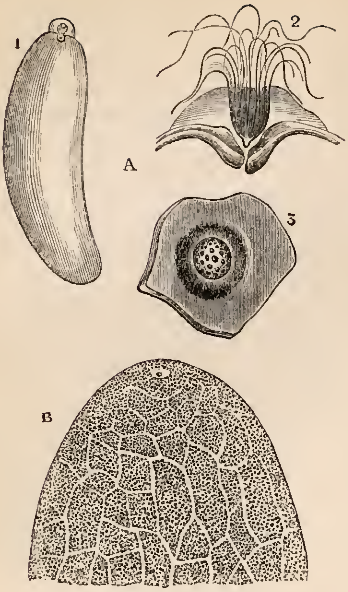
eighty species. This must furnish ample proof of the universality of the existence of the micropyle in this class of animals, when we consider the minuteness of the object and the difficulty of obtaining specimens in a condition suitable for the investigation. Leuckart has stated, indeed, that in all instances in which the ova were ripe and favourable for examination, he was enabled to assure himself of the presence of this apparatus.

In a certain number of instances, amounting to about a dozen, Leuckart farther found that the spermatozoa adhere to the micropyle, and that a certain number of them pass into the ovum by this aperture. He observed that a

&c., of the Ova of Insects, chiefly pupiparous, in Müller's Archiv. Nos. 1. 2. and 3., February and July, 1855, p. 90., *et seq.*, with five plates, with 122 figures. There can be no doubt that both of these authors made the independent discovery of this curious structure. Perhaps the priority claimed by Leuckart, may be accorded to him, as he had previously stated the probability of its existence in his article "Zeugung," published in 1852, p. 906.

Fig. 77*.



Ovum and Micropyle of Dipterous Insects. (*From Leuckart.*)

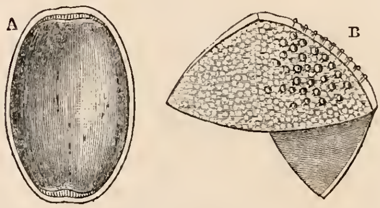
small mass, formed of the spermatozoa which have met with the ovum in its descent through the female passage, comes to be lodged in the depression of the micropyle, and is fixed in that situation by a lid or covering of albuminous matter. It is somewhat remarkable that the greater part of this mass remains for a long time apparently without any change, even when embryonic development has advanced to a considerable extent; but he ascertained that a few of the spermatozoa belonging to the mass, usually not more than three or four, really enter the ovum and effect the change of fecundation. We are, however, as yet at a loss to conjecture what farther purpose may be served by the mass of persistent spermatozoa near the micropyle. Leuckart has also made the novel and interesting observation, that the depression and aperture of the micropyle become at a later period converted into a deeper funnel, which is connected directly with the mouth of the embryo, and undoubtedly serves, according to this author, to convey nourishment from without to the embryo. The head of the embryo lies, according to Leuckart and other observers*, in all instances, at that end or pole of the ovum which is uppermost in the oviduct, as may be most easily observed in ova of the cylindrical form, such as those of the common house-fly; but according to Leuckart, the micropyle is not, as Meissner had stated, always at that end, being sometimes at one, sometimes at the other, and occasionally at both poles. The provision for the escape of the embryo, however, is usually at the upper or anterior pole, while the lower or hinder pole more generally serves to fix the ovum, as it is often pediculated or otherwise modified in its form in connection with this purpose.

In some Insects, as is shown in the accompanying figure of the ovum in Pulex irritans, the micropyle consists of a number of foramina nearly of uniform size.

Fig. 78*.



Ovum of Pulex irritans. (*From Leuckart.*)

A. Entire ovum, magnified, showing the micropyle apparatus with a number of foramina at both poles.

B. Portion of the chorion with the micropyle foramina, more highly magnified.

In a previous part of this article allusion has already been made to the great facility with which the development of the ova of insects may be traced, in their successive stages, as they lie in different parts of the tubular ovaries and oviducts. According to the Interesting observations of R. Wagner †, the upper end of the fine ovarian tubes are filled with a number of germinal vesicles. Wagner supposed indeed that these were at first nucleoli or germinal maculæ, and that a vesicle was developed round each macula; but Leuckart‡ and Stein§ were never able to detect the germinal vesicles before they already possessed the macula. The primitive yolk arises as in most other animals—first, by the collection of a clear substance immediately round the germinal vesicle, and by the subsequent deposit in this matrix of the fine granules of the vitelline substance; later still the delicate vitelline membrane is formed, perhaps by the consolidation of a film of the primitive yolk-substance.

As the ova attain a larger size, each one being situated in the lower part of its compartment

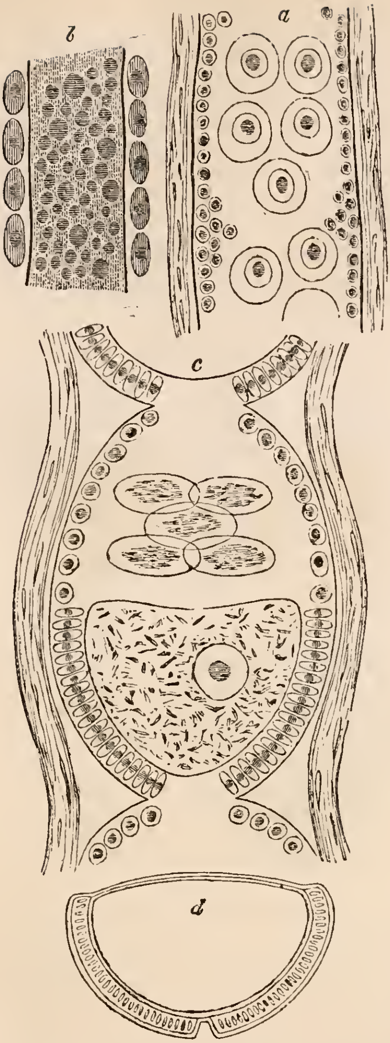
Fig. 79*



Development of the ova of Lepidopterous Insects. (From Hermann Meyer.)

b. A small portion of the upper part of the ovarian tube from the larva of Saturnia Carpini. The entire lines mark the basement membrane of the tube; externally elongated epithelial cells are placed on it; internally a number of larger and smaller free nuclei are imbedded in an albuminous fluid.

a. A similar portion of the ovarian tube from Bombyx Mori more developed. The external epithelial cells are visible now only as elongated nuclei; a part of the internal cells now form a lining to the wall of the tube, while others of a larger size, which have become complete cells, towards the centre, form the primitive ova; of these last only a few undergo farther development.

c. One of the loculi or chambers of the oviduct of Hyponomeuta variabilis. The wall of the tube with its external epithelial nuclei as before, enclosing now the entire loculus and the small portions of the adjacent ones represented in the figure. The lower half of the loculus is occupied by the developed hemispherical ovum in which the several parts, viz. germinal vesicle with macula, yolk and vitelline membrane, are seen. The lining cells of the oviduct are seen to be elongated and modified in structure preparatory to their forming along with the albumen one of the external coverings of the ovum (chorion). In the middle of the upper half of the loculus there are the remains of five aborted primitive ova.

d. Section of the coverings of the ovum of Harpyia vinula, which may be taken as an example of the hemispherical ovum of Lepidopterous insects.

of the oviduct, there are to be seen in the intervals between the ova numbers of large clear globules or cells, which have been supposed to furnish the materials for the growth of the ovum ; but it appears more probable that these are merely abortive ova or germinal vesicles, which, though at first similar in size and structure to those which have been farther developed, have undergone a retrograde process, and are ultimately removed by absorption.

The production of the chorion or shell membrane does not take place till the ovum has attained nearly its full size. It appears to proceed in part from the consolidation, over the whole surface, of one or more layers of albuminous fluid secreted from the wall of the oviduct. But the observations of Hermann Meyer* have shown, in an interesting manner, that a part of the outer membrane is also derived from a conversion into it of the inner cellular or epithelial lining of the oviduct, at the place where it is in closest contact with the surface of the ovum. Many of the varieties in the appearance and structure of the external covering may probably depend on the different modes of development of these cells. As to the origin of the micropyle, it does not appear to proceed, as has been supposed by Meissner, from the mere deficiency of these cells in a certain space; and it is not dependent, either, on its pre-existence in the vitelline membrane. On the contrary, according to Leuckart, it is formed in the chorion before it appears in the vitelline membrane ; and it is not in any way connected with an early pediculated condition of the ovum, which, as is well known, never at any time exists in insects.

Before leaving the history of the ovum in this class, it may be proper to make the following addition to what was stated in an earlier part of the article in reference to the remarkable modification of the reproductive process, by which, in the Aphides and several other insects, many individuals are produced without the formation of true ova, or the concurrence of the two different sexual products. The learned editor of the American translation of Von Siebold's "Comparative Anatomy of the Invertebrate Animals," Dr. Waldo Burnett, has given, at p. 464. of that work, a short statement of his own observations on the origin and mode of formation of the repeated broods or colonies of Aphides, made on a large species of that insect, viz., A.

* Zeitsch. für Wissen. Zool., vol. i. p. 190.

Caryæ, and of his views as to the nature of this process of non-sexual reproduction in general. The viviparous Aphides, according to Dr. Burnett, are neither male nor female, and do not possess, as has been supposed, any ovaries or oviducts. The new colony already begins to be visible within the body of its parent before the latter has itself been brought forth. The substance in which the new progeny takes its origin consists, at first, either of a single nucleated cell of $\frac{1}{3000}''$ in diameter, or of a small mass of these cells attached in the same place as that occupied by the ovary in the oviparous females. These masses increase in quantity, are subdivided by a kind of notching into more numerous masses ; and each of these being inclosed in a capsule, the whole come to be arranged in a continuous row or series. There is not, however, any germinal vesicle nor segmentation, as in the sexual ova ; and when development of the new insects is complete, it is by falling into the abdominal cavity, and by escaping through a genital aperture (porus genitalis) that the offspring is excluded.

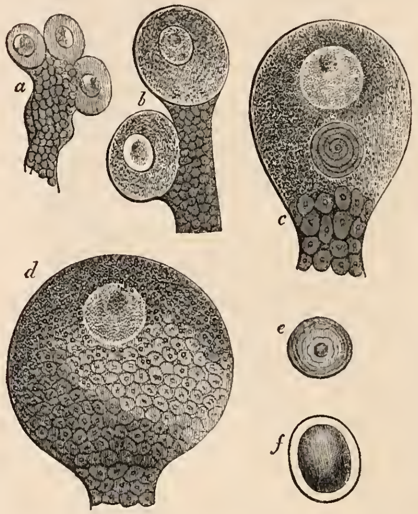
With regard to the origin of the cellular mass or germ from which the non-sexual progeny proceeds, Dr. Burnett states that a small mass, of a different appearance from the germinal part of the ovum, is seen to be included within the arches of the embryo ; and the next colony is produced from this mass. He regards this process as analogous rather to one of internal gemmation than of true generation, coinciding therefore more nearly with the views of Leuckart and Carpenter than of Steenstrup and Owen.

Arachnida.—The ova of nearly all the higher Arachnida do not differ much in their internal structure from those of Insects ; but they do not present the same varieties of external form. Their mode of first origin is also very different. All the higher Arachnida are, like Insects, of separate sexes. The Tardigrada are hermaphrodite; and in these as well as some other simpler Arachnida, as Pycnogonida and Acari, the ovum, though proportionally of large size, is of extremely simple structure, approaching very nearly to that of the lowest classes of Invertebrate animals.

The ova of the higher Arachnida are generally spheroidal ; the chorion or external membrane is generally smooth ; the vitelline membrane is slender, clear, and structureless ; the yolk-substance is not unfrequently coloured, often purplish, consisting of a considerable quantity of large oily-looking globules, smaller granules of various sizes, and larger corpuscles which have been looked upon as cells, but which Leuckart states are only aggregated masses of granules held together by a viscid substance. The germinal vesicle is proportionally large, placed eccentrically, and possesses a macula, which in some genera is simple and flattened, as in the Scorpion, in others multiple and granular, as in Epeira.

The formation of the ova may be observed in Arachnida with great ease, from the manner in which they are disposed in the ovary, projecting like bunches of grapes from the central part of that organ, in almost every stage or degree of advancement. The process has been carefully observed by Wittich * and others. So soon almost as the ovum begins to be formed, it causes a bulging or projection of the membrane from the surface of the ovary ; and when that has somewhat increased in size, the ova hang or project from the surface in small pediculated ovi-capsules. According to Wittich, V. Carus †, and Leuckart, the part of the ovum which earliest makes its appearance within the small ovicapsules is the germinal vesicle. At first it appears quite simple and without a macula, which last soon after-

Fig. 80*.



Ovarian ova of the Spider. (*From Wittich.*)

a. Small fragment of the ovary of Epeira diadema from which three ova project in the early stage of their development previous to the formation of the yolk: the germinal vesicles are enclosed in the membrane formed by the bulging out of the ovarian substance.

b. Two ova similarly situated, but more advanced ; the primitive granular yolk substance intervening between the germinal vesicle and vitelline membrane.

c. An ovum still more developed ; the germinal vesicle occupies the upper part ; in the finely granular yolk substance below is seen the dark body regarded by some as a yolk nucleus, presenting an appearance of concentric lamellar structure ; towards *c.* in the figure, or close to the connecting pedicle, the large nucleated cells are seen, which usually occupy that situation, and appear to give rise to the cellular yolk substance.

d. More advanced ovum greatly increased in bulk, the pedicle diminished, and the yolk completely occupied by the larger cells or corpuscles; the yolk nucleus has disappeared or is obscured.

e. & *f.* Different forms of the yolk nucleus or dark body, which for a variable time is placed within the ovum during its formation.

* Die Entstehung des Arachnideneies im Eierstock, &c., Müller's Archiv. for 1849, p. 113.

† Zeitsch. für Wissen. Zool., vol. ii., 1850, p. 97.

wards appears as a small dot or nucleolus. The yolk begins, in the same manner as we have had occasion to state in many other animals, first by the clear deposit of a basement substance round the germinal vesicle, and the subsequent formation of opaque granules in it; the vitelline membrane is of later formation. As the egg increases in size, the larger corpuscles and the fat globules gradually appear. The ovarian ova of several spiders contain besides the usual parts another body of a peculiar kind, the nature of which seems still involved in some doubt. This body is eccentrically placed near the yolk mass of the primitive ovum, and is of considerable size, viz. about $\frac{1}{240}''$, of a yellowish colour, and, during the earlier part of its existence at least, consisting of concentric layers of a hard granular matter. V. Carus* has compared this body to the yolk-nucleus of the Frog's ovum; and both he and Von Siebold seem disposed to consider it as in some way or other the source of the granular substance of the yolk; but according to Wittich this view is not well founded, as he has observed the body remaining in the ovum till it reaches maturity, though it loses its concentric laminated structure, and becomes clearer and vesicular. Von Siebold, on the contrary, states that it gradually disappears. The large clear or oily globules appear, according to Carus, to be produced from near the pedicle of the ovum, at a place where there is fixed a group of cells apparently destined for their formation.

No observations have as yet been made, so far as I am aware, on the existence of a micropyle in the ova of Arachnida.

Almost all the Arachnida are oviparous. The Scorpions are an exception, however, bearing their young alive; and it is deserving of notice that in this family the embryo is developed in the ovum while it still remains in the ovary. In the greater number of this class embryonic development commences in a blastoderm, which covers only a part of the surface of the yolk, situated in what may be called its lower part or pole †; and the segmentation of the yolk is therefore limited or partial, as in Insects. In the higher Arachnida the steps of this process do not appear to have been yet satisfactorily observed. I may refer, however, to the researches of Kaufmann of Lucerne on the development of the Tardigrada, as affording clear and beautiful illustrations of the process of segmentation, which is shown to be complete in the lower Arachnida.‡

Crustacea.—All the animals of this class are of distinct sex; but in the allied Cirrhipedia hermaphroditism most frequently prevails. In some of the Cirrhipedes, however, it has been shown by Mr. Darwin § that the sexes are also distinct, as in some of the species of the genera Ibla, Scalpellum, Alcippe, and Cryptophialus. In these instances the males are very minute, and are attached, almost like parasites, to certain parts of the more developed females, the place of their attachment varying in different species. It is interesting to observe that these males, as in the case of several of the Epizoa, are often of the most rudimentary organisation.*

The ova of the greater number of Crustacea, especially the more highly organised genera, belong, like those of most of the Articulata, to the group in which a considerable amount of nutritive yolk is present along with the formative part, and in which the process of segmentation in the latter is partial. The formative disc is situated on the lower surface of the ovum; and from that part the development of the embryo emanates. Even among the higher decapodous Crustacea, however, the ova are of very various sizes †; and in the lowest genera, as among the Entomostraca, the ova are proportionally the largest, although they are of the simplest structure, and present the smallest amount of nutritive yolk; so that, in this as in other classes of animals, magnitude alone is no true criterion of the internal structure of the ovum.

The ova of this class have been described principally by Rathke ‡, by Erdl §, R. Wagner ||, Leuckart ¶, Leydig **, and others; but the knowledge both of their structure and their mode of formation is yet far from being sufficiently minute or complete. They present, indeed, many varieties, which renders it difficult to give any general description of them. The following may however be stated. The ova of Crustacea are often variously and brilliantly coloured. The yolk-substance consists of a large quantity of clear globules of considerable size, having the aspect of oil globules, in which the colouring matter chiefly resides. In some ova these globules attain the size of $\frac{1}{450}$ of an inch. There is also a more fluid granular matter in the yolk, and in the more mature ova there is a layer or disc of granular corpuscles on one side which afterwards is the seat of segmentation and embryonic formation. The germinal vesicle is of considerable size, in some instances possess-

§ Monograph of the Sub-class Cirrhipedia, &c., printed by the Ray Society, 1854, p. 27, &c.

* It is also a remarkable fact, pointed out by Mr. Darwin in his interesting Researches, that even among the hermaphrodite species there are sometimes distinct male individuals attached parasitically to the hermaphrodite animals; these have been called complementary males.

† Thus, for example, the ova of the river crawfish (Astacus fluviatilis) are twice as large as those of the common lobster.

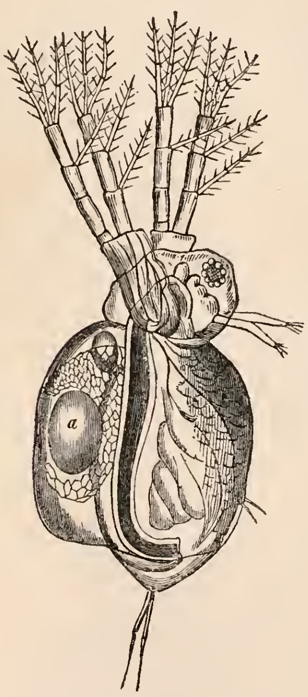
ing a single nucleus, in others multiple maculæ.

The formation of the ova may be observed with ease in any of the smaller isopodous Crustacea. According to Leuckart in Oniscus or Armadillo, it is essentially the same as in the Arachnida. The ova consist at first of germinal vesicles, originating below the epithelial lining membrane of the ovarian sac. The yolk-substance first appears as a clear deposit round each germinal vesicle; minute opaque granules are then formed in this substance, and subsequently the larger albuminous and oil globules gradually make their appearance. The vitelline membrane, which is very delicate and structureless, is added at a comparatively late period, in the Oniscus for example, when the ova are about $\frac{1}{120}''$ in diameter.

In many of the Crustacea the ova also acquire a chorion or shell membrane of considerable strength. On arriving at the lower part of the female passages, the ova of many genera also receive an addition of a peculiar so-called albuminous secretion, which becomes coagulated in water, and thus, when the eggs are laid, serves to glue them together in heaps or to cause them to adhere to the hinder feet, caudal plates, &c., of the parent, where, as is well known, they remain during the whole

Fig. 81*.



Ephippial ovum of the Daphnidæ. (*From Baird.*)

The figure represents a profile view of the female of Moina rectirostris (one of the Daphnidæ) showing at *a.* the ephippial ovum in its usual place on the back of the animal.

progress of embryonic development. In the Monoculi and some other Entomostraca, there are marsupia or pouches appended to the genital orifices of the parent, in which the ova are retained during the formation of the young.

In all the bisexual Crustacea the ova are fecundated while still within the body of the female parent; but the phenomena and period of this process have not yet been acurately determined, partly perhaps in consequence of the peculiar form and motionless condition of the spermatic corpuscles belonging to the greater number of this class. No micropyle has yet been observed in the crustacean ovum.

From the observations of several naturalists it is now well ascertained that in the entomostracous Crustacea, there commonly occurs a production of young individuals without impregnation, somewhat in the same manner as previously described in the Aphides. "In the Daphnia," says Dr. Baird *, "it is now clearly ascertained that a single copulation is sufficient, not only to fecundate the mother for life, but all her female descendants for several successive generations;" and it was considered probable by Jurine, that in some species this might extend to the fifteenth generation.

In the Daphnia and other similar Entomostraca, the ova are transferred from the ovary into a cavity situated below the shell on the back of the animal, which has been called uterus, perhaps erroneously, and there undergo development. But at certain seasons many of these Entomostraca produce ova of a different kind from those now referred to. To these the name of winter or hybernating ova has been given, as they appear to be adapted, from the strength and impermeability of their external coverings, to resist the injurious effects of cold and other atmospheric influences during the winter season. These ova are generally in smaller number than those of the ordinary kind, frequently two, sometimes only one; and they are contained and undergo development in a peculiar case, which is formed on the back of the animal below the shell, nearly in the same situation as the matrix for the ordinary ova. This case, which afterwards separates from or is abandoned by the animal, forms a sort of hump or saddle on its back, and has hence been named the ephippium, and the eggs have been called ephippial ova. These ephippial ova, according to Baird, are already fecundated by the original impregnation of the female parent, and do not require, for themselves nor for their progeny for several generations, any renewed or special impregnation.

It appears from the observations of Jurine, Strauss, and Baird, that at the time when the ephippial ova are about to be formed, a sudden change takes place in the appearance of the ova, by the deposit of a quantity of dark granular substance. This appears to be transferred

* Nat. Hist. of the British Entomostraca, Ray Soc. Public., p. 79.

into the cavity behind, in which an increased growth of substance round the ova and within the shell gives rise to the production of a two-valved case for containing the ova. According to S. Fisher of St. Petersburg *, the formation of the ephippial ova may be noticed during the whole season, from the middle of July onwards; and it may therefore be inferred that these ova have for their object the preservation of the species in the heat of summer when the ponds are liable to be dried up, as well as by resisting the cold of winter.

Von Siebold † states that these hybernating ova contain no germinal vesicle; and Dr. Burnett, in his translation of Von Siebold's work, has adduced various arguments in favour of the view that this is an instance of "internal gemmiparity" (as he regards the corresponding phenomenon in Aphides) rather than the production of true ova. Sufficient data are still wanting, however, to form a decided opinion on this subject, as we cannot at present distinguish between the ova of the Entomostraca which are the result of fecundation, and those which are formed and developed independently of the concurrence of the male.‡

Annulata.—In the class of Annulate Worms, including the Leeches, Earthworms, Nereids, and Amphitrites§, although considerable varieties present themselves in the modes of reproduction, there is yet a greater degree of uniformity in the structure of the ova than in some of the classes previously referred to.

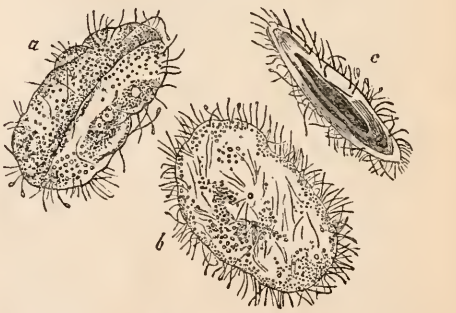
In the greater number the ova are nearly spherical in form, of rather small size; the yolk-substance is generally finely granular, and segmentation is complete; the germinal vesicle is clear, with a distinct single macula, or one which is elongated or only slightly divided into subordinate particles. In most ova of Annulata there is, in addition to the inner transparent vitelline membrane, a chorion or external membrane of considerable strength, and not unfrequently a superadded layer of albuminous substance, which unites the ova in groups or cocoons, or serves to attach them to other bodies. ‖

In Clepsine, among the Hirudinea, the yolk-substance differs from the common form above described, being composed rather of larger-sized globules; and in another genus belonging to the same order, Piscicola, according to Leydig ¶, there are peculiarities of structure which have not as yet been referred to any general law. In the ova of these animals the covering is double, consisting of a delicate internal vitelline membrane, and an external envelope or chorion, to which a layer of distinct flattened and nucleated cells is adherent; and within the vitelline membrane there is a collection of nucleated cells which displace and partially surround the usual finely granular or formative yolk-substance. Leuckart* informs us that the same peculiarity exists in Pontobdella; but the nature and destination of this inner cellular part of the ovum does not appear as yet to be understood in either of the animals mentioned.

In the Piscicola, Leydig observed the ovum, while within the ovarian cavity, to be completely surrounded for a time and enclosed by a consistent mass or covering of spermatozoa; and it has been observed that in this animal the germinal vesicle has not in general disappeared till some time after the ovum has thus encountered and been enveloped by the mass of spermatic substance.

In the Lumbricus, Meissner † has made the novel and interesting observation, that previous to the encounter of the spermatozoa with the ovum, the latter loses the vitelline membrane which before covered it, and that the spermatozoa then penetrate, in great numbers, the whole surface of the exposed yolk.

Fig. 82*.



Ova of the Lumbricus during fecundation. (*From Meissner.*)

The figures represent three views of the ova of Lumbricus agricola, *a.* & *b.* on their flat sides, *c.* seen edgeways. Over the surface spermatozoa are seen penetrating the vitelline substance, giving to it on a large scale the appearance of a ciliated surface. The ovum which has now reached the receptaculum seminis is without vitelline membrane, the yolk being thus directly exposed to the action of the spermatic masses; but the vitelline membrane existed at an earlier period and disappeared by solution in the course of the descent of the ovum.

The development of the ova in Hermella has been minutely described by Quatrefages; and this may be taken as an example of the general nature of this process among the

† On the penetration of spermatozoa, &c., in Zeitsch. für Wissen. Zool. vol. vi.

Annelida. According to this description, the first germs of the ova consist of minute germinal vesicles formed in the ovarian substance; they soon acquire the single macula or nucleus. After undergoing some enlargement, these germs fall into the abdominal cavity, and there acquire, by deposit round them, the clear primitive vitelline substance. In this substance opaque granules, which are at first colourless, are subsequently deposited; and as these extend outwards from the germinal vesicle, and accumulate in quantity so as to increase the bulk of the whole ovum, a delicate vitelline membrane is added externally. The germinal vesicle attains a diameter of about $\frac{1}{950}''$, and its macula of $\frac{1}{2500}''$; and when the several parts of the ovum which have been mentioned have appeared, and the yolk is now coloured, the whole ovum has a diameter of about $\frac{1}{330}''$.

The superficial part of the yolk consists of minute coloured granules. Within this there are larger oil-like globules free of colour, and in the innermost part a somewhat viscous transparent fluid.*

According to Leydig, the germinal vesicle in Piscicola becomes enveloped by a second vesicle or cell-wall before the formation of the yolk-substance; but it is suggested by Leuckart that he may have been misled in this by the appearance often presented by the clear and somewhat highly refracting substance which in many animals precedes the formation of the opaque yolk. If this is not so, the fact observed by Leydig would constitute a marked departure from the usual homological relations of the ovum.†

Rotifera. — Although most zoologists are now disposed, on the ground of the analogies in the most important parts of their general structure, to place the Rotifera among or close to the Articulate Worms, yet in some respects their mode of reproduction presents a marked correspondence with that of the lower Crustacea. Thus they have, in common with some of the lower Crustacea, the occasional separate condition of the sexes, the preponderance of females, the imperfect development of the males, the proportionally large size of the ova, and the production of winter ova as well as the ordinary kind; on the other hand, the simpler structure of the ovum and its complete segmentation are more similar to what is observed among the Vermes.‡

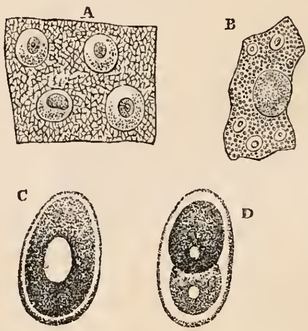
* Quatrefages, it is to be observed, designates the enveloping membrane ovarian and not vitelline membrane, which last he holds is wanting in these ova.

† Farther interesting views of the ova of this class will be found in Milne Edward's memoir in the Annal. des Scien. Nat. for 1845, vol. xxiii. p. 145; and in his article ANNELIDA in this Cyclopædia, to which I must refer the reader; in Grube's Untersuch, über die Entwickel. der Clepsine, Königsberg, 1844. H. Koch, Ein Worte zur Entwick. von Eunice, with an Appendix by Kölliker, on Exogone and Cystonereis.

‡ See Leydig, On the Structure and Systematic Position of the Rotifera, &c., in Zeitsch. für Wissen. Zool., vol. vi.; and C. Vogt on the same subject in vol. vii. of the same work.

The relation of the sexes in Rotifera has only recently been in any degree understood, and that only in a few genera; and there are still many points requiring elucidation. The greater number of the animals, in fact, which till lately have been known or described in this class have been females; and as yet the males or male organs have been ascertained only in a few genera. Some are certainly of separate sexes, as Notommata, and the allied Rotifer of which the male was first discovered by Brightwell*, and of which the development was described by Dalrymple†, Others seem to be hermaphrodite, as in Megalotrocha, described by Kölliker‡; in Euchlanis, by Schmidt§; and in Lacinularia socialis, by Leydig.‖ But according to Huxley¶, there may still be some doubts as to the bodies described as spermatozoa, and as to the arrangement of the male organs in the Lacinularia.

Fig. 83*.



Ovarian ova of Rotifera. (*From Huxley.*)

The figures represent the formation and development of the true or ovarian ova of Lacinularia socialis (one of the Rotifera). A. and B. are small fragments of the ovarian substance showing the primitive ova with their germinal vesicles and maculæ; in B. one of the ova more advanced than the rest. C. represents the mature ovum. D. the same undergoing the first stage of segmentation.

The ova of Rotifera have been observed by Ehrenberg and many other microscopists. They are of comparatively large size, but yet belong to the group of ova possessing the simpler kind of structure, the yolk substance being quite finely granular, and undergoing a complete segmentation. The germinal vesicle is large, and possesses a distinct single macula; and the whole ovum is inclosed in a clear vitelline membrane. No micropyle has yet been discovered, nor have the time and

phenomena of fecundation been minutely observed.

The formation of these ova may be traced with facility in the substance of the ovary, in consequence of the transparency of the animals. The nucleated germinal vesicle seems first to make its appearance; the granular yolk substance follows; and the vitelline membrane is last formed.*

The Rotifera present another example of the formation in the autumn season or before winter, of that variety of the reproductive body which has been called winter egg, and which has already been noticed under the Entomostraca. These bodies were observed by Ehrenberg in Hydatina and Brachionus, by Dalrymple in Notommata, and by Huxley and Leydig in Lacinularia. They are twice the size of the ordinary ova, are formed in very small numbers, probably only two, as is most common in Daphnia, and contain no apparent germinal vesicle. Mr. Huxley† appears to have pointed out very clearly the distinction between true or ordinary ova and these reproductive bodies. He says, at p. 16 of his paper, "The true ova are single cells which have undergone a special development, the ephippial ova are aggregations of cells, in fact larger or smaller portions, sometimes the whole of the ovary, which become enveloped in a shell and simulate true ova." Mr. Huxley

Fig. 84*.

Formation of *Ephippial ovum in Lacinularia Socialis.* (*From Huxley.*)

A. represents a portion of the ovary massed together and undergoing a change of structure preparatory to its conversion into the ephippial ovum.

B. the ovum now complete, the external investment distinct.

C. the same having now its contents divided into two portions. The ephippial ova differ from the ordinary ones in their mode of formation, and in having three investments.

has traced minutely the process of conversion of the substance of the ovary into such an ephippial ovum, or rather the protecting covering of the two ova which are contained in the ephippium; and his observations seem to show a manifest difference between these and the ordinary ova. The same follows also from Mr. Dalrymple's researches on Notommata. The correspondence of the number and general structure of these ova in Daphnia and the Rotifera is also deserving of notice. These winter ova, besides being much larger than the ordinary ones, differ from them also in structure, having three investing membranes; and they appear designed, like those of the same kind in other animals, to resist the cold of winter and other hurtful influences.

It would appear that these ephipphial ova, like those of Daphnia, do not require fecundation. Leydig, though distinguishing the two kinds of ova, regards the hybernating ova as only modifications of the ordinary ones; while Huxley considers them rather as peculiar buds like those of Aphis or Gyrodactylus.*

Turbellaria.—Under this class three orders of the animals allied to the Planaria may be brought, according to the researches of Quatrefages and others, viz., the two kinds of Planaria with simple and ramified alimentary canal, or Rhabdocœla and Dendrocœla, and the Nemertides or Miocœla. The first two orders are hermaphrodite; in the third the sexes are distinct. The ovology of this class is known principally from the interesting and beautiful researches of Quatrefages †; but the history of the structure and formation of the ova is still far from being complete.

The ova of the Planariæ are of various magnitudes, and present some differences in their structure. For the most part they contain only the finely granular yolk, but with occasionally some oil globules interspersed. It is only in the earliest stages that the germinal vesicle is perceived with ease, in consequence, probably, of the opacity of the yolk-substance, and the dark colour of the external envelopes.

In most of the genera the germinal vesicles and the yolks are formed in separate organs, as in the trematode animals, to which the Planariæ are nearly allied, but in some, as Macrostomum, these two organs come to be combined in one. At first the yolk-mass, in descending and meeting with the germinal vesicles, unites a number of them into a connected chain; but somewhat later the ova are separated into distinct spheres, and a vitelline membrane is formed to enclose each of them.

Just as occurs in the body of the adult Planariæ, there is also in the ova a remarkable tendency to subdivision by fission. Thus, in the commencement of the development of the ovum, it is liable to become divided into distinct masses, so as to give rise to the development of a number of embryoes from one ovum. Such, at least, is the view entertained by some; but there may be doubts as to whether the ovum so divided is really simple,

* Leuckart, loc. cit.
† Loc. cit.

* See on this subject also, Burnett's translation of Von Siebold's Comparative Anatomy, p. 150.

† Mém. sur quelques Planariées Marines, in Annal. des Scien. Nat. 1845, tom. iv. p. 169; and Mém. sur la Famille des Nemertiens (Nemertea), id. lib. 1846, tom. vi., p. 269. The Rhabdocœla are known chiefly by the researches of Schmidt, Die Rhabdocœlen Strudelwürmer des süssen Wassers, Jena, 1848; and of Schultz, Beiträge zur Geschichte der Turbellarien, 1851.

or is rather a collection or aggregation of a number of germs surrounded by a common yolk; in fact, as has been suggested, an ovarian sac containing a number of ova.*

The manner in which the spermatozoa reach the ova for fecundation does not appear to have been ascertained with accuracy.

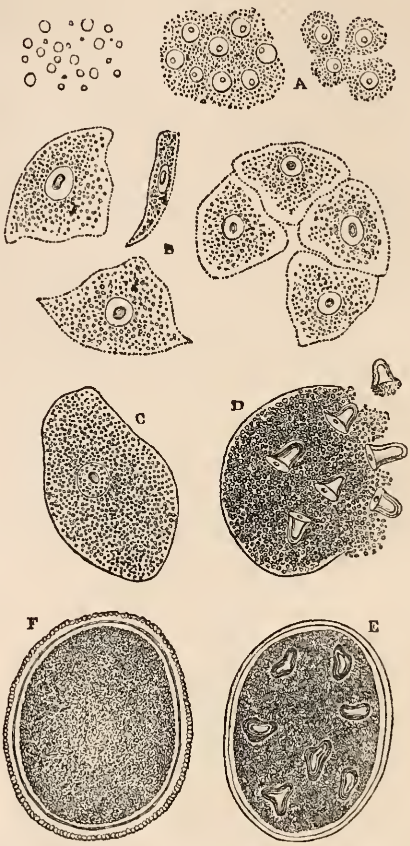
Entozoa.—The ovology of the Helmintha or Entozoa has received considerable attention from physiologists, both on account of the interesting nature of the phenomena presented by its study, and because of the anxiety to discover the mode of production of these parasites within the bodies of other animals. From the researches on this subject which have been prosecuted with great assiduity by a number of observers in recent times, not only have many doubtful points been solved as to the origin of the Entozoa, and the views of naturalists greatly modified in regard to the history of these animals, but considerable assistance has also been received in the elucidation of general questions in ovology. I will give a short sketch of what has been most recently ascertained on this subject under the three divisions of the Nematoidea, including all the Round Worms, the Trematoda, and the Cestoidea including the Cystica. All the animals belonging to the first division are bisexual, and the production of the embryo is direct from the ovum, without metagenesis or metamorphosis; in the two other divisions hermaphroditism prevails, and development is indirect, or accompanied by metagenesis and metamorphosis in the greater number.

Nematoidea.—The genital organs in the first of these orders present the same favourable circumstances as those of Insects for the observation of the structure and formation of the reproductive elements in their successive stages, as in the different parts of these tubular organs there are to be found at once the spermatic cells and spermatozoa, and the germinal cells and ova in every conceivable degree of advancement from their earliest apparition to the state of maturity.

In the Ascarides and most of the round worms, the upper closed extremities of the two genital tubes of the female correspond with an ovary, or rather as a portion of it which may be regarded as a germ-forming organ; for in this upper part of the tube are produced only the nuclei or nucleated cells, from which the germinal vesicles derive their origin. A second portion of the tube, in which the granular yolk substance is added, is to be looked upon also as a constituent part of the ovary, and may be called the yolk-forming or vitelligenous organ. Next follows a constricted part of the tube, which may be termed oviduct, in which the ova meet with the spermatic corpuscles and undergo fecundation. From this the ova pass into the fourth compartment, a dilated portion which has been called a uterus, and below this the two genital tubes finally unite into a common vagina.

In the Ascarides, the process of formation

Fig. 85*.



Development and fecundation of the ova of Ascaris mystax.

A. Earliest stage of the ova as they are found in the cœcal or uppermost part of the ovarian tube; some from the highest part are mere molecules, others a little farther down are minute nucleated cells (germinal vesicles or germs of the ova), and round these the primary yolk granules are beginning to collect.

B. Ova from the second part of the ovarian tube in which they are closely pressed together and arranged in a radiated manner round the axis or centre of the tube. To the right, four of these ova are represented adhering together; to the left, two ova are shown with their flat surfaces, and one with its thin edge towards the observer. The external dotted line represents the surface of the basement substance of the yolk in which the opaque vitelline granules are deposited; there is as yet no vitelline membrane; the germinal vesicle and macula are very distinct.

C. An ovum from the oviduct; a faint marginal line indicates the place where the vitelline membrane is afterwards formed. The germinal vesicle still visible, though obscured by the yolk granules; the ovum has now assumed an ovoid shape.

D. Softened state of the ovum at a slightly later stage, when it has met with the spermatic cor-

* Burnett's transl. of Siebold's Compar. Anat. p. 140.

puscles; which are held by Nelson thus to penetrate or gain access to the vitelline substance.

E. Ovum more advanced; the vitelline and albuminous membranes formed; clear highly refracting spaces resembling altered spermatic corpuscles are seen in the yolk substance.

F. Ovum after fecundation; uniform structure of the yolk substance previous to the appearance of the embryonic cell and commencement of segmentation. The chorion has now become tuberculated.

of the ova appears to consist, first, in the production of minute cell-germs in the uppermost part of the ovarian tube immediately adjoining its cœcal termination. It does not appear to be fully ascertained whether these germs are originally, as some have supposed, the maculæ or nuclei, or rather, as others hold, the germinal cells or vesicles themselves: the latter opinion appears to be the most probable. Second, the granules of the yolk-substance very soon collect round the exterior of the germinal vesicles. These granules appear at first to be suspended in fluid; but a little later, as they come to collect round the germinal vesicles, they are united together in a mass by a firmer but clear basement substance, and when the minute ova have somewhat increased in size, the outline of this clearer basement substance of the yolk is distinguishable. There is not, however, at first any external or vitelline membrane; of this Dr. Nelson and I have convinced ourselves by repeated observations in Ascaris mystax.*

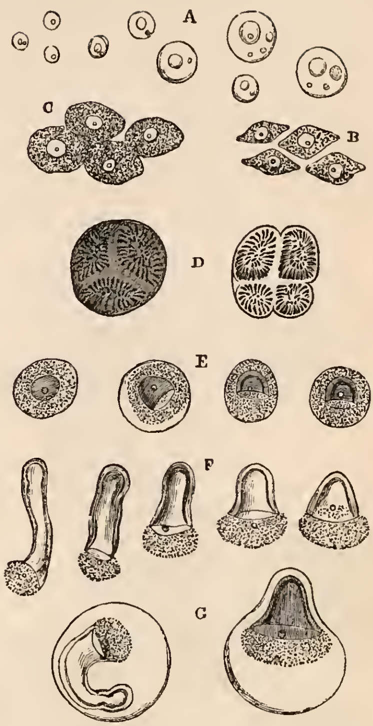
The ova, as they continue to descend in the vitelligenous part of the tube in immense numbers closely pressed together, assume the form of subtriangular flattened bodies, and come to be arranged in series of three, four, or more, in a short spiral round the centre of that part of the ovarian tube which constitutes the yolk organ, as round a central axis, but without being united together by any common stalk or other structure. A prodigious number of ova are thus packed together in a very small space.

In passing through the next part of tube, which forms an oviduct, the ova are detached from the spiral and closely-set position, and being surrounded by fluid, which must here be secreted within the tube, descend one by one through its narrower part. At this place they encounter the spermatic corpuscles when they are present, and undergo the change of fecundation; but whether fecundated or not, the ova now lose their germinal vesicles, alter their form from that of flattened triangles to oval, become for a time much more yielding and soft, and somewhat later begin to acquire an external covering which they have not previously possessed.

The peculiar motionless and tailless spermatic corpuscles appear, therefore, to come into contact with the ova when the yolk is exposed directly to their action. According to the interesting observations of Dr. Henry

* See Nelson's paper on the Reproduction of the Ascaris Mystax in the Trans. Roy Soc. of Lond. 1852, p. 563., pl. 28, figs. 48. and 50.

Fig. 86*.



Development of Spermatic Corpuscles in Ascaris mystax.

This figure is introduced to show the several stages of development of the peculiar acaudal and motionless spermatic corpuscles of the Ascaris mystax.

A. shows various stages of the primary sperm-cells or rather sperm-germs; in the more advanced of which towards the right, internal cells are seen forming by endogenous production within the primary germ-cells.

B. & C. show the second stage, in which the separated germ-cells have each become covered by a finely granular mass collected round them; in B. this process is beginning; in C. it is completed, and the sperm cells thus formed have assumed an ovoid shape.

D. Two views of sperm-cells in the third stage, in which a quadrifid division of the whole cell has taken place preparatory to the escape or separation of the spermatozoon-cells, usually four in number, proceeding from each sperm-cell.

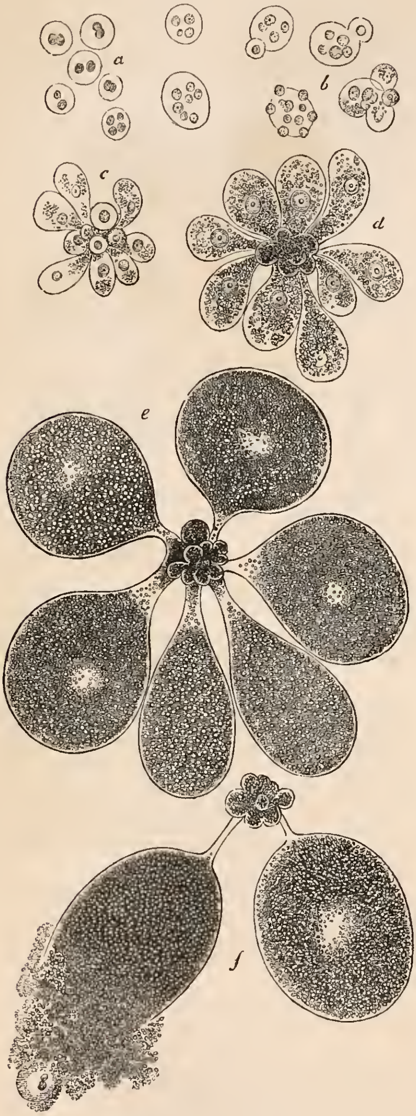
E. Various views of these spermatozoon cells in which the radiated linear marking (seen in D.) has disappeared, and is again resolved into granules; the nucleus is seen from above in the left-hand figure; in the three others being viewed in profile the appearance of the bell-shaped spermatic corpuscle with the nucleolus is perceptible.

F. Exhibits from right to left the various progressive stages of the bell-shaped corpuscle into the test tube form; the remains of the nucleolus and granular substance are seen towards the mouth of the flask-shaped bodies.

G. Illustrates the effect of water in developing "Sarcode" on the exterior of these corpuscles in two different stages of their advancement.

Nelson,* a peculiar softening of the ova, which may be caused by the rapid imbibition of fluid at the time the changes above mentioned are taking place, renders them peculiarly liable to be impressed by the spermatic corpuscles at

Fig. 87*.



Development of ova in Mermis albicans, belonging to the Gordiacei. (*From Meissner.*)

a. Germ-cells from the upper or cœcal end of the ovarian tube, their nuclei undergoing subdivision.

b. Various stages of farther multiplication of the internal cells, which in the more advanced are seen to approach the surface of the original cell, and to cause the bulging of its membrane by the enlargement of the internal cells, which last constitute the primitive ova.

c. & d. Groups of primitive ova thus formed; some of them much more developed than others, presenting internally the nucleated germinal vesicles and yolk granules and attached in pediculated capsules, which are formed by the extension of the membrane of the primary germ cells.

e. A group of these ova more advanced; the opaque granular yolk increased in quantity so as to obscure in part the germinal vesicles; the pedicles much narrowed and somewhat elongated; the external ova are nearly mature; those in the centre remain abortive.

f. Two similar ova now ripe, a part of one of them is artificially burst, showing the escape of the yolk granules and germinal vesicle with a double macula. The remains of the pedicles when detached from the central mass constitute, according to Meissner, the micropyle aperture.

this period; and Nelson is of opinion that these corpuscles even penetrate completely into the yolk-substance, and ultimately combine with it. Little doubt can be entertained that a combination of the spermatic and vitelline elements in some manner takes place at this time, whether by the direct interpenetration after the mode described by Nelson, some may be inclined to doubt; but at all events the spermatozoa act immediately on the vitelline substance at this stage of the progress of the ovum. *

As the ovum descends in the next part of the tube or uterus, the external membrane becomes more dense, additional layers are deposited upon it, and at last it acquires more

* Loc. cit., p. 576.

* Professor Bischoff has, in his recently published tract "Wiederlegung des von Dr. Keber bei den Naiaden und Dr. Nelson bei den Ascariden behaupteten Eindringens der Spermatozoiden in das Ei," &c., Giessen, 4to., 1854, called in question the accuracy of Nelson's observations, and asserted that Nelson's spermatozoa are only epithelial particles belonging to the female passages. In a subsequently published paper, entitled, "Bestätigung des von Dr. Newport bei den Batrachiern und Dr. Barry bei den Kaninchen behaupteten Eindringens der Spermatozoiden in das Ei, Giessen, 25th March, 1854," although Bischoff has seen reason to alter his previous views as to the phenomena of fecundation in the Ascaris mystax, he still in that paper, and in a special memoir on the subject, published in the Zeitsch. für Wissensch. Zool., 1854, vol. vi. p. 377. adheres to the view that the bodies which I, along with Nelson and Meissner, regard as spermatozoa are no more than epithelial cells. I have elsewhere shown that this view is altogether untenable, and that no doubt can now prevail as to the corpuscles in question being the product of development from the spermatic cells of the male Ascaris, and as to the possibility of their direct action on the ova within the female previous to the formation of the vitelline membrane. Meissner has also given the most satisfactory evidence on the same point in his memoir on the penetration of the spermatozoa into the ova of animals, contained in the same volume of the last quoted work, though this author takes a different view from Nelson and myself as to the manner in which the spermatozoa are admitted into the ovum in Ascaris mystax, believing in the existence of a vitelline membrane and micropyle, in the same manner as in Mermis and other Gordiacei, which he has so well described. With regard to this view as applied to the Ascaris mystax, Bischoff's observations, Nelson's, and my own, give me the greatest confidence in asserting that there is at first no vitelline membrane in this animal at the time when the ova first meet with the spermatic corpuscles.

or less of a minutely tuberculated structure on its external surface. The ovum becomes of a regular short oval or nearly spherical form. If fecundation shall have occurred, the embryonic vesicle or cell makes its appearance, and the phenomena of segmentation follow in rapid succession.

Fig. 88*.

Formation and fecundation of the ova of Nematoid Worms. (According to Meissner.)

a. A portion of the ovarian axis and early ova attached to it from the ovarian tube of Strongylus armatus. The axis column occupies the centre of the tube, and the ova are suspended to it by pedicles, supposed by Meissner to form micropyle apertures when they are detached.

b. View given by Meissner of a set of the nearly ripe ova of Ascaris mystax, which he conceives are thus connected by pedicles to a central axis.

c. Two mature ova of the same surrounded and in part penetrated by spermatic corpuscles. At the narrow angles of these ova a spermatozoon is seen passing into the interior by what Meissner has regarded as a micropyle formed by the detached pedicle. In the ovum to the right a spermatic corpuscle is seen in the vitelline substance. The existence of such a micropyle aperture and pediculated attachment of the ova in the Ascarides I regard as doubtful.

In others of the Nematoid Worms and more especially in Strongylus and the Gordiacei, it would appear from the researches of Meissner, that the first germs of ova which take origin in the uppermost part of the ovarian tube multiply by an endogenous production, and that in this manner groups or bunches of the primitive ova are produced which are connected together by pedicles arising from the

Fig. 89*.

Formation of ova and fecundation in Gordius Subbifurcus. (From Meissner.)

a. A small portion of the ovarian tube with groups of the ova partly within and partly escaping from it.

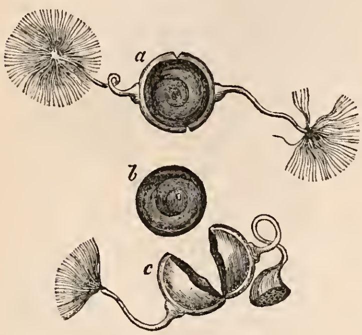
b. Three of the mature ova from the lower part of the oviduct surrounded by the spermatozoa. The ova are now isolated, and the pedicle of each is open, and is regarded by Meissner as a micropyle, by which spermatozoa, as represented in two of them, enter the ova. The germinal vesicle is still to be seen.

elongated membrane of the original germ-cell which remains as a covering of the whole. A certain number of these ova make progress in development while others probably become abortive. As the ova enlarge they are more spread out in the tube and take something of the spiral disposition which exists in the Ascarides, but with this difference, as already noted, that the various ova remain connected together by the attachment of their pedicles to a central axis or stem running down the middle of the ovarian tube. On the subsequent detachment of the ova by the breaking of these pedicles, according to Meissner, a micropyle aperture is formed in each ovum for the admission of the spermatozoa. The accompanying drawings from Meissner's Memoir will give a sufficiently clear idea of his views on this subject.

The ova of the nematoid worms constitute a marked example of the simpler kind of ovum in which the formative yolk is present, and in most but not in all of which segmentation is complete. This process was first made known through the interesting researches of Kölliker *, in Müller's Archiv., 1843, p. 68, and Bagge, in his Inaugural Dissertation.† The memoir of Reichert in Müller's Archiv., 1847, contains very correct views as to the formation of the spermatic cells.

The accompanying figure from Meissner‡, gives a representation of a remarkable form of the external capsule of the ova occurring in some of the Gordiacei (Mermis nigrescens).

Fig. 90*.



Mature ova of Mermis nigrescens. (*From Meissner.*)

This figure is introduced to show the very peculiar capsule in which the ovum is enclosed.

a. Ovum taken from the uterus with embryo enclosed; the chorion and shell capsule with chalazæ or brush-like processes attached to the latter.

b, c. The shell capsule *c* burst across the equatorial groove, allows the ovum *b* to escape with the chorion and embryo contained within it.

The ova of Trematoda are generally of a long-oval form, and of middle size. They are enveloped by a shell membrane of considerable firmness, and which is not unfrequently of a dark brown colour. The yolk-substance contains fat corpuscles simple and compound; and there is a germinal vesicle present, which, however, from the deep colouration and other circumstances, is often very difficult of detection.

In these animals an interesting peculiarity in the arrangement of the reproductive organs exists, in the separation of the germ-forming and yolk-forming portions from each other; in the first of these organs germinal vesicles or clear nucleated cells alone being produced, in the other the opaque granular fatty matter which furnishes the vitellus. This arrangement was first described by Von Siebold in 1836.§ The germ organ is generally in the form of a rounded sac, which is filled with the nucleated germ-cells or vesicles in various stages of development. The vitelline organ is double, each one consisting of cœcal tubes, in which the opaque granular yolk-substance is secreted.* The ducts of these two organs meet in a common cavity or uterus, and the germs descending into this cavity are there enveloped by a portion of the vitelline mass, and shortly afterwards an enclosing vitelline membrane is formed. These animals being hermaphrodite, the vas deferens of the male organ or testicle leads into the uterine cavity; and it would appear, therefore, that in many cases, if not in all, impregnation takes place by the access of the spermatic corpuscles to the elements of the yolk and germinal vesicle, just at the time when they are brought together to form the ovum.

This separation of the germ-forming and yolk-forming parts of the ovarian organ, which is so apparent in the Trematoda, is not in truth so great a departure from the more familiar structure of other animals as might at first be thought; for, as Leuckart has well observed, there are other examples of the same disposition, or an approach to it. Thus in Insects and in Nematoid Worms, as we have seen, it is from distinct parts of the genital tube that the germs and yolk are produced; and more or less of the same arrangement exists in all instances in which the form of the ovary is tubular.

The Cestoidea present a great similarity to the Trematoda in the arrangement of the organs by which the ovum is formed. Indeed, notwithstanding the difference of their antecedent stages of development, the structure of the mature sexual joint or proglottis of the tapeworm, offers so great a resemblance to that of some of the Trematoda, that they have been regarded as identical by several recent observers. In each sexual joint of the tapeworm, the testicle and the two parts of the ovarian organ coexist, and, as stated in an earlier part of this article, arrive at maturity simultaneously in the posterior or oldest segments of the body. Van Beneden has, in his recent work on the Cestoid Worms†, described very clearly the structure and relations of the germigenous and vitelligenous parts of the eproductive organs in the complete segments or proglottides of a variety of Cestoid worms. The ova originate in the first mentioned of these organs as germinal vesicles, and, passing into the vitelligenous part, meet with the yolk-masses formed there. Near the same place is situated the seminal vesicle, from which, doubtless, the spermatic substance easily reaches the ovum as it descends in the course of its formation. The ova then acquire an external envelope, and pass into the cavity termed a uterus. As they come to be accumulated in gradually increasing quantity in the latter cavity, they distend it to a great degree, so as to cause it to pervade in various forms, ramified and others, the whole body of

* See his admirable memoir on the first changes in the fecundated ovum, principally referring to the Entozoa.

the proglottis; and finally they are discharged from this, usually after the separation of the joint from the main tapeworm, by the irregular rupture of the outer wall, or by a genital aperture. Here, then, we have another instance of the combination of the several component elements of the ovum together with the sperm, previous to the enclosure of the whole by a membrane so as to give the form of a complete ovum.

The ova of most of the Cestoidea, as in the common tapeworms, are of proportionally small size. The external envelope is firm, thick, and nearly homogeneous; sometimes, however, presenting a slight appearance of fine radiated striæ passing through it, which recalls the structure of the thick membrane of the Fish's ovum. The vitelline substance is very finely granular, or almost clear; the germinal vesicle is perceived with difficulty, but is of large size.* In some Cestoids the external envelope is of a brown colour, as in the Trematoda, and in others presents peculiar forms and prolongations from its surface. A delicate vitelline membrane is described within the outer covering by some authors.†

The segmentation of the yolk appears to be complete; but this process has been observed only in a few instances.

Of the ova of the Cystic Entozoa nothing need here be said, seeing that it has already been shown that the several genera of this order, viz., Cysticercus, Cœnurus, and Echinococcus, are only larval and aberrant forms of the Cestoid worms, and being immature animals, never produce ova, excepting through their more advanced stage of cestoid development.

Echinodermata. — The different orders and families of this class are all of distinct sex, so far as is yet known, with the single exception of one of the Holothurida, viz., Synapta (S. Duvernæa), described by Quatrefages‡ as presenting a combination of the testicles and ovaries in one organ, resembling in some measure that which exists in the Gasteropodous Mollusca.

In the females of Echinus, Asterias, and Holothuria, the ova have been studied with care by different observers. In all of them the ova present, when mature, more or less of a deep yellow, orange, or red colour, which belongs to the yolk-substance. This substance is finely granular, and is enclosed, at least in some, as Echinus, by a delicate vitelline membrane; but in others, as Holothuria, there is a considerable deposit of an albuminous layer of a peculiar structure, which, from its adhering closely to the vitelline membrane, obscures the latter envelope, and thus has made its existence doubtful to some observers. This albuminous deposit also exists in Echinus, but is in that animal distinguishable from the vitelline membrane.*

The colour and opacity of the yolk-substance in the mature state of the ovum usually prevent our perceiving the germinal vesicle; but in the earlier stages of formation, when the ovum is of lighter colour or even quite clear and transparent, a germinal vesicle with a single distinct macula is easily perceived. This vesicle has disappeared in the ova which are deposited. The segmentation of the yolk is complete in the Echinodermata: the process has been fully traced by Sars in Asterias†, and by various observers in some other genera.

It was in the ovum of Holothuria tubulosa that Professor Johannes Müller first made the novel and interesting discovery of an aperture leading through the thick external membrane towards the yolk; an observation which has been confirmed by various other physiologists‡, and has been productive of important consequences in its extension to a number of other animals in which such an aperture was not previously suspected to exist. Müller brought this observation before the Berlin Academy, and it was noticed in the printed report of the proceedings in 1851. A more detailed account of his observations on this subject is given by Müller in his Archiv. for 1854 (p. 60.). The very thick covering of the ovum of Holothuria presents an appearance of radiated lines running through it perpendicularly to the surface, which resembles in some degree the marking in the membrane of the Fish's ovum, but is not so distinct, and does not appear, as in it, to be produced by visible tubes or pores passing through the membrane. The canal of the micropyle pierces the whole thickness of the radiated membrane; but Müller conceived that it did not perforate the delicate vitelline membrane placed on its inner surface. Leydig, however, and Leuckart are of opinion that the canal passes completely into the interior of all the egg-coverings, and reaches the surface of the yolk, so that it may convey the spermatozoa to that body. The entrance of the spermatozoa has not, however, as yet been actually observed.

According to Leydig, the thick membrane may consist of several layers united together, such as, internally the vitelline membrane, the thick albuminous part in the middle, and externally the nucleated layer formed by the remains of the ovarian capsule. Leuckart and Leydig have also pointed out the fact that the formation of the canal of the micropyle in the egg of Holothuria proceeds from or is connected with the original attached and pedicu-

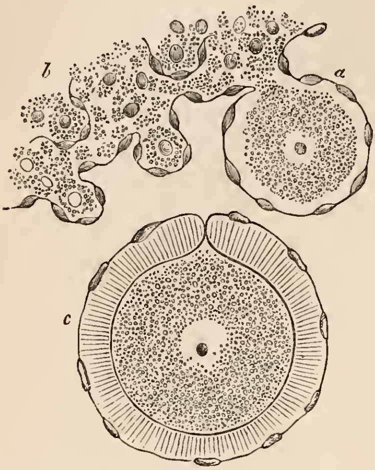
lated condition of the ovum in the ovary, that it is in fact the remains of the divided pedicle after the ovum is separated from the place of its original formation.

Fig. 91*.



Ovum and Micropyle in Holothuria tubulosa. (*From Leydig.*)

a, b. A small portion of the ovary from the inner surface, containing ova in various earlier stages of their development; three of them project from the inner surface, of which *a* is the most developed. In this one the pediculated attachment and enclosure of the ovum by the nucleated ovarian membrane is seen, the yolk granules and the germinal vesicle with its macula.

c. A more advanced ovum now separated from the ovary. Externally the nucleated remains of the ovicapsule are represented; inside this the thick albuminous layer marked with radiated lines, and lined closely by the vitelline membrane; both these, as well as the ovicapsule, being perforated by the micropyle formed at the place where the pedicle formerly existed.

The micropyle aperture has also been observed in other Echinodermata, viz. by J. Müller in Ophiothrix fragilis, in which he states its diameter to be $\frac{1}{1200}''$, and by his son Max Müller in Sternaspis thalassemoides.* This aperture has not yet been observed in the ovum of Echinus. In the fecundated ova of this genus, however, Derbès observed spermatozoa to have passed through the thick external albuminous covering, but not within the more delicate vitelline membrane; but in this animal the external covering is more like a layer of soft albumen than a dense membrane as in Holothuria.

The ova of Echinodermata take their origin, like those of other animals, by the formation of the germinal vesicles. These have been observed by Leuckart in the Holothuria tubulosa, beginning to be formed in the ovarian substance, which they cause to bulge or project when they enlarge, so as to hang into the ovarian cavity. The yolk-granules then come to be deposited round the vesicles, rendering the ova opaque, but during all this time the ovum is attached and enveloped by the original capsule derived from the ovary; the albuminous layer is then deposited, and the ovum being detached, the micropyle remains, as already stated, as the perforation in the pedicle of attachment.*

Polypina. — Although the greater number of the Polypi are commonly multiplied by a process of gemmation, as has already been stated in a former part of this article, yet they are all capable of attaining sexual completeness, and are also reproduced by means of fecundated ova. From the varieties, however, presented by the form both of the gemmules and true ova in different genera of Polypes, considerable difficulty has been experienced in determining the exact circumstances in which the ova are produced, and the distinction between the germs from which true ova and those from which gemmæ are formed. This is more especially the case among the ciliobrachiate Polypes or Bryozoa, which in their general organisation approach very nearly the tunicate Mollusca, but which in their mode of reproduction resemble closely some of the Polypes.

The ova of the common Hydra, already referred to in a previous part of this article, present the character common to the class, of being enveloped by a firm covering or shell membrane, which seems to be formed from modified cells, and which is sometimes beset with rough processes or projecting bristles or barbed spines somewhat like those of the Bryozoa.

In the Tubularidæ and Sertularidæ the ova are formed in ovigerous capsules, which may be regarded as modified individuals or polype-heads of the compound animal formed by gemmation. In some instances these are detached from the parent stem, as in Tubularia indivisa†; in other genera they remain attached, and their ova, or the ciliated embryos developed from them, are discharged from the cavities in which they are formed‡; but as the phenomena of the production of these ova have been fully described by Professor Rymer Jones in the article Polypifera, it is unnecessary to enter into farther details with regard to the process in this place.

* The micropyle was represented in the ovum of Holothuria tubulosa by R. Wagner in his Icones Zootomicæ, tab. xxxii., fig. 12., before its nature was known. The first discovery of a micropyle in the animal ovum is therefore due to J. Müller. The next observations of a similar nature are those of Leuckart and Keber.

* In addition to the memoirs previously quoted, descriptions of the ova of Echinodermata will be found in the following: viz., those of Comatula by J. Müller, in Mem. of the Berlin Academy for 1841; of Asteracanthion, in Wagner's Prodromus, and in the 5th Part of Carus and Otto's Tabulæ Anat. Compar.; those of Echinus by Derbès, loc. cit.; and by Krohn in Beitr. zur Entwick. der Seeigellarven, Heidelberg, 1849, &c.

† Sir John Dalzell, Remarkable Animals of Scotland, &c.

‡ Dumortier and Van Beneden's Researches, in Mem. of the Acad. of Belgium, 1842, tom. xvi.

In Hydractinia rosea, Van Beneden ascertained the existence of the germinal vesicle and nucleus within the ova while still contained in the capsule; and it appears that in all true ova of the Hydrozoa the vitellus, which consists of finely granular substance, undergoes a complete segmentation in the same manner as in other animals in which it presents a similar structure.

In the common fresh-water polype, in which ovigerous capsules, or ova, and spermatic capsules were found coexistent on the same individuals, I observed sometimes the spermatic capsules brought into contact with the surface of the ova by the bending round of the body of the polype at the time when the spermatozoa were being discharged. This took place previous to the formation of the firm external covering; but I could not determine whether fecundation had thus taken place or whether any spermatozoa had penetrated the ovum.

In some of the Hydrozoa, as in the common green polype, the ova are single, while in others as in Hydra fusca, figured by R. Wagner*, there are several ova enclosed in the same capsule.

It is remarkable that, while in some Hydrozoa the ova are developed from animals which retain the polype form in their complete sexual condition, or from modified polype heads, in others, as in Coryne, Fritillaria and Campanularia dichotoma, it is only from a medusoid progeny separated from the polype stock that the true fecundated ova are produced.

In Anthozoa, the most of which, as Actinia, Alcyonium, Veretillum, Gorgonia, and the Corallines are hermaphrodite, the ova consist of finely granular yolk, germinal vesicle and macula, and undergo complete segmentation.

The Bryozoa may be most appropriately considered in this place, as they present considerable analogy to the compound polypes in the mode of their reproduction. They are of separate sexes, and appear to be propagated in three modes, viz.: 1st, by gemmation; 2nd, by true fecundated ova; and 3rdly, by bodies which have long been regarded as ova, but which according to Professor Allman's recent researches may rather be considered as peculiar encysted gemmules, and may probably be analogous to the so-called winter ova of Daphnia and Lacinularia to which reference has previously been made.

The development of the true ova of Pedicellina observed by Van Beneden has been already described.† In this instance the ova are arranged in clusters surrounded by a transparent capsule. In each ovum the finely granular yolk undergoes a complete segmentation. The germinal vesicle possesses a single macula.

According to Van Beneden and Dumortier‡, the ova of Alcyonella are developed in ovarian sacs connected with the inner end of the stomach. They are described as commencing by the formation of germinal vesicles with nuclei or maculæ, and as having subsequently the granular yolk-substance deposited round each vesicle; and these authors describe the same ova as acquiring at a later period the peculiar horny or cellular covering which forms the two-valved shell membrane long known as belonging to the winter ova of this and several other genera of freshwater polypes. But with regard to the nature of these bodies and the mode of their formation some doubts may arise in consequence of the researches of Professor Allman. The bodies in question are at first nearly spherical and of a light or milky colour; they become later of an oval form, and flattened or discoid, and the cells of the shell-covering are then developed, and acquire the deep brown colour which very generally prevails among these bodies when arrived at maturity, and which makes it impossible to trace farther the changes within the ovum. These cells are developed to a greater extent round the widest margin of the disc, so as to form there a thick ring or border, which is afterwards cleft in two when the valves of the shell open to allow the escape of the embryo.

The same authors have described the propagation of the Paludicella to take place in summer by means of buds, and in winter by

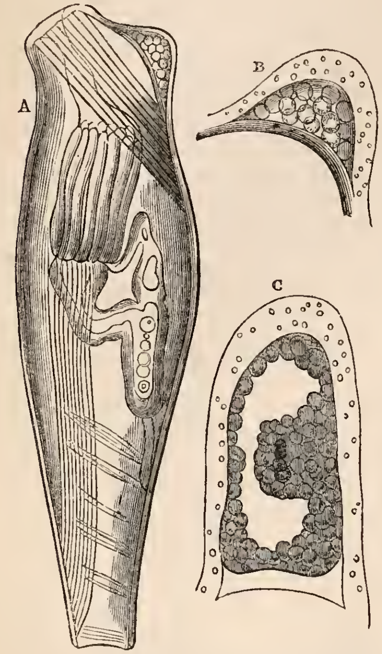
means of true ova, as well as by attached buds, which last are then covered by a strong corneous envelope, and have received the name of propagula. In Fredericella they describe a propagation by means of buds and by ova provided with the strong horny envelope. In Alcyonella and Lophopus, besides the usual propagation by buds, and by the common ova, these authors have stated that there is also a viviparous production of ciliated embryos from ova which remain within the parent animals; but they have not stated particularly the manner in which these ova originate, nor their difference from those which receive the corneous envelope. The difficulties presented by these varieties seem to be in some measure removed by the view offered by Professor Allman of the nature of the bodies last mentioned, to which I will now advert.

Fig. 93*.



Formation of buds in Paludicella. (From Van Beneden and Dumortier.)

a. One of the Polypes of Paludicella Ehrenbergii contracted within its cell, showing at the upper part towards the right the commencement of the formation of the bud by the growth of cells between the outer and inner layers of the cell-wall.

b. The same bud a little more advanced and more highly magnified, represented by itself. The vesicular cells which separate the ectocyst and endocyst are seen more distinctly.

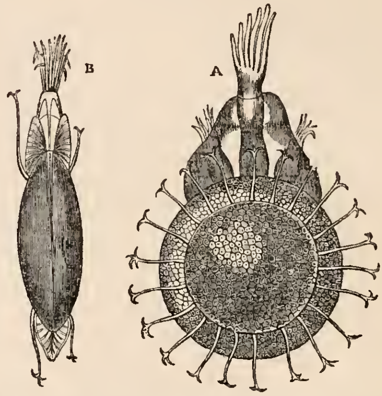
c. A more advanced stage of the same, internally; the part from which the embryo polyped arises is seen bulging out from the rest.

This figure has been introduced to show the difference between the process by which a true bud arises and that by which ova are produced.

It has long been known that the so-called winter ova, or the bodies provided with the corneous envelope, are formed chiefly towards the autumn and winter season; and the strength of their covering has generally been regarded as a provision for the protection of the germ from the hurtful influences of the winter season. During two seasons I have observed the production of these bodies from the Plumatella repens; and I have kept them through the winter till the polypes were developed, and issued from them in the ensuing summer.

From his careful observation of these bodies in several genera, Professor Allman has arrived at the conclusion that they are not, as was previously supposed, true ova, but rather separated gemmules; and he conceives that Van Beneden, who has described their form and structure so well, must have confounded them with some other bodies in their first or earlier stages, or has failed to distinguish between them and the true ova. This distinction Allman has succeeded in making by ascertaining that the true ova and these bodies do not arise in the same situation, and that these winter ova or gemmules do not in their earliest stages present any germinal vesicle or macula as the true ova do, and do not afterwards undergo any segmentation. They are formed, according to Allman, in the funiculus which connects the bottom of the stomach with the inside of the cell of the polypide, the same body which was described by Van Beneden and Dumortier as an ovary, but which Allman regards rather as analogous to the gemmiferous stolon of the solitary Salpæ. These bodies Professor Allman proposes to call stato-blasts. He farther discovered that there is a true ovary with genuine ova which may be distinctly observed in Alcyonella, and which is situated in the walls of the endocyst

Fig. 94*.



Winter ovum and embryo of Lophopus Crystallinus. (From Van Beneden and Dumortier.)

This is the same as that represented by Turpin under the name of "Cristatella mucedo." In A. the flat surface, and in B, the narrow edge of the ovum, is represented. The two valves of the egg covering have opened superiorly, and the embryo, which already possesses three crowns of tentacles, is seen escaping.

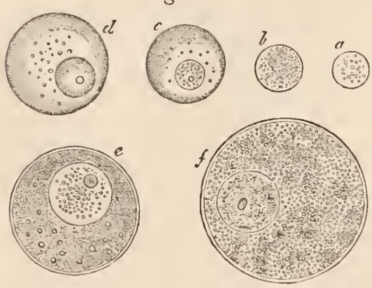
near the anterior extremity of the cell. A number of ova were found in the ovary containing the distinct germinal vesicle with macula. He also observed the segmentation of these ova in the usual manner, and the conversion of the segmented mass into a ciliated embryo, within which the new polype is subsequently developed.†

Should these observations prove correct and be applicable to the other instances of similar winter ova among the Bryozoa, they may tend to remove some of the difficulties which exist in regard to the various reproductive bodies occurring in these animals; but farther researches seem still necessary to point out in these and in other polypine animals more fully and minutely the relation between the three kinds of reproductive bodies, viz., true ova, separated gemmules, and attached buds.

Acalephæ.—It is remarkable that notwithstanding the very close relation in which these animals stand to the Anthozoid Polypes, the form of their ova is not the same. The Discophora (Medusæ) are of distinct sexes: the Ctenophora (Beroes) are hermaphrodite; the Siphonophora (Diphyidæ) are various, or bear, in the manner of compound animal stocks, a variety of zoids, sometimes of one sex alone, at other times of different sexes on the same stem.

The structure of the ova in Medusæ is extremely simple. They are originally formed from minute cytoblasts which soon acquire a single nucleus or macula, and are enclosed in a delicate external membrane. These constitute the germinal vesicles, round which the granular yolk-substance is gradually deposited in increasing quantity. The complete segmentation of the yolk has been observed by Von Siebold in Cyanea aurita.* The yolk-substance is often highly coloured, violet or yellow. In the former part of this article I have referred to the manner in which some compound Hydroida are propagated through their medusoid progeny. These medusoid individuals, like the ordinary Medusæ, are of separate sex; and they must therefore be looked upon as the complete stage of the polypine animals from which they have proceeded, whether they have their young developed while the parent remains attached to the nursing polype stock, or have assumed the separate and independent mode of life in a more complete state of development. There are many varieties in the degree of perfection to which they attain even while remaining attached to the polype; but the general principle of formation is the same throughout the whole of the hydroid animals, the remarkable and constant fact with regard to the mode of their reproduction being this, that the immediate product of development from the ovum which has been formed by sexual generation from a Medusa or medusoid animal is invariably an attached Polype, and that the medusa or medusoid is the product of a non-sexual process of gemmation from this polype stem.

Fig. 95*.



Development of the ova of Acalepha.

These figures give magnified views of the different stages of formation of the ova taken from the ovary of a large Rhizostoma. *a.* The primitive germ. *b.* The germinal vesicle now present in the primitive ovum. *c. d.* The same more advanced and enlarged, the macula has appeared in the germinal vesicle, and a few yolk granules are deposited in the clear vitelline substance. *e.* The yolk granules greatly increased in quantity and becoming opaque, a vitelline membrane is now formed. *f.* The same somewhat more advanced, the yolk granules are now collecting together to form corpuscles. The macula is assuming the elongated form.

Protozoa.—With regard to the Protozoa, or Infusoria and Rhizopoda, it is unnecessary to add anything here to what has been stated in the several articles on these subjects and in a former part of this one, excepting the remark, that continued researches appear to show that as the sexual distinction has not been detected, and may probably be absent in these animals, the nucleus of the monocellular forms of these beings may hold the place of the germinal vesicle in them, and that the processes of division and production of internal gemmules takes the place of true ovulation. At the same time it must be admitted that it is by no means improbable that the sexual relations may yet be discovered in the lowest monocellular animal bodies, as has recently been the case in some of the simpler and monocellular Algæ, and that as our knowledge of the process of reproduction in these beings is still very limited, it may be destined to undergo even greater progressive changes than those which it has suffered from the researches of the last few years.†

Porifera.—The bodies which have usually been regarded as the ova of Sponges, and to which a reference was made in the earlier part of this article, are of two kinds, viz. gemmules or detached ciliated portions of the

substance of the sponge, and certain spherical bodies enclosed by dense capsules, which are produced towards winter, and which appear to contain a number of germs, each of which is capable of being developed into a Protean animalcule, from which probably a sponge may proceed.* But it may be doubted whether these last-mentioned capsules are true ova or may not rather be of the nature of the gemmules, winter ova, or statoblasts of Professor Allman; and it is important to notice that Mr. Huxley has recently discovered in Tethya a different set of bodies, which contain all the essential parts of true ova, viz. vitelline membrane, yolk, germinal vesicle, and macula, and that these bodies, which are situated between the cortical and central substance, are imbedded in a mass of cells together with spermatozoa.† Although the individual living particles of the sponge closely resemble simple ciliated infusoria, and the mass may, therefore, be viewed as an aggregate of these minute beings, yet its analogies with and transitions towards the fungiform polypes are so great, that we may expect ere long that the phenomena of its reproduction may be placed in a new and clearer aspect by the continuation of the researches now noticed, and by others of a similar kind.

RECAPITULATION AND CONCLUSION.

Having now stated in detail the principal facts that have come under our knowledge with regard to the form, structure, and mode of origin of the ova of different animals, it may be proper, in bringing this article to a close, to endeavour shortly to deduce from these facts the most general results to which they appear to lead. These results, together with some reflections on our subject, may be stated under the following heads, viz. 1. Definition of the ovum, as related to its own structure, and its history in connection with the reproduction of the species. 2. Recapitulation of the most general facts ascertained by the comparison of the ova of different animals. 3. Morphology of the ovum; homology of its parts; and relation of the ovum to other organic structures. 4. Phenomena attendant on the maturation of the ovum. 5. Relation of the ovum to fecundation by the male sperm. 6. Immediate effects of fecundation on the ovum; and relation of the ovum after fecundation to the first commencement of the process of embryonic development.

1. Definition of the ovum, as related to its own structure, and its history in connection with the reproduction of the species.

In the commencement of this article the ovum was shortly defined as "the product of parental sexual generation from which the young of animals are developed (produced)." This definition appears correct and sufficiently comprehensive; but should it appear desirable to substitute for it a more precise description of the characteristics of the animal ovum, the following may be proposed as applicable to the ovum throughout the whole animal kingdom, without involving any merely theoretical view of its structure and constitution, viz. "the ovum may be shortly described as a detached spheroidal mass of organised substance, of variable size, enclosed by a vesicular membrane, and containing in the earlier periods of its existence an internal cell or nucleus; these parts, formed by the female individual or organ of animals, are capable, when fecundated by the male sperm of the same species, of giving rise, by the series of histogenetic and organogenetic changes known under the general term of development, to an embryo, from which either directly or mediately the individuals of the animal species to which the parents belong are reproduced."

We thus separate from the category of true ova all those bodies of an apparently reproductive kind which are not the direct product of an act of sexual generation. To such bodies, the nature of which is as yet doubtful, and probably somewhat various, the indefinite appellations of buds, bud-germs, gemmæ, spores, winter ova, ephippial ova, statoblasts, &c., have been given according to the circumstances in which they are severally produced.

In all animals, then, with the exception of the Polygastric Infusoria and Rhizopoda, the occurrence of sexual generation and the formation of true ova are proved to be the regular and constant means for the permanent reproduction or maintenance of the species. In the exceptional instances now mentioned, and even in some others possessed of the sexual distinction, the best known and most common multiplication of individuals takes place by a subdivision of the parent body, either by fissiparous cleaving or by gemmation; but in them also it can scarcely be doubted that there are other means by which the permanence of the species is maintained.

All the most accurate recent investigations lead to the conclusion that the production of the young of all organised beings, even the simplest of the Protozoa, does only occur by direct connection through some organised medium with other beings of a similar kind or species. We are forced, therefore, to conclude that in the propagation or production of these simple beings, in circumstances where their more ordinary fissiparous or gemmiparous mode of multiplication cannot be admitted to have taken place, there must have passed from the bodies of the progenitors minute particles of organised substance (capable, as we know, of being suspended in the atmosphere, and of resisting during a long period many of those influences which generally prove inimical to animal development), which particles, when brought into circumstances favourable to the progress of the vital processes, undergo the cycle of changes necessary for the reproduction of beings similar to those from which they sprang. If there is any constant law which seems more certainly

* See Carter in Annals of Nat. Hist. vol. iv. p. 89.

† See Mr. Huxley's paper in Annals of Nat. Hist., 2nd series, vol. vii. p. 370.

than others to result from all recent researches into the history of organic nature, it is this necessary connection by descent of one being or set of beings from another.

In all animals, with the exception of the simplest tribes already referred to, the descent from parent to offspring is through a product formed and perfected only by the concurrence of male and female organs; but we are still at a loss to determine whether the unseen germinal bodies by which the Protozoa are reproduced are of the same or of a different nature. The structure of some of these germinal bodies as described in the earlier part of this article (p. 7., &c.), bears a very great resemblance to that of true ova; but yet the sexual distinction of the parent animals has not yet been discovered. The recent researches of naturalists indeed show that our whole knowledge of the history of the Protozoa may be considered as only in its infancy. The discoveries as to the encysted stage of existence among the Vorticellæ and Gregarinæ and others, the phenomena of conjugation observed in Gregarina and Actinophrys, the entire knowledge lately gained of the form, structure, and habits of the Foraminifera, all point to important future discoveries and modifications of our hitherto crude and imperfect views of these tribes of beings, and must make us refrain from attempting at present to form any opinion or even conjecture as to the modes of their reproduction; while at the same time the recent discoveries as to the existence of the sexual distinction in the simplest forms of plants encourage the hope that ere long the reproduction of the Protozoa may, in a similar manner, be removed from the obscurity in which it now lies hidden. It does not appear necessary from these considerations that our definition should make any direct reference to animal bodies of the nature of which our knowledge is still so imperfect.

The result of development from a fecundated ovum in all vertebrate and in a considerable number of invertebrate animals, is the formation of an embryo which, by a process of progressive growth, arrives at maturity, and assumes the form, structure, and habits, either, as the case may be, of a hermaphrodite animal, or of the parent of either sex. In a certain number of these instances, as in Batrachia, Insects, Crustacea, and others, growth is not altogether continuously progressive, but is subject to one or more breaks or changes as it were, which are marked by some change in the mode of life, or some difference in structure of the individual. To such marked changes in the course of the development or growth of an individual animal proceeding from a fecundated ovum, the name of Metamorphosis is given.

But from the facts narrated in the earlier part of this article, it appears that in a certain number of the invertebrate animals, such as those which have been referred to under the heads of Echinodermata, Polypina, Acalepha, Tunicate Mollusca, Trematode and Cestoid Entozoa, Annelida and Insecta, a very different result may, either regularly and constantly in some, or only occasionally in others, attend the first development from the fecundated ovum. To this modification of the developing and reproductive process the appellations of Alternate Generation or Metagenesis have been given, of which terms the latter may perhaps be the most appropriate. The phenomena which have been described under this head are so very various, that it is difficult, if not impossible, to give a short and general statement of their nature. The difference between this and the better known form of direct generation may, however, be stated nearly as follows:—In the Metagenetic form of reproduction the individual formed by the development of the fecundated ovum is generally different in aspect, structure, and mode of life from the parent or parents by which the ova were produced; this individual, or zoïd, though possessed, in many instances, of an organisation and of powers which fit it for the efficient performance of many of the most important acts of independent animal existence, is yet wanting in the attribute of perfect animal maturity, viz., the sexual organs and activity, and is consequently incapable by itself of an act of true generation, or, in other words, of the formation of fecundated ova, by which alone the species can be permanently reproduced. In such instances, then, it is only by the formation from these intermediate beings of others which are sexually perfect, that the generative act can be repeated. There are two phenomena requiring to be distinguished in connection with the most common forms of this process; the one the frequent multiplication of the imperfect intermediate beings, or zoïds; and the other the production either directly or by a succession of acts of development from the intermediate beings of those which are sexually perfect, or which resume the form belonging to the parents from which the fecundated ova were derived. It seems proper, therefore, to distinguish between an act of true sexual generation, and that by which new beings are formed from the intermediate individuals (or so-called nurses of Steenstrup, or zoïds of other authors); the first consisting invariably in development from a fecundated ovum; the second being probably more analogous to a process of budding or gemmation from a parent stock. It must be confessed, however, that we have still much to learn regarding the phenomena of this process, before we can form any general notion of its nature. The whole subject is replete with the deepest interest not only in connection with the history of reproduction, but in its influence, as stated in some parts of the preceding article, on the whole range of zoological classification and distinction. Our extended definition comprehends an allusion to these phenomena.

Lastly, the ovum may be considered as having two phases or stages of existence; the one in connection only with the female parent or female organ, in which the greater part of the organised material first to be employed in development is provided, and in which the ovum arrives at a certain stage of maturity; and the other in its relation to fecundation, or to the influence of the product of the male by which its developing powers are awakened or called forth. The mature ovarian ovum may therefore, in one sense, be looked upon as complete, if we regard only its own structure; but here its progress would be arrested without the occurrence of fecundation, and if we view it, therefore, with reference to its more important destination as the means of continuing the animal species, the ovum can only be regarded as perfect when that hitherto inscrutable change has been effected on its substance by admixture with the minute elements of the sperm in fecundation. The constancy of this law in the whole animal kingdom, with the exception of those of the Protozoa already referred to, makes it proper that our definition should make reference to fecundation as the means of perfecting the ovum. To the nature of this process itself a further allusion will hereafter be made.

2. Recapitulation of the most general facts ascertained by the comparison of the ova of different animals.

The ova of animals in their complete state may be considered as consisting of two sets of parts which are of very different relative importance in connection with the development of the embryo: the first of these sets of parts belong to the ovarian ovum, and are formed previous to their quitting that organ; the others are subsequently formed, and may be looked upon as accessory. These last often present great varieties, so as to cause the external form and appearance of the ova of animals to differ widely, while the ovarian part much more nearly corresponds. To this ovarium ovum we shall principally confine our present remarks.

An extended comparison of the ovarian ova of animals belonging to almost every family of the animal kingdom has shown that, notwithstanding great differences in size, and some variation in form and structure, they all agree in consisting of three essential and nearly similar parts before the period of their detachment from the ovary: these are, 1st, The internal nucleated cell or germinal vesicle with its macula or maculæ; 2nd, The vitellus, or yolk-substance; and 3rd, The enclosing vesicular envelope, or vitelline membrane. In all animals there is, also, a general similarity in the manner in which these parts are formed and combined so as to constitute the ovarian ovum; the germinal vesicle is the first produced, and may be regarded as the ovigerm; the yolk-substance next gradually envelopes it or is deposited round the germinal vesicle, and in general the vitelline membrane which encloses the whole is the latest formed.

The most marked differences among the ova of animals are connected with the structure of the yolk and the relation which it bears to the formation of the germinal part out of which the embryo is afterwards developed. Founding upon this difference, three groups, two principal and one subordinate, may be distinguished among the ova of animals:— 1st, The group of small-yolked ova, to which belong those of Mammalia and a considerable number of invertebrate animals, such as most Mollusca, the lower Crustacea, most Annelida, the Entozoa, Rotifera, Echinodermata, Acalepha, and Polypina. In this group, the ovum is generally of small or of moderate size, as a whole; the vitelline substance consists entirely or chiefly of fluid with fine granular particles, and the entire yolk undergoes segmentation: the entire yolk mass, therefore, is directly *formative*, or is employed from the first in the formation of the blastoderm or organised substratum in which the embryo is developed: the germinal vesicle is in this group usually of small size, and has only a single macula, or one composed of very few particles.

The second principal group comprehends the large-yolked ova, such as those of Birds, Scaly Reptiles, Cartilaginous Fishes, and the Cephalopoda, to which, perhaps, may be added Insects, Arachnida, and most Crustacea. In this group, the largely developed yolk contains, suspended in its basement, homogeneous substance, two kinds of organised corpuscles, viz., 1st, A certain portion of the small granular part, similar to that of the small yolked ova, which occupies a limited but determinate place in the ovum, and in its centre the germinal vesicle is situated; and 2nd, A larger portion of spherules, cell-like or other corpuscles of greater magnitude. It is the first or finely granular portion only which is immediately germinal, or which is subject to segmentation and forms the basis of the blastoderm; the remainder, or large cellular portion, is only secondarily employed in supplying nourishment to the embryo or its accompanying organised parts in the progress of their development. In the ova of this group, therefore, we distinguish the formative or directly germinal portion of the yolk-substance from the indirectly *nutritive* portion. In these ova, the germinal vesicle is also proportionally large, and the contents of the vesicle, though consisting in the earliest stages of their formation of a single macula, or of a very small number, very soon become converted into very numerous maculæ, or into a fine granular pulp.

The third, or subordinate group, may comprehend the ova of Amphibia, or scaleless reptiles, and osseous fishes, to which, perhaps, may be added some of the invertebrate animals mentioned under the second group. The ova of this group are intermediate in their structure between those of the first and second: they have certainly the greatest affinity with the large-yolked group, but there are many gradations among the ova of this kind, among allied species of animals, and it is chiefly on the ground of the incompleteness of the segmentation that I have thought it proper to arrange them in a separate group.

It may be remarked further, that in all animals, whatever may be the ultimate structure of the yolk, the primitive yolk, or that which is first formed, is invariably of the finely granular kind, — the cellular or large corpuscular yolk-substance is of later formation. These two parts remain distinct from each other, and the finely granular or formative yolk is that in which the germinal vesicle is invariably imbedded. In those instances, such as the Bird, Reptile, &c., in which the large cellular yolk greatly preponderates over the formative yolk-substance, the latter assumes in the later stages of formation the shape of a flattish disc on one side of the greater mass of the yolk, with the germinal vesicle placed in its centre.

The vitelline membrane presents some varieties in structure, being in some animals very delicate and homogeneous; in others, as Mammalia, remarkably thick, tough, and elastic, but without visible structure ; in a third set, exhibiting peculiar structure, such as the finely tubular perforations of the external membrane of the fishes' ovum, or the radiated markings in the ova of Holothuria or Cestoidea ; but in these last three instances the vitelline membrane is probably associated with additional layers of substance derived from a different source from that which forms the homogeneous membrane.

A remarkable peculiarity has recently been discovered in the enclosing membrane of the ovarian ovum of some animals, in the aperture or micropyle which has been observed in osseous fishes, insects, some Crustacea*, the Acephalous Mollusca, some Annelida, Holothuria, and some other Echinodermata. There seems reason to believe that a similar aperture exists in the ovum of Batrachia and Cephalopoda; and it is very probable that it may yet be discovered in other animals. At the same time it is right to state that in Mammalia and several other animals it has been most carefully sought for without success. This aperture appears to be designed to admit the spermatozoa into the cavity of the ovum, or into contact with the yolk-substance and germ, in those instances especially in which the egg coverings are thick and tough, and fecundation is late of occurring.

The relation of the ova to the ovaries or organs in which they are produced, exhibits considerable varieties in different animals. 1. The most common is that in which the germs of the ova arise within minute close follicles or vesicles, which are imbedded in the more or less solid or loose stroma of the ovary ; the follicle enlarging with the ovum as its other parts are added till the period of of maturity, when, periodically, the follicles open for the escape of the ova. 2. In a second form, as in Nematoid Worms and Insects, the germs of the ova are produced free in the upper part of an ovarian tube, and the yolk-substance, &c. are added gradually as the egg germs descend through successive portions of the tube : here no true dehiscence is necessary to allow of the escape of the ova. 3. In a third form, as in Trematode and Cestoid Entozoa, distinct organs are provided for the formation of the ovigerms and the yolk-substance, and these last are brought together and combined into the spherical form of an ovum in another part of the genital apparatus. 4. In the greater number of animals the germs for each ovum appear to arise singly, and the ova are thus isolated from the first ; but it would appear that in some animals these germs arise in groups, perhaps by development from a common germ, so that they are from the earliest period connected together by pedicles. Yet, with all these differences, there is to be perceived, on the whole, a general similarity in the plan of formation of the parts of the ovum itself in different animals. This plan may be generally stated as follows.

The germinal vesicle is universally the first part of the ovum which makes its appearance ; it does not appear to be nucleated or to possess its macula from the first in all instances, and this macula cannot therefore be regarded as the centre of its formation. The germinal vesicle is generally at first only a minute point ; it soon enlarges, however, and either possesses from the first, or at a very early period acquires, its macula or nucleus. In animals with the solid follicular ovary, each follicle is occupied by a single ovum, which begins within it as a minute germinal vesicle. The delicate wall of the follicle is also perceptible at the same time as the ovigerm ; indeed, there is reason to believe that it even precedes the commencement of the formation of the ovum, though this is a point not yet fully determined. In those animals, on the other hand, in which the ovary is tubular, the ovigerms appear, in some instances at least, to arise in groups within cells; and it may be a question whether these cells bear to the ovigerms arising within them the relation of the ovarian follicles of solid or closed ovaries. Whether this be so or not, that relation is in most instances speedily changed, as the ova soon become free, or, in others, are attached by a pedicle to a common stalk.

The wall of the ovarian follicle consists at first of an extremely delicate vesicular membrane, which is the same as that to which the name of ovicapsule or ovisac has been given. At a very early period, and while the ovum consists of no more than the germinal vesicle, the homogeneous wall of the follicle is lined with a layer of flat cells somewhat analogous to some forms of epithelium : this is the commencement of the structure which in Mammalia afterwards forms the tunica granulosa, and the fluid and cellular contents of the Graafian follicle. It appears to have various destinations in different animals.

The second stage in the formation of the ovum is the deposit of the vitelline substance around the germinal vesicle. In most animals the yolk-substance, when it first begins

* It has been inadvertently stated in a preceding part of this article (p. 116.) that the micropyle had not been observed in the ova of Crustacea, whereas Meissner has ascertained its presence in that of Gammarus. (See his Memoir in Zeitsch. fur Wissen. Zool. vol. v. p. 284.)

to be formed, is scarcely granular, and in some instances quite clear, consisting of a viscous blastema, and as it increases separating the germinal vesicle within from the ovarian follicle, which expands proportionally. Very soon, however, and in many animals indeed from the first, fine opaque granules make their appearance, as if by precipitation or deposit, in the clearer basement substance, and thus the primitive yolk-substance of the ovum in all animals is formed. In most instances there is a time during which the ovum, consisting of germinal vesicle, with a small quantity of primitive yolk, exists, without any other covering than that given to it by the ovarian follicle; but as the deposit of the finely granular yolk increases, and at a very variable period in different animals, the vitelline membrane is formed round its exterior. The addition of this covering may be regarded as the third stage in the formation of the ovum. The manner of the origin of the vitelline membrane has not yet been accurately observed; and it is probable (as will be hereafter stated) that the coverings known under this name may have different modes of origin; but if we restrict our attention at present to such simple ova as those of Mammalia, I believe it may be stated as extremely probable that the so-called zona pellucida which constitutes the vitelline membrane of the Mammiferous ovum, takes its origin by the consodidation of the superficial part of the basement substance of the primitive yolk.

It appears probable that in the large-yolked ova, such as those of the bird, the vitelline membrane, which we find enclosing the whole mass of the yolk, owes its origin to a different source; and I am inclined to believe that in this and in many other animals the membrane which we term vitelline, as being the immediate investment of the yolk, is not of the same nature with the zona pellucida, or the simple homogeneous vesicle of the smaller ova, but rather a structure of later formation, which owes its origin to the fusion, or amalgamation, or to some other change in the outermost layer of cells which form the nutritive yolk of these animals.

In connection with this view, it is important to remark, that at that earlier stage of formation of the bird's egg when it consists entirely of formative or primitive yolk, there is an approach to the formation of a zona, in the existence of a very distinct, clear, and consistent marginal portion of the yolk blastema, from which the yolk granules seem to retire. When the large cellular or nutritive yolk is formed, this temporary zona seems to disappear, and to be replaced externally by the permanent vitelline membrane already mentioned.

In those animals in which the ovigerms arise by development within cells so as to be connected in groups (Gordiacei), and in some others, the vitelline membrane, or a substitute for it, seems to be formed from the earliest period in a different manner from that now described.

The germinal vesicle is unimacular in general in the small-yolked ova, and multimacular in the large-yolked ova, and also in the intermediate kinds. In the latter it is rare to observe the earliest stage in which the macula is still single: the multiplication of the maculæ takes place with remarkable rapidity, and apparently by a process of endogenous development, or possibly by division. The ultimate destination of these maculæ is still a subject of doubt.

3. Morphology of the ovum; homology of its parts, and relation of the ovum to other organic structures.

Should the views be correct which have now been stated with regard to the relations of the parts in the mature ovarian ovum, and the manner in which they are formed, it will be apparent that a strict homology or anatomical correspondence can be pointed out in regard only to some of the parts which are recognised under similar designations, as respectively belonging to the ova of different animals. All physiologists will probably be disposed to look upon the germinal vesicle or ovigerm as corresponding or homologous in the ova of all animals, and, notwithstanding the great differences known as to its more simple or multiple condition, the same view may also be taken of the structure known as nucleus or macula. The primitive or finely granular yolk-substance, more especially that which immediately surrounds the germinal vesicle, and is afterwards employed in the formation of the blastoderm or embryogerm, seems also to have a similar origin, structure, and relation in all animals. But beyond this it is more difficult to trace the homological correspondence; for under the names of cellular yolk-substance and vitelline membrane it appears that there have been brought together parts of which the origin, structure, and relations may be dissimilar in different animals. There seems at least to be sufficient reason, from what is already known of the varieties of the enclosing membrane, or so-called vitelline membrane, to establish a distinction between several forms of that structure; as, for example, between the vitelline membrane, which exists from the earliest period as a pediculated sac in connection with the ovarium, as in Holothuria; that which is derived from the extension of the wall of the original germ-cell in grouped ova, such as have been described by Meissner in Gordiacei; that which is later formed round the ovum of Mammalia as a zona pellucida, by the consolidation of the outer layer of the primitive basement substance of the yolk; and that which in the bird and other animals whose ova are similarly constituted, appears to derive its origin in part, at least, from coalesced cells corresponding to those of the tunica granulosa of the ovarian capsule on the exterior of the cellular yolk.

With regard to the cellular yolk itself, we must refrain from any attempt to establish its homology till we shall be more fully acquainted with the mode of its production; for it is still undetermined whether it arises by cell formation within the primitive vitelline membrane through some change in the substance of the primitive yolk, or whether it is derived, as I am inclined to believe may be the case in birds and some other animals, in a space external to these parts, and more in connection with the cellular contents of the ovarian follicle.

In limiting, then, our comparison to the parts of the ovum in a bird and a mammifer, we may regard the germinal vesicles as homologous in both; the finely granular germinal disc of the bird's ovarian egg as homologous with the whole vitellus of the mammiferous ovum; the zona pellucida of the mammiferous ovum as temporarily represented by the clear outer band of the primitive yolk, which is seen in the bird's ovarian ovum when of a diameter of from $\frac{1}{40}$ to $\frac{1}{20}$ of an inch; the cellular yolk of the bird's egg, and its enclosing vitelline membrane as probably homologous with the fluid and granular contents and lining tunica granulosa of the ovarian follicle of the mammifer, and not by any means with the corpus luteum of a later period, as has been suggested by some. The albumen of the bird's egg has its homologue perhaps in the similar deposit which the ova of several Mammalia acquire in their descent through the Fallopian tube. The chorion of the ovum of Mammalia, being an after growth, has probably no true homologue in the bird's egg, unless we should regard the shell membrane and shell as occupying this place.

Many ovologists have thought it of importance to establish a comparison between the ovum or its parts, and some one or other of those microscopic structures which, since the publication of the discoveries of Schleiden and Schwann, have been known as organised cells. Schwann himself, though looking upon the entire animal ovum as a cell, entertained some doubts as to the exact nature of the comparison to be instituted for its several parts. These doubts are not yet removed, and the progress of knowledge has tended rather to diminish than to increase the appropriateness of the comparison, more especially from the somewhat various and indefinite nature of the bodies which are now recognised as organised cells.

It cannot be denied that, if we regard merely the structure of the simpler ova of small animals, we find in them the general characteristics of an organised cell, as these have been usually understood; that is, we find the external structureless vesicular cell-wall, the internal granular contents, and the internal nucleus or inner cell with its nucleolus. But when we consider more fully the whole history even of the most simple ova, and extend our regard to the structure and history of the more complex forms of ova, we perceive many circumstances which render the comparison with detached animal cells inapplicable.

Leuckart remarks, in his article Zeugung, previously referred to (p. 815.), that if we attempt to deduce the most general result from what has been ascertained as to the formation of the ovum, it is this, that "the animal ovum is formed by deposit round the germinal vesicle." The progressive formation of the parts of the ovum, therefore, would appear to differ widely from that which Schwann held to occur in most cells. But our whole knowledge of the various forms and modes of production of cell-like structures has been extended, and has undergone some modification since the time of Schwann; and there are now known to be not a few cell structures which are formed by external deposit of matter round a nucleus, nearly in the same manner as occurs in the ovum. In this view, therefore, the simpler kinds of ova might be regarded as examples of "deposit cells."

The great variation in the magnitude of different ova, and the prodigious size which some of them attain, as compared with the minute and generally microscopic size of the organised cells of the animal body, cannot by itself be received as a conclusive argument against the cellular constitution of the ovum; but the complexity of its structure, its relation to fecundation, the peculiar micropyle of the outer wall in some, the separation of the germinal from the nutritive part of the yolk-substance, and the new formation of cells after segmentation in a limited or more extended space over the yolk in the interior of the vitelline membrane, are so widely different from any thing belonging to the history of other cells in the animal body, that we are forced to regard the ovum rather as a structure of a peculiar kind than as a mere modification of a cell.

The germinal vesicle it might be held, both in its structure and its mode of origin, merits, more justly than the whole ovum, the comparison with an organised cell. But even in its history there are points of difference, and we are still too little acquainted with the mode and consequences of its disappearance at the time of the maturation of the ovum, to warrant our making more than a vague and general comparison of the germinal vesicle to an organised cell. In admitting that the ovum, or its germinal vesicle, present some of the features of the organic cellular structure, we ought always to bear in mind that they are the source of all the other cells from which the animal body is developed.

The manner of the very first origin of the germ of the ovum is still involved in obscurity, for we only know of the existence of an ovigerm when the germinal vesicle has attained an appreciable size. Whence the first germs of the germinal vesicles proceed can as yet be matter only of conjecture. Without entering here upon the debated ground of the origin of organised cells in general *, I would venture to express the opinion, that as there is no ovigerm without a parent, so there is no new organisation without previously existing, and at some time or other connected, organisation. Hence, notwithstanding the appa-

* See upon this subject the very interesting and suggestive Review by Mr. Huxley in the Brit. and For. Med. Chir. Review for October, 1853.

rent isolation of the origin of cells in blastema or intercellular substance, it might still be held that the unseen germs of new cells contained in that blastema may have derived their origin from other cells or organised parts proceeding from cells. And thus, in regard to the first origin of the ova of animals, it is fair to conjecture that the germs from which they spring have taken their descent from parent cells or structures derived from cells through the organs appropriate to their formation. But here observation fails to assist us further, and we are lost in the region of speculation.

If, however, with the reservations now stated, it should be thought desirable to compare the ovum to the organic cellular structures, the germinal vesicle may be regarded as the simple cell of the ovum, the whole ovum as a complex cell; the first of these being formed probably by expansion from a minute point or molecule, the second by superposition or external deposit round the internal cell; but both at the same time presenting features which are peculiar to themselves, and different from those which characterise other cells of the animal economy. The different and separate formation of the germinal vesicle and yolk, which is perceptible to some extent in the ova of most animals, is placed in its most striking point of view by those instances in which, as in Trematode and Cestoid Entozoa, there are distinct germigenous and vitelligenous organs, and those in which, as in Nematoidea and Insecta, the ovary is tubular, and the formation of the several parts of the ovum goes on progressively in different parts of the tube.

4. Phenomena attendant on the maturation of the ovum, and its discharge from the ovary.

The ovum naturally undergoes in the ovary a progressive development till it arrives at the state of maturity, when it is usually separated from the ovary by a process of dehiscence, is conducted through the female passages either to be excluded or laid, as in oviparous animals, or to be retained in a uterus or other part of the female organs in viviparous animals during uterogestation. The maturation of the ova and their separation from the ovary is in many animals periodical and independent of fecundation. This natural periodical separation of the ova has been termed *Ovulation* by some authors.*

The change which the germinal vesicle undergoes at the period of the maturation of the ovum has naturally attracted much attention, from the hope that through the observation of this phenomenon some explanation might be obtained of the first origin of the germ round which, after fecundation has taken place, the segmenting and organising stratum is collected, from which the blastoderm is produced; but it must be allowed that as yet little success has attended our efforts to detect the connection, if it exists, between these two processes. In almost all animals the germinal vesicle is lost to view at the time of the maturation of the ovum, and generally before or about the time when the ovum leaves the ovary. In large-yolked ova the maculæ of the germinal vesicle become very numerous by their multiplication and sub-division at an early period; while in the small-yolked ova, as has been observed in a few animals at least, the increase in the number of the maculæ does not take place till immediately before the diffluence or disappearance of the vesicle. The more minute phenomena of this diffluence are as yet very imperfectly known. In some animals, as Mammalia and Birds, it has been observed that shortly before the diffluence of the vesicle, its delicate wall undergoes a softening or approaching solution, so as to make it impossible to separate the vesicle entire. After this, when the diffluence is complete, the contents disappear from the situation they have previously occupied, but what becomes of them has not yet been determined. In some instances, as Birds and Batrachia, it has been observed that, after the diffluence of the germinal vesicle, the germinal part of the yolk, which previously consisted exclusively of small opaque granules, is now mingled throughout with clear hyaline spherules, somewhat similar to the dispersed maculæ of the germinal vesicle; but it is only matter of conjecture that these clear spherules have been derived from the germinal vesicle or its maculæ.

In a few instances, as in Ascaris, it has been thought that the entire nucleus or macula of the germinal vesicle has remained undivided, and it has been supposed that it has of itself constituted the germ of the embryo-cell, which afterwards occupies the centre of the first segmenting mass of the yolk, and whose progeny by division exists as nuclei in the interior of the successively increasing segments of the cleaving germinal portion of the yolk. A recent observation by J. Müller seems to lead the way to a different view of this phenomenon. He has observed * in one of the Mollusca, the Entoconcha mirabilis, that the germinal vesicle does not disappear or undergo a change at the time of the maturation of the ovum, but remains discernible as the foundation of the clear *embryonic-cell* which occupies the centre of the yolk mass when segmentation is about to take place. Remak † has been led, by his observations on the Batrachian ovum, to

* The observations of Bischoff had long ago shown that in the periodical dehiscence of ova which accompanies the heat of female quadrupeds, the ova may be detected, though unfecundated, in the course of their descent through the Fallopian tubes and uterus (Periodische Losreifung, &c., 1842), and some observations appear also to have shown that the same is the case in the human female at the periodical return of menstruation. (See a paper by H. Letheby, M. B. in the Philos. Trans. for 1851, p. 57., where two cases are described in which ovules or their remains were detected in the Fallopian tubes of unimpregnated women who had died at or about the menstrual period.)

* Archiv. der Physiol. 1852. Leydig in the same.

† Untersuch. über die Entwickel. der Wirberthiere.

doubt the correctness of the view hitherto generally adopted as to the entire disappearance of the germinal vesicle in that instance, and holds it as probable that a part of it at least remains in connection with the formation of the embryonic cell. These statements are sufficient to show that the phenomena of the dehiscence of the germinal vesicle and its relation to the subsequent changes in the ovum induced by fecundation are as yet very imperfectly understood, and that the discovery has still to be made of the link in the chain of connection between the last stage of existence of the ovigerm, and the first origin of the nucleus round which the subsequent organising process of segmentation begins. But that some such connection exists, all who have made a study of this part of the history of the ovum are inclined to believe.

5. Relation of the ovum to fecundation by the male sperm.

The act of fecundation is necessary for the perfection of all true ova. In the production of gemmæ or buds, in the multiplication of nonsexual individuals, and in the various examples of Metagenesis previously referred to, the germs from which the new products arise may be nucleated cells or groups of these, and may without doubt be the descendants of the original cell-germs of ova; but for their development into the new beings produced from them, no combination, so far as is yet known, with the product of cells of a different kind, as in fecundation, is necessary. It is otherwise with all true ova. Their germs may be the descendants through the ovary of an original cell-germ, from which the animal bearing the ovary was produced; but for the generation of an ovum the ovigerm must be subjected to the influence of the sperm, and for its development there is required a new process of organisation, inaugurated by segmentation, which is the invariable consequence of fecundation, and is the first obvious change in a fecundated ovum leading to embryonic formation.

The developed form of the spermatic substance * is in by far the greater number of animals that of minute ovoid or rounded particles of various form, with each of which is connected a long and extremely delicate filament, which moves with vivacity in a vibrating or oscillatory manner when immersed in water and various bland animal solutions. There are other less common forms of spermatozoa, such as those of Crustacea and Nematoidea, which have not the filamentous appendage, and are motionless. The vibratory motion of filamentous spermatozoa bears some resemblance to that of some kinds of fine cilia, and is the most apparent indication of the active state of their vitality.†

It is now ascertained beyond doubt that in a number of animals the spermatozoa come into direct contact with the yolk substance and embryogerm, or with the internal contents of the ovum. The actual entrance of the spermatozoa into the ovum has been observed in Mammalia, Batrachia, Osseous Fishes, Insects, Nematoid Worms, some Mollusca, and Echinodermata; and there have been ascertained circumstances regarding the ova of other animals which warrant the inference that the spermatozoa enter the ovum in many more than those in which the phenomenon has already been actually observed. After long continued doubt and much discussion of this point, physiologists are therefore now generally agreed that in all instances a direct action of the spermatozoa in substance on the contents of the egg is necessary to fecundation. The manner of access of the spermatozoa to the interior of the ovum is probably various in different animals. In a few, as Trematode and Cestoid Entozoa, the sperm is mixed with the contents of the ovum, viz., the germinal vesicle and yolk, at the time when these are brought together from the separate organs in which they are formed: in some, as the Nematoid Worms, and probably also in some other animals, the sperm comes in contact with the ovum previous to the formation of an enveloping membrane; in a third set it seems probable that, as in Lumbricus, and perhaps in some Mollusca and Hirudinea, the vitelline membrane which had existed at an earlier period is dissolved or removed previous to fecundation, and the ovum or yolk substance and germ are thus left directly exposed to the action of the spermatozoa, which in Lumbricus have been observed in great numbers penetrating the substance of the yolk.

In the majority of animals, however, the sperm only reaches the ovum at a later stage of its formation, when it is already covered by the vitelline membrane or other envelopes, and through these coverings, therefore, the spermatozoa must pass to gain access to the yolk and germ. In a certain number of animals the vitelline or enveloping membrane appears to be quite entire and closed on all sides, so that, as in Mammalia, in which Martin Barry was the first in 1843 to perceive with certainty the entrance of the spermatozoa into the ovum, these bodies must in some way, not yet fully known, pass through the consistent wall of the enclosing membrane; but in other animals, as first discovered by J. Müller, a special aperture or perforation of the egg-covering exists, apparently destined to allow of the more rapid entrance of the spermatic bodies. This *micropyle* apparatus, sometimes consisting of one, and at others of a number of apertures, has now been observed in several Echinodermata, in Acephalous Mollusca, in all Insects, and in Osseous Fishes; and it is more than probable that it exists in a considerable number of other animals in which it has not yet been detected. But still, making due allowance for the probable extension of discovery in this direction, the care and accuracy with which the micropyle apparatus has since its first discovery been sought for without success in Mammalia and

* See the article Semen.

† See especially the recent researches of Kölliker on the Sperm in Zeitsch. fur. Wissensch. Zool. vol. vii.

some other animals, in which, had it been present, it could scarcely have escaped so careful a scrutiny, warrant the belief that in a certain number of animals the spermatozoa do actually penetrate the apparently entire egg-covering.

It is not my design to enter here upon the consideration of the mode and nature of the action exerted by the spermatic matter or the spermatozoa in producing the changes of fecundation. Upon this subject the reader may with great advantage and interest consult the latter part of the article Semen in this Cyclopædia by R. Wagner and Leuckart, the papers of the late Mr. Newport in several recent volumes of the Philosophical Transactions, and the learned article by Professor Leuckart on Generation contained in the fourth volume of R. Wagner's Handbuch der Physiologie. I will only remark in passing that from Mr. Newport's and other researches it appears that while the actual mixture of an appreciable quantity of the spermatic substance is necessary to induce fecundation, the extreme rapidity with which the action takes place, the minuteness of the quantity of the spermatic matter which is sufficient to induce it, and the fact now observed in a variety of instances that the spermatozoa which have entered the ovum remain apparently little changed for a considerable time after the changes of the ovum consequent on fecundation have made some progress, — lead to the conclusion that there is something in the nature of this action inconsistent with the idea that it is one of mere combination in substance of the developed contents of the male and female generative products. But whether this is to be referred to the class of "contact actions" of which themselves so little is known, or to what other kind of action it may be compared, the ascertained facts do not enable us in the least to determine. The almost universal presence of vibratory motion in the spermatozoa during the time in which they retain their fecundating power, naturally led physiologists to connect that motion with the fecundating action; but on the other hand, the occasional, though rare examples in which the spermatozoa are entirely motionless, seem sufficient to cause the rejection of the view that the force which produces the vibratory motion is identical with that which calls forth the series of histogenetic and organogenetic changes which result from fecundation.

But the consideration of this subject would lead us into the discussion of the whole question of vital forces, which in its present unsatisfactory state it is desirable to avoid. The physiologist agrees, for the sake of convenience of expression, to adopt the terms of power, property, force, &c., to denote the conditions necessary for the occurrence of certain actions or changes. He employs the term vital force merely as the indication of the supposed cause or causes of an ascertained regular sequence of vital phenomena; but all philosophical accuracy rejects the idea of any unseen separate and single force which is at work in bringing about the sequence in question. The fecundating power of the semen is an expression used only for convenience to denote the invariable sequence or relation as cause and effect which has been observed to subsist between the contact of spermatic matter with the ovum, and the changes in the latter which follow on the act of fecundation. We might with as much propriety have given a name to a separate power residing in the egg or its germ which render it susceptible of fecundation, as of a special power belonging to the semen by which that susceptibility of the ovum is acted upon. The efficient cause of the process of fecundation can only be educed, as in all physical as well as vital changes, from a perfect knowledge of all its phenomena, and the statement of the efficient cause of such actions is only the expression of the most general and best known law to which a full acquaintance with the phenomena enables them to be reduced. Fecundation is to be regarded as a purely vital change, seeing that it takes place only in the usual conditions of vitality; but, like all other vital changes, it appears more probable that a variety of conditions of the organic matter rather than any one known property or condition are necessary for its occurrence.

In endeavouring to deduce the most general phenomena which accompany this remarkable change, it may be said that fecundation consists essentially in the mutual action of two different organised bodies, which are respectively formed from two different cells; the ovigerm and the spermgerm. If we may form any general conclusion from what may be so well observed in Nematoid Worms, the development of the ovum and the spermatic cells from their respective germs is remarkably similar, for in both the internal cell is developed from a minute molecule from within, while the external part is deposited from without. The spermatozoa are formed in connection with the nucleus or nuclei of the sperm-cell; and the germinal part of the ovum, though it consists mainly of the granular part of the yolk, which is directly formative, very probably comprehends also in some shape or other the effused contents of the germinal vesicle. In this way, then, we may conjecture that in the act of fecundation the products of the original cell-germs meet and combine or mutually influence each other. The cell-germs, then, are the links in the chain of organic connection between either or both the parents and the progeny capable of being developed from the fecundated ovum. Such a view, though still in a great measure speculative, seems to be in accordance with the facts known as to the perfect transmission of the structure and qualities of either or of both parents to the offspring.[1]

6. Immediate effects of fecundation on the ovum; segmentation, and first changes of the ovum related to the commencement of embryonic development.

It does not come within the scope of the present article to describe in detail the process of fecundation, or the phenomena which follow it, but it may be proper to state here in a general way the relation which subsists between the earliest changes occurring after fecundation, and the commencement of those phenomena of a histogenetic nature which precede the formation of the embryo itself. The most obvious and constant of these changes is that known as the cleavage or segmentation of the yolk, — a process which has been observed in the ova of all animals, and is not less interesting from its own nature, than from the bearing of its phenomena upon the explanation of the earliest organising process of embryonic development, and upon the whole subject of histogenesis.

The segmentation affects only that part of the ovum of animals which is directly germinal or formative; and it results in the production of that layer of organised cells, of variable extent, in the centre of which, in a determinate position and direction, the rudiments of the embryo are first formed. The process of segmentation is, therefore, the prelude to the formation of the Blastoderma or germinal membrane of Pander.

The extent, therefore, to which segmentation affects the yolk differs greatly according to the amount of the yolk-substance which is directly germinal; that being in some animals the whole, and in others only a fraction of the yolk, in proportion to the part which is only indirectly nutritive. In that group of ova, then, to which those of Mammalia belong, and which we have called the small-yolked, the entire yolk, or, at all events, its superficial layer, being directly formative, or being involved from the first in the production of the Blastoderm, the segmentation is complete, or the process of cleavage affects the whole mass of the finely granular yolk within the zona or vitelline membrane. In those ova again, such as we find in the bird among vertebrate, and the cuttlefish among the invertebrate animals, in which the formative yolk has the most limited extent, and consists only of a finely granular disc near the surface of the much larger mass of the cellular nutritive yolk, the segmentation is confined to that disc alone, and is therefore, in some respects, widely different from that which occurs in Mammalia. In the intermediate group of ova belonging to Batrachia and Osseous Fishes, there are many gradations of transition from the complete to the partial cleavage, so that in some, as the common frog, it is nearly, but not entirely, over the whole yolk; while in others, as in the salmon or osseous fishes, it does not extend over more than a third of the surface of the yolk.*

In the greater number of instances there is recognised in the mass of the whole yolk, or in its germinal part, immediately previous to its undergoing segmentation, a clear simple cell, generally nucleated, which was not before perceptible; to this the name of *embryo-cell* has been given, in order to distinguish it from the germinal vesicle, from which it has hitherto been believed it is in some measure distinct. In other instances a clear spherule or space only is observed in the place of the embryo-cell, and in a few animals no clear part of this nature has yet been detected. The division of the embryo-cell accompanies, or rather immediately precedes, that of the germ-yolk, so that each mass formed by the cleavage, grooving, or segmentation, as the case may be, contains as its nucleus or centre an embryo-cell, or clear spherule of its own, descended from the first cell or spherule of the same description.

The process of segmentation, whether it involves the whole ovum, or is limited to a larger or smaller disc of the yolk, proceeds in most animals with a certain degree of geometric regularity, so that the number of germ-yolk segments are successively multiplied so as to be in the numbers 2, 4, 8, 16, 32, 64, &c., until by the ultimate division a vast number of small globular masses are formed, which occupy principally the surface of the yolk over all its germinal portion.*

The last result of the segmentation is the production of the blastoderma or germinal membrane in which, by other changes, the rudiments of the embryo subsequently make

* The more important phenomena of the yolk-germ cleavage or segmentation have been ascertained principally by the following observations: viz. 1st. of Prevost and Dumas in Batrachia, as early as the year 1824, and subsequently of Rusconi and Von Baer in the same animal; 2nd. of Bischoff and Barry in Mammalia, in 1838–39, their observations being confirmed by myself in 1840, and greatly extended by Bischoff before the publication of his work upon the development of the rabbit, in 1842; 3rd. of Bagge in 1841, and of Kölliker in 1843, on Nematoid Worms; 4th. of C. Vogt in the Salmonidæ and in the Alytes Obstetricans in 1842; 5th. of the same author, of Quatrefages, and many others in various invertebrate animals; 6th. in its most limited form the phenomenon was first well described by Kölliker in Cephalopoda in 1844; and 7th. in birds by Bergmann in 1846, by Coste in 1848, and by myself in the following years. The observations on this subject are far too numerous for quotation; those especially which have been made in experiments by artificial fecundation are most favourable to the investigation of the segmentation and other phenomena which follow immediately on fecundation. And in all these instances, as well as in very numerous others, the occurrence of segmentation and the regularity of its phenomena are so constant that we may regard it as one of the best established series of facts in organic nature. The observations with regard to segmentation in the ova of insects, which are still imperfect, form the only exception to the foregoing statement with which I am acquainted.

* Reference is here made chiefly to the best-known and most common kind of segmentation, in which this process consists in the massing of the granular and fluid substance of the yolk round the embryo-cells or clear spheres as centres; but it is right to state that there is another form of this process, as yet only observed in some of the Cestoid and Nematoid Entozoa, in which the yolk, either clear or granular in its structure, does not appear to follow the divisions of the embryo-cells, but the gradually increasing progeny of the latter assimilate or combine more and more with the yolk, so that at last, when the germinal part of the ovum is entirely occupied with new cells, the original yolk has quite disappeared. The nature of this process, as compared with the more common form of yolk segmentation, is not perhaps as yet fully understood.

their appearance. According to most ovologists, the last globules formed by segmentation are the nucleated organised cells immediately constituting the blastoderma. A different view of the process, however, in Mammalia, has been taken by Bischoff, very decidedly set forth in his two most recent works on the development of the guinea-pig and the deer; according to which the last resulting spherules formed by segmentation are not true cells, and that previous to the formation of the blastodermic cells, the yolk-germ falls completely into an amorphous or homogeneous finely granular substance, out of which, secondarily, the blastodermic cells are produced by a process of cytogenesis. It seems probable that, in the different classes of animals, there may be considerable variety in the degree of perfection in organisation or advance in cell-structure to which the segments of the yolk have attained at the period when the development of the embryo begins to manifest itself. But in the higher animals at least the weight of evidence appears to me in favour of the view that the process of segmentation results directly in the formation of blastodermic cells. The fact now established by the observations of Reichert in Entozoa, in 1841, of Ransom in osseous fishes, and more particularly those of Remak in Batrachia, that a delicate membrane is formed over the surface of each of the segments as they appear, and that the last and smallest segments possess a delicate membranous envelope, appear to show that, in these animals, each segment has the structure of an organised cell, and is very similar to, if not identical with, those of the blastodermic lamina.

The origin of the embryo-cell is still involved in obscurity. Most ovologists are disposed to connect it in some way or other with the previously existing germinal vesicle, or some part of its contents, and more especially the nucleus. For the solution of this question, as already remarked, a more accurate knowledge of what happens to the germinal vesicle at the time of that disappearance which has been so commonly observed at the period of the maturation of the ova of almost all animals, will be required. Does the macula remain, as has been alleged by some, to form the nucleus or the whole of the embryo-cell? Or, in other cases, if the multiplied maculæ are dispersed among the granules of the germinal yolk, are they again collected together into a mass or spherule to form the embryo-cell? Or, again is the embryo-cell formed out of other materials, and not necessarily either partially connected with, or wholly derived from, the germinal vesicle? And finally, might it not be, according to some recent observations, such as those of J. Müller on Entochoncha and those of Remak on the frog, that the disappearance of the germinal vesicle is not attended with the dispersion of its contents, but is a phenomenon caused only in a certain number of animals by the solution of the delicate external wall of the vesicle, and by some change in the position and consistence of its contents? Further observations will be required to determine this point; but if in the meantime we regard it as most probable that the embryo-cell is in some way or other connected in its origin with the germinal vesicle, we might further found upon this the speculative view that the blastodermic cells and the blastema from which unquestionably, by a histogenetic process of cell-division and multiplication, the various textures and organs of the animal body are produced, may be regarded as the descendants of the original cell-germ from which the ovum was developed combined with the sperm. We should thus trace the organic cellular connection between the succession of parents and offspring, which I have stated to be one of the most general facts in organised nature.

The observations respecting the very remarkable movements of the yolk, before and during the earlier stages of the segmenting process which have now been recorded by several physiologists, must excite the liveliest interest, and suggest subject for much reflection as to the evidence they may afford of the causes of this change, or, if we may use the expression, of the forces by which segmentation is brought about. There seems to be little doubt that the embryo-cell (and its nucleus first of all) is the earliest to become divided, and that the process of cleavage then proceeds from the surface of the segmenting mass inwards towards the cell; but in what relation the nucleus, granular substance of the yolk, and ovicell-membrane stand to each other in this process, must be left to be determined by future researches.

Of the other early changes in the ovum which immediately follow fecundation and precede embryonic development little need here be said. They consist principally in the greater degree of consolidation and compactness acquired by the germinal part of the yolk, and in the formation in most animals of a clear space between the surface of the yolk-substance and the enclosing vitelline membrane. It is in this clear space, or, as it has been called by Newport, respiratory chamber, that the spermatozoa have been observed in those instances in which they have been ascertained to penetrate into the cavity of the ovum. There is another phenomenon of the same period, which has now been so frequently observed, and which is of so peculiar a nature, that it must not be passed over without notice; I allude to the appearance in the respiratory space of one or more clear and highly refracting spherules, nearly of the size of the germinal vesicle, but quite independent of it. These clear hyaline-like globules have been observed in the ova of Gasteropodous Mollusca after fecundation by almost all those who have attended to the ovology of this class of animals, among whom may be mentioned Dumortier, Pouchet, Van Beneden, Nordmann, and Vogt; in the Annelida by Quatrefages; in Mammalia by Bischoff and Barry; and in Batrachia by Newport. From the observations of Quatrefages in Hermella they appear to be excluded or expressed, as it were, from the clear basement-substance of the yolk; and Bischoff states that they gradually disappear, or are dissolved without obvious change. We are at a loss to determine what office these globules may have in connection with the changes of the ovum at the time they appear.

Lastly, I would notice the interesting relation which appears to subsist between the situation of the germinal vesicle and the centre of the germinal membrane afterwards formed, or the germinal pole of the ovum, and the conformity in the direction of the line of the first cleavage of the yolk with that of the principal axis of the embryo in vertebrate animals. The first fact has been observed in all animals, and the latter has been ascertained by Mr. Newport's researches in Batrachia, and by observations which I have myself made in the bird's egg during its descent through the oviduct. These facts, as yet inscrutable in their nature, point to interesting laws relating to the connection of the first phenomena of development, which may be worked out by the further prosecution of these inquiries.

In the preceding part of this article we have considered chiefly the anatomical structure of the ova of animals, and have made little mention of their chemical composition. The knowledge of the latter subject is as yet very imperfect. In a recent Memoir* Messrs. Valenciennes and Fremy have given an account of an extended series of experimental researches in which they have been engaged, with a view to determine the differences in the chemical composition of the ova of different animals, and although this investigation is still necessarily incomplete and fragmentary, they appear already to have arrived at some interesting results. The following are some of the more important of these results.

The albumen or white is not exactly of the same composition in the eggs of different birds; but it generally contains albumen with salts and a compound of sulphur in solution. In the yolk of birds' eggs they recognise the principle first distinguished by Dumas and Cahours as *Vitelline*, a substance precipitable by mixture with a large quantity of water, and apparently more nearly resembling fibrine than albumen in its composition and some of its properties. The phosphuretted fat of the yolk is somewhat similar to the cerebral fatty matter.

The glairy white of the eggs of cartilaginous fishes is very different from that of birds' eggs, being neither soluble in water nor coagulable by heat nor acids to the same degree. It seems to contain only traces of organic matter. The angular and tabular particles of the yolk of cartilaginous fishes are composed of a principle which these authors regard as peculiar, and have named *Ichthine*. This substance is insoluble in water, alcohol, and ether, and, on being dissolved by hydrochloric acid, gives no violet colour, as albumen does. It is dissolved by all the concentrated acids, and by dilute acetic and phosphoric acids. Its composition is stated to be as follows: carb. 51; hyd. 6·7; nit. 15; ox. 25·4; phosph. 1·9.

* See Journal de Pharmacie, &c., vol. xxv. pp. 321. and 415., and vol. xxvi. p. 5., 1854.

In the ova of osseous fishes these authors do not find the same organic principle, but have detected two others in variable proportions. One of these, which they have named *Ichthidine*, exists only in small quantity, and is absent in some fishes: it is quite soluble in water. The other which is more generally prevalent and in larger though variable quantity is precipitated by water into a viscous substance. This has been named *Ichthuline*. Messrs. Valenciennes and Fremy have ascertained the interesting fact that while these principles, especially ichthuline, exist in large quantity in the ova at an early stage of their growth in the ovary, they gradually diminish in quantity or are changed as the ova approach maturity, and give place chiefly to albumen, which holds the phosphuretted fat in suspension. In the salmon's egg there is a large proportion of ichthuline, which is the cause of their becoming opaque when water enters the yolk. These authors propose indeed this character as a test of the maturity of the ova, as they are not rendered opaque by water when mature. It would be interesting to know whether fecundation produces any immediate chemical change on the principles of the yolk. The composition of ichthuline is stated to be as follows: carb. 52·5; hyd. 8; nit. 15·2; ox. 22·7; phosph. 0·6; sulph. 1.

The ova of Batrachia seem to resemble most nearly those of cartilaginous fishes, in so far that the tabular particles of the yolk are composed of ichthine. The external gelatinous covering is described as a tissue of hyaloid membrane which absorbs water in a determinate quantity.

The ova of Ophidia and Sauria resemble nearly those of birds in the composition of the white and yolk, containing the principle vitelline in the latter. The yolk of the Viper presents the singular peculiarity of becoming gelatinous by immersion in water.

In the ova of several Chelonia they have detected a different principle from vitelline to which they give the name of vitelline. This principle is soluble in potash, and has the following composition: carb. 49·4; hyd. 7·4; nit. 15·6; ox. and phosph. 26·7.

Among the invertebrate animals Messrs. Valenciennes and Fremy have examined the ova in several classes. In the Crustacea they have given much attention to the investigation of the curious colouring principle of the ova, which appears to be the same as that existing in the shell, and which being green in the moist state passes into red in a variety of circumstances. They have isolated this colouring matter by a very simple process, and give an interesting account of its properties, especially of the circumstances causing it to change to red, such as the action of alcohol, boiling, desiccation, placing in a vacuum, friction, &c.

The ova of Arachnida and Insects are

quite different from those of Crustacea in their composition, containing albumen, fatty matters, and a large quantity of a substance precipitable by water.

The ova of Mollusca differ greatly in composition from those of other animals: more particularly in the entire absence of fat from them.

From these researches it appears that there are considerable differences in the chemical composition of the ova of animals of different great groups, and even among those not far removed from each other in the zoological scale, and that there are also considerable differences according to the state of advancement of the ova of the same animal, more especially it would appear that a marked change of composition takes place at the period of complete maturity. The researches referred to appear to have brought to light several new organic principles which are modifications of albumen or belong to the same class, and which may be considered as *Vitelline principles* as belonging to the yolk of different animals: such are Vitelline, Ichthine, Ichthidine, Ichthuline, and Emydine.

The full citations of different works and memoirs on the subjects of this article render it unnecessary to give any detailed bibliographical list at its termination. I may, however, call the attention of the reader to the following works already cited, as forming the principal basis of modern knowledge of ovology and development, viz.: The Inaugural Dissertation of *Pander* on the Development of the Chick, published in 1817. The History of the Egg before Impregnation, by *Purkinje*, in 1825. The Epistola of *Von Baer*, in 1827. The contributions of *Von Baer* and *Rathke* to *Burdach's* Physiology, in 1827 and 1828. The various Memoirs by *Rathke* at different times, and *Von Baer's* Lectures on Development, completed in 1837. The Systematic Manual of Development by *G. Valentin*, in 1835. The Prodromus and contributions by *R. Wagner*, in 1836. and the Manual of Physiology by the same author. *J. Müller's* Physiology, and especially the English translation of the more recent edition. The researches of *Martin Barry*, in 1838 and 1839. The various contributions of *Bischoff*, beginning in 1838: His Systematic Treatise on Development in 1842, and his Monographs on the Development of the Rabbit in 1842, of the Dog in 1845, of the Guinea Pig in 1852, and of the Deer in 1855. The researches of *Coste* beginning in 1833; his work on Comparative Embryology in 1837, and his large and beautifully illustrated work, as yet unfinished, beginning in 1850. The works of *C. Vogt* on the Alytes Obstetricans (Batrachia) and on the Embryology of the Salmonidæ, in 1842. Lastly, the recent and valuable researches of *Remak* on the Development of Vertebrata in 1853–1855; and the republication of *R. Wagner's* Icones Physiologicæ by *Ecker*. The works relating to the invertebrate animals are much too numerous for quotation. I will only mention the researches of *Kölliker* on the Cephalopoda, of *Quatrefages*, *Vogt*, and others on the Mollusca, Annelida, &c., and those of *J. Müller* on the Echinodermata.

I would also refer the reader to the excellent report on the progress of discovery in regard to the Ovum by *Thomas W. Jones* in the Brit. and For. Medical Review for Oct. 1843, to *Bischoff's* article on the History of Discovery in Development, and its application to the explanation of Malformations in *Wagner's* Dictionary of Physiology, to *Leuckart's* Article on Generation in the same work, and to *Vrolik's* Memoir on the Explanation of Monstrosity from the History of Development, and to his article Teratology in this Cyclopædia. A large amount of information on the whole of our subject will also be found in *C. Vogt's* interesting Letters on Living and Fossil Animals in 1851; in *Victor Carus's* System of Animal Morphology in 1853; in *Van der Hœven's* Manual of Zoology, with additions by *Leuckart* in 1850–1856; and in the English works of *Carpenter*, *Owen*, and *Rymer Jones* on Comparative Anatomy and Physiology.

In now bringing this article to a close, the author owes an apology to the conductors and the readers of this Cyclopædia for the extreme tardiness with which it has appeared. The delay has arisen, in part, from personal circumstances which need not be mentioned here, and in part from the nature of the subject of which the article treats. In the original plan of the article, it was intended that it should comprehend, along with the history of the ovum, an account of the development of the embryo. But as time advanced, and every successive year added new and important matter to our knowledge of the science, and greatly modified the statement of facts previously regarded as established, it became more and more difficult, especially in the hands of one interested in the experimental investigation of many of the individual facts, to present a systematic and at the same time clear and brief description of the researches of physiologists on the subject of development. The author regrets deeply that he should thus be prevented from furnishing the readers of the Cyclopædia with this part of the article as originally intended. But at the same time he believes that when the recent rapid progress of many departments of the subject is considered, and the vast number of details which would be required to embrace even the shortest account of the origin and formation of all the textures and organs of the animal body, the knowledge of which forms a science that is coextensive with the whole range of anatomy and physiology, it may be thought that he has in present circumstances judged rightly in abandoning the attempt to compress into a limited space the statement of so extensive and important a branch of physiological inquiry.

(Allen Thomson, M.D.)

PANCREAS (Πάγκρεας*, Gr.; *Pancreas*, Lat.; *le Pancréas*, Fr.; *die Bauchspeicheldrüse*, Germ.; *Pancrea*, Ital.). The pancreas is an azygous, non-symmetrical, glandular organ, possessing a duct, and, therefore, belonging to the category of *true glands;* connected anatomically with the alimentary canal, and physiologically with the function of digestion.

On taking even the most superficial and general view of this organ, two or three things cannot fail to strike the attention: one is, the close affinity and strong contrariety which it at the same time displays to the salivary glands†—affinity in point of appearance and structure, being, like them, a typical representation of a conglomerate gland,—contrariety in point of situation and function, the one being placed at the very threshold of the alimentary canal, the other at an advanced position in it; the one acting on raw material, and having in part at least a mechanical use‡, the other having to do with material far gone in the process of assimilation, and possessing a function, whatever it *may be*, certainly *not* mechanical in any degree.

Another striking circumstance is its wide diffusion. It exists in all vertebrata;—mammalia, birds, reptiles, and most fishes, all possess a pancreas, and that quite independent of what the nature of their food may be, animal, vegetable, or mixed; a fact that one would have imagined would itself have prevented the adoption of the old views with regard to its function.

Another circumstance, not less striking, is its constant relation to the duodenum: whatever may be the other modifications of the alimentary canal, from the straight and simple tube of some carnivora to the voluminous apparatus of the vegetable feeders, or whatever may be the modified form of the pancreas itself, still, if the organ exists, its relation to the duodenum is invariable; if there is a duodenal fold, it is placed in it; and if there is not, it makes the closest approximation to an analogous position that is possible: indeed the uniformity of this relation is so invariable, even under circumstances where it would appear to be indifferent, that one cannot but regard it as one of those instances of conformity to type in which uniformity appears to exist for uniformity's sake.

The arrangement of the subject of this paper that most naturally suggests itself, is to treat first of the structure, and then of the functions of the organ. I shall therefore arrange my observations under the following heads:—

1st. The descriptive anatomy of the human pancreas, including an account of so much of its structure as may be made out by a naked-eye examination.

2nd. Its minute or general anatomy.

3rd. Its comparative anatomy, including those modifications both of the form and ultimate structure of the gland that the animal series exhibits.

4th. The physiology of the pancreas,—the *rôle* that it plays in the function of digestion.

Lastly. A short account of some of the most striking pathological changes that the organ is liable to.

I. Human Anatomy.

Situation.—The pancreas is so placed that for its display it is necessary to open the cavity of the great omentum. This may be done either by dividing the gastro-hepatic omentum and depressing the stomach, or by detaching the gastric layer of the epiploon and turning the stomach up, or by dividing the transverse mesocolon and turning up both transverse colon and stomach. In either of these ways the cavity of the omentum is opened, and the organs concealing the pancreas are removed.

Placed transversely across the upper part of the abdominal cavity, and closely applied to its posterior wall, the pancreas extends from the duodenal fold on the right to the hilum of the spleen on the left, across, therefore, the epigastric into both hypochondriac regions. It is not perfectly transverse, however, but extends from the right a little upwards as well as to the left; it corresponds to the level of the first and second lumbar vertebræ and to the splitting of the two laminæ of the transverse mesocolon: it is post-peritoneal, being invested by that membrane only on its anterior surface.

Relations.—By its right extremity it is closely engaged in the curvature of the duodenum, to the inner border of which it is intimately attached, and which it often receives into a groove more or less deep, formed by a projection of the gland to a slight extent on the anterior and posterior surface of the intestine. Sometimes this groove is very slight, and the relation of the margins of the gland and intestine merely that of apposition; at others, the inner margin of the duodenal fold will be deeply imbedded in the gland substance, the projection both in front and behind being considerable. More frequently, however, the gland trespasses much further behind the intestine than it does in front, so much so occasionally as to separate it in a great degree from its posterior relations. The structures on which the posterior surface of the pancreas rests are, the vena cava, the bodies of the vertebræ, the aorta, the crura of the diaphragm, the left kidney, its supra-renal capsule and renal vessels, the lower part of the solar plexus with the commencement of the plexuses thence proceeding, as the aortic and superior mesenteric; the splenic vein passing from left to right, the superior mesenteric vein and artery, the vena portæ, the common bile duct, many lymphatic vessels and glands, and the commencement of the thoracic duct and vena azygos. To all these structures it is intimately attached by cellular tissue, and to the irregular surface which they form it is, as it were, moulded or modelled, so that when it is care-

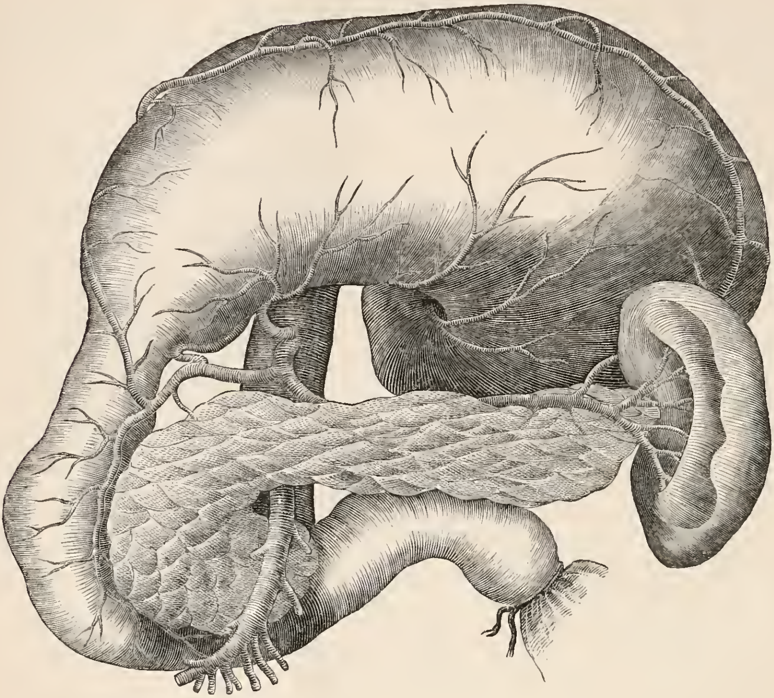
* παν κρεας, all flesh.

† This striking resemblance suggested to the older anatomists the name of "salivary gland of the abdomen," an appellation first given to it by Siebold.—Historia Systematis Salivalis.

‡ See Bernard's experiments on the secretion of saliva.

fully dissected away, it presents eminences and depressions corresponding to them, as, for instance, the longitudinal furrow occupied by the splenic vein, and the deep groove in

Fig. 54.



Human Pancreas, shown in situ *by throwing up the stomach.* This drawing was taken from a young subject in which the curvature of the head of the pancreas, following that of the duodenum, was particularly well shown.

which the superior mesenteric artery and the vena portæ are received.

In front it is in relation with the posterior surface of the stomach, which rests on it when empty (tanquam pulvinar, *Sœmm.*), and moves freely upon it; but when this organ is distended with food, it recedes from it, and its lesser curvature comes into more immediate relation with the gland. In cases in which the stomach is situated lower down than usual, as in emaciated individuals, where a great part of the small intestine occupies the cavity of the pelvis, the pancreas comes into relation in front either with the liver, or with the anterior wall of the abdomen, from which the gastro-hepatic omentum alone separates it, and through which it may be easily felt. This disturbance of the normal relations always exists, according to Cruveilhier, whenever the vertebral column can be felt immediately behind the walls of the abdomen. The pancreas is also in relation, in front, with the angle formed by the ascending and transverse colon and with the commencement of the duodenum.

The upper border is in relation with the splenic artery, for the reception of which it is grooved, and which often runs in a canal formed in the substance of the gland through its entire length; it is in relation also with the Spigelian lobe of the liver, with the first portion of the duodenum, and the cœliac axis.

The lower border is bounded by the inferior horizontal portion of the duodenum, from which it is separated, near the middle line, by the superior mesenteric vein and artery, which notch it, and which also separate it from its reflected portion or head.

The right extremity is engaged in the duodenal fold in the manner described, and is in relation with the ductus choledochus. From the intimacy of its attachments to the duodenum, it always accompanies this intestine in its displacements, so that when the duodenum is situated lower down than usual, which happens in displacements of the stomach downwards, the head of the pancreas is always removed in the same direction.

The left extremity is in relation with the left kidney, and with the spleen upon which it is sometimes flattened and blunted, and sometimes slightly enlarged, and to which it is attached by the intervention of the splenic veins, which send many branches into its substance: sometimes it does not extend quite so far as the spleen by half an inch or an inch.

Shape.—From its elongated form, the pancreas has been described by anatomists as possessing a body and two extremities; and of these extremities one, which is enlarged and clubbed, has been called the *head;* the other, tapering and acuminated, has been called the *tail;* the middle portion, the great mass of the gland, being the *body:* other describers* have suppressed the body altogether, and described as the tail all that portion which is not included in the curved intumescence at the right extremity, which they designate the head. Indeed the imaginations of anatomists have been largely drawn on to supply analogies whereby to illustrate the shape of this organ. Some have compared it to a hammer,—some to a dog's tongue; among them all I think the best is that which compares it to a pistol.

But, passing by these fanciful resemblances, the pancreas, from its transverse elongation and antero-posterior flattening, presents for description a right and left extremity, an upper and lower border, and an anterior and posterior surface; and these parts I shall describe in succession in the order in which I have mentioned them.

The *right extremity*, to which the name *head* has been assigned, is that portion which is engaged in the duodenal curvature, and to which, from its occasional separation from the rest of the gland, the name of *lesser pancreas* has also been given†: it differs from the rest of the gland in being thicker and more massive, curved instead of straight, and situated on a more posterior plane. It is thus formed:—when the pancreas, in passing from left to right, has arrived at the duodenum, it becomes closely attached to that viscus, and follows its course, first downwards, and then to the left, passing by its extremity, behind the superior mesenteric vessels, for which it thus forms a sort of groove or channel. It is by the fusion and massing of this curvature that the head is formed; but in very young subjects, and in the lower animals, the curvature of the pancreas is as conspicuous as that of the duodenum, and by separating it from its attachments, and straightening it out, all appearance of head vanishes, and it becomes a long prism, or flattened cylinder of even thickness throughout.

In the human adult, however, it is impossible thus to unravel and straighten the right extremity; and the fusion of the parts has often proceeded to such an extent as entirely to obliterate the original curvature, the groove for the vena portæ and superior mesenteric vessels being the only trace of its concavity.

The *left extremity* gradually tapers, getting both narrower and thinner; it is sometimes bifurcated, sometimes blunted and flattened against the spleen, and sometimes slightly enlarged; it presents nothing for special description.

The *upper border* is much thicker than the lower, so much so, that some anatomists have described the gland as being prismatic. In the middle the cœliac axis rests upon it; to the right the hepatic artery and first portion of the duodenum are in contact with it, and to the left it is deeply grooved by the splenic artery.

This groove does not run along the top of the border, parallel to it, but crosses it obliquely from behind forwards as it passes to the left extremity, curving over it, as it were, so that while the commencement of the artery is behind the pancreas, its terminal branches are in front (see *fig.* 54.). Sometimes this groove is converted into a canal, by the gland closing over it.

The *lower border*, much thinner, is tilted rather forwards to the right, by the passage of the superior mesenteric vessels beneath it, which separate it from the third portion of the duodenum; on the left the inferior mesenteric vein passes beneath it to join the splenic.

The *anterior surface* looks upwards as well as forwards, and is convex both transversely and longitudinally; it is the only portion of the gland that is covered by peritoneum: from this circumstance, as well as from its being the free surface, it is very smooth.

The *posterior surface* contrasts strongly with the anterior, for being uncovered by peritoneum, and closely applied to all those structures against which it lies, it presents many irregular elevations and depressions, corresponding with the uneven surface which these structures contribute to form.

Size and weight.—The size and weight of the pancreas are liable to great variety, and hence different authors have stated them very variously. Wharton* gives its weight as five ounces; Meckel, from four to six; Cruveilhier states its limit as six ounces, but thinks that a healthy pancreas may be as small as two ounces and a half; Sœmmerring also considers six ounces a maximum, but carries his minimum as low as an ounce and a half. According to Krause and Glendinning, its usual weight is from two and a quarter to three and a half ounces. Its size is stated by Meckel as six inches long and one thick; Ellis gives its length as seven inches; Quain and Sharpey, from six to eight inches, with an average breadth of an inch and a half; according to Wharton, its length is about five inches, its greatest breadth one and a half, and its thickness one inch. Of all these weights and measurements I think that of Wharton, which is the earliest, comes nearest the truth; only his measurement of length is too little. From a large number of observations I find the average weight to be from four to five ounces, the length seven inches, the greatest breadth an inch and a half, and the thickness three quarters of an inch. It is smaller in women than men, but only in proportion to the difference of size. Sœmmerring says† that it is proportionately larger in the fœtus and the new-born infant

* Meckel, Manuel d'Anatomie.

† Some anatomists, as Professor Ellis, make the *head* synonymous with the lesser pancreas, independently of this separation.

* Adenographia, p. 72.

† "In nondum nato homine et brevi adeo post partum, majus pro corporis mole videtur quam in adulto." Corp. Hum. Fab.

than in the adult; a statement that my own frequent observations have verified.

The specific gravity of this gland, according to Muschenbroeck*, is, compared to water, as 2029 to 1000.

General appearance.—The best view of the external appearance of the pancreas is obtained on its anterior surface where it can be seen, through the peritoneum covering it, without any disarrangement of its structure. It is seen to be of a pale, clear, flesh colour, in which it strongly contrasts with the white cellular tissue investing it, with the yellow fat with which it is often surrounded, and with the grey and dingy coloured absorbent glands which lie contiguous. On looking more closely, it is seen to be mapped out into lobules, and this mapping out is sometimes more conspicuously marked by the septa of areolar tissue that separate the lobules being loaded with fat. The lobules are of very various shapes and sizes, from an eighth to three quarters of an inch in diameter, closely packed so as to fit into one another, and presenting an even general surface. But on a closer examination we see that these lobules are themselves subdivided by less conspicuous septa into a great number of smaller lobes; and these again, especially if assisted by a little separation with a fine knife or needle, are seen to consist of numerous minute granules, or acini, as they are termed, which, as far as the scrutiny of the naked eye goes, appear to constitute the ultimate structure of the gland; but, as we shall see more fully presently, the microscope shows these in their turn to consist of aggregations of follicles, and therefore to be truly compound. Thus a mere inspection of the external surface of the pancreas gives an indication of its internal structure; we see the acini by their aggregation constituting the lobules, the lobules the lobes, and the lobes the whole organ; the association by which these parts are bound together being more and more intimate as we descend from the greater to the less; but all of them, even the smallest, that come under the cognisance of the unassisted vision, being truly composite: this is a common character, and indeed a general description, of all conglomerate glands. The pancreas in consistence is moderately firm, the lobules having a considerable degree of hardness, but the whole gland having a certain laxness about it, from the way in which the lobes are hung together by areolar tissue.

There is no proper capsule to the pancreas: the areolar tissue which invests it does so very unequally in different parts, and is strictly continuous on the one hand with that which attaches it to neighbouring parts, and on the other with that which penetrates between its lobules to the internal parts of the organ. On the anterior surface this areolar tissue is so deficient that the structure of the gland is in no way concealed by it.

Internal structure.—On cutting into the pancreas, we see that it is the same throughout its mass as it is on its surface; that it is solid and homogeneous; that one part exactly resembles another; that there is the same aggregation of the acini into lobules and of lobules into lobes, and the same nesting in capsules of areolar tissue by the elasticity of which the acini and lobules are made to protrude from the cut surface, whereby it becomes granulated and nodular; and this irregularity of surface is almost the only difference between the appearance of a section and that of the external surface as just now described. A good idea of the absolute and relative size of the different elements may be obtained by a section: the lobes may be said to have an average diameter of $\frac{1}{3}$ of an inch; the lobules $\frac{1}{12}$, or $\frac{1}{4}$ of the lobes; the acini $\frac{1}{70}$ of an inch*; but all the measurements are liable to the greatest variety.

The areolar tissue, less abundant than in the salivary glands, consists almost entirely of the white fibrous element, and the areolæ are very lax and large: it is most abundant near the centre of the gland around the duct, and about the head of the pancreas, where it forms a firm and intimate union between the gland substance and the duodenum.

The duct of the pancreas, which has been called the canal of Wirsung, from its discovery by that anatomist in the year 1642, passes from left to right throughout the entire length of the organ, beginning within a few lines of its splenic extremity, by the union, at an acute angle, of two or more minute ramusculi, and emptying itself into the duodenum at or near the junction of its vertical and inferior-horizontal portions. Its course is somewhat sinuous; it lies, on the average, about equidistant between the upper and lower margin, but nearer the posterior than the anterior surface. It is altogether concealed by the gland structure, even its point of entrance into the wall of the intestine. After originating in the manner described, it receives continuously in its course small branches which enter it at right angles, and which, unlike the main duct, are perfectly straight and not sinuous, and mostly single and unbranched, each coming from its own appropriate lobe, without receiving any accessory branches from neighbouring ones; so that they look, as Cruveilhier has said, like the legs of a centipede, of the which the main duct forms the body. By these tributary ducts the calibre of the main canal is gradually increased till it reaches a diameter, at the right extremity of the gland, of $\frac{1}{8}$th of an inch. It is of an opaque white, and therefore easily distinguishable from the gland substance. Its walls are thin and elastic, but dense and firm. In the tenuity of its walls it stands in strong contrast with the ducts of the salivary glands; but, like them, it is continuous, by its external loose fibrous coat, with the areolar tissue of the gland. Just before entering the intestine the duct com-

* Introd. ad Philosoph. Natur., p. 556.

* This last measurement is taken from the rabbit, as it is difficult to isolate the acini of the human pancreas, or to take their measurement *in situ*, without isolation; but the measurement in the human subject very nearly approaches it.

monly receives a large tributary branch, often nearly as large as itself, coming from the head of the pancreas. This occasionally remains permanently distinct, and opens into the intestine by a separate orifice (see *fig.* 55. B, *c*), a condition always present, according to

Fig. 55.

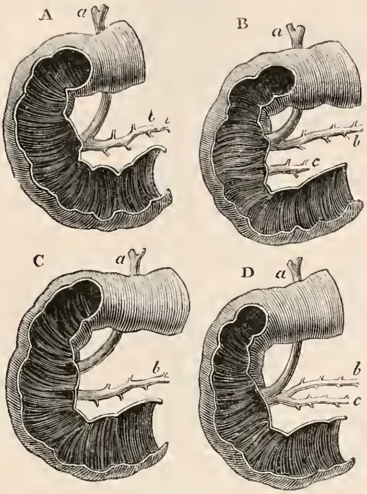


Diagram of the principal Varieties to which the termination of the pancreatic duct and its relation to the bile-duct is liable in the human subject, arranged in their order of frequency.

A. The normal arrangement, showing *a*, the bile-duct, and *b*, the pancreatic, terminating by one orifice.

B. Showing the separate termination of *c*, the accessory duct from the head, or lesser pancreas.

C. The main duct, *b*, terminating by an orifice distinct from the choledoch.

D. Two parallel and equal ducts *b*, *c*, are here seen joining the bile-duct at its orifice. This is a case of "double pancreatic duct."

Meckel, in the early fœtus, so that this irregularity is essentially nothing but an extension of a fœtal condition into adult life. When this duplicity of orifice exists, the separate duct from the head of the pancreas has its own little papilla, proportionately smaller than the normal one, and separated from it about $\frac{3}{4}$ths of an inch or an inch. It is usually lower down, though sometimes higher up, than the main orifice. It has been observed by Cruveilhier, that when there is one duct opening by a distinct orifice appropriated to itself alone, there is always another opening into the duodenum in the normal way in common with the ductus choledochus. According to other authorities*, however, the pancreatic duct and the bile duct will sometimes open on the mucous membrane of the duodenum by two entirely distinct orifices, when the former is single and there is no secondary one, as seen in *fig.* 55. C. Occasionally the pancreatic duct is double throughout its whole length, the two running side by side and communicating, just before

* Sœmmerring, Corp. Human. Fabrica.

their junction, with the ductus choledochus, as shown in *fig.* 55. D. Sœmmerring asserts that there are sometimes three ducts distinct throughout and opening separately. All the varieties of method of termination of the pancreatic duct have been collected and analysed by Tiedemann*; and he has come to the interesting conclusion that they all have their analogues in the different arrangements found in the various species of the lower animals.

The method of termination of the pancreatic duct, and its relation to the ductus choledochus, is rather curious. The duct, unlike the ducts of the salivary glands, which have a long course after leaving the gland before they terminate, passes at once from the gland to the intestine at a point where the former is closely applied to the latter, so that it is quite covered up and has no peritoneal investment. At this situation it comes into contact, at an acute angle, with the ductus choledochus, which has descended to this point either in a groove of the pancreas, between it and the intestine, or in a complete channel through the gland substance. The pancreatic is placed to the left of the choledoch duct; and, maintaining this relation, the two perforate obliquely the duodenum about the middle of its second portion and at the left side of its posterior wall.

Side by side they perforate in succession the muscular, the fibrous, and the mucous coats, which they elevate into a ridge when injected or when a probe is passed into them, and after an oblique course of about eight lines, they open into the bottom of a little papilla situated in a transverse fold near the junction of the middle with the third portion of the duodenum.† In their transit through the walls of the intestine they are separated by a valve-like process, composed of the tissues that constitute their walls, which gradually gets thinner and thinner till it terminates at the base of the little olive-shaped ampulla about two lines in depth, into which the cavity of the papilla is dilated; and since the mucous membrane lining this ampulla is of the same structure as that lining the intestine, and unlike that lining the ducts, these latter must be said to open by two distinct orifices at the base of the papilla, and not by one at its apex, as is usually described; in fact the lining membrane of the cavity of the papilla is part of the general mucous surface of the

* Sur les différences que le canal excréteur du pancréas présente dans l'homme et dans les mammifères. Journal Compl. des Sciences Médicales, tom. iv. p. 370.

† The point of immergence of the pancreatic duct is variously stated by various authors. *Sœmmerring* gives it as from three to twelve fingers breadth below the pylorus; *Meckel*, from three to four inches, but possibly amounting to ten; *Quain*, three to four inches; *Cruveilhier*, at the lower part of the second portion of the duodenum; *De Graaf*, quatuor digitis transversis sub pyloro; *Gavard*, five fingers breadth from the pylorus; and so on. That given in the text, which coincides with Cruveilhier, is the normal one; the extremes are very exceptional.

duodenum.* Towards its orifice the duct more or less enlarges itself; but at its very aperture, on the contrary, it undergoes a contraction. The appearance of a valve guarding the orifice depends merely on the partition which separates its mouth from that of the choledoch duct. Occasionally near the orifice, occasionally higher up, there is a valve-like process projecting from its inner surface ; but this is not constant either in its situation or its existence.

From the narrowness of the duodenal orifice of the pancreatic duct, from the movable and yielding nature of the eminence upon which it opens, and from the oblique course of the duct through the walls of the duodenum, it follows that the pancreatic fluid and the bile may pass freely *into* the duodenum, but cannot regurgitate from it into the ducts. "On this subject," says Cruveilhier†, "I have made several experiments. I have forcibly injected both water and air into the duodenum, included between two ligatures, but nothing escaped; on the other hand, I have injected the same fluids from the duct into the duodenum, which I was thus able to distend at pleasure. But then, on compressing the bowel with great force, I have never been able to cause the slightest reflux into the ducts." The spur-like process formed by the lining membrane reflected upon itself at the junction of the ductus choledochus and the pancreatic duct, extending down to the duodenal orifice, does not prevent the fluid of one canal from passing into the other. Thus the pancreatic fluid might regurgitate into the ductus choledochus, and, on the other hand, the bile might enter the pancreatic duct, if these canals were not habitually full. Moreover, this spur-shaped process between the two canals cannot arrest the flow either of the bile or pancreatic fluid, by being applied to the orifice of the one or the other duct.

Fig. 56. is a diagrammatic representation of the manner in which the ducts traverse the walls of the duodenum and terminate in the papilla, and of their relation to one another, and to the coats of the intestine.

Vessels.—The *arteries* of the pancreas, which, for the size of the gland, are large and numerous, are, like those of other conglomerate glands, contributed from many sources, and are derived from the branches of the cœliac axis, and from the superior mesenteric. The principal are the pancreatico-duodenalis of the hepatic and the pancreatic branches of the splenic artery,—one of which, the *pancreatica magna*, sometimes runs nearly the whole length of the gland, accompanying the duct from left to right. The branches from the

superior mesenteric are mostly derived from that small twig which, given off just at the lower border of the pancreas, anastomoses with the pancreatico-duodenalis. The *veins* empty themselves into the superior mesenteric and splenic.

The *lymphatic vessels* have not, that I know of, been demonstrated, nor have I been able to detect them myself: they are supposed to enter the lumbar glands in the neighbourhood.

The *nerves* are derived from the solar plexus, and enter the gland at different parts, accompanying the branches from the arteries of the cœliac axis.

II. Microscopical Anatomy.

Gland substance.—The subject of the microscopical anatomy of the pancreas is one of great difficulty, and, until I came to examine it for myself, I had no idea how great. The delicacy and tenuity of the structures, even when seen most advantageously; the destruction of all their natural relations, and consequent impairment of the value of observations by cutting, tearing, or compression; the rapid change that takes place in the microscopical elements themselves, in whatever medium they are placed for examination, by deliquescence, solution, or endosmosis; the conflicting character of different appearances; and the discrepancy of many of them with the interpretations

* Sœmmerring considers the *apposition* of the two ducts in the wall of the intestine a *junction*, and the partition between them merely a valve: indeed, it is to that portion of the bile duct, so joined by the pancreatic, that he restricts the appellation *ductus choledochus*. "*Ductus choledochus, id est ductus hepaticus, cysticus, et pancreaticus in unum conflati.*" (Corp. Hum. Fab.) A definition as unphysiological as it is inconsistent with critical anatomy.

† Descriptive Anatomy.

given by the most trustworthy authorities, all conspire to invest the practical investigation of the subject with an amount of difficulty and doubt greater, I think, than that which would beset almost any other path of microscopical research. And I may add to this, what would naturally be its accompaniment, a deficiency on the part of the authors that I have consulted, in that very kind of information that the practical difficulties of original research make one crave in others. The only observations on which I think reliance is to be placed for the solution of the difficulties that the examination of a structure so involved and delicate as the one under consideration presents, are observations made with the microscope on the parts, fresh, *in situ*, unaffected by re-agents, and undisturbed by such manipulation as shall interfere with the normal relations of their minute anatomy; and such observations I cannot find. Müller's descriptions and drawings on this subject, in his admirable monograph, "De Glandularum Secernentium Structura Penitiori," are either taken from the parts unmagnified, or magnified with such low powers as make them valueless for the solution of the special difficulties of the case. The same observation applies to the accounts of the minute structure of the pancreas contained in the ordinary works on descriptive anatomy, from their being descriptions of the minute structure as seen by the naked eye, or as made out by a coarse kind of disintegration, or by mercurial injections.

The most satisfactory microscopical examinations of the pancreas may be made, I think, from those of the *Rodents*; for in them the gland being spread out in its proper mesentery in an arborescent or seaweed-like form, it is in some parts so thin as to transmit sufficient light for its examination without any compression or dissection whatever; indeed, along the edges and in some of the smallest lobules, the ultimate follicles are distributed in a single layer only. This arrangement makes a careful and satisfactory scrutiny much easier; and I shall, therefore, in this part of my paper, draw principally from the appearances of the gland in these animals, as the rat, rabbit, mouse; at the same time the close approximation in ultimate structure to the human pancreas will make my observations apply as well to the gland in man as in these lower mammalia.

On putting a minute lobule of the pancreas of a rat or mouse under the microscope, we see a number of follicles grouped together, of various forms and sizes, constituting, by their grouping, the acini of the gland, or ultimate granules visible to the naked eye; and when the acinus is constituted by a small number of follicles, and isolated, the whole of it may be brought under the field of the microscope at once (as in *fig.* 57.). These follicles are formed by the involution of the *limitary membrane* of the gland, and they contain the *secreting epithelium*, and within that (at least under some circumstances) a *central cavity*. These elements of the follicle — the basement membrane, the epithelium, and the cavity — I shall consider in succession.

Fig. 57.

Minute lobule or acinus of the pancreas of a Mouse, showing the two forms or stages of the epithelium, and the varied forms and sizes of the ultimate follicles (magnified 180 *diameters).*

a. The basement or limitary membrane.—It is to the modification and arrangement of this fundamental tissue that the pancreas (in common with all other glands, either follicular or tubular, simple or compound) owes its shape and appearance as a conglomerate gland, and its position in the gland series as a "compound gland with canals of the ramified type having follicular extremities."* From this membrane, as from a starting-point, the distribution and anatomy of all the other elements of the gland structure proceed. The branched character of the ducts, the particular manner in which the follicles are grouped, the racemose or panniculated character of their clusters, the isolation of the epithelium within them, the amount and arrangement of the areolar tissue without them, and the form of the capillary network, all result from the particular way in which this basement membrane is laid down. To this simple truth anatomists have been a long time in coming. Malpighi first, in 1665, announced the fact that the compound glands were mere multiplications or repetitions of the simple ones, and that all glands consisted of tubes with blind dilated or undilated extremities, which received the secretion from the blood and poured it into the excretory duct. This view, after having some doubt thrown upon it by the researches of Ruysch and the experiments of Haller, has been entirely confirmed and greatly elaborated by the labours of Müller, who, in his great work on the inti-

* Müller, Physiol. by Baly, vol. i. p. 444.

mate structure of glands, has contributed more than any other author to our knowledge of this particular section of general anatomy.

In the human pancreas the follicles are so closely packed that their individual shape cannot well be seen; but in the rodents the arborescent arrangement of the gland exhibits them well; and they are seen, when isolated, to be ovoidal or nearly spherical*, although, in the central part of the lobule, they become variously polygonal from mutual compression. The outline, however, even where they are not compressed, is not that of smooth spherules, but presents slight convexities corresponding to the epithelium within them; but the endosmosis of water, by detaching the epithelium from the basement membrane, and at the same time distending the follicle, causes these convexities to disappear. There is great difference in the size of the follicles, some being as much as $\frac{1}{200}$th of an inch in diameter, some as small as $\frac{1}{800}$th; and the extremes in size will often be contiguous, a very small one packed among many large. The average size of a pancreatic follicle is about $\frac{1}{500}$th of an inch. The number of follicles in a single group varies still more, being from half a dozen to a hundred or even more. In the rodents these groups are often entirely separate from one another on every side; but in most of the mammalia their isolation is not so complete, and they are more or less massed and fused together.

Fig. 58.

Isolated cells of mature secreting epithelium from the pancreas of the Rat, showing their opaque granular contents. (Magnified 400 *diameters.)*

β. The epithelium is of the glandular type, spheroidal or polygonal in shape, varying in diameter from $\frac{1}{1500}$th to $\frac{1}{2000}$th of an inch, and presenting two distinct appearances, indicating, I think, two stages of development — an early stage, and one of more complete maturity. The cells of the early stage are smaller, more spherical, homogeneous in structure, and most abundant at the peripheræ of the follicles or in immediate contact with the basement membrane. The more advanced cells are larger, of more varied shape, full of granular contents, and loosely aggregated towards the centre of each follicle. I consider the form first described to be the early stage because the cells are so small, are in contact with or near the cell-generating surface, and are free from secretion contents. The others, I imagine to be the more advanced stage, from their greater size, their loose and unattached appearance, the similarity of their granular contents to that of the secretion when free, and the want of definiteness of outline in many of them, which seem dissolving in their own contents, the cell-wall having disappeared, and the cluster of contained granules merely marking its situation. (See *fig.* 57.) In neither of the stages can I detect nuclei. From the great opacity of the more advanced cells, and their grouping towards the centre of the follicle, they give a portion of pancreas, viewed with a low power, a mottled appearance, a dark spot marking the centre of each follicle, and the number of dark spots showing the number of follicles, which, in some parts, from their close packing, could not be otherwise counted

When the follicles are ruptured, the epithelium escapes, and the two forms may be seen floating freely about. *Fig.* 58. represents some of the more advanced cells; they are magnified 400 diameters, and are seen to be filled with the particular granular matter which imparts to them their darkness and opacity, and which differs only from the free granular matter floating about in the secretion in being localized and confined by the vesicular envelope of the cell. What might be called the granular or molecular base of the pancreatic fluid, is evidently the contents of these mature cells, liberated by the rupture or solution of the cell-wall.

The cells that have attained this appearance, although they may be grouped together, as seen in *fig.*, 57. are never adherent to one another. The less advanced cells, however

Fig. 59.

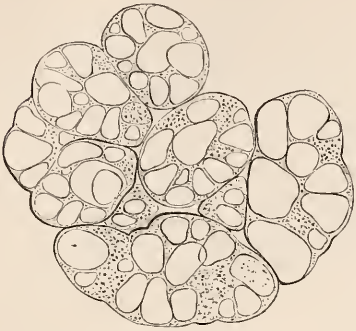
or those in contact with the membrane of the follicle, are often so closely adherent, that when they escape from their containing follicle they form little crescentic masses, as seen in *fig.* 59., the convexity coinciding with the follicle-membrane, the concavity with the central space, and the adherent surfaces of the cells presenting the appearance of radiating lines, passing from convexity to concavity at right angles to them: this close package of the epithelium gives it a columnar appearance; and, indeed, some of the little crescentic groups referred to closely resemble the scraps of sheaths of columnar epithelium shed from an intestinal villus during digestion.

Sometimes, instead of the follicles being filled with distinct epithelium cells, they appear to contain a number of variously-sized globules, of a smooth, homogeneous, and highly refracting appearance, surrounded by a medium of much less refracting power, and

* In Cruveilhier's Anatomy, p. 533. note, it is said that the ultimate follicles of the pancreas are cylindrical, while those of the salivary glands are slightly dilated. (?)

finely granular. These globules are of various shapes, according as they are isolated or com-

Fig. 60.



Appearance of homogeneous globules of various sizes and shapes, occasionally seen in the follicle of the pancreas. From the Rat. (*Magnified* 200 *diameters.*)

pressed by neighbouring ones. They range in size from $\frac{1}{1500}$ to $\frac{1}{400}$ of an inch, and are evidently not contained in any cell-membrane. (See *fig.* 60.) The appearance, in my opinion, results from a spontaneous solution of the epithelium in the follicles, and a separation of the different elements of the secretion; but what are the particular circumstances that determine it I do not know; the longer the object is kept under the microscope, the more marked is the appearance, and the larger the globules, from their running one into the other: it is possible that endosmosis may have something to do with it, for I do not remember ever to have seen the appearance in specimens promptly examined immediately after death.*

γ. Occasionally there is an appearance of a central cavity in each follicle, the epithelium lining it in a single columnar-looking layer, and leaving a central space unoccupied. The central space thus left is very small, not exceeding in diameter that of the thickness of the epithelial layer lining the follicle; it is only now and then that this appearance can be detected, and even then it requires careful focussing to see it satisfactorily: it may either arise from the epithelium being shed in successive generations of layers,—one passing from the follicle as the succeeding crop is produced,—or it may be explained by the mere liquefaction of the central and older cells, which, escaping in a fluid form from the follicle, leave the peripheral cells with a definite and even surface. At any rate, it is a rare thing to see the appearance clearly, and when it is visible, it requires accurate focussing for its satisfactory display; for if either the nearer or more distant surface of the follicle is in focus instead of the centre, all appearance of cavity vanishes, and the follicle seems to be full of epithelium. Perhaps it is in part owing to this, and in part to the fact that the condition accompanies a particular and transitory stage of the secretion, that it is

Fig. 61.

A group of follicles from the pancreas of a Rat, viewed so as to bring their central cavity into focus. (*Magnified* 150 *diameters.*)

not more frequently visible. I have represented it in *fig.* 61., as seen in a group of follicles from the pancreas of a rat: it displays the proportional thickness of the central cavity and the epithelial lining, and shows one or two follicles, where, from being out of focus, the cavity is not visible and the follicle appears solid throughout. It was sketched immediately after death.

Duct.—The duct of the pancreas, like that of other conglomerate glands, consists of three coats: a middle, elastic, dense, fibrous, and white; an external, loose, and areolar; and an internal epithelial. Between the middle and internal there is probably a basement membrane, described, indeed, by some authors, but which I have been unable to detect.

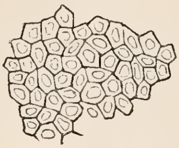
The middle coat consists of a firm, dense, and matted stratum of fibrous tissue, mainly longitudinal in direction, but closely interwoven and netted together, very much resembling white fibrous tissue in appearance, but evidently not consisting of this entirely, as the striation is not removed by acetic acid. A certain amount of clarification, however, is produced by adding the acid, and the fibres that remain visible afterwards appear to consist of a particular form of yellow fibrous tissue, extremely fine, so as to lose the characteristic appearance of double outline and even calibre. These fibres are exclusively longitudinal and parallel, except towards the outer surface of the duct where they interlace. Besides these, acetic acid displays, irregularly and sparingly scattered, some transverse and some longitudinal, the nuclei of some unstriped muscular fibres. These fibres I have never been able to isolate or see satisfactorily, for the density and opacity of the fibrous tissue previous to the addition of acetic acid renders them invisible: they lie near the inner surface, and, from the paucity of the nuclei, must be very few.

The external coat is merely the loose areolar web which connects the duct to the

* Since writing the above, I have had satisfactory evidence that the appearance is owing to endosmosis. I have seen the globules form under the microscope from their first trace to their attainment of a size equal to that shown in the figure. Sometimes the endosmotic current is so strong as to cause visible movement in the contents of the follicles; the globules are the endosmosed fluid, the intervening material the granular contents of the follicle; in fact, the secretion. I have thought it worth while to retain the figure and description, as it is an appearance that might very easily give rise to error.

gland substance, and is continuous with that which pervades the whole gland: it differs not, therefore, from that which has been already described.

Fig. 62.



Tesselated appearance of columnar epithelium lining the pancreatic duct. (*Magnified* 200 *diameters.*)

The epithelium is columnar, arranged apparently in a single stratum, and presenting a beautiful honeycomb appearance of closely-packed hexagons and pentagons, when looked at on its free surface. Further up, however, near the extremities of the ultimate ducts, the epithelium changes its character, and becomes more globular, as is shown in *fig.* 63, which represents a portion of the epithelial lining of a duct, about $\frac{1}{400}$ of an inch diameter, from the human subject. A certain approximation is here seen to the form of secreting epithelium, with which, however, it strongly contrasts in its clearness and freedom from granular contents.

Fig. 63.

Portion of epithelium lining a small duct $\frac{1}{400}$*th of an inch in diameter. From a Rabbit.* (*Magnified* 300 *diameters.*)

There is every probability of the existence of a basement membrane here as in other sub-epithelial situations, and it is probably continuous with that which alone constitutes the walls of the ultimate ducts: for the fibrous and muscular elements gradually diminish as the ducts get finer, until in the smallest that are seen all fibrous appearance has vanished, and a homogeneous membrane alone remains. According to Henle the homogeneous wall of the smallest ducts consists of fibres fused and run together in a plane; — a supposition that would imply the non-existence of this membrane in the larger ducts, where they are not so fused.

Capillaries. — The arrangement of the capillaries remarkably resembles that of fat. They form a close and pretty even-meshed net work, open on all sides, among the meshes of which the follicles lie, just as the vesicles do in the case of fat; so that the closeness of the plexus is a measure of the size of the follicles. Their general appearance is well seen in the accompanying figure (*fig.* 64.).

Fig. 64.

III. Comparative Anatomy.

Invertebrata. — Certain organs connected with the alimentary canal have in some of the higher invertebrata received the name of pancreas; but they have done so rather from their position and inferred function than from any certain evidence of their use, or from their anatomical structure. In *Gasteropoda* we find the first indications of the organ, and it presents in them the form of a single, long, blind, glandular sac, communicating with the beginning of the intestine; such a pancreas may be seen in the different species of Aplysia and Doris, Tritonia and Scyllæa.

Cephalopoda.—The Tetrabranchiate Cephalopods possess, attached to the upper part of the intestine, a laminated sac, which receives the canal into which the two main hepatic ducts unite, and which diverts the bile by a peculiar development of one of its laminæ, from flowing into the gizzard. Professor Owen considers that the follicular structure of this and the other folds of membrane sufficiently indicate its glandular character, and regards the entire laminated pouch as a more developed form of pancreas than the simple cæcum, which we have just described as representing that gland in some of the Gasteropods.

Vertebrata. — *Fishes.* — At the commencement of the intestinal canal, close to the pylorus, are found, in most osseous fishes, certain cæca or blind tubes, budding out from the wall of the canal, which from their position have received the name of *pyloric appendages*, and have been regarded by most anatomists as the analogue of the pancreas in higher animals. In their most simple form— that of a single, or two or three short buddings of the intestinal wall, not differing from it in the structures that form them, the analogy would hardly suggest itself, but by gradual steps we are conducted from this simple representative of the organ, through a series of forms of increasing complexity, to a structure bearing some analogy to a conglomerate gland, and at any rate deserving to be considered a special glandular appendage to the alimentary canal; the cæca becoming more and more numerous as we ascend in the scale, and the whole organ more and more concentrated. Thus in the Sandlance (*Ammodytes lancea*), and Polypterus there is but one pyloric cæcum; in most of the Labyrinthibranchs, in many species of Amphiprion, in the Angler (*Lophius piscatorius*), Turbot (*Pleuronectes maximus*), and Mormyrus there are two; in the Perch (*Perca fluviatilis*), the percoid Popes, the Asprodes and Diploprions, three; in the Miller's Thumb (*Cottus gobio*), and Father Lasher (*Cottus scorpius*), from four to nine; in the Gurnard (*Trigla*), from five to nine; in Scorpæna and Holocentrum, six and upwards; in the Pilchard (*Cupea pilcardus*), and Lump-fish (*Cyclopterus lumpus*), there are fifty, and upwards of fifty in the Tunny (*Scomber thynnus*); in the Cod (*Gadus morrhua*), there are upwards of 120: and in the Sturgeon (*Acipenser sturio*) and Paddle-fish they cannot be counted.* But the increased complexity, and divergence from the simple cæcal form, is not produced only by the greater number of the appendages. As they increase in number, they more and more coalesce at their bases, so that many cæca open by few orifices, and thus the character of the gland is gradually changed, becomes clustered and branched, and passes from the tubular to the racemose type. Thus, in the Pilchard, fifty tubes communicate with the intestine by thirty orifices; in the Lump-fish the same number by six; in the Tunny, by five; in the Sword-fish (*Xiphias gladius*), there are but two orifices; and in the Sturgeon, the whole mass of cæca, by continually uniting and re-uniting, come at last to empty themselves into a single tube, equivalent, in fact, to a short and wide pancreatic duct.

The reasons which have induced anatomists to regard this organ as the analogue of the pancreas are these.

* Owen's Lectures on Comparative Anatomy.

In the first place, the *situation*; it is placed at the pyloric extremity of the intestine; and besides this general similarity in situation, there is this special one, that the hepatic duct has the same relation to it as it has to the pancreas in higher animals. If there is but one orifice, as in the Sturgeon, the hepatic duct opens at its base; if many, at the base of one of them.

Secondly. If they were merely multiplications of surfaces to which food was to be exposed, we should find food getting into them; but this is never the case. I have not been able to detect any alimentary materials in even the largest of them; their function therefore must be that of pouring forth some special secretion.

Again, it is not the way, the particular method, in which surface is multiplied; that is done by modifications of the lining membrane of the intestine, the mucous structures, alone — by folds, villi, crypts — and not by extension of the whole intestinal wall, muscular and sub-mucous, as well.

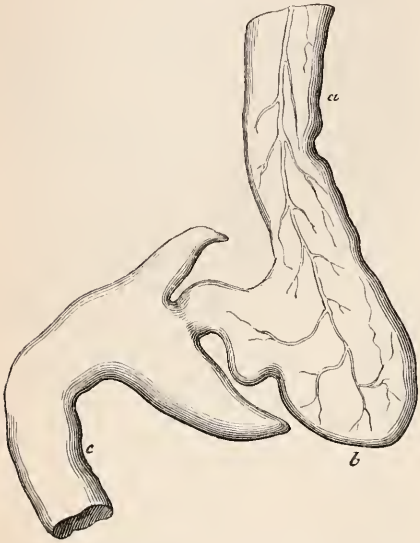
Lastly, the filling up of all the intervening stages from simple tube to conglomerate pancreas goes a great way to prove the essential identity of the extreme forms.

But what is very remarkable with regard to these appendages is their entire absence in many classes of fish. In all the Abdominal Malacopterygii, except the Salmonidæ and Clupeidæ, they are wanting; in most of the Labroids, Gabioids, Cyprinoids, and Lucioids, they are absent; in the Apodous Malacopterygii, in the Lophobranchs and Plectognats there is no trace of them; nor in the genera Antennarius, Malthæus, and Batrachus In some cases they appear to be wanting in consequence of their place being supplied by a more elaborate mucous surface, as in the highly developed stomach of the Anarrhichas, and the glandular palate and long intestine of the Carp (*Cyprinus*); in others, their absence seems to be but a part of a general simplicity of the alimentary apparatus, as, for instance, in the Dermopterous fish. In the Eel, where there are no cæca, the mucous membrane at the pylorus suddenly becomes thick, vascular, and spongy, and continues so for about an inch; and on pressure an abundant secretion may be squeezed out of its wall, of an appearance exactly identical with that found in the pyloric appendages where they are present.

It is difficult to seize on the law of their existence; we may, however, say that they are, for the most part, wanting in fish that live on vegetable substances, although there are many similarly circumstanced that are carnivorous and very voracious. Their development, or their relative size, their number and complication, are probably in proportion to the activity of digestion and rapidity of growth; the Salmonidæ, the Clypeidæ and Scomberidæ, seem to indicate this: in these last these pyloric cæca exhibit a remarkable complexity.

In the Turbot (*Pleuroneetcs maximus*) these cæca are seen in their most rudimentary form; they are two in number, ample, conical, and recurved, projecting back from the duodenum at its very commencement, so as to give it a barbed or arrow-head appearance, as seen in the drawing (*fig.* 65.). The stomach in this fish is very small, and the duodenum

Fig. 65.

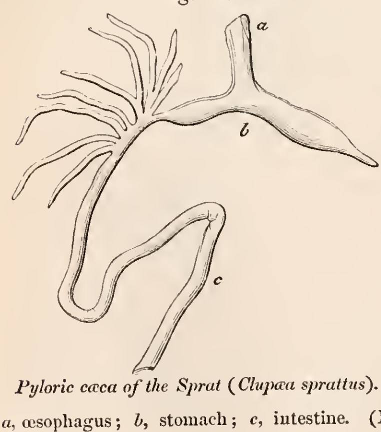


Pyloric cæca of the Turbot.

a, œsophagus; *b*, stomach; *c*, intestine. (Drawn one-third the natural diameter.)

very large, and the food probably passes into the intestine with but little delay. The cæca in this case must be considered an exception to the rule I have above laid down, that they are never filled with the contents of the alimentary canal; for in the specimen I examined they were completely stuffed with tæniæ, with which also the intestine was filled.

Fig. 66.



Pyloric cæca of the Sprat (*Clupæa sprattus*).

a, œsophagus; *b*, stomach; *c*, intestine. (Natural size.)

In the *Sprat*, the pyloric cæca are nine in number, long, slender, and simple (see *fig.* 66.): the upper five unite together at their bases, and open into the duodenum, close to the pylorus by one orifice; the last four open separately, each by its own orifice, in linear series along the duodenum.

In the *Gadidæ*, as in the *whiting* (*fig.* 67.), the cæca are arranged in the form of a ring,

Fig. 67.

Alimentary canal of the Whiting (*Merlangus vulgaris*), *showing the pile of cæca around the pylorus.* (*One half the natural diameter.*)

constituting a frill around the intestine, and consits of four bunches, each containing about thirty cæca. These unite and re-unite till they terminate, each bunch, in a single duct; so that there are finally four orifices, so placed as to fall on two converging sides of a triangle, of which the orifice of the hepatic duct would form the apex. As each bunch contains thirty cæca, there are a hundred and twenty

Fig. 68.

One of the four bunches of pyloric appendages of the Whiting, isolated; showing their union and reunion till at length they end in a single tube.

in all. The appearance of the frill of pyloric cæca is shown in fig. 67, and one of the bunches separate in fig. 68.

In the *Salmon* this apparatus of cæca is much more voluminous. It is not condensed around a particular portion of the intestine, but extends linearly, from close to the duodenum for a distance of about eight inches along the intestinal wall; each cæcum opens by its own separate orifice. There is no coalescence or fusion, so that on looking on the inside of the intestine there are seen as many orifices as cæca; they form a double row on each side, so that altogether there are four rows, and are arranged with the utmost regularity. The amount of secreting surface of these cæca must be very great; some of them are ten inches long, and as big round as a tobacco-pipe; they rapidly increase in length from the first three downwards, and the third from the stomach is generally the longest. They then gradually diminish, slightly in calibre, considerably in length, to those furthest down the intestine, which are about three inches long. Altogether the secreting surface of these cæca must considerably exceed that of the rest of the alimentary canal, and the whole apparatus, taken together, is next to the liver, by far the largest of the viscera. Each double row contains about thirty, so that altogether there are sixty cæca, and as the average length of each cæcum is $6\frac{1}{2}$ inches, the whole length of secreting surface must be 390 inches, or upwards of 32 feet.

Fig. 69.

Portion of the alimentary canal of the Salmon (Salmo salar), showing one double row of cæcal appendages and the pyloric extremity of the other.

a, œsophagus; *b*, stomach; *c*, pylorus; *d*, small intestine; *e*, gall-duct. (One-third the natural diameter.)

In their internal ultimate structure these cæca exhibit considerable variety; in many the mucous surface is closely laminated; in some it is covered with flattened, fused villi with crypts thickly planted between their bases. In the Herring (*fig.* 70.) the structure is very peculiar: on looking vertically on the internal surface it is seen to be mapped out into hexagonal and pentagonal cells about $\frac{1}{150}$ of an inch in diameter, very evenly and geometrically arranged, and each filled with a mass of epithelium. The septa between them appear to consist of submucous fibrous tissue, and on making a section and looking at it laterally they are seen to project between the acervuli of epithelium, and rather beyond them, and to have no epithelial investment of themselves. The masses of epithelium are seen to be of a spheroidal form and very smooth outline, though I could not distinguish any basement membrane or capsule wall of which they might be supposed to be the contents, or any special structure determining their outline. I have thought this structure sufficiently peculiar to give a figure of it. A represents the appearance on looking down on the surface; B, a view of the wall in section, seen with a lower magnifying power.

Many anatomists deny the true pancreatic nature of these pyloric cæca, and assert that many fish possess, over and above them, a true glandular pancreas, analogous in structure to the pancreas of higher animals. Weber first described such an organ in the *carp*, as interlaced with the lobules of the liver, and, so to speak, confounded with them, but having a proper excretory canal opening into the intestine by the side of the cystic; he also thought that he had seen traces of a pancreatic duct in the *pike*. Much more recently Alessandrini described the same excreting duct, as also the volume and position of the pancreas, in the same fish. In the *Silurus glanis* MM. Brandt and Ratzebourg have taken for the pancreas a glandular body very like the liver in appearance, stretched as a layer between the folds of the gastro-hepatic omentum, enveloping the cystic canal and accompanying it as far as the intestine. These three examples of malacocopterygious fish have no pyloric cæca, and this glandular structure might be considered as replacing them; but Alessandrini has also described in the *sturgeon*, the walls of whose intestinal canal are particularly glandulous and in which the pancreatic cæca form an elaborate apparatus, a proper pancreas with an excretory duct opening into the intestine in the middle of a tubiform papilla about an inch from the pyloric orifice. In this last case Cuvier believed the body indicated as the pancreas to be a lobe of the liver. "The tubiform papilla," he says, "truly exists; indeed I have found two, besides that appertaining to the choledoch duct. In one of the examples it formed a sort of *cul-de-sac*; in the other the fibre which was introduced conducted to a canal which took a direction towards the liver. I have clearly seen an excretory duct in a very large silurus, piercing the intestine of the side of the choledoch; but that canal was, in my opinion, hepatic, for the glandular substance taken as the pancreas was evidently continuous with the right lobe of the liver, and formed, as it were, a middle lobe; its appearance was in other respects the same, except that its colour was rather clearer in consequence of its substance being less thick at that part. The duct discovered in the *pike* certainly exists, as far as my researches go; but that, again, is an hepatic canal, for I have not seen any body distinct from the liver from which it takes its origin, or which could be considered as a pancreas. The same must be said of the *carp*, where Meckel could discover neither a pancreas nor pancreatic duct, in spite of the indications of Weber." Still more recently Stannius has enumerated many fish in which a parenchymatous pancreas may be found; but the description added to his enumeration is so meagre and general that nothing can be verified upon it.

Fig. 70.

B, a section vertical to the surface, showing the flattened spheroidal shape of the acuvuli of epithelium, and the amount of projection of the septa between them. (Magnified 60 diameters.)

Reptilia. — In the reptiles we make a great approach to the structure of the pancreas of higher animals both in general form and structural appearance. It exists in them all, and generally maintains that intimate relation to the end of the stomach and commencement of the intestine which we see so constant in birds and mammalia.

In the *Batrachia*, the pancreas is situated in a proper mesentery or meso-gastrium of its own, extending between the lesser curvatur of the stomach and the duodenum, and, according to Cuvier, is more developed in *terrestrial* batrachians than in *aquatic*, in those that take their nourishment out of the water than in those that hunt and seize it in the water. In the *Frog* (*fig.* 71.) the pancreas is shaped not unlike that of the human subject, but its broad end is in the opposite position; it is about three quarters of an inch long, weighs ·27 of a grain, and is of a yellowish white colour and soft consistence; it is in close apposition with the duodenum all the way along. From near the large end it sends up a process clothing and concealing the gall duct as far as the gall bladder, the neck of which it invests. The whole of the gall duct, till the point of its immergence into the intestine, is thus concealed in the substance of the gland, and it might at first sight be mistaken for the pancreatic duct; but, by carefully nicking it and introducing a fine hair, the hair may be passed up to the liver. The most careful dissection could not reveal a proper duct; probably small ducts from different

Fig. 71.

parts of the gland open into the biliary duct as it passes through. The organ maintains the same relations in the *Toad;* in the *common toad* it is yellow, straight, and elongated. In the *Tritons* it is perceived with difficulty; Cuvier describes it as appearing like a semi-transparent riband sending one bifurcation to the spleen, and another to the duodenum at the point of insertion of the biliary canals. In the *Siren* it resembles in miniature, as far as external appearance goes, the pancreas of the sturgeon, and joins the intestine by many parallel canals considerably in front of the cystic.

In *Ophidian* reptiles, the pancreas varies greatly both in volume and form; sometimes it is elongated, often globular and pyramidal, sometimes divided into two triangular lobes, and this variety of form obtains even in congeneric species; thus, in the *Cæcilia albiventris* it is thick, and pyramidal, and in the *Cæcilia interrupta, lumbricoïdes*, and *dentata*, it is straight, elongated and slightly forked. It is always placed to the right of the commencement of the intestinal canal and head of the stomach. Its substance is red with a tint of yellow, and soft, more rarely firm and consistent, and often divided into distinct lobes. In this respect it does not at all resemble the salivary glands of these animals, but those only of mammifera. Its intimate union with the spleen is very remarkable in the *true serpents*, whilst in the *genus Anguis* and *Cæcilia* the contact and adhesion at this point does not exist.

In the *Saurian* reptilia the pancreas is often applied against the pyloric portion of the stomach and the commencement of the duodenum; or it may be said to have two branches parallel to the stomachal sac, one of which accompanies the biliary canal, and the other adheres to the spleen, and these reuniting terminate at a point more or less approaching the pylorus; it is almost always contiguous to the choledoch canal, which often traverses it before arriving at the intestine. According to Cuvier, its volume is greater in saurians living on vegetable food; and its smallness in those that are carnivorous he believes to be compensated, as in fish, by the agency of the mucous and intestinal secretion of the abundant glandular apparatus with which their alimentary canal is furnished. In the *Lacertidæ*, and *Iguanidæ*, the pancreas is very much developed.

Chelonia. "In many respects," says Cuvier, "the animals of this order are in the same conditions as birds. The jaws are similarly armed, the salivary glands are but little developed, and as the volume and importance of the pancreas in birds has appeared to us to be in inverse ratio to the means of mastication and insalivation, we might antecedently conclude that the chelonia would also possess a considerable pancreas." At the same time he adds, that the superior masticatory power of the horny jaws of the chelonia over the bills of birds, and their taking their prey generally in the water, considerably impairs the closeness of the analogy. In the common *turtle*, the pancreas (*fig.* 72.) firmly adheres to and embraces the spleen; from that point it radiates towards the duodenum, being thick, amassed, and irregularly arborescent above and to the right, and continued in a long and tapering tail to the left: it is closely attached to the duodenum along its whole extent, a distance of about fifteen inches. The duct, nearly as large as in the human subject, passes to the right, and enters obliquely the choledoch duct, as that canal is perforating the thick intestinal wall, in a way very analogous to that already described in the human subject. The gland substance has a very peculiar appearance; it is dense, opaque, nearly white, and along its edges the lobules are scattered in the clear gelatinous-looking cellular tissue in which the gland is embedded, and appear to be quite distinct from each other; but on dissecting them out from this gelatinous bed, they are seen to be attached by little pedicles—in some of gland substance, in some apparently merely of the duct of the lobule and its vessels — to the rest of the gland. It is the most arborescent and ramified pancreas I have seen, next to the *rodents*, but not so flattened, nor spread out so much in one plane. When looked at as an opaque object with a low power (one inch focal distance), the mapping out of the follicles is very prettily seen; but the same circumstance that lends them their

Fig. 72.

s, spleen; *m*, branch of superior mesenteric artery; *c*, gall-bladder.

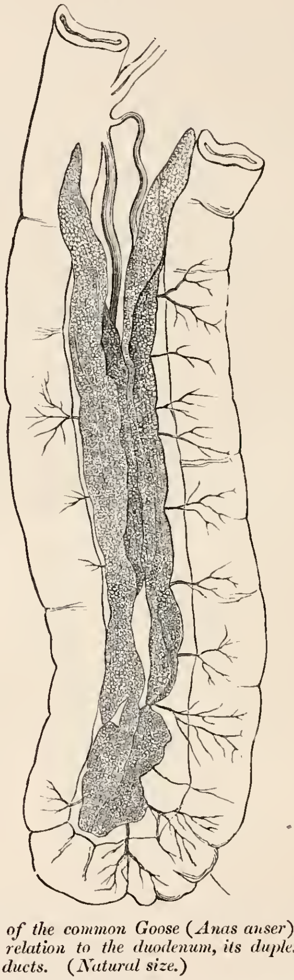
white opacity, — their fulness, that is, of a densely opaque granular material—prevents their being seen to advantage as transparent objects, or with a high power; they are so opaque that nothing of their structure can be distinguished. When ruptured by pressure, their contents escape, and are seen to consist of two very distinct materials; one, the aforesaid fine granular matter; the other of clear, spherical, uninuclear cells of about $\frac{1}{1000}$ of an inch diameter. One would imagine antecedently that these would hold the relation to each other of secreting epithelium and elaborated secretion; but the cells are so clear, so free from granular contents, and there is such a complete absence of any intermediate appearance, that I am at a loss in what way to interpret them.* The duct opens by a single orifice, and in a way admirably adapted for preventing the regress of the secretion, or the entry of the contents of the alimentary canal into it. If the aperture in the centre of the papilla by which the bile duct terminates is opened up, it is found to lead into a lacuna, or *cul-de-sac*, of about half an inch in length, embedded obliquely in the walls of the intestine. At the bottom of this lacuna is a second papilla, the real termination of the pancreatic duct. Now, if the movableness of the external papilla and the smallness of its aperture were not sufficient to prevent the ingress of the contents of the alimentary canal, yet the very force that might drive in some of these contents through the outer papilla, would press the walls of the lacuna firmly against the orifice of the internal one, and so effectually close it; nothing could be more efficient than this form of double orifice.

The duct in all reptilia always enters the duodenum, generally separate, sometimes in conjunction with the choledoch, and is almost always simple.

Aves. The pancreas of birds is proportionally larger than in any other animals; and when we remember their deficiency in salivary apparatus, its great development would at once suggest a function, in some degree, at least, supplementary to those organs. Another circumstance peculiar to birds and indicative of the importance of the part that the gland plays, is that the ducts are generally many, two and three, and that they open by separate orifices, and often at a considerable distance from one another; so that the secretion may be poured forth on different and widely separate portions of the alimentary contents at one and the same time, a circumstance that must greatly increase and expedite its action.

Birds, we know, seize and swallow their food generally without any mastication, and therefore it is not until it gets to the gizzard that it is subjected to any mechanical force capable of breaking it up. This, therefore, takes place immediately before entering the duodenum, and this throws the function of mastication close down to the pancreas, so that from its situation, as well as in other respects, it should have an insalivating function. It is always enclosed between the two arms of the duodenal flexure (*fig.* 73.); the duodenal portion of the gland being, so to speak' alone developed. It is retained in this position by the gastro-hepatic and gastro-colic omenta, which sometimes simply attach it to the border of the intestine, and sometimes allow it to be free and floating. There is considerable variety in its shape, but it is always more or less elongated and slender: sometimes it is undivided and single, in some species deeply cleft, in others consisting of two portions, or a double pancreas, quite distinct, each having its own duct; sometimes it is divided into three as in the pigeon. But

Fig. 73.



Pancreas of the common Goose (Anas anser), showing its relation to the duodenum, its duplex form, and its ducts. (Natural size.)

* The follicles appear to contain only the granular material, and in a minute duct I saw a number of the nucleated cells. It is possible that they may be a form of epithelium restricted to the terminal ducts, by whose rupture and compression they escaped, as the granular matter did from the follicles.

these arrangements are liable to considerable variety, and perfectly independent of the intimate structure and function of the gland, for in different individuals of the same species, the arrangement of the ducts is generally the same, however the segmentation of the gland may vary. The gland substance is firm, much more dense than in other orders, and not divided so distinctly into lobes and lobules: it has a finely granular and mottled appearance, in colour pink, or a little yellowish, or brownish. The pancreas seldom communicates with the intestine in birds by a single canal, the ducts are generally either two or three in number, and each continues independent and separate to its orifice. They do not communicate either with one another or with the biliary canal: although, however, exceptions are very rare, Cuvier has met with an instance in the *stork*, in which the single pancreatic and hepatic ducts united and opened by a common orifice.

The following table, altered from Cuvier, shows the number of the pancreatic ducts in several orders of birds, and their relative situation with regard to the hepatic and cystic ducts; it also shows the relation of these last to one another. That canal which is first indicated has its insertion the nearest to the pylorus; P. stands for *pancreatic*, H. for *hepatic*, and C. for *cystic*.

We see from this table, that, as a rule, the

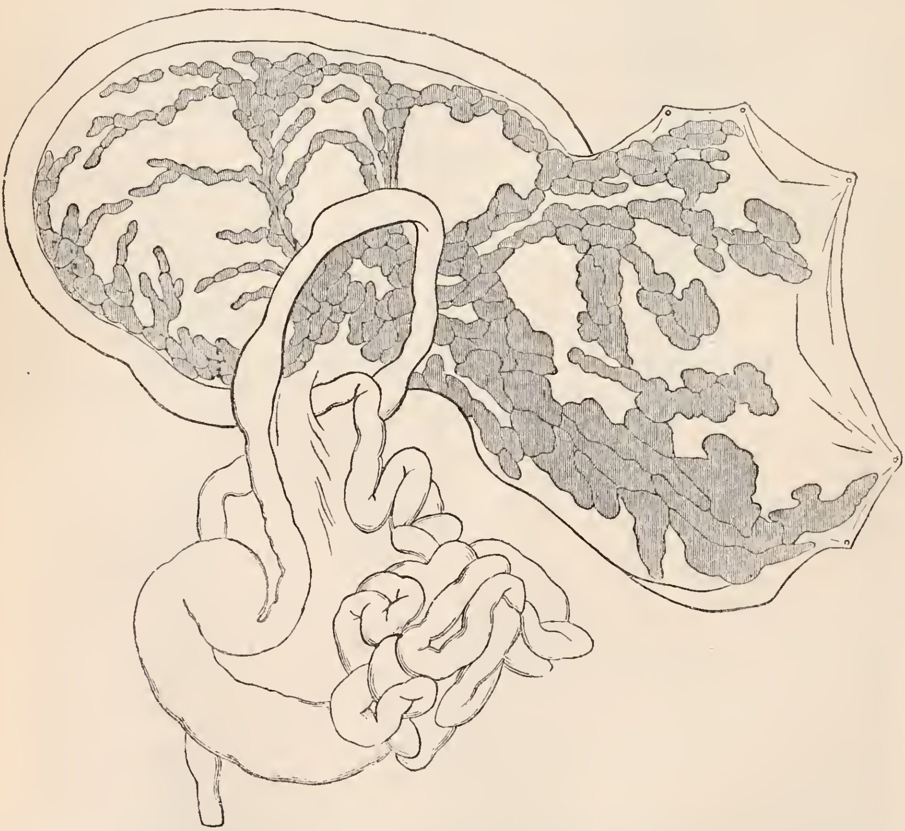
pancreatic secretion is the first poured into the intestines, and the cystic bile the last: and always when there are three pancreatic ducts, the secretion reaches the intestine early by one of them, and the others have their openings close to the bile ducts, either before or between them. It is not safe, however, to draw any physiological conclusions from these relative positions, even supposing them to be constant; for the ducts are so close to one another, that the mixture of the fluids must take place immediately, and their action on the food be simultaneous. In one instance, however, this is not the case; in the ostrich the bile duct opens close to the pylorus, while the pancreatic is three feet removed from it; this is the greatest separation of the two ducts of any with which I am acquainted in the animal kingdom. It would present, if ostriches were commoner birds, great facilities for experiment, and implies an action in both the secretions entirely independent and autocratic.

Mammalia.—The chief differences between the pancreas in other mammalia and man relate merely to its colour, its consistence, its more or less marked division into lobes, its form, its volume, its union into a single mass, or its separation into two distinct parts, lastly, its position and relations with different portions of the peritoneum. Its form is generally more or less that of a narrow band, divisible into two portions; one, the *duodenal*, following the curvature of the duodenum, and placed vertically or obliquely; the other, *gastro-splenic*, extending transversely, and therefore opposite the other, from the duodenum to the spleen, against which it always abuts; the latter is always developed, the former is often inconsiderable or suppressed, and must be considered merely as an accessory portion. The various forms and arrangements of the pancreas do not appear to have anything to do with its essential structure or function, or the particular exigencies of the animal; they seem to depend entirely on the relations of the neighbouring organs, the presence or absence of an abundant mesentery, the free movement of the duodenum, &c., and to be influenced by considerations of package.

In the *Ourang* the form very much resembles that of man; in most other *Quadrumana*

Fig. 74.



Pancreas of the Rat (natural size), shown by throwing up the duodenum, together with its proper mesentery, and the free process of peritoneum extending thence to the left, in which the gland ramifies. Its arborescent form and great extent are well shown.

it is irregular. In the *Carnivora* it is always large in proportion to the size of the animal*, both the duodenal and gastro-splenic portions being highly developed. In the *ox*, from the distinctness of the two portions, the organ has a bilobed appearance. In the *horse*, from the gastro-splenic portion being double, it has a trilobed form. But the most remarkable pancreas is that of the *Rodents;* it is spread out in an arborescent manner, in an extensive mesentery that imparts free movement to the long duodenum, and extends towards the left in a sort of omentum, which underlays the stomach. (*Fig.* 74.) Confined thus between the two layers of a mesentery, the ramified lobes of the pancreas lie all in one plane. Although their distribution is somewhat irregular, they more or less radiate in their general direction from the point at which the duct enters the intestine, which in the *rabbit* is nine inches or a foot from the pylorus. That part of it which occupies the duodenal mesentery must be considered the representative of the duodenal portion, and that spread out in the omentum underlaying and attached to the stomach, as the gastro-splenic. Altogether, this arborescent pancreas of the *Rodents* is very voluminous, particularly in the *rat*, from which the drawing was taken.

The pancreatic duct has in Mammalia generally the same branched character as in man, the greater and lesser branches corresponding to the lobes and lobules; usually there is but one orifice, rarely more, and most commonly it enters the intestine near the pylorus, although sometimes a great way removed from it. In most of the *Carnivora* it is, as a rule, united with the choledoc duct: in some cases it presents at the point of its immergence into the intestinal canal a sort of ampulla, in which the secretions probably mingle before their entry into the intestine. There are, however, considerable varieties of insertion — in the lion two pancreatic ducts join the choledoc separately, one near the other. But whether the ducts enter by a common orifice, or by two neighbouring ones, or whether there are one or two pancreatic ducts, has, probably, no physiological import whatever, as it cannot make any difference whether the secretions are brought into contact just before or just after entering the bowel; and this belief of the non-essential character of these varieties is strengthened, or rather proved, by their occurrence in closely allied species of the same genus, and even in different individuals of the same species. Cuvier says that he has observed, although very rarely, in the domestic cat, a lateral reservoir for the pancreatic secretion, analogous to the gall bladder. Its duct, about the size of the cystic, was an inch and a half long before it united with a trunk formed by the union of two pancreatic ducts, a principal and an accessory, and, together with this, formed a common duct analogous to the ductus communis choledochus. Tiedemann has detected a similar pancreatic reservoir in the common seal. The greatest distance from the pylorus at which the pancreatic duct enters the intestine occurs, I believe, in the *Rodents*. In the rabbit this distance amounts to a foot or upwards; and this arrangement, by giving a considerable length of small intestine whose contents are not acted on by the pancreatic secretion, has afforded special facilities for experiment.

* See the physiological portion of this article, page 104.

III. Physiology.

Anatomy always implies physiology, — structure, function; and the mind passes from the one to the other by a ready and almost irresistible transit. In fact, organisation is but the accumulation, in certain parts, of certain material agents, the sum of whose common action gives as its result the function of the organ, and both the nature of the elements so accumulated, and the method in which they are built up, are determined by, and have sole reference to, the work to be done. Physiology invariably stands to anatomy, even in its ultimate and minutest details, in the relation of final cause. Now, there are certain anatomical conditions that always indicate physiological importance; among these are *volume* and *constancy*, — constancy in existence, and constancy in structure. In all these respects we should be led to infer from the consideration of the anatomy of the pancreas that it possesses essential functions; for it is always of considerable size, has a very wide range of existence, throughout the whole of Vertebrata, from the lowest fish to the highest mammal, and is analogically represented in many Invertebrata; and, lastly, in structure it exhibits with very few exceptions, throughout this wide range, a remarkable sameness.

The opinions entertained by the old anatomists with regard to the office of the pancreas were many and various. The earliest anatomical writers do not seem to have been aware of its existence*; some thought that its object was to underlay the stomach as a cushion or pillow, and to serve for the distribution of vessels; others, that it admitted the chyle from the intestines; others, that it purified the dregs of the chyle; others, that it served for the spleen a purpose analogous to that of the gall bladder for the liver; others, that by it were thrown off the gross and used-up dregs of the blood; others, that the organ was formed for the reception of the excretion of the nerves; others, finally, taught that the pancreatic secretion was not only useful, but played a vital and essential part in the organism. The first opinion, which was of very ancient date, was held by Vesalius†; but it is at once refuted by a reference to those animals, birds and fish, for example, in which the pancreas is frequently remote from the stomach. The second view, that the pancreatic duct admitted the chyle from the intestines, is assigned to Baccius and Folius, who both maintained that it

* Hippocrates nowhere mentions it.

† De Humani Corporis Fabrica, i. 5. cap. 4. De Omento.

served for the transit of the chyle from the intestine to the liver and spleen. Very early investigation, however, showed the fallacy of this view, as it proved that the fluid of which the pancreatic duct was the channel always passed *to* the intestine and never *from* it. The fourth opinion is ascribed to Veslingius, who says, in speaking of the pancreas*, *Usus hujus canalis obscurus non est, nam cum acrem quendam felliqne non dissimilem succum exhibeat, palam est excrementum tale, per coctionem ulteriorem a chylo separatum, allici intra hunc atque in duodenum intestinum expurgari.* This view, which is simply refuted by saying that the secretion obtained from the pancreas does not in any way resemble bile, that it is not "felli non dissimilem," was supported by Asellius, Riolanus, and others. De Graaf accounts for it by supposing that the tube introduced into the duct for the purpose of obtaining the secretion became covered with the bile accumulated about the common orifice of the two ducts, which it might very well do, either on being inserted or withdrawn, and that this, becoming mixed with the pancreatic secretion which it had withdrawn, gave rise to the erroneous opinion that that secretion had a resemblance to bile. The fourth opinion, that the pancreatic duct was the excretory canal of the spleen, which was maintained by Bartholini, is refuted by the simplest anatomical considerations, and was further disproved by De Graaf, who, to show its fallacy, extirpated the spleen of a dog, and, two months after the extirpation, obtained the pancreatic secretion unaltered. The fifth view was based on similar supposed anatomical relations between the pancreatic duct and spleen. It is assigned to Lindanus, and was refuted by the same considerations as the last. The theory that the pancreas carried off the excretion of the nerves was based on the old view that the nerves distilled the animal humours and spirits. All these views are perhaps rather amusing than interesting, and are among the curiosities of science. They show us how much our medical forefathers were disposed to take for granted, and how disposed they were to run alone when the shell was still on their heads. The true doctrine that the pancreas furnished an important secretion of its own was first advocated by François de le Boë Sylvius †, who first insisted on its acidity, and who attached great importance to its pathological conditions. Indeed, he made its derangements the cause of nearly all the ills that flesh is heir to; in the same way that Spigelius did his lobe of the liver. It was in consequence of the interest which the lessons of Silvius excited that De Graaf, his pupil, undertook his admirable researches *De Succo Pancreatico*, and succeeded, in 1662, in first obtaining the pancreatic secretion from the living animal: the most important point was thus ascertained, and the materials supplied for further investigation.

* Syntagma Anatom. cap. 4.

† Thes. 37., De Usu Lienis et glandular.

With the view of obtaining the fluid, De Graaf first put a ligature round the duodenum, including part of the pancreas, but failed in obtaining the desired result, in consequence, as he imagined, of the ligature about the pancreas cutting off the supply of blood from which the secretion was obtained, and so putting a stop to it. He then put a ligature round the duct at the point of its immergence into the intestine, but again failed in getting any secretion, which he attributes to its escape by the small ducts wounded in exposing the larger one. His third attempt consisted in binding together two pieces of wood, compressing the intestine over the point of entrance of the duct so as to close it. This time he was successful: the duct was distended with a clear and limpid fluid, but he could not obtain it in sufficient quantity to subject it to any examination. With the view of obtaining some notable quantity, he instituted a fourth experiment by making a longitudinal incision into the duodenum, and inserting into the orifice of the duct the narrow mouth of a little flask; but again he failed, from the air included in the flask barring the entrance of the secretion. To obviate this, in his fifth experiment he perforated the upper part of the flask with a little hole, and this time he succeeded, in the space of five hours, in getting the flask more than half full. But the secretion obtained was bitter in taste and yellow in colour, and, attributing this to a certain admixture of bile from the uncleansed intestine, he improvised the following ingenious apparatus to obviate that source of fallacy. He took a long-necked flask, with a hole bored in the upper part of its belly, and around the neck of this flask he fastened a cord furnished with rings, by means of which it could be firmly fastened to the intestine; a quill of a wild duck, cut so as to form a little slender tube, was then fixed into the neck of the flask, and made to fit tightly by pasted paper being rolled round it. Into the smaller extremity of this quill tube was fixed a plug made of some soft wood fitting sufficiently tight not to be forced in by the pressure of the soft parts it would come in contact with, but sufficiently easy to be withdrawn by a string fastened to it, and which passed through the quill into the flask and out of the flask through the little hole. The object of the plug was to prevent the intestinal contents from blocking up the quill and so obstructing the flow of the pancreatic secretion. Then ("sublato ejulatu vicinis molesto, duarum laryngis cartilaginum particulas exscindendo," as he says of the poor dog with great simplicity and coolness) the abdominal cavity is laid open, an incision is made into the duodenum, the quill, closed with the little plug, inserted, the flask sewed to the intestine by means of the rings, the parietes sewed up so as to allow the protrusion of the flask, the plug withdrawn by the string, and the flask covered so as to prevent the entry of any foreign matter through the little hole. To obviate the escape of the secretion through a second pancreatic duct, which, he says, he found very common, he closed this second orifice by an ingenious method of compression. With this apparatus he succeeded in getting a free supply of pancreatic fluid, as clear as spring water, but slightly viscid, and varying in taste, from salt to acid, rough, acidulo-saline, or insipid. De Graaf's memoir is well worth reading, and is, considering the time in which it was written, and in spite of the necessary admixture of a good deal of mediæval physiology, a model of sagacious forethought and patient research. He insists strongly on the acidity of the fluid, not only in the dog, but in man, and affirms that he and many others found it to possess an acid taste in a man who had been suddenly killed, and whose body was still warm. But it is necessary to bear in mind his coarse and superficial means of examination, and the bias with which he undertook his researches from his strong attachment to both the physiological and pathological views of Sylvius.

Schuyl*, also a disciple of Sylvius, adopted a process analogous to that of De Graaf, and succeeded in obtaining a quantity of the secretion, amounting to two or three ounces, in three hours; he pretends that what he collected had an acid taste, and affirms, moreover, that it coagulated milk. The researches of Wepfer†, Pechlin‡, Brunner§, and Bohn|| did not confirm the assertions of De Graaf and Schuyl. These observers found the pancreatic secretion turbid, whitish, not acid, but having a taste slightly saline, like that of lymph. Succeeding experimenters agreed no better with regard to the qualities of this liquid. Viridet¶ said that he found it acid in most animals, and pretended that it sensibly reddened litmus. Hauermann**, on the contrary, denied that it had this effect. Fordyce†† found that of the dog to be colourless, watery, and salt in taste, and affirmed it to be composed of water, mucus, soda and phosphorus. Meyer‡‡ has examined the pancreatic juice in a cat, which he found in the vesicular reservoir which is sometimes met with in that animal. It appeared transparent, viscid, and had an alkaline taste; it coloured the mallow dye red, and red litmus paper blue. Meyer says further that he found in it albumen, chlorides of sodium and ammonia, and a peculiar matter giving a violet precipitate, with chloride of tin. Lastly, Magendie found§§ the pancreatic juice in a dog to be yellowish, inodorous, and with a saline taste. He adds that the liquid is alkaline, that it coagulates with heat, and that in birds it is altogether albuminous; at least, that, exposed to heat, it coagulates like albumen.

With such various opinions as to the qualities of the secretion, it is not surprising that the views of its function should have been discrepant, and accordingly we find that many hypotheses, often far-fetched and extravagant, were adopted to explain the part which the pancreatic fluid played in digestion. Some thought that it had for its destination the separation of the chyle from the excrements; others, that it served to temper the acridity of the bile; others, again, thought that it diluted the chyme, or that it dissolved that portion of the food which had not been digested in the stomach; that it contributed to its assimilation, &c. Haller, after exhausting himself with conjectures, can only say, "Plura possunt esse officia liquoris nondum satis noti;" and Magendie, fifty years later, admits that it is impossible to say what the *rôle* of the pancreatic fluid may be.

Such, then, were the opinions expressed, or rather the ignorance confessed on this subject, when in 1823 the Academy of Paris proposed the function of digestion as the subject of a prize dissertation, and two of the essays sent in, which were considered by the Academy worthy of honourable mention — the one by Professors Tiedemann and Gmelin, and the other by MM. Lenret and Lassaigne — threw so much additional light on the subject, and furnished results which so long constituted the staple of our certain knowledge of the function of the pancreas, and so much of which still remains unquestioned, that they deserve special consideration.

Lenret and Lassaigne, thinking that the failures of recent experimenters to get any of the secretion arose from the smallness of the duct in the animals employed, selected the horse, and succeeded in obtaining three ounces in half an hour of a limpid liquid, with a slightly salt taste, alkaline reaction, specific gravity of 1·0026, and containing ·9 per cent. of solid matter. Sulphuric, nitric, and hydrochloric acid slightly troubled it, and alcohol formed a more abundant cloud, precipitated after a time in white flocculi; an aqueous solution of chlorine determined a light flocculent precipitate; infusion of gall-nuts occasioned a yellowish deposit; lastly, nitrate of silver and protonitrate of mercury showed the existence of chlorides, and oxalate of ammonia that of lime. On treating the solid residuum with alcohol and evaporating, it yielded a transparent viscid matter, with a salt and sharp taste, the non-crystallizable portion of which consisted of an azotised substance precipitable by many metallic salts and solution of gall-nuts. That portion of the residuum of the pancreatic juice which had been exhausted by the alcohol was then heated with distilled water, when this latter showed on evaporation a certain viscosity, indicating the solution of an animal principle in it. The result of the entire qualitative analyses, the further details of which I need not give, was as follows: —

"Not content," say these observers, "with this first experiment, we undertook a second with the same success*, and the results furnished by analyses were absolutely the same: from which we infer that the pancreatic juice possesses a perfect analogy with the saliva both of man and the horse, these two liquids containing absolutely the same fixed principles, nitrogenous and saline, and almost exactly the same quantity of water.† The attempts of these authors to obtain the pancreatic secretion of a dog, after the manner of De Graaf, were all unsuccessful; ten times they tried, and as often failed; a few drops were all they could procure. Their data, therefore, are all taken from the secretion as they found it in the horse.

Tiedemann and Gmelin ‡ obtained the pancreatic fluid from the dog, the sheep, and the horse—that is, from one carnivorous and two herbivorous animals; and their results present the most striking discrepancies with those of the contemporaneous experiments of Lenret and Lassaigne. In the dog this fluid, which was obtained abundantly, was limpid, with a faint blueish, opalescent cast, and a mucilaginous feeling like the white of egg diluted with water, a slight but sensibly saline taste, the first portion faintly *acid*, the portion last secreted slightly alkaline, and so abundantly albuminous as to be rendered semi-solid by heat nitric acid, &c. A hundred parts of the secretion contained —

‡ Recherches Expérimentales Physiologiques et Chimiques sur la Digestion. Jourdan's translation, p. 24. et seq.

The secretion of the sheep was acid, and, like the other, ropy between the fingers like white of egg, and limpid; it was perfectly solidified by heat, and contained —

Solids (desiccated)	5·19
Water - -	94·81
	100·00

Of these solids nearly 60 per cent. were albumen. The secretion in the horse resembled in all its reactions that of the sheep, except that the albumen was not so abundant.

The summary conclusions at which these authors arrive, are that the pancreatic fluid contains —

1. In solids, in the dog 8·72, in the sheep 5 per cent.
2. The solids consist of —
   a. A large amount of albumen, about half of the dry residuum.
   b. Osmazome.
   c. A substance reddened by chlorine, found only in the dog.
   d. A caseous substance, probably allied to salivary matter.
   e. A small amount of free acid, probably acetic, present in all these specimens. It is worthy of remark, that that portion of the pancreatic fluid which was secreted last was slightly alkaline: this change probably depended on the enfeeblement of the nervous influence resulting from the operation.
   f. The ash consisted of alkaline carbonate, chloride, phosphate, and sulphate, and carbonate and phosphate of lime.
   g. The alkaline sulpho-cyanide is not met with in the pancreatic secretion.
   h. The alkali consists of a *large quantity of potash*, and a very *small portion of soda* salts.

If we compare the composition of the pancreatic secretion in the dog and the sheep with that of the saliva, we find the following differences:—

1. The solid residue of the saliva does not equal half that of the pancreas.
2. The saliva contains mucus and a peculiar animal (*salivary*) matter. If it contains albuminous or caseous matter, these subtances are, in every case, in very small quantity. On the contrary, the pancreatic fluid contains an abundance of albumen and caseous matter, but not a trace of mucus, and true salivary matter, if it exists, is in very small quantity.
3. The saliva is neutral, or contains a little alkaline carbonate. The pancreatic secretion contains a little free acid.
4. The saliva contains sulpho-cyanide of potassium; in the pancreatic fluid there is none.
5. The other salts are nearly the same.
6. It results, therefore, that those physiologists who think the pancreatic secretion identical with saliva are in error.

There is, then, an entire discrepancy between these two authorities with regard to the pancreatic secretion—its physical qualities, reaction, amount of solids, chemical constitution, the conclusions they infer, &c.

Very lately this subject has been taken up by several able physiologists, and Bernard*, Frerichs †, and Bidder and Schmidt ‡, have given to the world the results of careful and elaborate researches both into the physical and chemical characters of the fluid and its physiological action. I shall describe first the observations of these inquirers on the qualities of the secretion, and, afterwards and separately, their views of its physiological office. It is very remarkable, that the differences in the accounts given by these recent investigators are very closely analogous to those existing between the results of the researches above described. They all agree, however, as to the invariable alkalinity of the secretion, the absence of sulpho-cyanides, the existence of a specific nitrogenous principle, and, in general, to its possession of strong differential characters when compared with saliva.

According to Bernard, the pancreatic secretion obtained artificially during the life of the animal is of two very distinct kinds, which he characterizes as *normal* and *morbid;* the former obtained when the experiment is made under favourable circumstances, before inflammation has attacked the pancreas, or which is collected from a dog possessing a permanent pancreatic fistula; the latter always secreted in great abundance when the symptoms of inflammatory reaction appear in the pancreas and in the wound in the abdomen.

The *normal* secretion, which, adopting Bernard's view, is of course *the* secretion, he describes as a colourless, limpid, viscid, ropy fluid, without any characteristic odour, and having a saline taste very like that of the serum of the blood. It is constantly alkaline. Exposed to heat, it is converted into a solid white mass; the coagulation is as entire and complete as that of white of egg, the whole becomes solid, not a drop of free liquid remaining. The other reagents of albumen equally precipitate it. The alkalies produce no precipitate, and redissolve the organic matter when it has been previously coagulated by heat, alcohol, or the mineral acids. But, although exhibiting the same reactions, Bernard believes that this nitrogenous principle is essentially distinct from albumen, not only in a physiological point of view, but in its inherent nature; and, as a proof of this, he cites the fact, that when it has been coagulated by alcohol and dried, it is easily and entirely redissolved in water, whilst albumen, similarly treated, is not dissolved to any appreciable extent. § These characteristics of the fluid, which are given from the dog, Bernard says obtain equally in rabbits, horses, and birds. The *morbid* pancreatic fluid, which is alone thrown out when the experiment is tardily or roughly performed, and which always succeeds to the other when the experiment is happy, is watery, without any viscosity, has a saline and nauseous taste, is of very low specific gravity, and gives hardly any precipitate on the application of heat, nitric acid, &c. It is poured out very abundantly: Bernard collected from a dog more than half an ounce in an hour, whereas of the normal he found 31 grains a maximum. The normal is not transformed into the morbid secretion suddenly, but gradually, losing, as it becomes more and more watery, its physiological properties, of which at last it is quite destitute. This observation of Bernard's is very important, as showing the facility and extent to which the fluid may be changed, and doubtless it goes some way to explain the discrepancies of the accounts which different observers have rendered, but it is not entirely sufficient for this, as, in some hands, a watery fluid with but little albuminous matter and of very low specific gravity seems to have been obtained at once, even under circumstances the most favourable.

Frerichs, who has made a most complete analysis of this fluid *, and with whose account Lehmann † agrees, describes it as colourless, clear, very slightly tenacious, without taste or smell, of alkaline reaction and a specific gravity as low as 1·008 to 1·009; heat, alcohol, and acid, produce but a slight turbidity; of solid constituents he found it contain but 1·36 per cent. in the ass, and 1·62 in the dog.

Schmidt's account is something intermediate between the other two; he describes the fluid as ropy and viscid, and as being coagulated by heat into a milky mass, from which white flocculi subside, leaving above a clear, strongly alkaline fluid. He agrees with Bernard in the solubility by water of the precipitated and dried albuminous matter; he states the specific gravity of the fluid at 1·031, and the quantity of solid constituents at 9·924 per cent.; in one case the amount of solids reached 11·56 per cent.

The following are the quantitative analyses of Frerichs and Schmidt:—

§ Bernard believes this to be the active matter of the secretion, as it imparts to the water the peculiar viscosity and physiological properties of the pancreatic fluid.

* Op. cit. p. 842—849.

† Physiol. Chem. (translated by Day), p. 112. et seq.

The exact nature of Frerichs' *water extract* — Schmidt's *organic matter* — is not determined; it is *a substance resembling albumen or casein*, but not identical with albuminate of soda, with casein, or with ptyalin. It coagulates only imperfectly when heated (probably from its containing an alkali), is precipitated by acetic acid, but slowly redissolved in an excess, especially if heated; it is precipitated by nitric acid and by alcohol; on the addition of chlorine-water it separates in grayish flakes. It is to this substance that the pancreatic fluid owes its principal chemical and physiological properties.

Bernard found a considerable quantity, and Frerichs a smaller amount (·026 per cent) of a *butter-like fat*.

The pancreatic secretion is peculiarly prone to putrefactive change. Bernard found that when exposed to a low temperature, it might be kept for many days, and that by the reduction of the temperature the viscidity was increased, approaching a jelly-like firmness. If, on the other hand, it was kept at a temperature of 40° to 45° centigrade (about 105° Fahr.), it became rapidly modified, and in the lapse of a few hours quite altered, giving out a nauseous odour, presenting a cloudy deposit, and losing its property of coagulation by heat. In the heat of summer and in stormy weather, this change takes place almost instantaneously, so that great care is necessary in maintaining at a low temperature both the pancreatic fluid and the animal furnishing it, lest the alteration should take place whilst it is still in the vessel in which it is being collected. Frerichs found that after exposure to the air for a few hours it developed a distinct odour of putrefaction. Bernard observed that the deposit that was produced at the moment of the alteration of the fluid, had sometimes a peculiar soft, silky appearance, and he always found in that case, on examining it by the microscope, a large quantity of acicular crystals, having the characters of crystals of margarine or margaric acid.

The secretion is not constant, but intermittent, and is entirely regulated by the process and stages of digestion; all observers agree in this. Bernard killed three dogs in three different conditions with regard to the function of digestion — one just after a meal, as digestion was just commencing; another four hours after a meal, when digestion was at its height; and a third after a twenty-four hours' fast. In the first, the tissue of the pancreas was slightly turgid with blood, and the secretion the most abundant, and this he has always found to be the case; he collected upwards of two grammes an hour; in the second, the pancreas was highly turgid — "*gonflé de sang, et comme erectile*," and the amount secreted less than a gramme an hour; in the third it was white, exsanguine, the duct empty and collapsed, and the amount secreted in many hours hardly enough to moisten the inside of the little reservoir adapted for its reception.

The information respecting the absolute quantitative relations of the secretion is very defective. We have seen that Lenret and Lassaigne obtained three ounces from the horse in half an hour, and Bernard from the dog thirty-one grains an hour; Frerichs collected three hundred and eighty grains from an ass in three quarters of an hour, and forty-five from a hound in twenty-five minutes; but these statements, as well as those of Colin *, become valueless from the fact that the animals experimented on were not weighed. The most reliable estimate is that of Bidder and Schmidt; they say a dog yields a grain and a half per hour for every two lbs. of weight; therefore an adult man weighing about 140 lbs., would secrete in twenty-four hours nearly five ounces of pancreatic juice, containing 225 grains of solid residue. But it is doubtful whether any safe data as to quantity are furnished, or can be furnished, by any experiments made by measuring the amount procured artificially from the living animal; the abnormal condition of the gland produced by the experiment must be such, and the consequent disturbance of the secretion so great, as to throw doubt on the most careful and exact estimates. The case in which the quantity seems most likely to be normal is that in which the secretion is obtained, as in some of Bernard's experiments, from a permanent fistulous opening. All observers confirm Bernard's statement as to the exsanguine and passive condition of the gland in animals fasting.

The natural stimulus of the secretion is, no doubt, the digestive process going on in neighbouring organs, producing, through the medium of the sympathetic nervous connections, a vascular engorgement of the pancreas and an exalted nutrition of its secreting agents. Possibly the pressure from a distended stomach may have something to do with it; and there is reason to think that the presence of food in the duodenum is both a stimulus to the secretion and to its discharge; for on the application of chemical and mechanical stimuli to the inner surface of the duodenum near the orifice of the duct, the amount discharged is sensibly increased. Possibly food of one nature in the duodenum may be a more exciting stimulus to the secretion than another. Whether this is so, whether the amount secreted would be excited more by an animal than a vegetable food, whether it bears the same relation to the volume of the gland in Carnivora and Herbivora, or whether the volume of the gland is always a direct measure of the amount secreted, are questions upon which, as yet, our information is very defective. They are, however, not unimportant questions; for there is every reason to believe that the quantity secreted is always in proportion to the exigencies of the digestive process, and their solution might therefore throw some light upon the function of the secretion. There can be no doubt that muscular movement and pressure facilitate the *discharge* of the fluid, as most observers, from De Graaf

* Comptes Rendus, vol. xxxi. p. 374, and vol. xxxii. p. 85.

downwards, have remarked that the act of inspiration, and violent respiratory or struggling efforts, always increase the rapidity of its flow.

The following is a tabular view of the statements of different observers of the principal characters of the pancreatic secretion :

	Tiedemann and Gmelin.	Leuret and Lassaigne.	Bernard.	Frerichs.	Bidder and Schmidt.
General Physical Qualities.	Limpid with a blue-white cast, like white of egg diluted with water, slight, but sensibly saline taste.	Limpid with a slightly salt taste.	Colourless, limpid, viscous and stringy; odourless; taste saline.	Colourless, clear, *slightly* tenacious, without taste, or smell.	Clear, colourless, viscid and ropy.
Reaction.	Dog { at first slightly acid, after slightly alkaline. Sheep, slightly acid Horse, ditto.	Alkaline.	Always alkaline.	Alkaline.	Strongly alkaline.
Specific Gravity.		1·0026		1·008 to 1·009	1·031
Amount secreted.	At the rate of one ounce per hour in the dog.	Three ounces in half an hour—*horse*.	*Normal* 31 grains an hour. *Morbid*. 279 ditto.	380 grains in ¾ of an hour—*ass*. 45 ditto in 25 min. —*dog*.	1½ grain every hour for every 2 lbs. weight.—*dog*.
Quality of Solids.	Dog, 8·72 per cent. Sheep, 5·19 ,, ,,	·9 per cent.		Ass . . 1·36 Dog . 1·62	9·924 per cent.
Amount of Albumen, &c.	Rendered semi-solid by some of the reagents of albumen —*dog*. Perfectly solid by heat —*sheep*. Abundant consistent flocculi on heat —*horse*.	*Slightly troubled* by the reagents of albumen. Azotised principles soluble in alcohol and water. *Absolutely the same as saliva*.	Entirely solid by heat, as white of egg: also the strong mineral acids and alcohol. The dried precipitate may be re-dissolved in water. No sulphocyanides.	*Inconsiderable* coagulation on heating. *Slightly* turbid on adding alcohol and nitric acid. Butter-like fat 0·026 No sulphocyanides.	Alcohol coagulates it into a miky mass, which deposits thick white flakes, leaving above a strongly alkaline solution. The dried flakes dissolve in water.

Function of the pancreatic fluid.—The first indication of the importance of the pancreatic juice to the process of digestion has been assigned to Valentin. He showed that it converted into sugar that portion of the amylaceous matter that had not been acted on by the saliva and had passed unchanged into the duodenum ; and he ascertained that both the expressed secretion and an infusion of the gland-substance exercised this transforming property in a high degree. Bouchardat and Sandras found that the pancreatic secretion of fowls and geese possessed this property, and immediately transformed starch into dextrine and grape sugar. On raising the fluid to 100° (centigrade) it became inert ; but the flocculi precipitated, either by heat or alcohol, on being redissolved exerted an influence exactly the same as the original secretion, and with the same power. In this albuminous substance they recognise the material of which, under the name of *diastase*, they had indicated the existence in the alimentary canal of granivorous birds. They profess themselves unable to define the action of this substance compared with that of diastase. Like diastase it is nitrogenous; and they regard it as the principal agent in the digestion of feculent aliments. They found, moreover, that a fluid of similar properties might be obtained by macerating for a short time portions of the pancreas, finely minced, in an equal weight of water. The fluid thus prepared converted a thick starch jelly into a thin fluid, without any viscosity, in the lapse of a few minutes. By many alternate precipitations with alcohol and solutions in water, as in the operation for the purification of diastase, a flocculent precipitate was obtained, which, rapidly dried, possessed a very energetic solvent power. The existence of a principle acting like diastase on fecula was equally demonstrated in the rabbit, the dog, and man.*

Within the last few years an additional and most important office has been claimed for the pancreas by M. Bernard†—that, namely, of emulsifying or saponifying the neutral fatty matters contained in the food, by decomposing them into glycerine and their respective fatty acids, and so rendering them absorbable. M. Bernard bases his views on two methods of proof — on experiments on the living animal, and on the secretion after its removal ; and his whole paper is characterised by an admirable completeness and most orderly logic. The first series of experiments consists in the admixture of various fatty matters — olive oil, butter, tallow, lard — with fresh pancreatic juice, alkaline, viscid, and possessing all the characters of the *normal* secretion ; a temperature about that of the body is applied, if necessary, and the mixture agitated. In every case a smooth, creamy emulsion is at once produced. In keeping the products of these experiments at a temperature above 100° Fahr. for fifteen or eighteen hours, he says the emulsion was perfectly maintained ; the appearance of the white creamy liquid was quite unchanged, nor was there, although kept in perfect re-

* Compt. Rend. t. 20. p. 1085.

† Archives Gén. de Médecine, iv. serie, t. 19.

pose, any separation between the pancreatic fluid and the fatty matters. After the lapse of some hours it became evident that the fat had not only been minutely subdivided and emulsified, but that it had, furthermore, been chemically modified. In fact the neutral fatty matter and the alkaline pancreatic juice, constituting at the moment of mixture a white liquid with an alkaline reaction, had, five or six hours afterwards, acquired a reaction distinctly acid. In examining what had taken place, it was easy to show, by the ordinary means, that the fatty matter had been decomposed into glycerine and a fatty acid. In the test-tube in which the butter had been subjected to the action of the pancreatic fluid, the butyric acid was easily recognised, even at a distance, by its characteristic odour. Bernard then goes on to prove, by the method of elimination, the unicity and propriety of this property of the pancreatic secretion, by showing that no other fluid in the body — bile, saliva, gastric juice, serum, the cephalorachidian fluid — is capable of exciting it: all these fluids mixed with the various fatty matters failed in producing an analogous effect in any degree.

This instantaneous emulsion, however, of neutral fatty matters, and their separation into glycerine and a fatty acid, is only effected by *normal* pancreatic juice; that is to say, a pancreatic juice, alkaline, viscid, and coagulating in a mass by heat or the strong acids. If, on the other hand, the oil is mixed with a *morbid* or *altered* specimen of the secretion — that is, watery, without viscosity, and not coagulating by heat,—its action on the fatty matters is nil, and a speedy separation takes place between the inert pancreatic fluid and the unmodified fatty matter.

Taking as a postulate the admitted fact, that it is the white, opaque, milky chyle alone that contains fatty matter, Bernard then proceeds to show by experiments on the living animal, that fatty matter thus modified alone finds its way into the lacteals, is alone absorbable, and that it is the pancreatic juice only that is capable of effecting this change. In all dogs killed in mid-digestion of fatty aliments, the fat was merely *fluidified* by the heat of the stomach, retained all its characters, and, on the application of cold, congealed on the surface of the gastric juice like the fat on broth. In the intestine, on the contrary, below the openings of the pancreatic duct, the fat could not be distinguished by these characters, but formed a pultaceous, creamy, emulsive material; and the lacteals were gorged with a white, homogeneous, milky chyle. But when the pancreatic ducts were tied, the fat remained unaltered in the intestine, and the lacteals contained nothing but a limpid chyle free from all fatty material, which had ceased to be absorbed in consequence of the abstraction of the pancreatic secretion.

Furthermore, in the rabbit (in which, by an arrangement altogether exceptional, the pancreatic duct opens into the intestine at a distance of 10 or 12 inches from the pylorus), another proof of the same fact may be obtained without any ligature or mutilation. If a rabbit be crammed with lard, and the intestines examined in mid-digestion, the fat contained in the small intestine above the opening of the duct will be found unchanged, while that immediately below and downward has undergone the emulsifying process. The lacteals, also, above that point are filled with a limpid chyle, while those arising immediately below are conspicuous for their milky, opaque contents. It is impossible, as Bernard says, to find, in the whole range of experimental physiology, a more elegant and simple method of proof.

The tardiness of physiologists in the discovery of this function may be explained, Bernard thinks, by their minds being preoccupied with the false notion that the pancreatic secretion was analogous to the saliva; and the assignation of this function to the bile by Sir Benjamin Brodie, he accounts for thus. Brodie performed his experiments on cats, and found that, after ligature of the choledoch duct, the lacteals contained no fat, and that the chyle was limpid and transparent. Shortly after, Magendie, with the view of verifying these experiments, repeated them on dogs, but found that the absorption of the fat and the whiteness of the chyle were in no way interfered with by the ligature of the gall-duct. Now in cats the pancreatic duct joins the choledoch before it enters the intestine; so that it is conceivable that Sir Benj. Brodie, having only in view the action of the bile, and attaching no importance to the pancreatic canal, had tied the one with the other: and thus the absence of fatty matter in the chyle may be explained. But in dogs the choledoch is completely separate from the two pancreatic ducts, so that after its ligature the flow of the pancreatic juice remains perfectly free, the fat continues to be emulsified, and the chyle to possess its characteristic whiteness. These experiments, therefore, are entirely in accord, and the difference of their results is strictly assignable to the different disposition of the ducts in the animals on which they were respectively performed.

Some little time ago, while engaged with Dr. Todd in some investigations upon this subject, I tied the gall-duct in some score of dogs, and invariably found that its ligature in no way interfered with the absorption of the fat and the perfect elaboration of the chyle. As long as the supply of the pancreatic secretion was not interfered with, the emulsifying of the fat was complete, and its absorption entire. I also repeated Bernard's experiments on rabbits, and obtained results in perfect accord with his views. I injected melted lard into the stomach, then gave them a meal of green food, and killed them in three or four hours. The point of immergence of the pancreatic duct was most distinctly that of the commencement of the opacity of the chyle: the lacteals above were filled with a fluid clear and limpid.

But these views, so neat and complete in themselves, and so nicely put forth by Bernard, have of late been vigorously assailed by the German school, and their fidelity and conclusiveness altogether impugned. Frerichs, and Bidder and Schmidt, have, by a repetition of Bernard's experiments, as well as by many ingenious and well-devised ones of their own, failed to verify any of his results, but have been led by them to conclusions with which they are altogether discrepant. These experimenters state that they carefully followed all Bernard's directions — they tied the pancreatic duct, and, having previously kept the animals on short food from twelve to twenty-four hours so that there might be no remains of the secretion in the intestine, fed them with fatty aliment, and killed them in from four to eight hours. They always found the lacteals "most beautifully injected, and the receptaculum chyli distended with milky chyle."

Frerichs found on tying the small intestine some distance below the opening of the pancreatic and bile ducts in cats and puppies, and injecting into the bowel below the ligature olive oil and milk, that after two or three hours the lacteals were filled with white chyle. He, however, believes that he has found the extreme comminution of fat, and hence in some measure its resorption, promoted by the bile and pancreatic juice; for when in cats that had long fasted, he cut through the small intestine near the middle, injected olive oil into both halves, and tied the two cut extremities, he found the lacteals springing from the upper part of the intestine always far more injected than those proceeding from the lower, which he attributes to the bile and pancreatic juice having access to the fat in the upper portion.

With regard to the permanence of the emulsion produced by the mixture of pancreatic juice and fat out of the body, Frerichs and Bernard are quite at issue; for while Bernard states, that on being examined fifteen or eighteen hours afterwards, it was found to be perfectly maintained, Frerichs affirms that the particles of oil soon separate again on the surface.

There certainly are some circumstances which detract from the conclusiveness of Bernard's experiments: one is, that the chyle contains far less fatty acids than the ordinary neutral fats; another, that other animal fluids, as soon as they begin to putrefy, cause a similar decomposition of the neutral fats; another, that Bernard's experiments merely had reference to the production of this change *out of the body*. This last deficiency has been filled up by Lenz.* He fed healthy cats with fresh butter, or, if necessary, injected it into their stomachs, and killed them in from six to fourteen hours afterwards. Although all the lacteals and the thoracic duct were distended with milky chyle, no trace of butyric acid could be detected in the stomach and intestinal canal, or in the thoracic duct, the portal vein, or gall-bladder. By further experimental investigation, he found that the metamorphic action was hindered by the acid gastric juice in proportion to the amount of free acid present, that a similar action might be artificially induced by other acids, as diluted lactic, tartaric, and acetic acid, and that it might be overcome by neutralising the free acid by bile, or by an alkali. Hence he concluded, that it is only in exceptional cases that the pancreatic fluid decomposes the neutral fats into acids and bases in the living body.

The argument derived from the experiment on rabbits has been thus explained away by Bidder and Schmidt. They say that if the rabbit is killed two hours after the fat has been given it the lacteals given off *between the pylorus and the mouth of the pancreatic duct*, are fully distended with white chyle very rich in fat; if not till four hours after the injection, the lacteals situated about three or four inches above the mouth of the duct are still filled; if at six hours, those only below the duct contain white chyle; and if not till eight or ten hours after, the first lacteals well injected with milky chyle are found to be situated ten or twelve inches below the duct. Hence it must have been by always killing the animals six or eight hours after feeding them with fat, that Bernard was able apparently to maintain his view. The facts of the case, say they, were simply these. The chyle had already passed onwards from the lymphatics proceeding from the first portion of the duodenum, and there was no more fat to be absorbed in that portion of the intestine when Bernard began the investigation. I cannot admit the correctness of this explanation given by Schmidt and Bidder, because some of the rabbits on which I repeated Bernard's experiments and verified his results were killed within four, or even three hours after the injection of the lard.

It was formally maintained by MM. Bernard and Barreswill, that the pancreatic juice when acidified had an equally solvent power on the precipitated protein compounds with the gastric juice, and that its acidity or alkalinity alone determined whether it should act on albuminous or amylaceous matters. This opinion has also been refuted by Frerichs.

Lastly, this physiologist ascribes to the pancreatic fluid a peculiar power of hastening the conversion of the bile into insoluble products, and so favouring its more perfect elimination. This view has been completely overthrown by the experiments of Bidder and Schmidt, who have shown, first, that the greater part of the bile is not thrown off with the fæces, as Frerichs believes; and, secondly, that the lime, to which Frerichs especially ascribes this power, only exists in very subordinate quantity in the pancreatic fluid.*

In taking a review of all that has been done with regard to the functions of the pancreatic secretion, we must admit that the only one that has been established beyond dispute is its sugar-making action on amylaceous matters.

* De Adipis Concoctione et Absorptione. Inaug. Diss. Dorp. Liv. 1850.

* British and Foreign Med. Chir. Review. On the "Chemistry of Digestion," by Dr. Day.

The whole subject is singularly full of contradictions and discrepancies, and it must be confessed is also singularly full of sources of fallacy. If Bernard's description of two kinds of pancreatic fluid, normal and morbid, be correct, it may go a great way to explain why those who, like Frerichs, have experimented with a watery fluid, poor in albumen, have failed to verify his results, and therefore it will vitiate their objections. It is almost impossible to help seeing something like a national bias in the adoption of one or the other set of opinions; for while Lehmann follows Frerichs and Schmidt and Bidder, the French physiologists as implicitly adopt the views of Bernard, and confirm his results. Even the action on starch, though *a* function of the secretion, can hardly be said to be *the* function; for the relative size of the gland is greater in carnivorous than in herbivorous animals (the weight being $\frac{1}{300}$th of that of the whole body in dogs and cats, and only $\frac{1}{600}$th in that of rabbits*), and further, as Bidder and Schmidt have shown, the greater part of the amylaceous food of the sheep is converted into sugar before it enters the duodenum. With such patent facts as these, and with objections to Bernard's views so many and so grave, I feel disposed to adopt the words of the learned translator of Lehmann, and say, that "we may fairly conclude that the *principal* uses of this secretion are still unknown."

V. Morbid Anatomy.

The interest that attaches to the deranged anatomy of the pancreas is the interest of obscurity — the interest of diagnosis; I may add, too, the interest of situation; in fact, it is from the situation of the organ that the importance and obscurity of its pathological relations at once result. Close to the stomach, duodenum, liver, spleen, kidney, aorta, cava, mesenteric glands, and cœliac axis, it finds itself in immediate relation with the great vascular, nervous, digestive and absorbent centres of the abdomen, and may either affect them secondarily, be affected by them, or furnish a source of fallacy and doubt as to whether it be it, or they, or both that are implicated: and while it is thus placed at the most important point in the whole range of *medical* anatomy, its situation almost completely precludes it from the advantages of physical diagnosis.

The pancreas enjoys an immunity from disease greater than most organs, but I believe this immunity is in part real and in part only apparent; for it cannot be doubted that one reason why the records of its morbid anatomy are so scanty, is that in so large a number of post-mortems, no examination of the organ is made at all. It is the last to be got at, and the cause of death having been ascertained, its examination is looked upon as supererogatory; besides, it is often obscured and mutilated in the removal of other organs, and its careful dissection from its situation, which is necessary to examine it satisfactorily, is troublesome and not very easy.

Its simplest morbid conditions, and most common, are those of —

a. Quantitatively perverted nutrition — hypertrophy and *atrophy*, *induration* and *softening;* and the commonest of all is,

Hypertrophy. — It is difficult to say precisely at what point hypertrophy of the pancreas commences, because the limits within which the size of the gland may normally vary are so extensive that a considerable excess of volume is evidently quite consistent with anatomical and functional health. Generally, the hypertrophy is not pure, but is associated with some induration; and in the majority of cases both the induration and hypertrophy appear to result from chronic inflammation, giving rise to some increase in the proper gland structure, but more to an effusion of lymph between the lobes and lobules by the partial organisation of which a great increase in the amount of the interlobular tissue is produced. This gives rise to an appearance of intersection by opaque membranous septa, giving the gland a scirrhoid character; and hence, by some this morbid alteration has been considered as the first step towards scirrhous degeneration, and by others as actual scirrhus. Whenever the colour of an enlarged pancreas is deeper and redder than natural it may be inferred that the hypertrophy is due to this chronic inflammatory action. Sometimes the enlargement is slight, sometimes it is very great. Dr. Fearnside* mentions a case in which the gland was four times its natural size, and could be felt as a large tumour during life, although the emaciation was not extreme. The results of the hypertrophy are very various; sometimes it gives rise to jaundice by pressure upon the gall-ducts; to dilatation of the stomach, dyspepsia, &c., by pressure on the duodenum and pylorus; to occlusion, even, of its own ducts†, and to many disturbances, functional and organic, of neighbouring parts, produced by its altered volume and relations.

Atrophy of the pancreas, mere diminution of volume unaccompanied by any other change, is sometimes idiopathic, but much more frequently caused by neighbouring disease, as for example, the pressure of some tumour. Morgagni found the pancreas atrophied from the pressure of a tumour in the liver. Dr. Hall found the same condition caused by a

* It is a singular thing that the very reverse of this fact, the assertion, namely, that the pancreas was larger in herbivora than carnivora, was advanced by Valentin in support of his views of the metamorphic action of the pancreatic fluid on starch. I had myself made some extensive tables of the absolute and relative size of the pancreas in carnivorous and herbivorous animals, and carnivorous and granivorous birds, those of a mixed diet, and in reptiles, also in young and old of the same species, but they are unfortunately lost; all I can say from recollection is, that in conformity with the statement in the text, I found the gland largest in carnivora, smallest in vegetable feeders, and intermediate in those of a mixed diet; its relative size was also inversely as the age, though apparently in no regular ratio.

* Medical Gazette, vol. xlvi.

† Copland's Med. Dict., art. Pancreas.

scirrhous tumour in the mesentery. M. Guerin observed this lesion produced by a similar cause. M. Berjaud by aneurism of the aorta; and M. Mondiere by scirrhous pylorus. In some cases it seems to be produced by arrest of its function, as when scirrhous disease of the pylorus has put a stop to the passage of food into the duodenum. Dr. Wolf mentions a case in which the atrophy seems to have been produced by the ossification of the pancreatic arteries and obstruction of the duct. I do not know if there are any symptoms by which idiopathic atrophy declares itself during life, and in those cases in which it is secondary, the symptoms are those of the primary disease and not those of the pancreatic affection. The degree of wasting is sometimes very great; Cruveilhier met with a case in which it did not exceed an ounce in weight.

Induration. — Sometimes the pancreas is found of a firmer consistence than natural, without any perceptible alteration in structure. It has been alleged that in these cases it is the secreting structure that is affected, the areolar tissue not being implicated in the induration, which imparts to the gland a more nodular or granular appearance and feeling. But whether this is so, I cannot say, as I have never submitted an indurated pancreas to microscopical examination. It is said to be not uncommon for induration of this kind to disappear, as happened in a case recorded by Mr. Lawrence, soon after exposure to the air.

Softening has been found to occur chiefly in persons suffering from scrofulous affections. Portal relates that he found the gland remarkably softened without any other change, in two children who died of measels. In confluent small-pox and malignant scarlet fever softening of the pancreas has occurred. Dr. Copland states that he has found it softened in cases of malignant remittent fever and scurvy, but only in conjunction with softening of other organs, as the spleen, &c.

b. Inflammation. — The number of cases in which post-mortem appearances of *acute* inflammation of the pancreas have been recorded is certainly very small. When it does occur the appearances are said to be great injection of the whole gland, imparting to it a brown-red colour and an unnatural softness and friability. In a case recorded by Mr. Lawrence, this brown-red colour presented a strong contrast with the pale anæmiated condition of the other parts. When the inflammation does not end in resolution, it may give rise to the *effusion of plastic lymph* on the surface, producing a general or partial false capsule, or to the *formation of pus* in its substance—pancreatic abscess. It is also *said* to end sometimes in *gangrene.*

In consequence of the effusion and subsequent organisation of coagulable lymph upon the surface of the pancreas it has occasionally been covered by a false membrane of great consistence. By the extension of the adhesive inflammation to some of the neighbouring organs, as the stomach, duodenum, liver, spleen, mesentery, mesocolon, &c., bands are occasionally formed, connecting the pancreas to one or more of these organs, which sometimes acquire so great a degree of hardness, as to be with difficulty divided with the scalpel.

In suppurative inflammation, whatever may have been its point of commencement, the pus is ultimately infiltrated into the interlobular tissue, and when the process of suppuration is completed, is generally collected into one cavity. In most cases, the inflammation being but partial, this cavity is of moderate size; but sometimes the suppuration proceeds to such an extent that the texture of the gland is almost entirely destroyed. In some instances, this destruction being complete, the purulent matter is contained in a membranous envelope, formed by the cellular tissue which covers the organ. Portal has seen more than two pounds of pus contained in a sac of this description. The character of the purulent matter in such cases seems to be various. According to Gendrin it is commonly inodorous and creamy; Portal, on the other hand, states that in complete suppuration of the pancreas, the pus is sometimes of an intolerable smell; not unfrequently it is combined with a clear yellowish fluid, and with a whitish curdy substance, the most dependent part being occupied with a grey powdery pus. This has been attributed to its admixture with the pancreatic juice.

In the great majority of cases, inflammation appears to extend to the pancreas from neighbouring organs; in some cases it becomes adherent to the stomach at a point where the latter is undergoing perforative ulceration, and I have seen a case where this adhesion had a conservative effect and served as a stopgap, whereby, when the ulcer had completely eaten through the coats of the stomach, the escape of its contents into the abdominal cavity was prevented. Portal speaks of abscess in the pancreas having been frequently observed in disease of the testicles, and mentions one case in particular in which, after the extirpation of a testicle and the ligature of the spermatic cord, a large quantity of pus was found in the cord, and a considerable abscess surrounding the pancreas; and he refers to Antoine Petit as adducing different examples of this kind in support of his objections to the practice of ligature. M. Tonnellé mentions two cases of puerperal peritonitis in which pancreatic abscess occurred. In Mr. Lawrence's case the patient died five weeks after delivery. It is to be regretted that in these cases more accurate dissections were not made, particularly with the view of ascertaining the condition of the venous connexion between the parts primarily affected and the pancreas: it is very possible that the inferior mesenteric vein might have been found in a state of inflammation, and the pancreatic abscess might have been from secondary purulent deposit transmitted to it by branches from the splenic vein after the junction of the inferior mesenteric vein with it.

The contents of a pancreatic abscess may be discharged in various directions. Sometimes they escape into the cavity of the abdomen; sometimes they pass into the stomach, and sometimes into the duplicature of the mesocolon, where they may be retained as in a sac, or, having perforated one of its laminæ, may be effused into the general cavity of the abdomen. It is supposed also that the pus of a pancreatic abscess may find its way into the intestinal canal, and be discharged by stool without any obvious communication being established between them. Thus, in a case communicated by Dr. Haygarth to Dr. Percival, in which, on dissection after death, the pancreas was found to contain a considerable abscess, blood and, at length, fetid pus had been discharged by stool during life.

According to Dr. Pemberton*, ulceration is a very frequent result of inflammation of the pancreas; and from the small degree of sensibility with which the organ is endowed, the destruction may go a great way without pain or any symptom previously existing which could lead to a suspicion that inflammation was going on.

Portal alleges that gangrene of the pancreas is a *frequent* consequence of its inflammation, and that he has met with it in several instances. In one case, which he particularly specifies, the pancreas was found, on examination, to be of a violet purple colour, softened, and allowing a blackish fetid humour to exude from its external surface. "In short," he says, "it was gangrenous almost throughout its whole extent." Gendrin quotes what he conceives to have been a case of gangrene of the pancreas, occurring after chronic inflammation, and suggests it as probable that in this, as in other tissues, acute inflammation passes readily and completely into the state of sphacelus, only in cases in which the organ has been weakened by previous disease.

e. Hæmorrhage.—I have only met with two cases of hæmorrhage in the pancreas: one recorded by Mr. Fearnside, in which the right extremity was occupied by a large coagulum; the other related by Storck, in which the pancreas was so large and heavy that it exceeded thirteen pounds in weight. On cutting into this mass, it was found to consist merely of a sac filled with blood, partly grumous, partly coagulated, and beginning, it is stated, to become organised.

d. Structural changes. 1. *Non-malignant; cartilaginous transformation.*—Many cases are on record in which the pancreas had been found cartilaginous; it is generally enlarged, nodular on the surface, and very hard. In the majority of cases, one or more neighbouring organs have been found similarly affected; but in some rare cases the pancreas has been the exclusive seat of the cartilaginous degeneration. In persons affected with it nausea, vomiting, thirst, pain in the epigastrium, &c., had existed, and it was probably the remote consequence of chronic inflammation.

Steatomatous concretions. — Portal states that the pancreas is sometimes found full of steatomatous concretions, hard or softened, white like suet, or yellowish like honey. Sometimes the pancreas is enlarged by this matter throughout its whole substance, sometimes it exists only in particular parts. Those who have died of scrofula, and in whom the glands of the neck, axillæ, groins, or mesentery were obstructed, had likewise the pancreas equally affected. He mentions a particular case in which the mesenteric glands were full of steatomatous concretions, and in which the pancreas, besides being enormously enlarged and full of similar concretions, was covered by one of the consistence of suet and more than five or six lines in thickness. In this case the surrounding cellular texture, the mesocolon, and the parietes of the stomach, were cartilaginous and thickened, in consequence, he supposes, of the pressure of the tumour. He states, however, that the pancreas has been found affected when no marks of scrofula were observable in any other part of the body. Meckel states that he has seen the organ changed to an almost tophaceous mass.

The steatomatous concretion of Portal seems to be identical with the *tubercle* of the present day; and accordingly, both in the human subject and in the lower animals, tubercles of the pancreas have been occasionally met with, particularly in cases in which the lungs had undergone a similar degeneration. M. Lombard states that of one hundred cases of tuberculous disease in children which he examined, he found, in five, tubercles existing in the pancreas.*

Cystic tumours; hydatids. — These are of rare occurrence. M. Becourt has described a preparation in the Museum of the Medical School at Strasburg, of a cyst of very large size in the body of the viscus. Dr. Gross has given the following description of one, in a communication to the Medical Society of Boston.† On opening the body, a voluminous fluctuating tumour of oval form was found situated beneath the right lobe of the liver, with which it had contracted intimate adhesions. It was placed between the intestines and the posterior abdominal wall, passed a little to the left of the vertebral column, and had in front of it the curvature of the duodenum. It contained from 10 to 14 ounces of a sero-sanguinolent fluid without clot, slightly viscid, and without any appearance of fatty matter. There was not a trace in its walls of any of the normal tissue of the pancreas, although it was evidently formed by that organ. It contained some very small calculi, resembling those ordinarily met with in the ramifications of the pancreatic duct, and two of these, from three to four lines in dia-

* On Diseases of the Viscera, p. 63. et seq.

* Library of Medicine, vol. iv.

† Archiv. Gén. de Méd. iv. serie, t. 218.

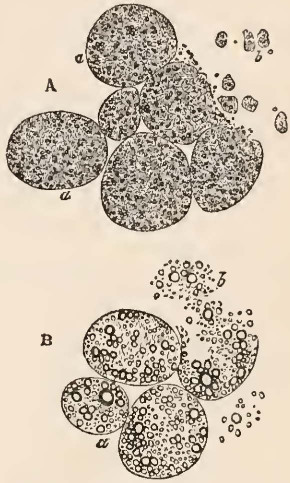
meter and rough on their surface, completely obliterated the opening of the pancreatic canal into the duodenum; they were composed of carbonate of lime. The rest of the pancreas — that is to say its left extremity — was about two inches long and very hard: *the pancreatic canal of this portion of the gland opened into the cavity of the cyst.* This circumstance, and the fact that that portion of the duct leading from the cyst to the duodenum was blocked up by the calculi, make it exceedingly probable that the cyst was primarily nothing but a dilatation of the duct in consequence of this obstruction. It is possible that this may be the origin of most of these cysts, and much to be regretted that the fluid contained in them has not been submitted to a rigorous examination, with the view of ascertaining whether it has any analogy to the secretion, or admixture with it. Two cases of retention of the pancreatic fluid recorded by Cruveilhier, confirm the probability of this supposition. "The dilated canal resembled a transparent cyst; the contained fluid was extremely viscid and clear, but of a whitish hue like a solution of gum arabic; it had a slightly saline taste; the collateral ducts were extremely dilated. There were some white patches, resembling plaster, in the centre of many of the lobules. This substance was more abundant in some of the lobules, and, when removed, presented the appearance of small lumps of plaster or chalk." These cretaceous lumps might have been of the nature of pancreatic calculus, which we have already seen associated with a cyst involving the duct, or the earthy remains of old tubercle.

Fatty degeneration. — I have frequently met with fatty degeneration of the pancreas, and all the instances in which I have detected it have been cases of *diabetes*. After finding it in four successive cases of this disease, I fancied that I had hit upon its cause and the secret of its true pathology. Although it seemed rather a "lucus a non lucendo" argument to attribute an undue formation of sugar to the derangement of a sugar-forming organ, yet in a class of bodies so full of instances of isomerism as the starch and sugar series, it appeared to me possible that an imperfect or depraved pancreatic secretion might give rise to the formation of an imperfect glucose incapable of those after changes by which it is worked out of the circulation. The meeting, however, with other cases of diabetes in which the pancreas was not fatty, and, still more, the perusal of M. Bernard's observations with regard to the part that the liver plays in the formation of sugar, and the disease of diabetes, dispelled my theory, and compelled me to regard the fatty state of the pancreas as the consequence, and not the cause, of the diseased condition, undergoing this degeneration in common with other organs; for I never found fat in the pancreas without finding it in enormous quantity in the liver and kidney. I may here remark, that I have not been able to confirm Dr. Johnson's observation*, that in diabetes, when the kidney cells contain a large quantity of oil, the hepatic cells contain an unusually small amount, and have a "starved" appearance; for I have invariably found the accumulation of fat in the liver and kidney cells, in cases of diabetes, in *direct*, and not in *inverse*, proportion.

* Diseases of the Kidney, p. 395.

The microscopical appearances of fatty pancreas are of two kinds, depending, I think, upon the length of time the degeneration has existed, and the amount of fat (*fig.* 75.). In one, the amount of fat is small, the globules very minute, confined to distinct epithelium cells,

Fig. 75.



Fatty Degeneration of the pancreas.

A. The process here is but slightly advanced, the oil-globules small, and the epithelium distinct, particularly where some cells have escaped, as at *b*; at *a*, too, within the follicles, they are visible.

B, another specimen, in which the fat was more abundant, and the destruction of the tissue complete.

and giving them, from the increased opacity it imparts to them, a more definite individuality (A. *a*.); in such a case, if a follicle is ruptured the epithelium escapes, each cell containing its own minute fat globules (A. B), and the amount of free fat, if any, is very small. In the other case, the appearance of individual epithelium cells in the follicle is altogether lost, the fat globules are larger and more numerous, and the rest of the contents indistinctly granular. (B. *a*.) Sometimes the oil globules completely fill the follicle; when in such a case pressure is applied, and the follicle contents forced out, no distinct epithelial cells are seen floating about, but all that is not fatty is amorphous and broken down. (B, *b*.)

2. *Malignant.* — *Scirrhus and carcinoma.* — These appear to be among the commonest affections of the pancreas. The disease generally affects, or commences in, a part only of the organ; and appears to be primarly pancreatic, for in some cases the pancreas alone has been found affected. Dr. Bigsby enume-

rates twenty-eight cases in which the disease appeared to be idiopathic, and in eight, which were of long standing, did not extend beyond the pancreas; more frequently, however, it implicates neighbouring parts in some degree, particularly the duodenum, stomach, and pylorus. It may exist without any increase of size, but more frequently is attended by some enlargement, which may be considerable. Scirrhus rarely goes on to ulceration, the associated lesions terminating fatally before that time. It often gives rise to constriction of the bile-duct and deep jaundice, and even compression of the aorta: this compression and constriction of the aorta have been known to occasion aneurismal dilatation above the seat of the constriction, as seen by Portal and Salmade.

Of the twenty-eight cases analysed by Dr. Bigsby, in seventeen the disease had not arrived at the stage of softening, although some of them had existed for years; it was purely scirrhus. In five cases he states the scirrhus had, at the time of death, passed into the soft state called *cephaloma* by Dr. Carswell, and *medullary sarcoma* by previous writers. Some parts, however, were as hard as cartilage; but others had all the pulpy, pale yellow, brain-like character of the second stage of scirrhus. In one case, the pancreas was changed into a sac, with a few shreds of cephaloma here and there on its sides. Lastly, in two cases no vestige of any form of scirrhus remained, the gland being altogether in a state of cancerous ulceration.

Fungo-hæmatoid disease has been found in the pancreas in three cases by Dr. Abercrombie, and in single instances by Dr. Bright and others. Dr. Copland found this lesion in the pancreas of a boy fourteen years of age; several other organs were also affectedby it.*

e. Calculous concretions in the pancreatic duct and its branches are by no means uncommon, and appear not unfrequently to be the cause of some of those morbid changes that have been already noticed. Sometimes they are manifestly in the duct; at others, though probably primarily so, they appear, from obliteration of the duct in which they were lodged, to be in the gland substance. They are usually white, but occasionally black; they vary much in shape, being sometimes round, and sometimes irregular; their size ranges from that of a pea to that of a small walnut, and their number from one to twenty; sometimes they are scattered throughout the gland, sometimes aggregated in a mass. Gendrin mentions that the pancreatic duct is sometimes clogged, not with distinct concretions, but with a chalky powder. In respect to chemical composition it seems probable that pancreatic calculi are liable to some variations. Dr. Pemberton† mentions having received one from Dr. Baillie from the human pancreas which consisted entirely of carbonate of lime; whereas, one from the ox analysed by Dr. Wollaston turned out to be phosphate of lime. Portal mentions that in a case in which he met with a dozen of light, round, whitish calculi in the pancreas, he found that when he reduced one or two to coarse powder, and threw this into boiling water, it readily dissolved; and Fourcroy states, as the result of his examinations, that pancreatic concretions are composed of phosphate of lime combined with some animal matter, just as is the case with salivary calculi.

* Medical Dict. Loc. cit.

† On the Viscera, p. 68.

There is one circumstance connected with the morbid anatomy of the pancreas worthy of special note, and with a short reference to this I shall finish this paper; it is

The occurrence of fatty stools in connection with pancreatic disease. Attention was first drawn to this subject twenty years ago by the simultaneous publication, in the eighteenth volume of the Medico-Chirurgical Transactions, of papers by Drs. Bright and Elliotson and Mr. Lloyd; but although the subject excited considerable interest at the time, it has since been suffered to lapse, from want apparently of due appreciation of its import; and it is only recently that it has emerged from its obscurity in consequence of the new interest with which recent physiological discoveries have invested it. It is only the most hasty and superficial glance that it will be possible here to give to this most interesting subject: for further details I must refer the reader to the original papers, to others that have since been published, and to an admirable article in the twenty-third number of the British and Foreign Medico-Chirurgical Review.

The first of these papers — first as much in importance as in time — was that of Dr. Bright. Not only was he the first to point out the pathological relations of this remarkable phenomenon, but his paper is distinguished by a singular clearness and impartiality, and by a thorough digestion of its carefully gathered materials. He thus describes the peculiar condition of the evacuations that first excited his attention: — "A portion more or less considerable assumes the character of an oily substance resembling fat, which either passes separately from the bowels, or soon divides itself from the general mass, and lies upon the surface, sometimes forming a thick crust, particularly about the edges of the vessel, if the fæces are of a semifluid consistence; sometimes floating like globules of tallow which have melted and become cold; and sometimes assuming the form of a thin fatty pellicle over the whole, or over the more fluid parts in which the more solid figured fæces are deposited. This oily matter has generally a slight yellow tinge, and a most disgustingly fœtid odour."

After detailing the cases, Dr. Bright institutes the following analysis of them:—"In all of these, chronic ailments terminated, sooner or later, in jaundice; and in all of them a great peculiarity in the character of the dejections existed. In the result of the examination after death we have likewise some circumstances which coincide in all — *obstructed* *biliary ducts; the liver gorged with bile; fungoid* disease attacking the *head of the pancreas;* and *malignant ulceration* on the surface of the *duodenum.* The question to be solved is, upon which of the conditions indicated or caused by these morbid changes, if upon either, the peculiarity of the alvine evacuations depended? That the obstruction of the biliary ducts, or even the total absence of all indication of biliary secretion, is not usually attended by the same peculiarity in the evacuations, many cases which have been cautiously detailed by various authors, and many which we have all observed, bear sufficient testimony; and I was therefore induced to ascribe it, either to the existence of malignant disease, or to that disease being situated in the pancreas. That the simple fact of malignant disease existing is not *necessarily* productive of such appearances in the fæculent matter, I infer from cases both of that form of disease and of melanosis in the liver to a very great extent being, within the scope of my experience, unaccompanied by any such discharge, though the evacuations were submitted to the most rigid observation. That simple ulceration in the bowels to any known extent, is not attended by any such symptom I am led to believe from knowing that neither in the most extensive ulceration of the large intestines in cases of dysentery, nor in the worst cases of ulceration of the small intestines in fever, in diarrhœa, or in phthisis, does anything of the kind occur. Whether, however, malignant ulceration of the mucous membrane is accompanied by this symptom I cannot assert, though I have often seen most extensive ulcers of the pylorus and of the rectum, where, although the evacuations were attentively observed, such fatty matter was not detected. As, however, a malignant ulceration of membrane did exist in each of the foregoing cases, it is not impossible that this was the cause of this symptom; but we must bear in mind that such ulcerations are *by no means* uncommon, and that the phenomenon of which I am speaking *is* uncommon; and that in each of the cases it was accompanied by another morbid appearance, which is not common; namely, the malignant disease of the pancreas. The fact of the intestinal ulceration having in each case occupied the duodenum does, however, somewhat diminish the weight of this observation, for that certainly is not so frequent an occurrence." By this process of elimination, and by the instance of other cases more or less analogous, Dr. Bright conceives that we may bring the circumstances of the diseased structure in connection with this symptom within a narrow limit — "*disease, probably malignant, of that part of the pancreas which is near the duodenum; and ulceration of the duodenum itself.*" To this conclusion, however, so carefully arrived at, subsequent observation has shown that exception must be taken: cases that have occurred since the publication of Dr. Bright's paper, and even quite recently, have proved that neither the malignant character of the disease nor ulceration of the duodenum is necessary to the production of the fatty stools. In a case in which fatty stools occurred, communicated to the Society of Medicine of Boston*, in one reported by Dr. Alfred Clarke, of Twickenham, in the Lancet for August 16. 1851, and in one referred to by Dr. Kirkes in his Handbook of Physiology†, the pancreatic disease appears to have been clearly non-malignant, and to have consisted in the conversion of the organ into a serous cyst in consequence of obstruction of its duct; and the duodenum seems to have been quite healthy. In two, however, of these cases, there was jaundice, and in the third deficient bile in the evacuations, so that the pancreatic disease was not *pure.* What we want for the clearing up of this subject as far as the pancreas is concerned is, a case in which the pancreas *alone* is affected, other organs not being even functionally implicated, and in which there is during life a clear presence, or a clear absence of fatty stools. Until such a case or cases can be brought forward, the light which this section of pathology has thrown upon physiology will still leave undetermined the relative importance, in effecting the absorption of fat, of the different digesting agents supplied by or poured into the duodenum.

PELVIS. (πελυξ, Gr.; *Pelvis*, Lat.; *le Bassin*, Fr.; *das Becken*, Germ.) — The pelvis is the bony girdle which connects the spinal column with the bones of the lower or hinder extremities.

It derives its name from its supposed resemblance in the human subject to a basin. Its figure, however, varies greatly in different animals. The description which follows, refers to the *human male pelvis*, which may be taken as a standard of comparison. It is composed of three principal pieces, two of which are symmetrical in shape, lateral in position, connected anteriorly, and called the *innominate* bones; and the third, called the *sacrum*, intervenes between the former at their posterior extremities, and connects them to the spinal column, of which it forms the inferior or posterior portion. Appended to the lower extremity of the sacrum is a small bone, the *coccyx*, — the representative of the caudal bones in the lower animals, — which, as influencing the shape and completing the formation of the walls of the pelvis, is considered as a part of it.

The Innominate Bone (*Os innominatum, coxarum, sive pelvis lateralis*, Lat; *l'Os d'ile, coxaux*, Fr.; *das ungenannte Bein*, Germ.; — *figs.* 76, 77.) is a bone of so irregular a shape as to leave it without a name in the fanciful nomenclature of the older anatomists. It is broad and expanded at the upper extremity, rounded and perforated at the lower, constricted in the middle like a figure of 8, and bent into a curve, with its concavity directed forwards, upwards, and inwards, at the upper end; and backwards and inwards at the lower, so as to form a segment of the pelvic circle.

Its *office* is to support the bones of the lower extremities; to transmit to them from the sacrum the weight of the trunk in the erect position; and to afford a basis of support in the sitting posture. It also forms a protecting enclosure to the important viscera within it, and gives attachment to the abdominal and leg muscles.

This bone is usually described in three separate portions, into which it is separable in young persons, and which are called, respectively, the *haunch bone* or *ilium* (*das Hüftbein*, Germ.; *l'Ileon*, Fr.); *the seat bone* or *ischium* (το ισχιον, Gr.; *das Sitzbein*, Germ.; *l'Ischeon*, Fr.); and the *share bone* or *pubis* (ὁ κτεις, Gr.; *das Schaambein* or *Schoossbein*, Germ.).

Of these three, the ilium forms the upper expanded portion, and the pubes and ischium the lower perforated portion; the former being placed before, and the latter behind the opening. In the perfect bone, however, these three are completely soldered together by bony union in the central constricted portion, where each contributes to form a deep cavity, externally, for the reception of the head of the thigh bone. From this cavity the three portions radiate; the ilium upwards, the ischium downwards, and the pubes forwards, each contributing to support the thigh bone by its central extremity. The innominate bone may, however, be most briefly described as one bone, consisting of two *surfaces*, *external* and *internal*; bounded by four *borders*, *superior*, *inferior*, *anterior*, and *posterior*.

The *superior border*, formed entirely by the ilium, is the most regular and the most extended. It forms an arch, directed from behind forwards and outwards, and curved laterally so as to present, on looking at it from above, the shape of an italic *f*; the smaller concavity being posterior and directed outwards; and the larger, anterior and directed inwards, contributing to form the general concavity of the internal surface. This border is thickened in a somewhat irregular manner, forming what is called the *crest of the ilium* (*a*, *c*, *b*), upon which may be traced an *internal* and an *external lip*, and a rough broad *central line*. These ridges are caused by the attachment of the abdominal muscles. The external lip is called, by some authors, *the superior curved line* of the ilium. The crest is very much thickened and irregular at the posterior extremity, where it terminates in a backward projection, the *posterior superior spinous process* (*b*). It is also thickened into an outward projection a little in front of the centre (*c*), and also in a less degree at the anterior extremity, where it projects forwards, forming the *anterior superior spinous process* (*a*).

The *anterior border* consists of an upper vertical portion formed by the ilium, and a lower oblique portion formed by the pubis. It commences above at the anterior superior spine, an inch below which it presents a similar projection called the *anterior inferior spinous process* (*d*), the two being separated by a smoothly edged *notch* (*u*). Below the inferior spine is another indentation, wider and less deeply marked, and forming part of the overhanging edge of the cavity for the thigh bone, and in which a muscle lies. To this succeeds below, another rounded, less strongly marked prominence, in which the ilium and pubes are united, called the *ilio-pectineal eminence* (*e*). From this point commences the oblique or inward direction of this border, which is for about two inches smooth and rounded for a muscle to glide over, and then presents a fourth well marked, acute, forward projection called the *spine of the pubis* (*f*), which is continued by a rough strongly marked ridge, the *crest of the pubis* (*f, g*), to the termination of this border in an abrupt right angle, the *angle of the pubis* (*g*). All these eminences result from the implantation of the tendons of muscles of the leg or abdomen.

The *inferior border*, composed partly by the pubis, but principally by the ischium, here commences. It is arranged first in a rough, indented, plane, oval, and vertical surface, which in the living bone is united by fibro-cartilage to innominate bone of the opposite side, and forms the *symphysis of the pubis*;—συμφυμι, to grow together (*h*). The posterior border of this articular surface is often raised into a ridge, projecting backwards, especially in old persons. Cruveilhier mentions one, observed in a woman who had borne many children, where this was a perfect crest. Below this point the border assumes a direction tending first downwards and outwards, and then, somewhat sharply, curving upwards and backwards. Just below the symphysis it presents a sharp, rough, irregular ridge, with a considerable outward eversion, affording attachment to strong fasciæ and muscles of the leg and perineum, and to the root of the penis. At the most depending part it gradually widens into a very rough, large, elongated, and rounded tuberosity, 3 inches long by 1½ broad at its posterior extremity, the *tuberosity of the ischium* (*i*). This tuberosity has a general inclination outward; and along its inner margin, which projects lower than the outer, is a raised ridge for the attachment of the great sciatic ligament. Upon it are implanted the large posterior leg muscles, and in the sedentary position the trunk is supported by it. Hence the name of this portion of bone (from ισχειν καθημενος—quod sustineat sedentes), and also its German appellation (Sitzbein or Sitzstück).

The *posterior border* commences above this tuberosity. Its direction is first vertical, and then irregularly horizontal. It is formed by the ischium and ilium. Above the tuberosity of the ischium is a rounded groove, in the fresh state covered by cartilage, and called the *small sciatic* or *obturator notch* (*k*), over which a muscle glides. Then occurs a sharp prominent process, turned considerably inwards, giving attachment to a strong ligament and some muscles, and called the *spine of the ischium* (*l*). Above this the border is thin, rounded and vertical, becoming gradually much thicker and finally curving sharply backwards and downwards. It thus forms a large *notch*, the *great sciatic*, formed principally by the ilium (*m*). To this succeeds a tapering, elongated, and depending prominence called the *posterior inferior spinous process of the ilium* (*n*), serving for the attachment of ligaments. The border then presents an insignificant rounded notch, with a thin edge; and finally terminates in the superior border at the *posterior superior iliac spine*, already described.

Fig. 76.

External view of the innominate bone.

The *external* or *femoral surface* of the os innominatum (*fig.* 76.) at its upper or iliac portion is directed outwards, backwards, and slightly downwards; at its central part outwards; while its pubic and ischiatic or lower part is directed forwards, downwards, and outwards. The iliac portion is broad and fan-shaped above, whence this upper portion is called the *ala* or *wing of the ilium*. It is convex at its anterior, and concave at its posterior portion, following the *ʃ* curve of the crest before mentioned. The concavity is termed by many writers the *external iliac fossa*. The convexity is increased by a ridge of thick bone, which passes vertically downwards from the thickened portion of the crest to the cavity for the thigh bone. At the posterior part of this surface, close to the termination of the crest, is an elongated rough impression of a somewhat triangular shape, having its base at the superior and inferior posterior spines, and tapering off gradually along the crest for about three inches, which marks the origin of a great muscle—the gluteus maximus, and which may be called the *gluteal impression* (1). In the middle of this surface is a slightly marked line of an irregular curvature, commencing posteriorly at the centre of the great sciatic notch, and, passing upwards and forwards, terminates in the crest a little posterior to the anterior superior spine. This is the *superior curved line* (2) — (*posterior* of Cruveilhier). Below this is another line of a like character, the *inferior curved line* (3) — (the *anterior* of Cruveilhier); which, commencing an inch below the other in the sciatic notch, gradually diverges from it, and terminates anteriorly at the inferior spinous process of the ilium. The surface presents numerous small circular openings for the admission of the nutritious vessels of the bone, all of which have a direction downwards towards the articular surfaces.

About an inch and a half below the inferior curved line is a large articular cavity for the reception of the head of the thigh bone, which is named the *acetabulum*, or *cotyloid cavity*,— κοτυλη, a cup; and εἶδος, like (4). This is a perfectly hemispherical excavation of about two inches diameter in the full grown male, and circumscribed by a rough irregularly raised *brim* or *circular border*, to which is attached the circumferential fibro-cartilage or cotyloid ligament of the hip-joint. When the bone is properly placed, as in the articulated skeleton, the axis of this cavity is directed outwards and a little downwards for the better adaptation of the femur; and to this end the posterior part of its circumference is much thicker and more prominently elevated than the anterior. Superiorly it is still more evidently prolonged outwards at the point where the before mentioned thick vertical ridge of the ilium springs from it. Inferiorly the border is interrupted for the space of an inch by the *cotyloid notch* (5), to the edges of which are attached the transverse and interarticular ligaments of the hip-joint, and which is continued into the centre of the cavity by a rough *depression* or *fossa*, for the reception of some lubricating glands and the interarticular ligament connected with the femur. The bottom of the notch is on the same plane as that of the depression, and affords an entrance for the vessels and nerves supplying the joints. The remainder of the cavity is a smooth and even *surface*, uniformly concave and circular, which is covered in the fresh state by a cartilage of a semilunar shape. The broadest part of this surface is above where the superior border projects. The posterior extremity is prolonged into a lip which a little overhangs the notch posteriorly, and terminates exactly opposite to the broadest part of the overhanging superior margin. The anterior extremity is the narrowest, being notched slightly by the groove below the anterior inferior iliac spine on the anterior border of the bone before mentioned. At the bottom of the cotyloid fossa may be traced two lines arranged in the shape of a T, the lower limb of which divides the cotyloid notch into nearly equal portions. These mark the fœtal division of the bone into three portions, of which the ilium contributes the two superior fifths, the ischium the inferior posterior two fifths, and the pubis the remaining anterior inferior fifth, to the formation of the cotyloid cavity. Externally, the *brim of the acetabulum* is convex, rounded, rough, and marked above and behind by the attachment of the capsular ligament of the hip-joint (6). It is here perforated by numerous foramina for the admission of nutritive vessels. It is much better pronounced above and behind, where it presents a broad, thick, convex surface, than in front where it is shallow, thin, and slightly depressed. The points where this difference is indicated are, the inferior spine of the ilium above, and the cotyloid notch below.

Springing from the cotyloid cavity are two branches of bone; one from the inferior part, thick, massive, directed downwards and backwards called the *descending ramus* or *body of the ischium* (*p*); and the other, from the anterior part, slighter in structure, and directed obliquely downwards, forwards, and inwards in the same plane with the ilium, called the *horizontal ramus* or *body of the pubis* (*q*). These are each prolonged at their further extremities into flattened tapering processes, which, altering the original direction of their respective portions of bone, one ascends obliquely inwards, and the other descends obliquely outwards, to unite with each other midway, at a point marked by a slight transverse line. They are named respectively the *ascending ramus of the ischium* (*r*), and the *descending ramus of the pubis* (*s*).* Together they form the inferior border of the innominate bone, and complete the formation of a large oval opening, situated immediately below, and a little internal to the cotyloid cavity, having its long axis directed obliquely downwards and outwards, and called the *obturator* or *thyroid foramen* (*o*) — θυρεος, a shield; and εἶδος, like. The edges of this opening are thin, bevilled off, and rough, for the attachment of a fascial ligament which closes the opening, and are formed entirely by the ischium and pubes. The external edge, instead of meeting the internal superiorly, is continued inwards in front of it, along the superior ramus to the spine of the pubes before described, forming a prominent rib of bone of a triangular shape (*q*), its base abutting on the cotyloid cavity. This rib is convex vertically, and concave laterally. Between it and the internal edge of the thyroid foramen is left a groove, called the *sub-pubic or obturator groove* (*t*), for the passage of a nerve and vessels, and which has a direction downwards and inwards. The junction of the horizontal and descending rami of the pubis is called the *angle of the pubis*, and it is hol-

* There has been much confusion in the application of names to these bones, the term *body* of the pubis is applied by some to the *angle*, and by others to the cotyloid portion only. The term *body* is confined also by some to the acetabular part of the ischium. The expressions *horizontal* and *descending* rami of the pubis and *ascending* ramus of the ischium were applied before a true knowledge of the pelvic obliquity was obtained. The former would probably be well superseded by the words *superior* and *inferior*, and those applied to the ischial rami by *anterior* and *posterior*, or *greater* and *lesser*.

lowed, rough, and broad in front, for the attachment of some muscles of the leg. There are numerous nutritious openings on this surface of the ischium and pubis, which are chiefly directed *towards* the cotyloid cavity.

Fig. 77.

Internal view of the os innominatum.

The *internal* or *pelvic surface* presents for examination a superior or iliac portion directed forwards, upwards, and inwards, and an inferior ischio-pubic portion directed inwards and backwards.

The iliac portion is rough at the posterior third, and is marked by a thick, massy, irregular prominence, just below the posterior extremity of the crest, which is continued to the posterior superior spine, and serves for the attachment of powerful ligaments which connect this bone to the sacrum. This may be called, for brevity, the *iliac tuberosity* (1).

An inch and a half below this is an angular or semilunar *articular surface*, the *sacral*, or *auricular* (2), to which the sacrum is attached in the complete pelvis. This surface is generally more or less rough and irregular, for the more firm attachment of the articular cartilage. It is composed of two elongated portions placed at right angles to each other, of which the inferior is the longer, and is directed horizontally backwards to the posterior inferior spine, parallel with and close above the upper boundary of the great sciatic notch (*m*, *n*), while the superior is directed vertically upwards towards the crest of the ilium, to which its raised anterior border is prolonged by a well marked ridge (3). At the angle of junction of these two limbs is generally to be seen a deep hollow, while the extremity of the inferior limb is bevelled off to correspond to elevations on the opposed surfaces of the sacrum. In the retiring angle formed by the auricular surface is a very rough depression for the attachment of inter-osseous ligaments (7).

The anterior two thirds of the internal iliac surface forms a complete smooth and regular hollow called the *internal iliac fossa* (4) for the reception of a muscle, which is continued downwards and forwards into the groove before described, below the anterior inferior spine of the ilium (*d* to *e*). At a small distance in front of the articular surface, is a large nutritious opening, directed downwards and forwards towards the cotyloid cavity, for the passage of the principal nutritive artery of this bone. Many others of less calibre, all directed downwards, also exist on this surface. Passing downwards and forwards from the angle of the sacro-iliac articular surface is a thick, rounded and arched ridge of bone (5), which serves to transmit the weight of the spine from the sacral articular surface to the femur at the cotyloid articulation. Just behind the ilio-pectineal eminence, before described, this line becomes more salient, and passes from this point to the spine of the pubes as a well marked projecting crest, the *ilio-pectineal line* (6), which serves for the attachment of a muscle of the leg, and some strong fasciæ. The internal surface of the pubis and ischium, and the small inferior, or true pelvic portion of the ilium, are seen below this line, which separates them from the iliac fossa. Posteriorly is seen a broad, flat surface (*p*), to which is opposed the cotyloid cavity externally, and the rough lines, marking the junction of the three component bones, are repeated more strongly and more extensively here than in the cotyloid cavity itself. They form a Y shape, the posterior limb of which is directed backward to the top of the great sciatic notch; one branch terminates at the pectineal eminence; and the other at the obturator opening, where it passes into the commencement of the subpubic groove (*t*), the termination of which was described with the external surface. Anteriorly is seen the inner aspect of the obturator foramen (*o*), and the posterior surfaces, and slightly marked line of union of the branches of the pubis and ischium (*r*, *s*), which are smooth, rounded off, and laterally convex for the apposition of the pelvic viscera. Below is the inner aspect of the great tuberosity of the ischium (*i*), which is also smooth and concave for the like purposes.

Internal structure of the innominate bone. — Like other irregular bones, the haunch-bone is composed of cancellous structure, encased in layers of laminated bone, more or less thick, as strength and tenacity are required. The thickest and strongest part of the haunch-bone is the arched, rounded rib, extending from the cotyloid cavity to the auricular surface and tuberosity of the ilium, which is the direct line of pressure from the spine to the legs. A cross section of this part of the bone is nearly an inch in diameter, generally, at its narrowest point. The descending rami of the ischia are the next in point of strength, for supporting the body in the sitting posture. These parts are composed chiefly of hard, laminated bone of dense section. The crest of the ilium is of a spongy structure, as also are the thick masses of bone at the tuberosities of the ilium and ischium, and around the cotyloid cavity. The thinnest parts of the bone are at the bottom of this cavity, and in the centre of the iliac fossa, at which places is so little cancellous structure, that the thin laminæ, forming the whole exterior of the bone, meet each other, and are so thin as to be sometimes translucent.

The Sacrum (Syn. *το ιερον*, Gr.; *Os sacrum, basilare*, Lat.; *l'Os sacrum*, Fr.; *das heilige*, or *Kreuz Bein*, Germ.) is a single pyramidal bone, flattened antero-posteriorly, and placed in the median line, with the apex downwards, the anterior aspect being directed downwards and forwards, and the posterior upwards and backwards.

Its *office* is to form a basis of support to the spinal column and its appendages, and, acting like the keystone of an arch between the haunch-bones, to transmit to them its superincumbent weight. It also encloses and protects the terminal divisions of the spinal cord, and transmits them to the inferior parts of the body, and it completes the pelvic cavity behind, and affords attachments to the strong muscles of the back. It presents for examination four *surfaces; anterior, posterior*, and *lateral*, a *base* and an *apex*.

The *base* (*fig.* 78. A) is directed forwards and upwards, and has a general resemblance to the upper surface of a vertebra, the lateral parts exactly corresponding to each other, as in most single bones. In the centre, anteriorly, is a large, plane, oval, articular *surface* (1) for fibro-cartilaginous union with the last lumbar vertebra, of which the long diameter is placed transversely, and about two inches long. On each side of this surface extends a large, fan-shaped, flattish mass of bone (2), spreading externally, with a rounded anterior border, arching laterally, and forming part of the brim of the true pelvis. On the posterior border is seen a rounded prominence. At the junction of the lateral masses with the oval articular surface posteriorly, two *articular processes* (*a, a′*) project upwards and backwards to articulate with those of the last lumbar vertebra. Their roots are marked anteriorly by deep grooves, in which lay the last lumbar nerves. Their *articular facets* are slightly concave, circular, vertically placed, and directed backwards and inwards, and receive between them their counterparts on the last lumbar vertebra. Springing from the roots of these processes, two long *laminæ* (1 B) pass backward and inwards with much downward inclination to meet each other in a stunted median *spinous process* (2 B), the commencement of the sacral crest. They correspond to the laminæ and spines of the true vertebræ. The *foramen* (3 B) enclosed by them is triangular in shape, and of considerable size, and is the superior opening of the *sacral canal*.

The *apex* (3 A) is a small oval, horizontal articular surface placed in the median line, with its long diameter half an inch in extent, and directed transversely. To it is articulated the base of the coccyx.

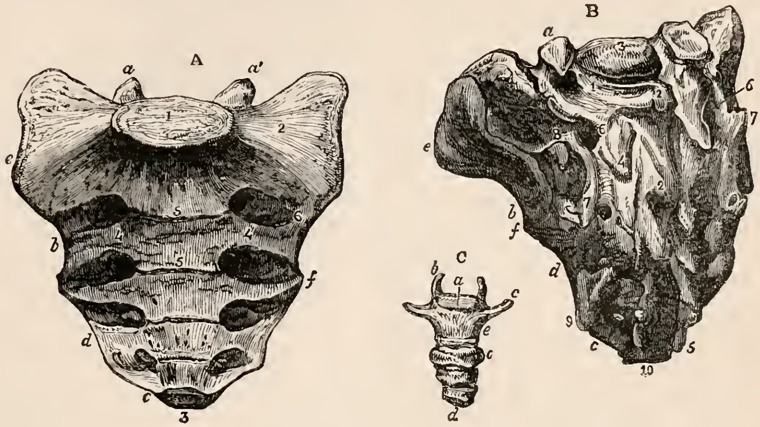
The *anterior* or *pelvic surface* is smooth and directed forwards and downwards, forming the posterior wall of the true pelvis. It is widest above, opposite the lateral masses of the base (*e*). A little below this point it is about three-fourths of an inch narrower (*b*). It then widens again to the extent of nearly half an inch (*f*), and then gradually tapers to the apex. It is considerably arched from side to side, especially at its superior part, where it has a transverse curvature, varying from half to three quarters of an inch in central altitude. Longitudinally, also, this surface is curved to a still greater degree, and with greater variations, upon the comparative extent of which, in male and female, anatomists are much disagreed.

On each side of the median line are four holes, the *anterior sacral foramina*, separated from each other by three rounded *transverse processes* of bone about half an inch wide (4), and placed at equal distances of rather more than half an inch from the median line. The two upper holes are of equal size, and much larger than the two lower. Each is connected to its fellow on the opposite side by four raised *transverse lines* (5), which mark the fœtal separation of this bone into five vertebræ; and extending outwards and downwards from each hole is a *groove* continued obliquely downwards to the borders of the bone (6). Below the last sacral hole, on each side, is a shallow notch, in the outline of the bone (*c, c′*), which is transformed into a foramen by the attachment of the upper transverse tubercles of the coccyx. There are many openings for nutritive arteries in this surface, directed generally towards the centre of the bone.

The *posterior surface* (*fig.* B) is rough for muscular attachments, and directed upwards and backwards. It is narrower than the opposing parts of the anterior at the upper part of the bone generally, by rather more than half an inch. According to Mr. Ward, a transverse section of the sacrum, an inch below the base (at the second sacral vertebra), shows that in this place the posterior surface is *wider* than the anterior by three sixteenths of an inch, so that the sacral wedge is here *reversed* in obliquity, which he considers of importance in resisting anterior dislocation of the sacrum. Above this point, the anterior surface is three sixteenths of an inch wider, and below, it resumes its superiority in width by four sixteenths. In some cases the back and front are of equal width; in others the anterior diameter exceeds the posterior throughout.

Its general curvatures are convex, following the concavities of the anterior surface. In the median line are four spinous processes (2), the first of which has been described with the base, connected by a sharp vertical ridge of bone, and corresponding to the four upper pieces or vertebræ of which the sacrum is composed, the whole being called the *sacral crest*. The last of these, and sometimes the two lower are divided by a *notch* (10), which opens u

Fig. 78.



A, *anterior surface and base of sacrum;* B, *lateral and posterior view of the same bone;* C, *anterior surface and base of coccyx.*

the *sacral canal* at its inferior termination, where it is much compressed antero-posteriorly. On each side of the sacral crest is a narrow vertical groove, corresponding to the vertebral laminæ, and bounded externally by four rough *tubercles*, the *articular* (4), the last of which are confounded with the bifurcated inferior spine, and project downwards in two *inferior sacral horns* (5), which are smoothed into facets posteriorly, to articulate with the coccyx. They correspond to the articular processes of the vertebræ. Immediately external to them, and on the same level, are the four *posterior sacral foramina* (6), of irregular size, but much smaller than the anterior, to which they are opposed in situation. The broad surfaces of bone between them present another continuous shallow vertical groove, external to which are three or four *tubercles*, the *transverse* (7), arranged vertically parallel with the holes, and corresponding to the tips of the transverse processes of the vertebræ. The highest of these are sometimes smoothed into a facet externally (8), by impinging upon the iliac tuberosity, and the *fourth* (9) is always *the largest and most prominent* for the attachment of the superficial posterior sacro-iliac ligaments. Close to the lateral boundary, opposite the two upper transverse tubercles, are two very rough, digital impressions for the insertion of powerful posterior sacro-iliac ligaments.

The *lateral surfaces* of the sacrum (*fig.* B) are broad above, and taper gradually downwards. When opposite the two last sacral vertebræ, they become narrow borders (*d*). Above, at the three upper vertebræ, they oppose the inner surface of the ilia — below, they form the inner margin of the great sciatic notch. At the upper broader portion these surfaces are bevelled off posteriorly, the posterior surface of the bone being at this part narrower than the anterior, and its plane being less distinctly different from that of the lateral surfaces. It is overhung by the tuberosities of the ilia. Close to the upper and anterior margins, occupying the two anterior thirds of the lateral aspect of the base, and extending as far downwards as the third sacral vertebra, at which point the anterior surface of the sacrum becomes, as before mentioned, broader, is a large, angular *articular surface*, the *iliac* or *auricular* (*e*), depressed along the centre, and exactly corresponding to the shape and irregular surface of the opposing articular surface of the ilium with which this bone is here jointed. The salient angle corresponds to the rounded anterior border of the lateral masses of the base, and the retiring angle, to the digital depression at the edge of the posterior surface. Two prominent portions may be particularly observed on this articular facet, one at the salient angle (*e*) on the first sacral vertebra, and another at the termination of the inferior limb (*f*) on the third sacral vertebra. They correspond to similar depressions in the opposed ilium.

The sacrum is traversed longitudinally down the middle, but nearer to the posterior than to the anterior surface, by the inferior termination of the *spinal canal*, which communicates with the anterior and posterior sacral foramina, the terminal nerves of the *cauda equina* being contained and distributed within it.

Internal structure of the sacrum. — The interior is composed of a closely reticulated mass of spongy bone, enclosed in thin, laminated surfaces. For its size, it is the lightest bone in the body, from being made up chiefly of cancellous structure. The laminæ, spines, and articular processes are, however, chiefly composed of dense bone.

The Coccyx (*fig.* c), the *huckle*, or *whistle* bone (named from its supposed resemblance to a cuckoo's bill, from κοκκυξ, Gr.; *Os coccygis*, Lat.; *l'Os coccyx*, Fr.; *das Steissbein*, or *Schwanzbein*, Germ.), is an appendage to the apex of the sacrum, and terminates the spinal column inferiorly.

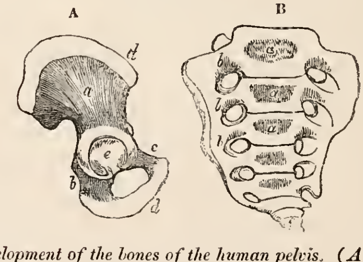
It forms the posterior boundary of the lower part of the cavity, and inferior outlet of the pelvis, assisting to complete its walls, to sustain its contents, and to attach some muscles of the leg and perineum. Its position is oblique from behind, forwards and downwards, but being normally movable on the sacrum, it yields to pressure in both ways. It is usually composed of four, rarely five pieces or tubercles, which are generally, but not always, soldered to each other, and diminished in size and completeness downwards. When in one piece, it presents a tapering, elongated, knobbed appearance with an *anterior* and *posterior surface*, two *lateral borders*, and a *base* and *apex*. The *base* presents a plane, oval, articular surface (*a*), corresponding to the apex of the sacrum, with which it is articulated, and sometimes ankylosed. Behind this, on each side, projects upwards and backwards a cornuated process (*b*), tipped with an elliptical articular facet, directed upwards and forwards, to articulate with the inferior sacral horns. Below these, the *borders* commence, presenting three alternate notches (*e*), and tubercular projections (*c*), of which the first are much the largest, and complete the sacro-coccygeal foramina. The borders are terminated by a knobbed, sometimes bifurcated *apex*, and give attachment to the sciatic ligaments, and some muscles (*d*). The first two of these notches are converted into holes by ligaments, for the passage of the posterior branches of the fifth and sixth sacral nerves. The *anterior surface* is slightly concave longitudinally, and smooth, to support the rectum. It has transverse markings, similar to the sacrum. The *posterior surface* is correspondingly converse and rough, to attach ligaments and muscles. The internal structure of this bone closely resembles that of the sacrum.

Developement. — The *innominate bone* is developed by *three* primitive and *five* complementary points of ossification.

The three *primitive* points commence in the three component parts of the bone, the ilium, ischium, and pubis respectively, from a single piece of cartilage of the general form of the bone. That of the *ilium* is placed in the thick, arched rib above the cotyloid cavity, (*fig.* 79. A, *a*), being apparent, according to Cruveilhier, the first in order, about the fiftieth day of fœtal life. Bischoff, however, says that the time of its appearance varies from the second to the fourth month, in different individuals. About the fifth month, it acquires somewhat of the form of the complete bone. That of the *ischium* is placed in the upper part of the descending ramus (*b*), and appears second in order of time, always later than the ilium, about the end of the third month, or, according to Bischoff, the fifth month. That of the *pubis* appears in the superior branch, near the ilio-pectineal eminence (*c*), at the end of the fifth month. Bischoff fixes it later than Cruveilhier, at the sixth or seventh month. At the period of birth, the cotyloid cavity is still principally cartilaginous (*e*), the ascending branch of the ischium, the descending of the pubis, and nearly the whole circumference of the ilium, still remaining in the same condition (*d*).

At the age of six or seven years, the branches of the ischium and pubis are united by bone. About the time of puberty, as first pointed out by M. Serres, a distinct *complementary* point of ossification appears in the cartilage dividing the bones in the cotyloid cavity, which soon including the whole of the Y-shaped cartilage at this part, and assuming its shape and serrated margins, finally unites them in the raised line before described. According to Meckel, the pubis and ischium join first with each other, and the ilium becomes united to them afterwards. At the same time appear the four remaining *complementary* points as epiphyses, in the following order: namely, 1. On the whole length of the iliac crest; 2. At the anterior inferior spine, not constant, and said to be more frequent in the male than the female; 3. Along the whole extent of the tuberosity of the ischium; 4. On the symphysial surface of the pubis, said by Beclard to be more often found in the female. All these are soldered to the bone, about the twenty-fourth or twenty-fifth year, the epiphysis of the iliac crest being the last to join.

Fig. 79.



Development of the bones of the human pelvis. (*After Quain and Sharpey.*)

A. Innominate bone of a full-grown fœtus; *a*, primary ossific point of ilium; *b*, do. of ischium; *c*, do. of pubis; *d*, *d*, cartilage; *e*, Y-shaped central cartilage.

B, sacrum and coccyx at birth; *a*, central ossific points; *b*, characteristic sacral do.; *c*, coccyx still cartilaginous.

The *sacrum* is produced by the soldering together of five vertebræ. Hence they have been called the *false* or *sacral vertebræ*. Occasionally six pieces have been found, and, more rarely, according to Sœmmerring, four pieces only are present. Each of these five pieces, as in the other vertebræ, results from three *primary* points of ossification, viz., one for each body or central portion, and two for the posterior lateral surfaces and laminæ of each vertebra. These appear later than in the true vertebræ, and are first manifest in the bodies of the three upper (*fig.* B, *a*), at the second or third month of fœtal life, and in the two lower at the fourth or fifth month. The lateral points are developed between the sixth and ninth fœtal months, and are united to the bodies (each after joining with its fellow opposite at the spinous tubercle) at from the second to the sixth years of age, beginning, according to Quain and Sharpey, at the *lowest* or fifth vertebra, and going *upwards*. Besides these, there are two *characteristic* points of ossification found in each of the three first sacral vertebræ, which are placed immediately above the three upper anterior sacral holes, exactly in the line of pressure from the ilia to the median line (*b*). These appear, from *above downwards*, at the same time as the posterior lateral centres just described. They unite first with the posterior lateral osseous points of their respective vertebræ, and with them join their respective central masses. Consequently, the three first sacral vertebræ have each *five* primary ossific centres, and the two last, each only *three*; the whole number of *primary* points of ossification in the sacrum being thus twenty-one.

At the age of sixteen years, the epiphysial or *complementary* ossific points begin to form, viz.: — On each articulating surface of the bodies of the sacral vertebræ is developed, as in the true vertebræ, a *horizontal plate* of bone, which, after coalescing with the bodies to which they respectively belong, finally (except the first and last) become soldered to each other from *below upwards*, commencing with the two last vertebræ, at from the sixteenth to the eighteenth years, and completing the formation of the sacral bone by the union of the two first vertebræ, at from the twenty-fifth to the thirtieth years. Between the eighteenth and the twentieth years begins the formation, by scattered granules, of four *lateral plates* of bone — one on each side, forming the iliac articular surfaces, opposite to the three first vertebræ — and one on each side, opposite the two last. These unite with the sacral bone about the same time that its upper vertebræ coalesce. The number of *complementary* points of ossification in the sacrum will thus be found to be *fourteen*, and the total number of sacral ossific centres thirty-five. M. Weber, however, assigns nine points of ossification to the first, seven to the second, and five to each of the three lower.

The *coccyx* is ossified by a single centre for each of its four pieces. Occasionally, in one of the upper are two ossific points. That of the highest piece first appears about the time of birth; that of the second bone is next evident, according to Beclard, at from five to ten years of age; the third, at from ten to fifteen years; and the fourth, at from fifteen to twenty. The two upper first unite together, then the two lower, the bone being consolidated by the union of the two resulting portions at various periods of life. In advanced life, and, more frequently, in the male subject, this bone is often found ankylosed to the sacrum. According to M. Weber, each coccygeal vertebra has two to four points of ossification.

Pelvic Articulations and Ligaments. — The *articulations* of the pelvis arrange themselves into; 1. those connecting the pelvis with the spinal column, or *lumbo-pelvic articulations*; 2. those of the pelvic bones with each other, or *proper pelvic articulations*; 3. those connecting them with the thigh bones, or *femoro-pelvic articulations*. The second class of articulations are those with which we have more immediately to do. The first class may be alluded to as necessary for elucidation of the subject. The last class come more particularly under the consideration of the hip joint.

The *ligaments* of the pelvis are of two kinds: 1. those which are closely connected with the several articulations, or *intimate ligaments*; and, 2. those which connect distant portions of its osseous structure, and are complementary to the articulations or *accessory ligaments*. The former will be best described with the articulations of which they form part.

Lumbo-pelvic articulations. — The sacrum, and through it the pelvis, is united to the last lumbar vertebra by exactly the same means as the vertebræ to each other, viz.:— First, by an *amphi-arthrodial* joint, composed of a thick *disc* of fibro-cartilage intervening between, and adherent to, their opposing articular surfaces; and strengthened by a continuation of the anterior and posterior common ligaments to the sacrum. Secondly, by two *arthrodial* joints invested with capsular ligaments, one for each of the articular processes. Thirdly, by the lowest members of the *ligamenta subflava* connecting the laminæ of the vertebræ with those of the sacrum, and by the lowest *inter-spinous* and *supra-spinous* ligaments connecting their spines. And, lastly, by an accessory ligament, which is a representative of the inter-transverse or oblique transverso-costal ligaments. This extends from the lower border of the last lumbar transverse process on each side, to the lateral masses of the base of the sacrum, its fibres expanding to the sacro-iliac symphysis and iliac crest. It is called the *sacro-vertebral* or *lumbo-sacral ligament*.

The fibro-cartilaginous *disc* is composed, like the other intervertebral plates, of an obliquely intersecting layer of fibres externally, and of a central, soft, pulpy portion, and differs only by gradually becoming much thicker anteriorly, like the body of the last lumbar vertebra itself. This allows of the curve of the spinal column at this part, which is the most salient point of the sacro-vertebral angle.

The *movements* of this joint are a limited antero-posterior motion with slight lateral flexure, somewhat less than that of the rest of the spinal column.

Proper or intra-pelvic articulations. — These consist of a joint uniting the sacrum and coccyx by a miniature *amphi-arthrosis*; of a joint on each side uniting the sacrum to the innominate bone posteriorly; and a single joint in front, uniting the innominate bones to each other. The three latter joints are of the kind usually denominated "*symphysis*," and considered by many as included also in the class "*amphi-arthrosis*."

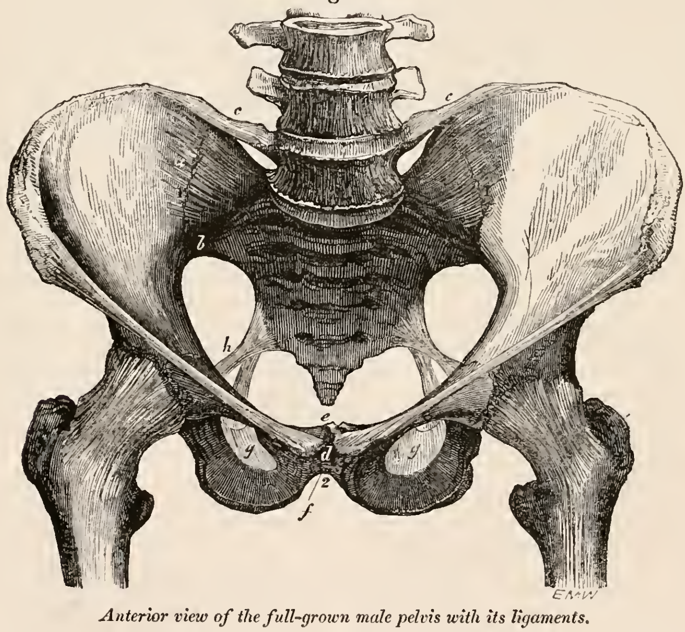
The sacro-iliac joints, however, most frequently presenting two *contiguous* surfaces and two separate plates of incrusting cartilage, ought rather, as Albinus remarked, to be considered as "*arthrodial*" forms of articulation, while the pubic symphysis occupies an intermediate or transitional position between the *fibro-cartilaginous* or *mixed*, and the *arthrodial* joints.

The *sacro-coccygeal joint* is composed of a fibro-cartilaginous *disc*, and an *anterior* and *posterior ligament*. The fibro-cartilaginous *disc* is a miniature of the intervertebral, intervening between and adherent to the opposed articular surfaces of these bones, being, however, less evidently pulpy in the centre. According to Cruveilhier, there is sometimes found a synovial membrane in the centre of this joint. The *anterior sacro-coccygeal ligament* consists of a thin layer of fibres passing from one bone to the other in front of the joint, and spreading over the whole coccygeal surface. The *posterior sacro-coccygeal ligament* is much stronger and more developed. It springs from the edges of the notched inferior opening of the sacral canal by a thick band of fibres, which includes also, as an investing capsular ligament, lined by a synovial membrane, the articular extremities of the sacral horns, and, gradually narrowing downwards, is attached to, and extends over, the whole posterior surface of the coccyx and its articular processes, covering in the inferior aperture of the sacral canal, and connecting the several pieces of the coccyx when they remain separate. In the latter case also are found *intra-coccygeal* articulations, small fibro-cartilaginous discs intervening between the several bones. This, according to Levret, is most constant between the first and second pieces of the coccyx, where it is sometimes met with in advanced age.

The *motions* of this joint, and those of the coccygeal bones, are simply antero-posterior flexure, and are sometimes, especially in females and young subjects, very extensive, forming, Cruveilhier says, a complete anterior projecting angle. This anatomist also mentions having seen many times *anterior* sacro-coccygean muscles; other anatomists also mention *posterior* sacro-coccygean muscles blended with the fibres of the ligament.

The *sacro-iliac joints* (*fig.* 80. 1.), one on

Fig. 80.



Anterior view of the full-grown male pelvis with its ligaments.

1, sacro-iliac symphyses; 2, pubic symphysis. *a*, superior sacro-iliac ligaments; *b*, anterior sacro iliac ligaments; *c*, ilio-lumbar ligaments; *d*, anterior pubic ligament; *e*, superior pubic ligament; *f*, subpubic or arcuate ligament; *g*, obturator membrane; *h*, sacro-sciatic ligaments; *i*, sacro-lumbar fibro-cartilage, forming the sacral promontory.

each side, are composed of an anterior or inferior portion, in which the opposing bones are covered with *cartilages* of an auricular or angular shape, and a posterior or superior portion where they are united by powerful *inter-osseous ligaments*, which fill up the retiring angle left by the cartilages. These are inclosed by *anterior*, *posterior*, and *superior* sacro-iliac *investing ligaments*.

The *cartilages* lining these articulations differ from those in the pubic symphysis in being almost totally wanting in the fibrous elements which are in the latter joint intermingled with them. Under the microscope a section of the sacro-iliac cartilages presents the ordinary appearance of cartilage incrusting the surfaces of arthrodial joints. They have been said by many writers to be completely incorporated together so as to form but one mass; but such is not the conclusion I have come to, except in a few cases, after many examinations carefully made in subjects recently deceased. The cartilages are very strongly adherent to, and follow exactly the shape of, the auricular articulating surfaces of the sacrum and ilium before described, their rounded projecting angles being the most depending part of the articulation. That on the sacrum is almost double the thickness of the iliac cartilage, which is somewhat less than one eighth of an inch thick. In the male, in a few instances, the two seem to project into each other by irregular prominences, and to be connected without the intervention of a regular synovial membrane. In these cases it has been remarked, that on the application of force, the cartilage separates from the ilium, leaving its auricular surface denuded. Much more frequently in the male, however, and always in the female and child, I have found, extending between them throughout, a completely smooth surface, apparently lined by a delicate *membrane*, and containing much thick synovia. The opposing cartilaginous surfaces are, in these cases, wavy or *ƒ*-shaped, when seen in a cross section, the sacral part being convex, and the iliac part concave in front, the reverse arrangement having place behind, the greatest depression being in the iliac surface, exactly at the angular junction of the two limbs of the auricular surfaces, at the most depending point of the articulation, and through which passes directly the line of pressure hereafter to be noticed (see *fig.* 89. *page* 144. *c, f*). At this point also, the breadth of the cartilaginous surface is the greatest, being generally about an inch. Towards the extremity of each limb the width gradually becomes less. The inferior or horizontal portion is longer than the other, generally being about two inches long, the superior or vertical portion being an inch and a half long.

Immediately posterior to, or rather above, this cartilage-covered surface, and filling up the digital depressions found there on each bone, are firmly implanted the *inter-osseous ligaments*, composing the remainder of the articulation. These consist of very strong and coarsely interlacing fibres passing almost directly from bone to bone, inclosing large meshes which are filled with a soft loose synovial looking fat, and containing many veins. Behind, these are continued into the deep posterior sacro-sciatic ligaments.

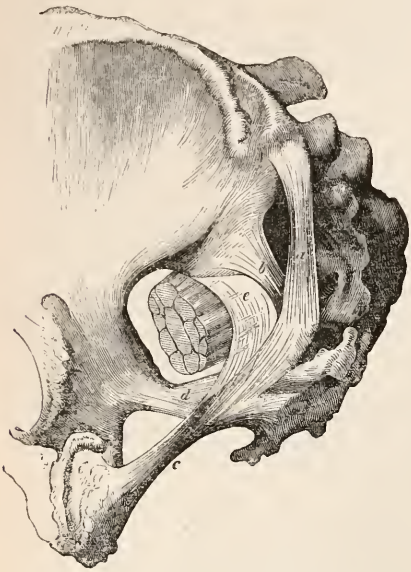
The *superior sacro-iliac ligament* (*fig.* 80. *a*) is a strong layer of fibres passing from the lateral masses of the sacral base to the posterior edge of the internal iliac fossa. It is continued in front to the *anterior sacro-iliac ligament* (*b*), similar in character to the last, but thinner and more feeble, passing from the first three bones of the sacrum to the superior border of the iliac notch. The former of these assist to prevent *downward* and *backward* displacement, and the latter *upward* and *backward* displacement; the position of the former being more anterior than superior, and the position of the latter more inferior than anterior in the proper position of the pelvis.

By far the most powerful of the ligaments of this articulation, and that which must be considered as the chief means of supporting the great downward pressure at this joint, are the *posterior sacro-iliac ligaments*. These are divided into *deep* and *superficial* layers of fibres.

The *deep* layer (*fig.* 89. *page* 144. *e*) passes from a well-marked prominence on the anterior surface of the iliac tuberosity, downwards and inwards, to the superior lateral part of the posterior surface of the sacrum, principally to the two upper pieces, external to the foramina; the fibres spreading out in interlacing bundles towards the broader surface of implantation on the sacrum, becoming longer as they become more superficial, and leaving meshes for the interposition of masses of loose fat, and the passage of numerous small veins. The erector spinæ muscles arise from the surface of this ligament, and cover it. To obtain a good view of these fibres, a transverse section along the brim of the true pelvis should be carried backward through the sacrum, as shown in the figures. This will show the manner in which the tuberosities of the ilium hang over the sacrum, suspended, as it were, between them by these ligaments. It will be more particularly explained when treating on the mechanics of the pelvis. The *superficial posterior sacro-iliac ligament* (*fig.* 81., next page, *a*) has been termed *oblique*, from the direction of its fibres; or *long*, from the extent of them. It is attached above to the posterior superior spine of the ilium, and passes downwards and obliquely a little inwards to be implanted into the fourth transverse tubercle of the sacrum external to the hole. To the sides of this ligament, which is almost subcutaneous, are attached the fascia lumborum and great gluteus muscle. This ligament is described by Cruveilhier to be attached to the third sacral vertebra. In all the cases I have seen, it is attached to the *fourth* transverse tubercle, which is the most prominent tubercular projection in the dried bone. Bichat erroneously calls it "*sacro-spinous*."

Attached to the same sacral tubercle, and passing *horizontally* outwards to be implanted into the posterior surface of the *inferior* posterior spine of the ilium, a point exactly corresponding to the termination of the horizontal limb of the sacro-iliac articular surface, is another well-marked ligament (*fig.* 81. *b*), which, being separated by a distinct cellular interval from the deep ligaments and distinguished by the more deeply seated position and horizontal direction of its fibres from the oblique ligament (*a*), and from the great sacro-sciatic ligament (*c*), I think merits the name of the *inferior* or *short superficial posterior sacro-iliac ligament*. This ligament has been hitherto apparently confounded with the great sacro-sciatic, which is attached to its lower border by a thin fibrous extension.

Fig. 81.



Posterior view of the ligaments of the pelvis.

a, oblique posterior sacro-iliac ligament; *b*, inferior posterior superficial sacro-iliac ligament; *c*, great sacro-sciatic ligament; *d*, lesser sacro-sciatic ligament; *e*, membranous expansion over the pyriformis muscle.

The ligaments which may be considered as *accessory* to this articulation are three in number — the *ilio-lumbar* ligament above, and the *greater* and *lesser sacro-sciatic* ligaments below.

The *ilio-lumbar* ligament (*fig.* 80. *c*) is a triangular fascicular ligament, thickest at the edges, and passing from the tip of the last lumbar transverse process, to which its apex is attached, horizontally outwards, and a little backwards to the posterior fifth of the inner lip of the crest of the ilium, along which its fibres spread as far forward as the inner projecting point of the posterior curve. To the outer side and behind this ligament is attached the quadratus lumborum muscle with the tendon of the transversalis abdominis, and to its front the psoas magnus muscle. Meckel describes this ligament as sometimes reaching as high as the transverse process of the fourth lumbar vertebra. He also describes a second ligament lower than the preceding, but arising from the iliac crest a little behind it. They are called by him, respectively, the *upper* and *lower anterior pelvic ligaments*, the latter corresponding to the sacro-vertebral ligament before described.

The *great sacro-sciatic ligament* (*ligamentum pelvis posticum magnum*, *fig.* 81. *c*) is attached behind, to the posterior inferior spine of the ilium by a membranous expansion (*e*); to the superficial posterior sacro-iliac ligaments with which its fibres are blended; to the posterior surface and borders of the two last pieces of the sacrum; and to the posterior sacro-coccygean ligament and borders of the two or three upper coccygeal bones. From this broad attachment its fibres pass downwards, forwards, and outwards to be implanted into the whole length of the raised inner border of the great tuberosity of the ischium. The fibres of this ligament are arranged in fasciculi, which cross each other in an X-like manner, so as to present, at the extremities, an expanded appearance, and in the centre a thick contracted rounded outline. The fibres which are placed superiorly in one extremity of insertion cross at the contracted part to become inferior at the other extremity, while those which are internal cross in the opposite direction to become external. Its superior border, consequently, is directed outwards and forwards, and its inferior border inwards, and both present a curvilinear outline. At its insertion into the sciatic tuberosity, the fibres of the lower border present a falciform margin having the concavity directed upwards along the inner edge of the tuberosity, where it is united to the fascia covering the obturator internus muscle. Its superficial or external fibres are continued over the tuberosity inferiorly into the tendons of the biceps flexor cruris, and semi-tendinosus muscles. Near the posterior extremity, this ligament is almost invariably perforated by a small hole, through which passes the coccygeal branch of the ischiadic artery. To the whole length of its external or posterior surface is attached the great gluteus muscle, which causes it when dissected to be very rough and flocculent. At the posterior half of its inner surface it is blended intimately with the lesser sacro-sciatic ligament, anterior to which it is smooth, and forms part of the boundary of the ischio-rectal fossa.

The *lesser* or *internal sacro-sciatic ligament* (*ligamentum pelvis posticum parvum*, *fig.* 81. *d*) lies internal to the last, in common with which it is attached posteriorly to the side of the two last pieces of the sacrum and of the two upper pieces of the coccyx. At its anterior extremity it is contracted into a pointed insertion into the spine of the ischium. The direction of this ligament is horizontally forwards and outwards, and its shape is triangular, so that its anterior contracted portion diverges from the great sacro-sciatic ligament, leaving a triangular opening between them through which pass the obturator muscle out of, and the pudic vessels and nerves into the pelvis This ligament, thus passing from the sacrum across to the ischium, converts the sacro-sciatic notch into a triangular or oval foramen through which pass the pyramidalis muscle, the gluteal, ischiadic and pudic vessels, and the superior gluteal and great and lesser sciatic and pudic nerves out of the pelvis. With its anterior or internal surface are blended the fibres of the ischio-coccygeus muscle, which exclude it from the ischio-rectal fossa, and render it rough when dissected.

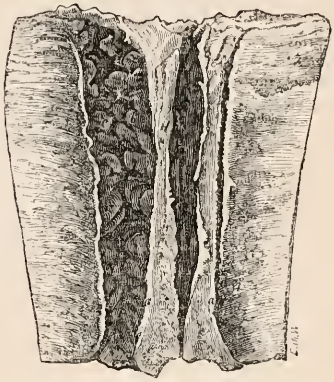
Sœmmering describes the lower part of the powerful lumbar fascia as a ligament connecting the ilia to each other posteriorly and to the lower spines of the sacrum. This fascia does, doubtless, act powerfully in clasping the ilia upon the sacrum between them. He calls it the *lateral sacro-iliac ligament*, or the *posterior lateral iliac ligament*.

The important part which these three accessory ligaments play in the mechanism of the pelvis will be hereafter shown.

The *movements* of the sacro-iliac joint are very limited indeed, its principal characteristic being compactness and strength, with just sufficient sliding motion downwards and backwards to break the shock of concussion passing from the lower extremities to the trunk. This is said by some to be increased in pregnancy and by parturition.

The *pubic symphysis* (*fig.* 80. 2) is an azygos joint uniting the innominate bones by their pubic portions in front. The osseous surfaces composing it are oval, with the long diameter directed downwards and backwards, and generally an inch and a half long, by three quarters broad. The planes of these surfaces not being directly opposed to each other, leave a larger interval of separation in front than behind. This interval is filled by a fibro-cartilaginous *disc*, which is correspondingly thicker in front, where the fibrous components are so numerous and strong as to constitute almost an interosseous ligament, and pass from one bone to the other in an oblique and concentric direction. Towards the central and posterior part this disc is generally mainly cartilaginous in structure, and is often, in females, separated in the middle by a chink forming two smooth, plane, oval contiguous *articular surfaces*, of various dimensions, sometimes irregularly laminar, at others with a delicate investing membrane. In parturient women these surfaces often extend over nearly the whole of the articulation, and are well marked in a figure given by Dr. Hunter, in the second volume of *Medical Observations and Inquiries*. In males, this separation is seldom present. The whole of the disc may, however, by maceration, generally be separated into two *plates* (*fig.* 82. *a*, *a*), of a denser and more cartilaginous structure than the rest, each strongly adherent to the bone by *mammilliform fibrous processes* (*b*), which pass into corresponding depressions in the osseous surfaces (*c*), and are connected to each other on opposite sides, by continuation of their fibres, arranged in oblique and concentric layers, which interlace obliquely with each other. (*d*) Dr. W. Hunter remarks, with Sandifort and Albinus, that the two cartilaginous plates (*a*,*a*), covering the opposed surfaces of the ossa pubis, are usually connected by a structure rather ligamentous than cartilaginous; and in a memoir on the pubic symphysis, gives an engraving of this arrangement. In several instances I have seen the fibrous processes which connect the plates with the bone very well marked, leaving on the bone, after maceration, deep conical pits. The above figure was taken from a macerated preparation of this joint. According to the observations of Tenon, these processes are directed into the bone downward and backward, as well as outward, and tend to prevent displacement of the cartilage in that direction. The *inter-laminar fibro-cartilaginous tissue* is very elastic and yielding, swelling out on the cut surface when lateral pressure is made on the bone, somewhat in the manner of the intervertebral discs. It often evinces a tendency to split in a lamellar direction after maceration. Around the circumference the concentric fibres become much more numerous and strong, and are continued into the peripheral ligaments. These are an *anterior*, *posterior*, a *superior*, and an *inferior* ligament.

Fig. 82.



Symphysis pubis after maceration.

a, cartilaginous plates of Dr. Hunter; *b*, mammillary processes on their osseous surface; *c*, corresponding osseous depressions to receive them; *d*, inter-laminar concentric fibro-cartilaginous tissue divided vertically in the centre.

The *anterior pubic ligament* (*fig.* 80. *d*) is a thick layer, passing between the anterior surfaces of the bones, strengthened by and blended with the oblique fibres of the aponeurosis of the external oblique muscle continued to the opposite pubic bone in front of the joint.

The *posterior pubic ligament* is the most feeble. It is composed of transverse fibres, somewhat scattered, and is remarkable in being raised by the posterior border of the pubic fibro-cartilage into a vertical ridge, in old persons often very evident to the touch. It gives attachment to the superior true ligaments of the bladder, and the anterior fibres of the levator ani muscle.

The *superior pubic ligament* (*e*) is formed by a thick, smooth layer of fibres often raised by a central ridge like the posterior, passing between the crests of the pubes, the superficial fibres extending over the greater part of the crests, and giving origin to the recti abdominales and pyramidales abdominal muscles, and linea alba.

The *inferior* or *sub-pubic ligament*, (*ligamentum arcuatum*, *f*) is the most powerful, passing from one descending ramus of the pubis to the other in an arched form. Its place of attachment to the pubis is often a well-marked surface, triangular, with the base upward, and half an inch in depth, corresponding in this respect to the outline of the section of this ligament. This ligament and the anterior are the most intimately connected with the fibro-cartilage of the joint. It unites below with the two layers of the deep perineal fascia or triangular ligament, between which it gives origin to the vertical compressores urethra, and forms the superior boundary of the pubic arch, the apex of which it rounds off and smoothens.

The *movements* of the pubic symphysis are confined to a slightly yielding sliding motion giving elasticity to the resistance of the pelvic ring.

The *obturator* or *thyroid membrane* (*g*) is a fascial aponeurosis rather than a ligament, which closes in the oval foramen of that name. It is composed of layers of fibres, intermingling in a circular direction, and generally congregated more in some places than others. These are attached to the rough narrow border of the descending branch of the ischium externally, but at the internal half of its circumference it is attached to the posterior *surface* of the ascending branch of the ischium and descending branch of the pubis, overlapping in this situation the borders of these bones posteriorly. Superiorly, it is interrupted by passing over from one edge of the sub-pubic notch to the other, so as to form the lower boundary of a foramen for the passage of the obturator nerves and vessels. Opposite the cotyloid notch its fibres are continued into the capsular ligament investing the hip joint. By its anterior surface, it gives attachment to the obturator external muscle, and, by its posterior surface, to the internal muscle of the same name. It is sometimes deficient in one or more places.

General appearance of the articulated Pelvis.—When the bones of the pelvis are articulated together, its whole appearance is that of a section of a cylinder or bent tube, having an *anterior*, *posterior*, and two *lateral*, and a *superior* and *inferior* aspects.

Its *anterior aspect* (*fig.* 80.) is bounded on each side by a line passing from the anterior superior iliac spine, along the anterior border of the cotyloid cavity to the ischiadic tuberosity on each side. It presents the pubic symphysis directed downwards and forwards in the median line, and the obturator foramina directed forwards, outwards, and downwards on each side. As first noticed by Cuvier, this oblique direction of the symphysis pubis is peculiar to the human species, that of animals being parallel with the axis of the body. In addition to these parts, already described, are two large notches formed by the approximation of the innominate bones. Of these the superior one, which may be called the *ventral notch*, is formed by the vertical and horizontal portions of the anterior border of the innominate bones on each side with the peculiarities before mentioned in its description. In the natural position of the pelvis this notch exposes to the view most of the internal surfaces of the pelvis to be described from the superior aspect. The inferior notch is formed by the oblique ascent towards the symphysis pubis of the branches of the ischium and pubis, forming what is termed the *sub-pubic arch*. Its apex is limited by the arched sub-pubic ligament, and there, in the male, it is generally about an inch wide, and at the base, between the ischiadic tuberosities, about three inches wide. The edges of this arch are in both sexes projected forwards, more or less, so as to present an inclined surface to the plane of the arch. This eversion as well as the measurements are, however, considerably greater in the female pelvis, hereafter to be considered.

The *lateral aspects* of the pelvis present the anterior half of the external surface of the ilia above; the cotyloid cavities directed outwards, forward and downwards, in the middle; and the descending branch and hinder part of the tuberosity of the ischia below, the latter being directed outwards and backwards.

The *posterior aspect* presents the posterior surface of the sacrum and coccyx in the centre, the most prominent point, in the erect position of the body, being the divided spine of the fourth sacral vertebra. On each side, next in succession, occur the overhanging and projecting tuberosities of the ilia, constituting two prominences next in importance, concealing the sacro-iliac articulations, and causing the lateral parts of the three upper sacral bones to appear as a deep groove on each side for the reception and origin of the powerful erector muscles of the back. Between these points also the last lumbar vertebra appears sunk between the two iliac crests, so that its upper surface is on a level with their most elevated central portion. Below the sacrum, the coccyx projects downwards and forwards in a salient median point, which separates and completes the inner boundary of the sciatic notches on each side, converted into foramina by the greater and lesser sacro-sciatic ligaments. The distance of the edges of the sacrum and coccyx from the spines and tuberosities of the ischia, and consequently the size of the openings, is less in the male than in the female; but the depth of the notches vertically is greater in the former. Above these are seen the posterior half of the external iliac surface, or external iliac fossa, surmounted by the rising crest.

The *superior aspect* (*fig.* 80.) reveals to view the whole of the *internal surface* of the pelvis, which presents two well contrasted portions, divided by a rounded edge or border, of which the superior is wide, expanded, and deficient in front, and is called the *large*, or *false pelvis;* and the inferior, narrower, more complete, and more compact, is called the *small*, or *true pelvis;* while the border which separates them is commonly expressed as the *brim*, or *superior outlet* of the true pelvis.

The *false pelvis* is formed laterally by the concave surface of the internal iliac fossæ directed upwards, forwards, and inwards; and posteriorly by the lateral masses of the base of the sacrum, directed upwards and forwards. In the middle is also seen, in the articulated pelvis, the anterior surface of the body of the last lumbar vertebra, filling up, with the pelvi-lumbar ligaments, the notch otherwise left between the ilia behind. The superior border of the false pelvis is formed by the ilio-lumbar ligaments (which exclude the iliac tuberosities), and the anterior three-fourths of the iliac crest, the most prominent point of which, in the proper position of the pelvis, is the centre of the posterior curve. It is terminated suddenly, in front, by the anterior superior iliac spine, where the ventral notch commences: by the deficiency of osseous structure at this part.

The *brim of the pelvis* is a heart-shaped opening, formed posteriorly by the body of the first sacral vertebra which overhangs the cavity of the true pelvis, so as to form a projection called the *promontory of the sacrum* (*i*), corresponding to the indentation in the emblematical heart-shape. On each side of this, the rounded arched anterior borders of the lateral masses of the sacral base continue the brim across the sacro-iliac joint, to the thick rounded ridge on the inner surface of the ilium, which is prolonged behind the ilio-pectineal eminence to the horizontal branch of the pubis where the brim becomes identified with the pectineal line. Finally, the brim is completed anteriorly by the shelving border of the body of the pubis, immediately behind the crest, and by the rounded superior part of the pubic symphysis. The part of the brim of the pelvis which is formed by the two portions of the innominate bone is sometimes called the *linea ilio-pectinea*, or, by some, the *linea innominata*. Sometimes the brim is called the *inlet* of the true pelvis.

The *cavity of the true pelvis* is formed laterally by the plane sloping inner surfaces of the lower part of the ilia, opposite the cotyloid cavities, and of the descending branches of the ischia, the latter being termed by obstetricians the *planes of the ischia*; in front, by the posterior surfaces of the branches and symphysis of the pubis, and by the ascending branches of the ilia; and behind, by the whole concave anterior surface of the sacrum and coccyx, the former being sometimes called the *hollow of the sacrum*. From the oblique position of the pelvis, the posterior wall, which is the deepest, also reaches the highest, and the lateral walls the lowest; the sub-pubic arch cutting out the anterior wall and leaving only the short symphysis pubis to represent it. The interval between the sacrum and ossa innominata behind, forming the sacro-sciatic notch, is completed and bounded by the sacro-sciatic ligaments, the inner surfaces of which are seen in this view. The inner surface of the coccyx is also seen to have an aspect directed upwards and forwards, and the spines of the ischia to project considerably inwards, so as to present two opposite points, the distance between which may sometimes be of great importance in parturition. This projection is much greater in the male than the female, and will be alluded to in the relative measurements of the pelvis. The cavity of the pelvis contracts uniformly downwards at the sides by reason of the inclination of the innominate bones; but, from the vertical curvature of the sacrum, the antero-posterior diameter is much greater in the middle than at the superior or inferior outlets, which are hence termed *straits*. The presence of the obturator foramina antero-laterally, and of the sacro-sciatic foramina postero-laterally, must also be remarked as constituting four openings, diagonally opposed to each other, capable, from the yielding nature of the structures filling them, of enlarging these diameters under sufficient pressure The great projection, forwards, of the coccyx and lower end of the sacrum may be considered as compensated for by the deficiency of the anterior wall in the sub-pubic arch directly opposite to them, gradually widening downwards as they advance. Both the forward direction of the coccyx, and the width of the pubic arch, are peculiar to the human species, and have reference to the erect posture.

The *inferior aspect* of the pelvis presents to view the *inferior strait*, or *outlet of the true pelvis;* which, on account of its more limited extent than the superior outlet, reveals nothing of the interior save the overhanging promontory of the sacrum. It is remarkable in presenting three bony *prominences*, viz., the two tuberosities of the ischia laterally, and the coccyx posteriorly, separated by three *notches*, placed opposite to each prominence respectively, viz., the sacro-sciatic, postero-laterally, and the sub-pubic notch anteriorly. The sacro-sciatic notches being closed by the great sacro-sciatic ligament, the completely formed opening thus assumes a lozenge shape, of which the lower part of the pubic symphysis and the tip of the coccyx form the extremities of the long diameter; the tuberosities of the ischia those of the short diameter; the oblique united rami of the ischia and pubes the antero-lateral, and the great sacro-sciatic ligaments the postero-lateral sides. Of these boundaries it is to be especially remarked, that the coccyx and those parts of the ligaments which are attached to it, are not *fixed* like all the previously described boundaries of the pelvis, but *movable*, on the sacro-coccygeal articulation, and consequently, the diameters of this outlet dependent upon them, viz., the antero-posterior and the oblique or diagonal, are increased or diminished by the movements of this joint backwards or forwards. The only fixed diameter of the inferior outlet of the pelvis is the transverse one between the ischial tuberosities. Of the prominent osseous points here seen, the lateral ischial tuberosities descend much lower than the symphysis pubis and coccyx, on account of the wavy outline and oblique direction of the innominate bones. It is upon these tuberosities only, consequently, that the trunk rests in the sitting posture, and not upon a tripod formed by them and the coccyx, as has been erroneously supposed by some older writers. The boundaries of the inferior outlet, from the same cause, do not, like those of the superior, lie all in one plane or level, but are bent, as it were, at the ischial tuberosities, into two planes; an anterior, terminated by, and nearly in a line with, the symphysis pubis, looking downwards and a little forwards; and a posterior, terminated by and including the coccyx, directed downwards and backwards, parallel with the superior pelvic plane, but varying with the extension of the coccyx downwards. The plane of this outlet, however, is usually considered to be marked by a straight line joining the lower border of the symphysis pubis and the tip of the coccyx; and its general direction to coincide with a line drawn perpendicular to this plane downwards and backwards.

Differences of the pelvis in the sexes. — Of all the bones in the human skeleton, those of the pelvis offer the most distinct characters between the male and female sex.

In the *female* (*fig.* 83.), the bones are lighter, shorter, and broader, less evidently marked by tuberosities and indentations resulting from the attachments of the tendinous structures, and have in a less degree the peculiarities, before described, of the articulations, as well as those resulting from their peculiar mechanism. The *iliac crest* is less arched, and presents less distinctly the *S*-like curve, the *iliac wings* are thinner and more expanded, and the *internal iliac fossæ* larger, mare shallow, and directed more anteriorly, and the *iliac ridge* extending between the cotyloid and sacro-iliac joints is less massy, less suddenly arched, and longer. The *ischia* do not converge so much towards the inferior outlet, and with the *tuberosities* are less massy, wider apart, and shorter, and the *spines* are less marked, and directed less inwards, and the *transverse diameter* of the *inferior strait* is greater. The *ascending branches* and the *descending branches of the pubes* are thinner, narrower, and more oblique, turn their inner borders more forwards, and at the same time afford a more rounded expansion to the *pubic arch*, at the expense of the *obturator foramina*, which are thereby rendered smaller and more triangular in the female. The *symphysis of the pubis* is not so deep, and the fibro-cartilage is wider, thicker, and more vertical in position; the united *angles* are more flattened posteriorly, and the *horizontal branch* is longer, thinner, and directed more transversely outwards, rendering the distance between the symphysis and the cotyloid cavity, and consequently the *projection of the hips* greater, and an increased *transverse diameter* of the *brim*.

The *sacrum* is wider and less arched transversely, and its *promontory* does not so much overhang the pelvic cavity, and thus the *superior outlet* has less of the heart shape, being in females more properly termed oval. This difference of shape is also contributed to by the less lateral obliquity of the superior branch of the pubes.

Whether the sacrum is less *arched transversely* in the female, I endeavoured to ascertain by observations taken from eighteen subjects, of which half were male and half female. A strip of lead $\frac{1}{8}$th of an inch thick was made to assume the form of the transverse curve of the sacrum, by being pressed across the anterior surface just below the promontory, and the breadth from one sacro-iliac joint to the other carefully marked off. From this, a line was drawn on paper, following the curvature retained by the lead, the extremities of which line were joined by a straight line, forming a chord to the sacral arc. The distance of the centre of this chord from the centre of the sacral curve was then measured. In the nine males, the height of the arch thus obtained varied from six to nine lines; in the nine females, five to nine lines,— the greatest number of the males being seven lines, and the greatest number of the females being six lines. In the single case of the female where the measurement was nine lines, the subject was old. When we consider, that in the great majority of instances the breadth of the sacrum *measured along the curve* was greater by $\frac{1}{4}$ to $\frac{1}{2}$ an inch in the female, these results will yield a still greater relative depth to the transverse sacral curve of the male.

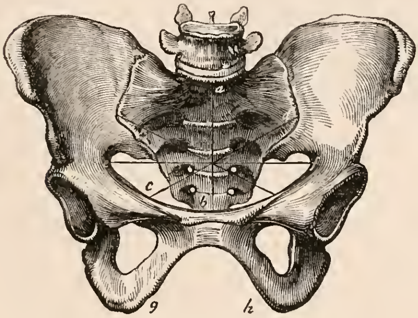
Besides this transverse arch, the *vertical curvature* of the sacrum is relatively much less in the female. This is more apparent in the direction of the three upper sacral pieces, which are generally little curved, and often almost plane in the female, while, in the male, the curve is most apparent in the centre and more uniformly distributed over the whole sacral surface. Upon this point, however, much difference of opinion prevails amongst anatomists; Meckel and Ward agreeing with the opinion here enunciated, while Cloquet and Cruveilhier maintain that the curvature of the sacrum in the female is *deeper* and more regular. The experiments of Mr. Ward, however, correspond more entirely with my own observations on this point. Mr. Ward observes, in addition, that the male sacrum often approaches the form of the female, but the female rarely to that of the male. In old women, however, I have often seen a great vertical curvature of the sacrum.

The *coccyx* is more moveable, more frequently in several jointed pieces, less projected forwards, and less frequently ankylosed to the sacrum in the female.

The *sacro-sciatic notches* in the female are wider and not so deep as in the male; the distance from the ischiadic spine and tuberosity to the sacrum and coccyx being greater, and the sacro-sciatic ligaments longer and more slender.

The peculiarities above mentioned give to the female pelvis a wider, shallower, more open, and less massy appearance than that of the male, and give rise to a still more important distinction derived from the *measurements* from one point to another, and from the relative *diameters* of the cavity and outlets of the pelvis. Another distinction will be presently found in the relative *angles* which the sacrum and whole pelvis form with the axis of the spinal column, and this again will influence the relative direction of the *axes* of the cavity and outlets.

Fig. 83.



Anterior view of the female pelvis, with lines of measurement.

a b, conjugate diameter of brim; *c d*, diagonal ditto; *e f*, transverse ditto; *g h*, transverse diameter of inferior outlet.

The measurements of the pelvis.—The most evident distinctions between the adult pelves of the sexes are derived from their comparative dimensions, and result from the important bearing they have upon the mechanism of parturition in the female. For this purpose, an average is taken from the measurements of many well-formed pelves, and one with the average results is adopted as the *standard pelvis*.

The measurements referring to the width of the pelvis are commonly spoken of as the *diameters* of the pelvis. They are taken at the brim, in the cavity, and at the inferior outlet, and are usually an *anterior-posterior* or *conjugate*, two *diagonal* or *oblique*, and a *transverse*.

At the *brim* of the pelvis, the antero-posterior or conjugate diameter is the distance between the upper part of the posterior surface of the symphysis pubis and the promontory of the sacrum (*a*, *b*, *fig*. 83.); the oblique, between the point of the brim nearest the pectineal eminence and the sacro-iliac joint of the opposite side (*c*, *d*); and the transverse diameter is the distance between the ilia at a point halfway between the sacro-iliac joint and pectineal eminence (*e*, *f*).

In the *cavity*, the antero-posterior diameter extends between the centre of the pubic symphysis, and the body of the third piece of the sacrum; while the oblique and transverse correspond to those of the upper outlet, on the same plane.

At the *inferior strait*, the antero-posterior extends from the lower extremity of the symphysis pubis to the tip of the coccyx; and the transverse, from the middle of the inner border of one ischiadic tuberosity to the other (*g*, *h*). An oblique diameter at the inferior outlet is not one commonly given by writers, although possessed of some importance in certain cases of deformity. In the table on the next page, there is the average of six measurements taken on the recent subject, before the shrinking of the ligaments, from the centre or junction of the ischio-pubic rami to the centre of the great sciatic ligament opposite. The antero-posterior diameter of this strait is capable of much increase by the mobility of the coccyx, which will also affect, in some measure, the oblique diameters, in an *opposite* degree, from the stretching of the great sciatic ligaments, a point which I think has scarcely been sufficiently noticed by accoucheurs.

Besides these, the distances between many other points may be of great importance to the accoucheur. Such are those pointed out by Naegele, to be presently noticed; the distances between the spines of the ischia, so much greater in the female; and another, which I have not hitherto seen definitively given, viz. the distance between the *lower edge* of the *symphysis pubis* and the *sacral promontory*, a measurement of considerable importance in the use of pelvimeters, to ascertain the conjugate diameter of the brim. This may be called the *lower* or *inclined conjugate diameter*, and it will be found to be, in most instances, half an inch more than the direct or superior conjugate diameter, being, in fact, the longest side of a triangle, having the conjugate diameter, and the breadth of the pubic symphysis for the other sides. The measurement of the *circumference* of the brim of the pelvis, and the proportion contributed to it by the sacrum, ilia and pubes respectively, announce a manifest difference between the pelves of the two sexes.

In glancing over the appended table, it will be seen that the male pelvis exceeds the female in most of its vertical dimensions, while the female pelvis is larger in the horizontal diameters. The depth of the true pelvis, however, measured at the sacro-coccygeal column, is greater in the female, on account of the greater size of the sacrum in that sex, and also because of the less total *vertical* curvature. The depth from the pectineal eminence to the lowest point of the ischiadic tuberosities laterally, and at the pubic symphysis anteriorly, show, on the contrary, a great superiority in the male; as also does the total depth of the whole pelvis, from the highest point of the ilium to the most depending part of the ischium, while the width between the iliac spines and crests are much greater in the female. The horizontal diameters of the pelvis may be said to depend upon the *ilio-pubic element*, while the depth or vertical measurement depends solely on the *ilio-ischion element*, so that, in the female, the former may be considered to prevail, and in the male, the latter element. This is remarkable, as constituting the different pelvic properties of certain classes of animals.

It will also be observed that the transverse diameter of the brim is the greatest in the dry bones, but this is so diminished by the presence of the iliac and psoas muscles and fascia, that, in the living female subject, the oblique is generally the best adapted to receive the long diameter of the fœtal skull. The soft structures diminish the antero-posterior diameters of the *brim* by about a quarter of an inch, and the transverse, by half an inch; the diameters of the *cavity* being lessened about a quarter of an inch; a fact which it is necessary to bear in mind in estimating the width in the living subject. The measurements in the third double column were taken from fourteen male and eighteen female subjects in the dissecting room of King's College, London, and are compared in the first column with the contrasted measurements of the male and female pelvis given by Meckel, and quoted by most English writers on the subject; and in the second column with those given by John James Watt, in his work on the pelvis.

[a] 4 inches (Burns, Ramsbotham, Lee, Cloquet, Velpeau, and Baudelocque). 4½ inches (Monro and Boivin). 4·3 inches (Rigby).
[b] 4 inches (Burns, Lee, and Cloquet). 4½ inches (Monro and Murphy).
[c] Increased to 5 inches or more by the mobility of the coccyx.
[d] 10 inches (Burns). 9·6 inches (Cloquet).
[e] 10 inches (Cloquet). 11 inches (Burns).
[f] 7 inches (Cloquet).
[g] 4 to 4½ inches (Cloquet).

The *circumferential measurement* of the *brim* in well-formed *males* gave in my own measurements 2 inches to each of the ilia, 3 inches to each of the pubes, and 4½ to the sacrum, which, allowing ¼ inch to each of the sacro-iliac cartilages and ¼ inch to the pubic, gives a total circumference of 15¾ inches. In the well-made *female* the ilia were found to be each 2½, the pubes each 3¼, and the sacrum 5 inches, giving, with the same allowance for the sacro-iliac cartilages and ½ inch for the pubic, a total of 17½ inches. Thus the superior size of the brim in the female seems to depend more upon the ilia than upon the pubes, although the *direct* distance between the ilio-pectineal eminence and the sacro-iliac joint differs little in the sexes, because of the greater curve made by the female ilia. The circumferential extent of the borders, at the plane of the *inferior outlet* in a female pelvis of average diameters, and dried with the sacro-sciatic ligaments attached, was 14 inches. In the fresh state it generally amounts to 15, as the ligaments shrink by drying, and would be extended to 16 inches, or more, by the extension of the coccyx and the elasticity of the ligamentous portions.*

* The circumferential measurement appears to be one not generally estimated as much as its utility in detecting variations of size depending upon *shape* would seem to call for, in the female pelvis. A reference to the subjoined table of *variations* of *dia-*

Burns gives also, in the female pelvis, the following distances:—

1. Between the symphysis pubis and inferior iliac spine, nearly - - 4 in.
2. „ sacro-iliac joint and the pubic crest of same side - - $4\frac{1}{2}$ „
3. „ sacral promontory and the obturator notch - - $3\frac{1}{2}$ „
4. „ sacral promontory and the acetabula $3\frac{1}{4}$ „
5. „ acetabula anteriorly - $4\frac{1}{4}$ „
6. „ posterior ridge of ilium and the superior and inferior anterior spines - 5 „
7. „ centre of iliac crest and the brim of the pelvis, direct - $3\frac{1}{2}$ „

One of these measurements was repeated by Velpeau, Stoltz, and Naegele, viz. from the sacral promontory to the centre of the cotyloid cavity, or sacro-cotyloid. Naegele in 54 and Stoltz in 40 female pelves, found the mean distance to be 3 pouces, 3 to 4 lignes (*pied du Roi*).

Dr. Murphy, considering that the true salient point or promontory lies on a level above the real pelvic brim, at the sacro-lumbar fibro-cartilage, gives also three more measurements made in the "inclined plane of the promontory," one *antero-posterior*, between the fibro-cartilage and the upper border of the symphysis, which he places at 4 inches, and two *lateral*, from the same point to the pectineal eminences, which are on an average about $3\frac{1}{2}$ inches, but which are seldom equal, because of the great tendency to deviation of this promontory from the median line. The latter seem to coincide almost with those given by Dr. Burns between nearly the same points, and the former with the conjugate diameter of the brim.

External measurements of the female pelvis, made on the living subject, have also been given, though from few data, as follows:—

1. External antero-posterior diameter, 7 to 8 inches.

2. External transverse, between iliac crests, 13 to 16 inches.

3. From great trochanter to the opposite sacro-iliac joint, 10 to 12 inches.

4. Depth of pelvis from top of sacrum to coccyx, 4 to 5 inches.

From the first of these, according to Baudelocque and Velpeau, 3 inches must be deducted for the thickness of the parietes, and from the second 4 inches. Boivin and Lachapelle doubted the utility of these measurements generally, because of the great variability in the thickness of the pelvic walls; and Dr. Davis has more recently found the thickness of the base of the sacrum to vary from 2 to 3 inches in 17 dead subjects.

The measurements of Naegele and Otto, with a view to determine the presence of obliquely deformed pelves, are of great importance in the practice of midwifery, and may be best given in this place. Out of forty-two female pelves of medium size, the best formed they could obtain, these observers found the following measurements:—

	Measurement. in.	lines.	Greatest Difference. lines.
1. From the sciatic tuberosity of one side to the posterior superior iliac spine of the other side - -	6	6	3
2 From the anterior superior iliac spine of one side to the posterior superior of the other side - -	7	3	3
3. From the spine of the last lumbar vertebra to the anterior superior iliac spine on both sides - -	6	8	4 to 5
4. From the great trochanter of one side to the posterior superior iliac spine of the other - - -	8	5	
5. From the middle of the inferior border of the symphysis pubis to the posterior superior iliac spine on both sides - -	6	4	2

Danyan, pursuing Naegele's system, found the great rarity of perfectly regular female pelves. Out of eighty female pelves he found fifty-nine differ, in the first measurement, from 1 to 6 lines. In the second measurement he found a difference, in fifty-eight pelves, of 1 to 11 lines; in the third, fifty-one differed from 1 to 7 lines; in the fourth, sixty-two from 1 to 9 lines; and in the fifth measurement, forty-eight pelves had a difference of from 1 to 9 lines. The table on the next page shows the great variety in the diameters of female pelves which may be considered as normal *pelves*. In males Dupuytren found the distance between the tuberosities of the ischia, in twenty-three subjects, to vary from 2 to $3\frac{1}{2}$ inches; and Velpeau, in forty subjects, to vary from $1\frac{3}{4}$ to 4 inches. In fourteen subjects I have found the least distance to be 3 inches, and the greatest 4 inches in the male, and measuring from the exact centres of the inner margin of the tuberosities. These observations on the male are of some importance with a view to the operation of lithotomy, when the stone is of great size.

Inclination of the Pelvis.—By making, in a well-formed subject, a direct vertical section of the spinal column, and drawing a line through the centres of the *bodies* of the axis and last lumbar vertebra, and by comparing with the transverse plane of such a

meter, will show how frequently the diameters are compensatory to each other; as this compensation may occur in *diameters not usually measured*, the circumferential extent seems in many cases to be required. Dr. Churchill gives the circumference of the brim as varying from 13 to $14\frac{1}{2}$ inches in the female, much less than I have generally found it on the fresh subject after the soft parts were removed.

line those of the superior and inferior outlets of the pelvis, the general inclination of the pelvis to the vertebral column is obtained. The line so drawn will generally be found to

VARIATIONS in the Diameters of healthy Female Pelves.

* Like male pelvis, diameters small.
† Smallest pelvis, transverse diameter of cavity $4\frac{3}{4}$, of outlet $4\frac{5}{8}$.
‡ Belong to the same pelves respectively (compensating diameters).

pass also through the bodies of the first dorsal and second lumbar vertebræ across their centres. The curved line of the vertebræ, in most well-formed subjects, cuts the straight line at these two points, in passing from the cervical to the dorsal, and from the latter to the lumbar curve.

The plane of the pelvic brim has been termed by Naegele and the brothers G. and E. Weber the *superior plane* of the pelvis, and that of the inferior outlet the *inferior plane*. These observers measured the angle formed by these planes with the ground-level in the standing position, *i. e.* with the horizon, or with a plane drawn horizontally, at right angles, to the above-mentioned transverse vertical plane, which, in the erect posture, was found to be perpendicular to the base of support. The angle which the superior plane of the pelvis forms with the transverse vertical plane or with the horizon is termed by them the *angle of inclination* of the pelvis, or the *pelvi-vertebral angle* (*fig.* 84. *page* 134.), (*a e*, *e c*).

It is remarkable that, in man only, are the boundaries of the superior outlet in one plane, *i. e. in man only is the direction of the superior pubic ramus in the same plane with that of the cotylo-sacral rib of the ilium.* In all other animals, as far as my own observations go, the pubis is bent backward or forward, so as to make an angle with the ilium, and the *pelvi-vertebral* angle is thus resolved into two angles, a *vertebro-iliac* and an *ilio-pubic*.

The angle of the *superior plane* was found by the Webers on the dead body, by fixing the connected spinal column and pelvis of a recent well-made subject, in plaster of Paris, to preserve the natural position, then making through the whole a direct vertical section, and afterwards measuring off the angles.

On making a transverse vertical section through the centres of the heads of the femurs and cotyloid cavities, they also found that, when the body is in the erect position and the pelvis at the proper angle, the cotyloid notch and depression, and the fibres of the ligamentum teres, have an almost *directly vertical direction*, and fall exactly in the transverse vertical plane of the vertebræ (*see fig.* 87. *page* 140., in which the line *a a'* lies in the plane of the transverse vertical section). It will be further seen, by inspecting the figure, that this plane, being continued downwards, crosses the obturator foramina, and falls very nearly in the line of suture of the ischio-pubic rami. And this will be found to be the case, with a plumb line dropped from the sacral promontory, which is cut by the above plane in the erect position of the pelvis. A detached pelvis may be placed in the erect living position, consequently, by keeping the posterior part of the notch the most depending point of the cotyloid brim, and its inclinations will then accord with those taken in connection with the spine.

In the consideration of these pelvic angles it must be borne in mind that the direction of the curve of the three last lumbar vertebræ, below the point where the great dorsal concavity terminates, is such that, if prolonged upwards, the axial line would pass out at the junction of the manubrium with the body of the sternum. This makes the *pelvi-lumbar* angle much *less* in man than the whole pelvi-vertebral; a circumstance to be borne in mind in comparing them with those of animals. In fact, the transvertical section just mentioned passes through the body of the third lumbar vertebra considerably posterior to its centre in most cases (*see a, b, fig.* 84. *page* 134.).

By an inverse method, proceeding on Roederer's plan from the horizontal plane (*fig.* 84. *g*, *d*), Naegele determined, with great care, the angle of the *inferior plane* of the pelvis in the living *female*. In 500 well-formed living females placed in the erect position, he measured the respective distances from the ground, of the tip of the coccyx, and of the lower border of the pubic symphysis. He found that in 454 the extremity of the coccyx was higher than the symphysis pubis, the greatest difference being 22 lines. In twenty-six only was it lower, the greatest difference here being 9 lines, and in twenty they were equal in height from the ground. In eleven pelves where he had the opportunity of verifying his observations after death, he found and figured one perfect pelvis, in which the tip of the coccyx was 8 lines higher than the lower border of the symphysis, which corresponded very nearly with the mean elevation of the coccyx above the symphysis, viz. 7·1 lines, drawn from the observations above detailed. From this he deduced the inferior angle of inclination of the pelvis (*f g d*) to be 10° to 11° with the horizon (*g*, *d*).

In a similar manner, in fifteen living *males* the brothers Weber ascertained the range of the altitudes of the coccyx and pubis to be from 10 millimetres, the extreme difference when the coccyx was lower, to 33·3 millimetres when the coccyx was higher than the lower border of the symphysis pubis, the mean height of the coccyx above the pubis being thus 23·1 millimetres. Then, by measuring the distance between the plumb lines dropped from each of these points, the coccyx and pubis, they ascertained the mean distance to be 75·8 millimetres. From these measurements they obtained the angle of the inferior pelvic plane with the horizon 16°·51. By measuring, in two dead subjects, the depth of the symphysis pubis, and the direct vertical distance from the tip of the coccyx to the sacral promontory, they deduced the angle of the superior pelvic plane. The superior angle, however, cannot with any certainty be calculated from the inferior in the living subject, on account of the uncertain length and curve of the sacro-coccygeal column.

In a well-formed or *standard* pelvis the two lines of the superior and inferior planes, when prolonged anteriorly, cut each other about 1½ inch anterior to and below the pelvis (at *c*), containing an angle of about 50° (*e c f*); but this will vary with the length of the sacro-coccygeal column.

According to Naegele the point at which the superior plane emerges posteriorly is also very variable. Most frequently it is the spinous process of the second lumbar vertebra, often that of the first, and sometimes between the second and third. Generally the upper border of the symphysis pubis was 3 inches, 9 to 10 lines lower than the sacral promontory, and on a level with the union of the second and third coccygeal bones. The sacro-vertebral projection I have generally found to be about the level of the anterior superior iliac spine in the male, and a little below this point in the female, in a straight position of the body.

The following table shows the pelvic angles of inclination in the sexes, and their difference in this respect, and is drawn from the above-mentioned experiments of the Webers on male, and of Naegele on female subjects.

	Male (Weber).	Female (Naegele).
Angle of Inclination of superior plane, or pelvic brim.		
With transverse vertical plane	155°	150° to 151°
With horizon	65°	59° to 60°
Of inferior plane, or outlet.		
With transverse vertical plane	106° 51′	101° to 102°
With horizon	16° 51′	10° to 11°*

By the inspection of the above table the greater inclination of the pelvis to the spine in the male will become evident, constituting another distinguishing characteristic of the sexes.

The older observers estimated the pelvic angles too low, as in the incorrect drawings of Albinus, Levret, and Cloquet, where the superior angle is given as 35° with the horizon, and, by Osiander, at 30°. Carus gives the superior at 55°, and the inferior at 11° with the horizon.

Angles of the anterior and posterior pelvic walls with the transverse vertical plane.—The pelvic inclination, in the opinion of Cruveilhier, depends upon the angle which the sacrum forms with the spinal column, giving more or less of obliquity to the innominate bones on each side. This angle (*fig.* 84. next page, *a e i*, and *fig.* 112. 1. *f a g*, *page* 173), which may be called the *sacro-vertebral angle*, I have, in as many opportunities as have occurred to me, endeavoured to ascertain and establish, with a view of comparing it with the pelvi-vertebral angle in the two sexes. To do this I made a vertical section of the pelvis (with as many vertebræ as possible attached to it), from behind forward in the median line, which showed clearly the angle made by the sacrum. Then, by intersecting the line of the transverse vertical plane of the spinal column drawn as before mentioned, by a line drawn in the mean direction of the three first sacral vertebræ through the centre of their bodies, angles closely approximative to the sacro-vertebral angle in the living subject were obtained, showing the following results:—

* Weber, however, found the angle of the inferior plane with the horizon to be but little less marked than that of the male; making it 4°·5 more than the angle of Naegele here given. Naegele remarks that the inferior angle is much more variable than the superior in ordinary cases.

In twenty-five males,

Nine were from 110° to 112°, five from 115° to 117°, nine from 120° to 125°, and two only 130°.

In twenty-five females,

Nine were from 120° to 125°, eight from 128° to 130°, five from 133° to 140°, two were 145°, and one, an aged subject, 118° only.

Fig. 84.

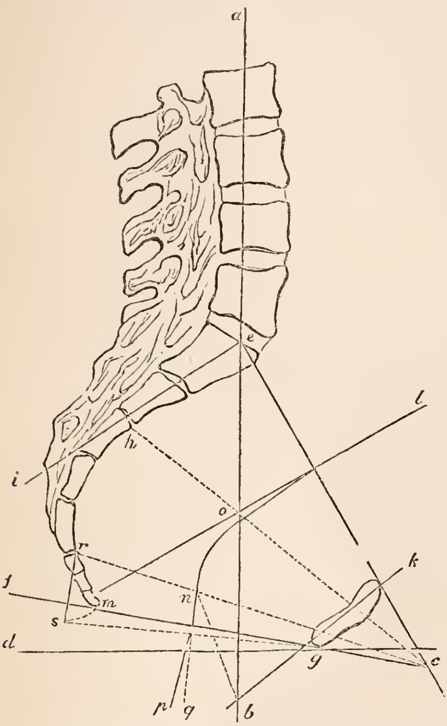

Diagram (slightly altered from Naegele) of a well-formed female pelvis, showing the angles of inclination and axes.

From these we may deduce 117° as the average sacro-vertebral angle in the *male*, and 130° as the same angle in the *female*. This remarkable average difference of 13° shows the much greater suddenness of the alteration of direction in the spinal column at its sacral extremity in the male subject, and is much greater than the difference of 5° to 6° in the pelvic inclination of the sexes compared in the tables of Weber and Naegele. But, in order more clearly to ascertain if the pelvic inclination invariably depended upon the variations of the sacro-vertebral angle, I compared the sacro-vertebral and pelvi-vertebral angles in nine male and nine female subjects. In the former, I found the *difference* between these angles to vary from 5° to 35°, and, in the latter, to vary from 5° to 25°. In one instance only, in a male, the sacro-vertebral was as large as the pelvi-vertebral angle. From these observations, which were very carefully taken, it would seem that *the total pelvic inclination does not exactly depend upon the sacro-vertebral angle;* and that, in *males*, where the average pelvic obliquity is *a little* greater, the average sacro-vertebral angle is *much* and *disproportionately* less. These results contradict, also, the assumption somewhat indefinitely stated by Blumenbach and others, on the authority of Bonaccioli, of Ferrara, that the sacrum inclines more backward, and that the sacro-vertebral angle is more prominent in the female than in the male.

If the long diameter of the pubic symphysis be continued in its direction downwards and backwards, it will, in a well-formed female pelvis, cut the transverse vertical plane of the spine, also prolonged, at an angle of 50° to 55° (*fig.* 84. *a b k*), which will be found to be about the complementary or opposite angle to the sacro-vertebral angle in the female. This shows the general parallelism of the anterior or pubic wall of the pelvis, with the upper part of the posterior or sacral wall, although, on account of the rapid thinning of the latter as it descends, its pelvic surface seems to diverge from the pubis. Naegele found the anterior pelvic wall to be often at right angles to the plane of the inlet, but the posterior generally somewhat more than a right angle. The great obliquity of the symphysis pubis to the transverse vertical plane of the vertebræ is one of the great characteristics of the human pelvis, as will be seen hereafter in the consideration of the comparative anatomy of the pelvis. The angle formed by the symphysis pubis with the horizon is given by Cuvier from 75° to 95°. This is much too large; from 35° to 40° is the true angle of the symphysis with the horizon in the human subject.

Ilio-ischial angle. — While the pubis in the human subject is continued in the same right line with the mean direction of the ilium, which coincides with the *cotylo-sacral rib* of that bone, the ischium is inclined *backwards*, forming an angle of 110° to 115° with the same rib of bone (see *fig.* 112. 1. *a c d*, *page* 73.), so that, while the pubes are directed *transversely* with regard to the pelvic cavity, the ischia are directed *vertically* along, and forming the sides of the cavity. This arrangement will also be found to be an important characteristic of the human pelvis, when compared with those of the inferior mammalia, in which the reverse of this arrangement will be found to prevail, viz., the continuation of the ischia in the line of the ilia, and the formation of an *ilio-pubic* angle.

Angle of ischio-pubic arch. — The angle at which the ischio-pubic rami tend toward each other, has been placed by Watt at 60° to 80° in the male, and 90° in the female; and by Sœmmerring at 75° for the male, and 95° for the female (*see figs.* 83, 80.).

Axes of the Pelvis. — The term axis is applied anatomically to the *line of direction* of any surface or plane, and, as it implies a right line, drawn at right angles to that surface or plane, it can only be applied with propriety to the outlets of the pelvis. As applied by some authors to the line which indicates the central point in any given plane of the pelvic cavity, it then becomes really a *curved* line, made up of an infinite number of perpendiculars drawn from any number of planes radiating from a centre placed anterior to the symphysis pubis. Since it is with regard to the mechanism of parturition principally that the axes of the pelvis are of importance, the angles formed by them, with the vertebral plane (transverse vertical), are stated in reference to the standard *female* pelvis more particularly. In the male subject, these angles will be somewhat greater, from the greater inclination of the pelvis in that sex.

The *axis of the brim* is a line drawn from the centre of the superior plane, and at right angles to it (*fig.* 84. *l*, *m*). This line cuts the prolonged vertebral plane exactly half-way between the symphysis pubis and the upper part of the third sacral vertebra, and forms with it an angle of about 60° (*a o l*). It may be taken also as the most nearly approximative axis of the pelvic *cavity* above that point. When prolonged at each end, it passes out at the umbilicus, and impinges upon one of the two last coccygeal bones, in a well-formed female. It is evident, however, that from the, great variety of the sacro-coccygeal curves, that the point where this line meets the coccyx will be variable. Hence, the observation of Watt, that a line joining the tip of the coccyx and the centre of the superior plane cuts the latter at an angle of 75°, is too definitive. M. Naegele, however, found that in a large number of female pelves, this line did meet the coccyx at some point or other.

The *axis of the inferior outlet* (*n*, *p*) is drawn at right angles to the centre of the inferior plane, and falls midway between the sciatic tuberosities. From the mobility of the coccyx, it will vary with the motion of that bone from its ordinary position to a position of extreme extension. In the ordinary position of the coccyx, this axis forms, with the vertebral plane, an angle of about 10°, and meets it near the centre of the upper surface of the body of the first sacral vertebra, impinging there upon the sacral promontory. When the coccyx is in a position of extreme extension, however, its tip describes the curve *m*, *s*, this axis is thrown more forward (*n*, *q*), and forms a less angle with the vertebral plane; while the plane of the inferior outlet itself is depressed (*g*, *s*), and its angle with the horizon (*s g d*) diminished.

The curved line (*l*, *o*, *n*, *p*), which indicates the *continued centres* of the planes of the pelvic cavity, may be divided into three portions indicated in the figure by the two dotted planes (*c*, *h* and *c*, *r*). The part from the plane of the outlet to the upper dotted plane (*c*, *h*), impinging upon the third sacral vertebra, may be considered to coincide, for all practical purposes, with the line of axis of the brim (*l*, *m*). The inferior dotted plane (*c*, *r*), drawn, like the former, from the point of junction of the planes of the brim and inferior outlet, to the tip of the last sacral vertebra, includes, with the upper dotted plane just mentioned, a *parabolic curve* (*o*, *n*), which does not quite coincide with the arc of a circle drawn from the ante-pubic centre (*c*). These two portions of the axes of the cavity are *fixed*, from the immobility of the pelvic walls which include them. But, below the inferior dotted plane to that of the outlet, the axis is directed more *forwards* (*n*, *q*), as the coccyx moves *backward* in the curve (*m*, *s*), a deviation which facilitates the exit of the fœtus in parturition. This forward direction of the axis at this part is increased also by the rounding off of the symphysis pubis at its inferior border. Each of the three portions passes midway between the corresponding and opposing surfaces of the symphysis pubis and sacro-coccygeal wall, the general vertical outline of which it nearly resembles, and between the lateral ilio-ischial columns. The latter, being equally inclined to each other downwards, cause no deviations in the plane which forms the centre of their lateral distances.

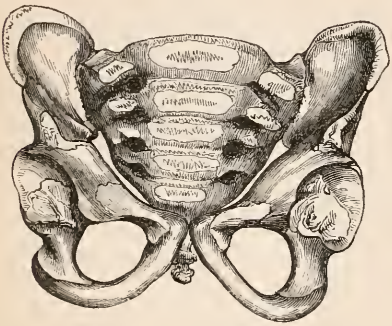
So that the so-called *axis* of the pelvic *cavity* is not one right line, as stated by Müller and Rœderer; nor is it properly expressed by perpendicular lines drawn from three planes, as Levret suggested; nor by a continuous geometric "*arc de cercle*," from the superior to the inferior plane, as G. Bang, Choulaut, Camper, and Carus concluded; nor by the meeting of the axes of the superior and inferior outlet, as is somewhat loosely stated by some more modern writers on obstetrics; but it is a more or less irregular parabolic curve, passing from the fixed axis of the brim, and moveable forwards at its inferior extremity with the moveable axis of the inferior outlet, with which it coincides below.

It may be here added, to prevent misconception, that the line of direction of the inferior outlet is in the living female inclined forwards in a much greater degree (*n*, *b*), than that of the osseous pelvis, by the prolongation of the posterior wall in the soft parts of the perineum.

General Development of the Pelvis. — In common with the inferior extremities, the pelvis, in the infant, is more tardy in arriving at adult perfection than the upper parts of the body; and this delay is more evident in the inferior or true than in the superior pelvis, and considerably facilitates its transit through the maternal structures. *At birth*, the iliac wings are flat, and their surfaces are directed more forwards and less inwards than in the completely formed pelvis. From the narrowness of the sacrum, and the shortness of the pubes, the transverse dimensions of the brim and cavity are very small, and the antero-posterior diameter, from this cause, is larger than the lateral, by $\frac{1}{4}$ to $\frac{1}{2}$ an inch. The shape of the superior opening is less rounded than in the adult, being of a sub-quadrate rather than an oval form. The cotyloid part of the ilia is completely cartilaginous, contracted, and less projecting, while the pubic arch is narrow and angular, and the tuberosities of the ischia are near each other so as to present a small opening at the inferior outlet. Sœmmerring remarks that the obturator foramen is more elliptical in the infant than in the adult. The depth and general appearance of the true pelvis is smaller than is proportionate to the iliac wings; and it is of nearly equal breadth throughout.

The *parallelism* of the lateral, as well as of the anterior and posterior pelvic walls is, I think, sufficiently marked and general to be considered as a characteristic of the conformation of the infant pelvis, as we shall find it to be of that of most of the lower animals, giving to it a square-sidedness which is well seen in the adjoining figure.

Fig. 85.



Pelvis of the Child at birth.

The sacrum and coccyx in the child at birth are much less curved, vertically, than they afterwards become, which causes the posterior wall to be longer than is proportionate. The coccyx, indeed, in many instances I have seen, was almost vertical. The sacro-vertebral angle is consequently much less marked than in the adult. Doubtless, muscular action, increasing as the development of the bones progresses, has a great effect in producing the diminution of the sacro-vertebral angle backwards in after life.

It is commonly stated by anatomists, that the infant pelvis is more obliquely placed on the spinal column than the adult pelvis. The inclination of the superior plane in the child has been placed by the brothers Weber at an angle of 154·66 with the transverse vertical plane. This is somewhat *less* than the inclination in the male, according to the same observers, viz. 155°.

The following table is the result of the measurements of the pelvic angles of five infants, made to ascertain the correctness of this statement. The angles were carefully taken, with much precaution against any abnormal displacement, so readily occurring in the pliant structures of the infant, by making an antero-posterior vertical section of the pelvis and whole spinal column with the whole of the soft parts attached, and in such a manner as would have tended rather to increase, than to diminish, the pelvi-vertebral angle.

	Angles.	
	Pelvi-vertebral.	Sacro-vertebral.
1. Fœtus at 6 months, *female*	150°	155°
2. " " *male* -	150°	145°
3. Infant at full term, 7 days old, *female* - -	150°	145°
4. Infant at full term, *female* - - -	150°	140°
5. Infant at full term, still born, large and well-made, *male* - -	140°	140°

It will be remarked that the greatest difference from the adult is observable in the *sacro-vertebral angle*, which is from 10° to 15° greater than the average female adult, and from 23° to 28° greater than the average male adult.

I should here state, also, that the results of my own measurements of the angle of the superior pelvic plane in adult male subjects, have given somewhat *less* angles than that stated by Weber.

According to Cruveilhier, a horizontal line, from the upper border of the pubis, meets the posterior wall much lower in the infant than in the adult, though the point at which he places it in the adult, viz., a little below the base of the sacrum, is much too high in the natural position of the pelvis, as will be seen by inspection of the diagram (*fig.* 84.). In all the infant pelves I have just given, the tip of the coccyx reached as low as the *lower border* of the symphysis pubis; both these points exactly coinciding with a line drawn perpendicular to the transverse vertical plane. This may, perhaps, be attributed to the greater flatness of the sacro-coccygeal wall in the infant, extending it further downward. In *No.* 5. the male child at full term, the *angle of inclination of the pubic symphysis* to the transverse vertical plane was only 25°, but in the last female child it was, 40°, both being less than the mean adult angle, 50°, before given, and showing, like the *sacro-vertebral* angle, a greater tendency to parallelism with the spine, as in the inferior animals, an analogy which is also seen in the elongated conjugate diameter.

Resulting from this tardy development of the pelvis, the bladder and greatest portion of the rectum, in the child at birth, are contained almost entirely in the abdominal cavity, on a level with the ilia or false pelvis, and only descend gradually afterward into their adult position with the slow development of the pelvic bones, assuming their permanent position about the period of puberty, a circumstance very necessary to be borne in mind in operations on these viscera in children below that age. Hence one cause of the greater prominence of the belly in children from the additional number of its visceral contents.

According to Dupuytren, the female pelvis differs very little from that of the male till puberty, at which period it has a general triangular form in both sexes, but, after that period, it becomes rapidly developed, and soon assumes its distinctive sexual character. The transverse diameters begin to exceed the conjugate, and, in the female, attain a great preponderance, constituting one of the great characteristics of the fully formed human pelvis, as distinguished from that of the lower animals.

In Autenrieth's method of calculating the pelvic dimensions, the dorsal, or posterior part, bears a proportion to the anterior or abdominal part, as 10 to from 11 to 14, in the infant of two years; while, in the adult pelvis, it was as 10 to from 16 to 22.

In *advanced adult age*, the pelvic inclination is said by Cruveilhier to be *increased* in consequence of the forward curvature, or drooping of the spinal column, which tends to arrive at the horizontal position, as in quadrupeds. To keep the centre of gravity between the lower extremities, the femurs, in old persons, are more flexed upon the pelvis, so as to be more directed towards the line of the superior pelvic plane. I have found, however, that in old subjects, although the angle of the pelvic plane with that of the *whole* spinal column is increased, yet the angle with the lumbar vertebræ only, is not so much changed, and that, apparently, the increased muscular traction on the sacrum and posterior part of the ilia by the muscles of the back acting upwards, and of those of the front of the thigh acting downwards, upon the anterior part of the pelvic lever, in order to preserve the erect position, produce this increased obliquity of the pelvis, which is generally accompanied by a corresponding *decrease* of the sacro-vertebral angle. This will be more fully comprehended when considering the mechanism of the pelvis.

Muscular Attachments of the Pelvis. — To afford a fixed point for the attachment of the numerous and powerful muscles acting on the trunk and extremities is one of the important offices of the pelvis. These may be classed as *posterior spinal* and *abdominal* groups acting on the trunk and spinal column; *extensor*, *flexor*, *adductor*, *abductor*, and *rotator groups* acting on the lower extremity; and *perineal groups* forming the moveable floor of the pelvis and acting on the genital and excretory organs.

1. *Muscles acting on the trunk and spine.*— The *posterior spinal group.*—The *longissimus dorsi* and *multifidus spinæ*, to the upper part of the posterior surface of the sacrum; the *interspinales*, to the superior border of the sacral crest; and, according to some, the *extensor coccygis*, to the contiguous posterior surfaces of the sacrum and coccyx; the *sacro-lumbalis*, to the middle part of the posterior third of the iliac crest, and to the contiguous sacral surface; and the *latissimus dorsi*, through the lumbar fascia to the external lip of the posterior half of the iliac crest and to the sacral crest. This muscle acts on the arm. The *abdominal group.* — The *obliquus externus* and *internus*, and *transversalis abdominis*, to the external lip, middle ridge, and internal lips respectively of the iliac crest, and also by their aponeurotic tendons to the angle, crest, spine, and pectineal line of the pubis (the external oblique tendon, under the name of Poupart's ligament, stretching across, from the anterior superior iliac spine to the spine of the pubis, and, under the name of Gimbernat's ligament, passing backwards to the linea-ilio pectinea; and the internal oblique and transversalis tendons enclosing the rectus abdominis muscle, and uniting to form the conjoined tendon); the *quadratus lumborum*, to the posterior fourth of the inner lip of the iliac crest; the *rectus* and *pyramidalis abdominis*, to the crest of the pubis; and the *psoas parvus*, when present, to the pectineal eminence.

2. *Muscles acting on the leg.* — The *flexor group.*—The *rectus femoris*, to the anterior inferior iliac spine and outer part of the cotyloid rim; the *iliacus*, to the whole anterior concave surface of the iliac wing — the *psoas magnus* is not attached to the pelvis, but acts upon it by passing over it along the pelvic brim; and the *sartorius*, to the anterior superior iliac spine and notch below it.

The *extensor group.* — The *biceps flexor cruris*, *semitendinosus*, and *semimembranosus*, to the depending middle and posterior parts of the ischial tuberosity; and the *gluteus maximus*, to the quadrilateral gluteal impression on the dorsum of the ilium, to the posterior surfaces of the two lower pieces of the sacrum, and of the two or three upper pieces of the coccyx, to the oblique sacro-iliac and great sacro-sciatic ligaments, and to the lumbar fascia.

The *adductor group.*—The *adductor magnus*, to the anterior part of the ischial tuberosity, and to the united ischio-pubic rami; the *adductor longus*, to the anterior surface of the angle of the pubis; the *adductor brevis* below the foregoing, to the same surface; the *pectineus*, to the spine, pectineal line, and horizontal ramus of the pubis; and the *gracilis*, to the rough internal border of the ischio-pubic rami and symphysis pubis.

The *abductor group.*— The *gluteus medius*, to the dorsum of the ilium, between the crest and superior curved line; the *gluteus minimus*, to the same surface between the curved lines; and the *tensor vaginæ femoris*, to the outer surface of the anterior superior iliac spine.

The *rotator group.*—The *pyriformis*, to the anterior surface of the sacrum between the four upper sacral holes, and passing out through the great sciatic notch; the *obturator externus*, to the inner half of the external circumference of the obturator foramen, and to the external surface of the membrane closing it; the *obturator internus*, to the internal surface of the same ligament, and to the borders of the foramen, and also to the surface of bone opposite the cotyloid cavity (this muscle passes out through the small sciatic notch, over which it is bent as over a pulley); the *gemellus superior*, to the outer surface of the ischiadic spine; the *gemellus inferior*, to the posterior extremity of the ischiadic tuberosity; and the *quadratus femoris*, to the external border of the same tuberosity.

3. *Muscles acting on the perineum and genitals.*—The *posterior perineal group*. The *levator ani*, to the middle of the inner surface of the symphysis pubis, to the inner surface of the ischiadic spine, and to the tip of the coccyx; the *ischio-coccygeus*, to the same inner surface of the ischiadic spine, to the lateral border of the coccyx, and to the inner surface of the small sacro-sciatic ligament; and the *sphincter ani*, to the tip of the coccyx.

The *anterior perineal group*.—The *transversus perinei*, to the middle of the inner border of the ischial tuberosity; the *accelerator urinæ* (or, in the female, the *sphincter vaginæ*), to the anterior part of the inner border of the ischial tuberosity; the *erector penis* (or, in the female, *clitoridis*), to the ascending ramus of the ischium; and the *compressores urethræ*, to the descending ramus of the pubis, and to the sub-pubic ligament.

Fascial Attachments.—Besides the foregoing, the pelvis also affords attachment to many important *fasciæ*, which are susceptible of division into *lumbar*, *abdominal*, *crural*, *pelvic*, and *perineal*.

The *lumbar fascia* is formed by the junction of the tendon of the latissimus dorsi muscle with the fascia vertebralis, and the united posterior tendons of the internal oblique and external division of the transversalis tendon, and it is attached along the sacral crest and posterior surface of the fourth sacral bone, and to the posterior half of the iliac crest, enclosing the sacro-lumbalis muscle.

The *abdominal fasciæ* are three in number, viz., the *fasciæ transversalis*, attached along the inner lip of the iliac crest, to Poupart's ligament, and to the crest, spine, and pectineal line of the pubis; the *fascia of the quadratus lumborum muscle*, or anterior division of the tendon of the transversalis, attached to the inner lip of the posterior fourth of the iliac crest, and to the ilio-lumbar ligament; and the *iliac fascia*, attached to the ilio-lumbar ligament, along the inner margin of the iliac crest, and to the anterior superior iliac spine.

The *crural fascia* or *fascia lata* is divided into three portions, named, from their respective attachments to the three portions of the innominate bone, *iliac*, *pubic*, and *ischiadic*. The outer lip of the iliac crest, the anterior superior spine, and Poupart's ligament, give attachment to the *iliac* portion, which separates the lateral abdominal from the external leg muscles; the spine, crest, angle, pectineal line, and descending ramus of the pubis, to the *pubic* portion, which separates the internal leg muscles from the anterior abdominal and anterior perineal group of muscles; and the tuberosity and ascending ramus of the ischium to the *ischiadic* portion, which separates the posterior leg muscles from the posterior muscles of the perineal group.

The *pelvic fascia* is composed of two portions, the *recto-vesical* and *obturator*, which, having a common attachment to the anterior surface and promontory of the sacrum, to the anterior and lateral parts of the pelvic brim, and to the iliac fascia, separate opposite the line of origin of the levator ani muscle, which arises between them, from the symphysis pubis to the ischiadic spine. The *obturator* division is attached to the inner margins of the ischiadic tuberosity and ischio-pubic rami, being connected with the falciform margin of the great sacro-sciatic ligament behind, and secluding the obturator muscle from the ischio-rectal fossa; the *recto-vesical* division, forming the anterior and lateral true ligaments of the bladder, is attached to the posterior surface of the symphysis pubis above the origin of the levator ani, and to the inner surface of the ischiadic spine.

The *perineal fascia* is divided into two portions, *deep* and *superficial*, which enclose between them the superficial muscles of the anterior perineal group, and also the bulb of the urethra and the crura of the penis. The *deep perineal fascia* or *triangular ligament* is subdivided into two layers, anterior and posterior, which enclose between them the membranous urethra, with its compressor muscles and Cowper's glands. They are both attached to the lower border of the pubic symphysis and sub-pubic ligament, and to the inner border of the united ischio-pubic rami, and intervene between the posterior and anterior perineal groups of muscles. The *superficial perineal fascia* covers in the anterior perineal region, and is attached to the anterior part of the inner border of the ischio-pubic rami, and to the anterior surface of the angle of the pubis.

The *crura of the penis*, or, in the female, those of the *clitoris*, may also be mentioned as implanted on the rough inner border of the ischio-pubic rami about their junction; as well as the *round uterine ligament*, in the female, to the anterior surface of the pubis.

Mechanics of the Human Pelvis.—When we consider the pelvis with regard to its architectural adaptations, and compare it with the principles of engineering, we are struck with the beautiful simplicity of the means by which it combines strength with elasticity, and lightness with capacity and unity of design. The weight of the trunk is to be transmitted through the lumbar vertebræ to the sacrum, and from thence to points of support, which vary with the position of the inferior extremities. In the erect position, these points are the femora. In the sitting position they are the tuberosities of the ischia.

The experiments of Weber have proved that though the centre of gravity of the *trunk* itself (without the legs) is placed in the transverse vertical plane as high as the sterno-xiphoid joint, yet the centre of gravity of the *whole body*, as marked by the point of section of the before-mentioned transverse-vertical with a horizontal plane, is placed only

8·7 millimetres above the sacro-lumbar joint, or just above the pelvic arch. All weight on the arch, such as that of the trunk, is supported most easily when its line of gravity falls through this part, and coincides with that of the whole body in the transverse vertical plane, and the trunk will be found to be thrown into such a position, when supporting heavy weights, as will tend to produce this effect. And, according to the researches of Rokitanski, when the sacro-vertebral angle and pelvic inclination is increased, as by hip disease, there is always a compensatory curve of the spine backward, to keep the centre of gravity above this point.

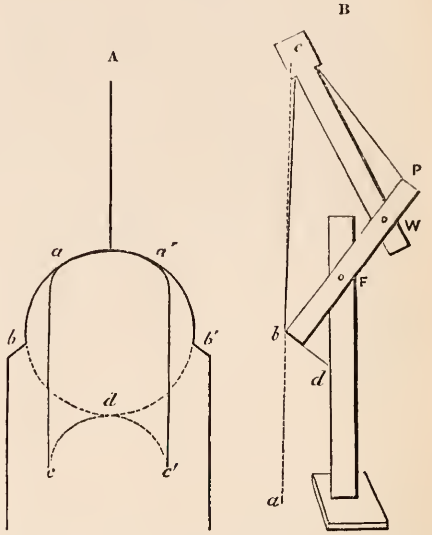
In artificial constructions for the purpose of transmitting a weight downwards from a central to two lateral points, a segment of a circle, or *arch* is most commonly made use of, and generally consists of two lateral curved portions, composed of separate parts or *voussoirs*, with an interposed substance between them called a *keystone* or crown-piece, of a wedge shape, and placed with the broad end uppermost. This wedge shape exactly corresponds to the interval which would be left between the lateral curved pieces, having their ends cut square. Any force operating on the keystone from above tends only to drive the broader part of the wedge further between the lateral pieces, at the same time pressing them nearer to each other, and so to increase the firmness of the arch, so long as the extremities are firmly fixed in the ground and prevented from starting outwards, which is generally accomplished by means of abutments.

Constructed upon this plan, the pelvis presents two lateral curved thickened buttresses or columns, passing from the cotyloid to the sacro-iliac articulations, and two others passing on a plane posterior to these from the tuberosities of the ischia along their descending rami, and through the ilia to the same sacro-iliac articulations; and interposed between each of these corresponding lateral pieces is the common keystone of both the arches thus formed, the wedge-shaped sacrum.

The sacrum thus forms the common culminating point of two arches, viz., the *cotylo-sacral* or *standing arch*, and the *ischio-sacral* or *sitting arch*. And the planes of these two arches are so directed as to coincide or become applied to each other at the top of the great sciatic notch, as may be seen by reference to the diagram (*fig.* 86. A, *a a′*). In this comparison, however, it must be borne in mind, that the extreme tenacity and strength of the material used, *bone*, obviates the necessity of the use of many pieces in the lateral portions, such as the "voussoirs" of stone arches, and is more analogous to the iron materials sometimes used for this purpose. And it is in these lines of pressure that we find the bulk and strength of the osseous structure of the pelvis most displayed.

The span of the cotylo-sacral arch being greater, and more elliptical in the female than in the male, where it is almost circular, renders them less able to support heavy weights; and on account of the greater distance to

Fig. 86.



A, *diagram of the pelvic arches:*—*b, a, b′*, cotylo-sacral arch; *c, a, c′*, ischio-sacral arch; *b, d, b′*, cotylo-pubic tie; *c, d, c′*, ischio-pubic tie.
B, *diagram of pelvic levers*:—*c, a*, line of gravity; F, *b*, pubic lever; F, W, cotylo-sacral lever; W, P, posterior spinal or iliac lever; P, *c*, direction of spinal power; W, *c*, direction of spinal weight; F, cotyloid fulcrum; *d*, femoral support.

which it separates the femurs, contributes to produce the waddling gait in running which is characteristic of this method of female progression.

Instead of abutments to prevent the extremities of the arch starting outwards, we often see, in artificial constructions, a connecting link or *tie* extending between these extremities to hold them together, or the circle of which the arch is a segment is completed below, as in tunneling.

Such a tie and completion of the circle we have in the horizontal rami of the pubic bones, for the cotylo-sacral arch, and in the united ischio-pubic rami, for the ischio-sacral arch; and they are connected in front, at the pubic symphysis, exactly as these two arches themselves are behind at the sacro-iliac joints.

By the vertical *ischio-pubic arch* thus formed, that portion of the pressure which has a tendency to push forward and upward the extremities of the ischio-sacral arch, is supported and thrown upon the cotylo-sacral arch, the whole weight of the trunk, in a sitting posture, being thus divided between them The ischio-pubic rami are the parts of the pelvis most liable to fracture, according to Cruveilhier, from the application of force acting on the ischia.

The *cotylo-pubic arch* not only resists the starting outward of the ends of the cotylo-sacral arch, but it resists their displacement inwards, which would result from the pressure of the femora in the direction of the necks of these bones. The effect of this pressure, when the pubes yield to it, is shown in the deformity which has been termed the *rostrated pelvis*, resulting from the crushing of these bones together. The cotylo-pubic arch also receives, in its concavity, part of the weight of the abdominal viscera, though, from the attachment of these to the spine, their chief weight is concentrated upon the common centre of pelvic arches,—the sacrum. The ilia are also generally supposed to support the intestines in a great measure; but this support, on account of their great obliquity in the erect position, cannot be so important as is commonly imagined, except, as in the case of the cœcum and rectum, through peritoneal attachments. The human pelvis, when thus taken in conjunction with the thorax, forms the base of a cone, the apex of which is the neck, a disposition for supporting the contained viscera which the erect position demands, and which contrasts strongly with the structure of quadrupeds.

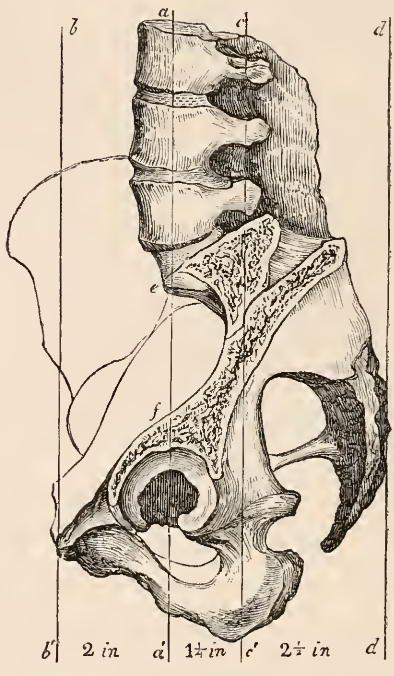
Again, the cotylo-sacral and pubic arches on each side, united at their extremities in the acetabula, form *two lateral arches*, on the centres of which rest the thigh bones. Against the lateral pressure exercised by the thigh bones, these two arches, connected, at their anterior and posterior extremities, by the symphysis pubis and sacrum, form, as Mayo observes, an elastic hoop. The ischia also contribute to this resistance against lateral pressure, and form, with the two other portions of the innominate bones, a sort of arched tripod, on the apex of which the femur is supported.

In addition to the buttresses already described, there is, placed vertically above the cotyloid cavity, a thick *rib* of bone, which transmits to the arched crest of the ilium, and through it and the sacro-iliac joint to the sacrum, a portion of the direct vertical pressure from the heads of the thigh bones. This thickened portion of the iliac wing has been mentioned in the general description of the bone as impinging on the iliac crest in the middle of its anterior curve. The division of the pressure thus produced, no doubt calls into action much more completely the elastic resistance of the pelvis, in sudden increase of weight. Thus in the sacro-iliac joint meet three buttresses or thickened lines of pressure, of which the *direct cotylo-sacral* is the central and principal one, the *ischio-sacral* the lowest and next in strength, and the *superior* or *indirect cotylo-sacral* the weakest.

But, besides merely supporting quiescent superincumbent weight, the pelvic arches are required to resist and break the force of shocks and concussions meeting with the inertia of the trunk, and passing from the lower extremities of the body to the vital and delicate cranial and thoracic structures. These dynamic requirements are met by peculiar modifications of the simple arch, combining with it, by an admirable adaptation, the qualities of an elastic spring.

First, the cotylo-sacral arch, on which the greatest number and force of shocks falls, is not placed *vertically*, but *obliquely upwards* and *backwards*, while the cotylo-pubic arch, being united to it at its extremities, and continued in the same plane over the femoral supports, forms the anterior arm of a bent lever of the first order, of which the cotylo-sacral arch is the posterior curved arm, the spinal column the weight, and the heads of the femurs the fulcrum (see *figs.* 87. and 86. B).

Fig. 87.



Drawing of a section of the pelvis in the cotylo-sacral arch, removing the left iliac wing. a, a′, line of *fulcrum* falling in the transverse vertical plane of trunk; c, c′, line of *weight* passing through centre of sacro-iliac joint; b, b′, line of *power* or pubic projection; d, d′, line of sacral projection; e, f, cotylo-sacral curve; a′, b′, pubic arm of lever; a′, c′, cotylo-sacral arm; a′, d′, length of gluteal arm; c′, d′, posterior spinal arm; g, posterior iliac projection.

The anterior or pubic arm of this lever giving insertion to the powerful extensor muscles of the thigh, which represent the *power*, is thrown upwards by the operation of downward force on the crown of the cotylo-sacral arch, calling these muscles into contractile reaction, which overcomes gradually the force of any shock operating at the posterior extremity of the pelvic lever over the fulcrum of the thigh bones. In well-formed male pelves, the pubic arm of this lever is increased in power by being longer than the cotylo-sacral by $\frac{1}{2}$ or $\frac{3}{4}$ of an inch, the one being 2 inches, the other $1\frac{1}{4}$ inch, in direct distance from the centre of the cotyloid support (*fig.* 87. *a′ b′*, *a′ c′*).* This gives the anterior muscles of the thigh greater power in resisting the downward force of the trunk at the sacral extremity of the lever.

But by the addition of the iliac and sacral projections posteriorly, the cotylo-sacral arm is increased in length by 2½ inches, as will be observed on reference to the figure (*c′*, *d′*), a disposition which evidently increases the power of the glutei muscles in maintaining the habitual erect position, and resisting any tendency to fall forwards, by extending the femora on the pelvis.

Again, if we follow the lateral curve of the sacrum at the brim of the pelvis, we shall find that it projects forward in the promontory of the sacrum, immediately under the point supporting the spine, so that its profile, taken with that of the ilium, as seen in the figure (*c f*), presents a curve with the concavity forward, in the manner of a C spring. It is worthy of remark, that, in the erect position, a plumb line, dropped opposite to the centres of the bodies of the axis and last lumbar vertebra, passes across the centre of the sacral promontory, and directly between the centres of the cotyloid cavities, as was proved by the experiments of Weber. Such a plumb line marks exactly the line of the transverse vertical plane of the spinal column before mentioned, which, when continued downwards, passes through the *sacral extremity* of the pelvic lever, and also through the *cotyloid fulcrum*, dividing equally and vertically the heads of the thigh bones, and crossing the ischio-pubic rami about their suture (*a a′*). Thus, the oblique C-like curve of the cotylo-sacral arch, or posterior bent arm of the lever, meets this plane at its two extremities, directing its concavity towards it like the arc of a circle to its chord; and contributes, by its elastic reaction, to break the force of shocks operating through the spine and femora. In deformed pelves, we generally find that the sinking of the sacrum, the crown of the pelvic arch, under the weight of the trunk, produces an increased curvature of the iliac bones *forwards* by the yielding of the C spring, and thus still further encroaches upon the dimensions of the pelvic brim.

The above considerations will illustrate the fallacy of the deduction of Cruveilhier in respect to the *statics* of the pelvis. This celebrated anatomist remarks, that "the articulation of the vertebral column with the pelvis is situated at the back part of that cavity, while the articulation of the femurs is anterior and lateral. The distance between them increases the space in which the centre of gravity can oscillate, without being carried so far forward as to pass beyond a perpendicular, from the cotyloid cavity to the base of support at the feet" (p. 514. vol. i. *Anat. Descrip.*). Now these experiments of Weber prove that the centre of gravity is directly *over* the cotyloid support, and cannot oscillate between these two articulations. The only oscillation of the line of gravity which can take place without falling is along the length of the basis of support — the feet.

Soon after, in reference to the sitting position, he says, "the tuberosities of the ischia being a *little anterior* to the cotyloid cavities, and *near the front of the pelvis*, the centre of gravity tends to pass behind the base of support; and the body easily falls backward in that position." Now, the tuberosities of the ischia, in the erect posture, are considerably *behind* the line of gravity, or transverse vertical plane, which crosses at or near the ischio-pubic ramal suture; and though, in the sitting posture, they are brought a little nearer the line of gravity, yet a much more satisfactory reason of the trunk more easily falling backwards than forwards, is because of the support of the hams in front, and the elevation of the coccyx behind above the plane of support.

Again, by the projection of the sacrum and tuberosities of the ilia behind the sacro-iliac joints, another lever, less powerful than the foregoing, is formed, having also the cotylo-femoral supports for its fulcrum, and the spinal column for its weight, the anterior arm of this lever being the cotylo-sacral arch (*fig.* 87. *a′*, *c′*), and the posterior, the overhanging tuberosities of the ilia and projecting sacrum (*c′*, *d′*). Measuring from the centre of the sacro-iliac articulation, the anterior arm is 1½ inch in direct length, and the posterior about 2 inches and a half. The power in this lever resides in the powerful muscles which pass from the sacral and iliac bones posterior to the sacro-iliac joint, to the osseous spinal projections and appendages above—viz. the longissimus dorsi and sacro-lumbalis, and its action is shown in the increase of the pelvic inclination on the change from the sitting to the standing position; the principal movement taking place in the sacro-lumbar joint. It acts to the most advantage when the *centre of gravity* of the *trunk*, from which it is derived, is thrown *in advance* of the cotyloid fulcrum (*a a′*), so that the lever, though apparently one of the second order (i. e. in which P and W are on the same side of the fulcrum), is in reality one of the first order, [in which the fulcrum may be between them, and supports both the power, P, and the weight, W. Hence, in the drooping of the trunk forwards in old age, the action of these muscles contributes, to produce the increased obliquity of the pelvic lever in the manner before described. This may be made more evident by inspection of the diagram (*fig.* 86. B), which is taken from a small brass model made to illustrate this point. It will be seen that the pressure on the cotyloid fulcrum, F, could not be W − P, as in the second order of levers, but must necessarily be W + P, and therefore in the first order of levers. P, in this case, may be represented

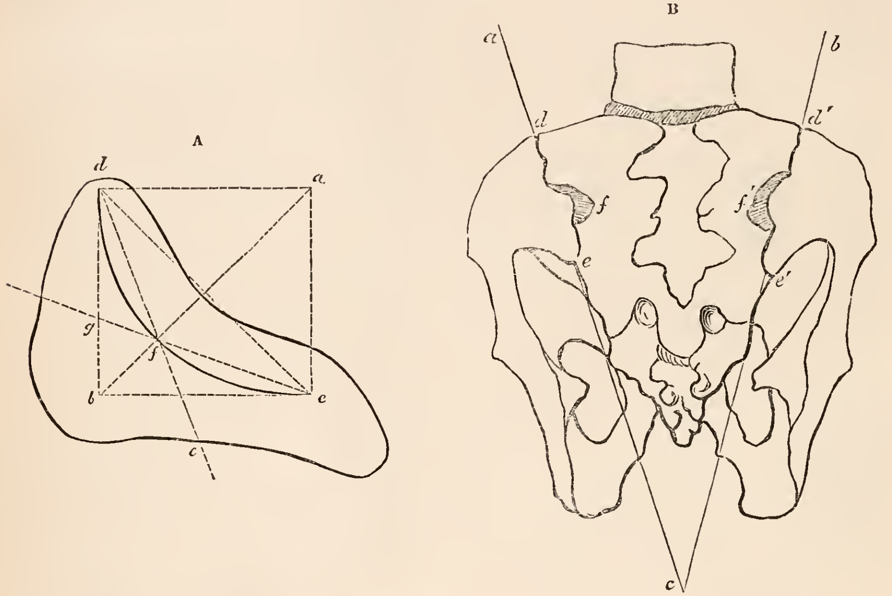
* The line *c c′*, in the diagram passes through the centre of the sacro-iliac joint,—at which point, a line drawn from the cotyloid fulcrum of the bent lever falls perpendicularly upon the line of action of the weight, transmitted obliquely in the sacral axis, — and this consequently, the effective point of power of the bent arm *f. e.*

by the line P *c*, and the line of gravity of the trunk, *c a*, and is doubtless considerably increased by the resisting tension of the anterior abdominal muscles acting through the extensors of the thigh on the femoral supports in the line *c b*, *b d*.

In the foregoing dispositions of the pelvic structure, the office fulfilled by the *sacrum* is so compendious and important as to call for particular attention to the shape and position of that bone, and the manner in which it is articulated with the ilia, so as to be at once firm and strong as a keystone, yielding as a spring, and moveable as a jointed bone. And we shall find all these requirements beautifully provided for.

First. The sacrum is wedge-shaped, when viewed at its anterior aspect, narrowing from *above downward*, especially along the surface immediately between the lower portions of its iliac articular surfaces in the plane *b*, *e* (*fig.* 88. A), which are inclined to each other at an angle varying from 15° to 30°, and averaging about 20°. When viewed from above at its base, as in *fig.* 89. *page* 144.), it also presents a wedge shape with the base directed *anteriorly*, the lateral masses of the base becoming narrower from *before backwards;* so that the

Fig. 88.



A, *diagram of the sacral auricular facet, natural size and placed as in the erect position of the body, with the lines of tension and pressure.* *a*, centre of action of the posterior deep ligaments; *d f e*, arc of sacral groove, forming a quadrant with the lines of tension, *a d*, *a e*; *d e*, chord of the arc; *d f*, *e f*, chords of the semi-arcs; *d g e*, sacro-vertebral angle; *d b e*, triangle forming the sacral "voussoir;" *b* and *e*, position of sacral "joggles."

B, *diagram of a transverse section of the pelvis in the line of the sacral axis, posterior view*; *a c b*, angle of vertical sacral wedge; *d*, *e*, depth of sacro-iliac articulations; *f*, interosseous sacro-iliac ligaments.

sacrum appears to be a double wedge, having its broadest part at the border of junction of the base with the anterior surface, and tapering from this point, both upwards and backwards and downwards and backwards.

Hence it has been stated by Cruveilhier to be liable to dislocation downwards and forwards, from the want of bony support in that direction. But the sacrum, in the erect position of the body, is placed, not vertically, but obliquely, with its base directed more forwards than upwards, and its anterior surface more downwards than forwards, so that the upper limb of the auricular surface is placed nearly vertically, and the lower nearly horizontally, as seen in *fig.* 88. A. The diminished breadth of the base of the sacrum posteriorly is due to the bevelling of the lateral surfaces for the implantation of the deep posterior and interosseous ligaments, as seen in fig. 88. (B, *e*), the bone not being here in apposition with the overhanging iliac tuberosities, — the area of absolute contact being confined to the auricular surfaces themselves. Again, the increased breadth of the anterior surface at the auricular angle *c* (*fig.* 89.), will be found, on careful inspection, to depend upon the presence of the pointed projections on each side, before described as received into corresponding depressions on the auricular surfaces of the ilia, which latter, being circumscribed below by a raised border, cause the sacrum to *bite* on the ilia here to a considerable extent, forming what is called, in engineering nomenclature, a "joggle" to the sacral "voussoir." By the iliac support thus received, the position of the sacrum is well protected against pressures, coming either directly downwards in the line *d*, *b* (*fig.* 86. A), or downwards and forwards in the direction of the line *a*, *b*; *b* being placed in the diagram upon the sacral projection. By measuring in eight sacra, the distances between the upper extremities of the auricular facets on each side, at the point *d*, marking them off on paper, and then taking the distances in like manner at *c*, which corresponds to the lateral notch opposite the second sacral vertebra (*see fig.* 78. A, *b*.), I found the line *d*, *c* to coincide pretty nearly with the mean direction of the superior vertical limb, and with the superior half of the central curved groove *d*, *e*; and to fall in a plane which was inclined to the one on the opposite side, so as to form with it an angle varying from 15° to 25°, and in all cases directed *downwards*.

Now, the sacrum is so placed in regard to the cotylo-sacral arch, and the line of pressure from above, that the angle formed by the surfaces of the base and anterior face is the narrowest point of a rapidly-expanding articular wedge placed antero-posteriorly. This is better seen by a lateral view of the auricular facet, with the bone in the natural oblique position, as in *fig*. 88. A. The facet will then be seen to have its angular projection pointing downwards and forwards in the direction of the cotylo-sacral arch in the line *a b*, and its two limbs diverging so as to present a broad surface of articulation with the ilia in the lines *b d*, *b e*, forming with *d e*, the triangular "voussoir" *d b e*. The depth of the keystone is the greatest distance between the anterior border of the superior limb, *d*, and the inferior extremity of inferior limb, *e* (*fig*. B), and is about $2\frac{1}{2}$ inches in the adult male. The wedge shape formed by them is well seen in the posterior view of a transverse section along the sacral axis, as in *fig*. B, where the lines *a c*, *b c* show the obliquity of the wedge, and form an angle *a c b*, of from 20° to 35°. In a direction downwards and *backwards*, then, the sacrum has, like an artificial "voussoir," or keystone, its broad end directed *upwards* towards the point of pressure.

But, as Cruveilhier has justly observed, forces acting in the curve of the lumbar vertebræ are partly counteracted by the elastic spring-like yielding of the lumbar and sacro-lumbar fibro cartilages; and by the lumbar curve they are, at the same time, directed *backwards* as well as downwards (viz., — at first in the direction of the line *d*, *f* (*fig*. 88. A), and then in that of *f*, *e*, which latter, produced to meet the vertical line *d*, *b*, at *g*, forms an angle *d g e*, of about 117°, *coinciding* with the average *sacro-vertebral* angle *in the direction of the sacral axis*), — thus tending to drive the broad end of the sacral "voussoir" between the narrower iliac intervals; and so, in relation to the direction of the *principal* forces acting on the pelvic arch, the sacrum becomes a true keystone.

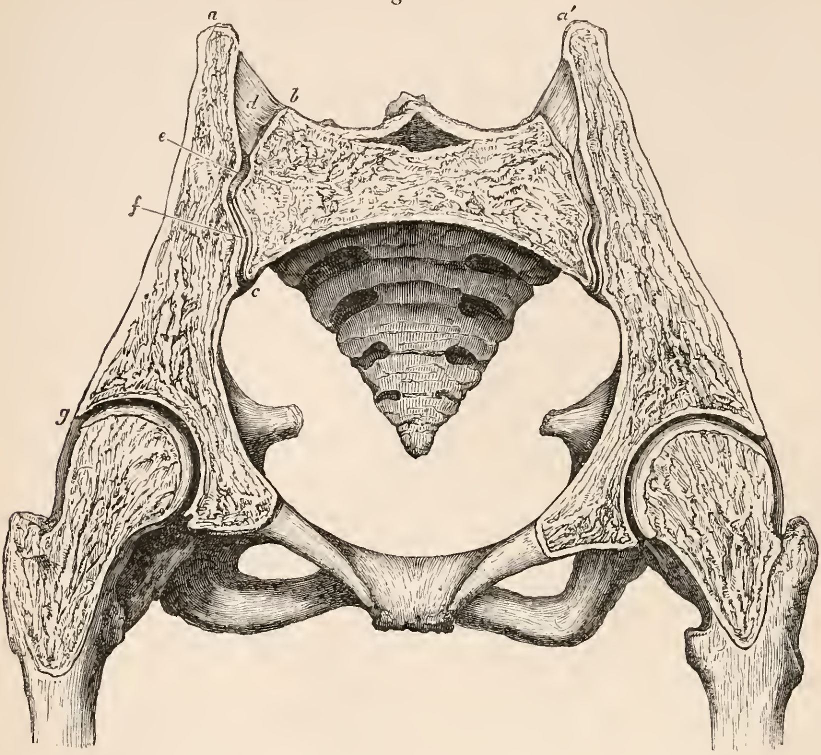
Another arrangement which would tend, from the obliquity of the bone, to counteract any forward displacement, is the sudden inversion of the vertical sacral wedge at the extremity of the lower limb of the auricular surface (*fig*. B, *e*), opposite the third sacral bone, at which point, we have mentioned in the description of the sacrum, the anterior surface becomes suddenly broader from above downwards; so that here the sacrum by another "joggle" again *bites* on the iliac. A third disposition preventive of this displacement has been pointed out by Mr. Ward, in the superiority of breadth of the posterior over the anterior surface of the sacrum, opposite the point *c*. (*fig*. A.), the middle of the inferior articular limb in many instances.

Behind and above the angular projection on the sacral facet is an elongated depression or *groove*, which passes along the centre of both limbs of the auricular surface, and receives a reciprocal elevation on the *iliac* articular surface (*fig*. 89. *f*.) Now this ridge on the iliac surface evidently bites in its turn on the sacrum, and presents another obstacle to anterior displacement in the superior limb, as well as to downward displacement at the inferior limb. The surfaces thus applied to each other, being so curved, *give a greater extent of apposition* than if they were plane, and, at the same time that they allow of a limited yielding of the sacrum to pressure, keep the surfaces continually in contact. And we shall find that, although the general shape of the articular surface is rendered angular by the "joggle" *b* (*fig*. 88. A), the groove and corresponding iliac ridge form a regular crescentic curve, or segment of a circle *d*, *f*, *e*, of which, in fact, the central internal projection of the tuberosity of the ilium above at *a* is the centre. Now it is to this prominence that the powerful deep posterior and interosseous sacro-iliac ligaments are mainly fixed above; and it is by being suspended by and moving on them in the radius *a*, *f*, that the sacrum slides on the ilia downwards and backwards in the direction of this groove on the reception of force from above.

That this motion, though limited, does take place, and in this direction, may very readily be proved, on the detached pelvis, by striking directly downwards on the upper extremity of three or four lumbar vertebræ cut off with it. The impulse will be almost entirely felt at the tip of the coccyx, in a direction upwards and backwards. That portion of it which is directed immediately downwards is checked by the powerful ligaments above mentioned, and is but little felt at the sacral promontory.

If a section of the whole pelvis, in the direction of the cotylo-sacral arch is made, as in the next figure, a very important element in the mechanism of the sacro-iliac articulation is brought to view; viz., the deep posterior and interosseous sacro-iliac ligaments, (*d*, *c*.) These ligaments are continuous one into the other, becoming shorter downwards, as the distance between the bones becomes less. They narrow also antero-posteriorly, so as finally to be received into the retiring angle formed by the limbs of the articular facet, at which point they are seen in the transverse section in the sacral axis in *fig*. 88. B, *f*. They are attached, externally, to the central prominence on the inner surface of the iliac tuberosities, *a*, *a′*, which project upwards and backwards, and are curved also a little outwards, the better to resist inward traction,

Fig. 89.



Section of the pelvis and heads of the thigh bones, made in the direction of the cotylo-sacral arch, a little below the pelvic brim; showing the antero-posterior sacral wedge, the suspending office and oblique direction of the posterior sacro-iliac ligaments, and the wavy section of the joint. *a*, iliac tuberosities; *b*, *c*, antero-posterior sacral wedge; *d*, deep posterior sacro-iliac ligaments; *e*, interosseous ligaments; *f*, auricular groove; *c*, sacral joggle; *g*, *c*, cotylo-sacral rib. (Drawing made from a recent section.)

following the lesser curve of the iliac crest. This thickened central portion of the tuberosities is placed above the angle of the articular facet, in the line of direction of the cotylo-sacral arch produced upwards through it. In the accompanying figure, the section, made almost in the plane of the pelvic brim, cuts directly through it. Passing downwards and inwards, the powerful fibres of these ligaments are attached to the upper external part of the posterior surface of the sacrum, *b*; and they suspend the sacrum between them somewhat in the manner of a suspension bridge, of which the iliac tuberosities are the suspending buttresses. This arrangement evidently considerably adds to the yielding elasticity of the sacro-iliac joint, and does much to lessen the concussions passing through it. It is evident also that it is in these ligaments that the most powerful preventive to *anterior* and *downward* displacement of the sacrum resides; for this could not take place without absolute rupture of their numerous fibres, resisting, as they do, all motion of the sacrum, except, in the limited sweep of the radii they form, a motion which exactly coincides with the mover ent of the sacrum proved by the experiment just mentioned.

But these ligaments, from their oblique direction inwards, at the same time that they resist downward pressure, pull with a corresponding force the sacrum and the ilia more closely together, and render, by this constantly tightening and bracing process, all the before-mentioned provisions for resisting displacement more effective, and, by a gradually increasing resistance, overcome the impelling force. To illustrate this effect, it may be mentioned that the effect of placing too much weight on the crown of an artificial arch is to cause the line of pressure (*c*, *a*, *c*, *fig*. 90. A), which ought to pass through the centres of the "voussoirs" perpendicular to their joints, to rise above the "*extrados*" at the apex, *a*, and to be brought within the inner surface or "*intrados*" of the arch, *b*, on each side; and this causes the voussoirs, *a d*, *d c*, to turn on each other at the edges nearest the line of pressure; and in consequence the crown of the arch sinks and opens below, *b*, and the haunches rise and open above, *d*, *d*. The sacro-iliac joints, being the haunches of

Fig. 90.

the cotylo-sacral arch, have in like manner a tendency to separate above and behind when the pressure on the sacrum is increased; and this tendency is counteracted by the strong posterior sacro-iliac ligaments. By the law of the resolution of forces, this tightening action of the sacro-iliac ligaments may be expressed by the opposite sides, *a b*, *c d*, of a parallelogram (*fig.* B), of which the line of direction of the ligaments, *b*, *c*, forms the diagonal, and the remaining sides, *a c*, *b d*, the sustaining power.

Lastly. Because of the oblique position of the sacrum with regard to the ilia, forces acting on the lumbar vertebræ have a tendency to throw the base or sacral promontory *downwards*, and to tilt the apex with the coccyx *upwards*, as is seen in the experiment of striking the separated extremity of the lumbar vertebræ before alluded to, by the impulse felt at the sacral promontory. It will be better understood by reference to the drawing and diagram of a model made to represent the action (*fig.* 91. A. and B). The tendency of the sacrum is to *turn round* the axis of the sacro-iliac joints in the curve *d f c*, (*fig.* 88. A.), and round the centre *a* (*fig.* 91. *c′*). To counteract this tendency of the base downwards and forwards, the strong *ilio-lumbar ligaments* (*a*) pass backwards and outwards from the last lumbar vertebra to the crest of the ilium, upon which it obtains a long and broad hold. And to resist the tilting upwards of the apex of the sacrum, are attached the extremely powerful *sacro-sciatic ligaments* (*b*), which aid also the *oblique sacro-iliac ligaments* to resist backward displacement.

Thus are constituted two strong yet elastic springs on each side acting upon the *concavities* of the lumbar and sacral curves, which have, perhaps, the most powerful influence of any that have been before mentioned, in breaking the force of shocks and concussions passing along the bones of the trunk and lower extremities. The importance of this office of the sacro-sciatic ligaments is seen in their great strength, and in the consolidation of the lower sacral vertebræ to which they are attached. The forward direction of the base of the sacral wedge when taken antero-posteriorly, as seen by looking from above, facilitates this elastic yielding of the sacral spring, as it evidently could not take place if

Fig. 91.

the double sacral wedge had a small diameter directed *forwards* as well as *downwards*, in which case it would be prevented by the ilia from moving in that direction at all.

Thus the pelvic supports of the trunk are a peculiar and admirable combination of *the arch* and the *suspension bridge*. Under heavy weights, the preparatory tension of the pelvic muscles, as the psoæ, pyriformes, and great glutei, will, by more closely approximating the sacrum and ilia, produce the conditions of the arch. But in sudden shocks, the strain will fall more immediately upon the ligamentous suspensory structures, as the *sacro-iliac*, *sacro-sciatic*, and *ilio-lumbar* ligaments, more calculated, by their resiliency, to break their force gradually, and finally overcome them.

The thick, strong, and elastic fibro-cartilaginous pads inserted between the opposing osseous surfaces of the sacro-iliac and pubic symphyses may be mentioned also, as contributing to deaden and break the force of shocks passing through the pelvic arches; and these being generally, as we have seen, arranged in two layers allowing of limited sliding motion between them, are better calculated to resist *sudden shocks* passing *obliquely* than single discs, such as the vertebral, which are chiefly disposed to resist *pressure* passing *directly*.

The posterior projection of the iliac tuberosities protects the sacrum, deeply situated between them, from direct force tending to produce anterior dislocation, while their internal direction prevents that bone from slipping backward between them.

The great breadth and size of the sacrum in the human pelvis — it being proportionally *larger* than that of any other animal — indicate its importance as the basis of support to the spine, and the crown of the pelvic arch; and, in connection with the admirable mechanical and architectural arrangements just described, present a wide contrast to the pelvic structures of animals; and prove the erect position to have been designed for the habitual expression of the dignity of man.

The thigh of man, when standing, forms one line with the trunk, and makes an obtuse angle with the posterior arm of the pelvic lever; but in quadrupeds it is directed much more forwards, and forms an acute angle with both the ilia and the spine. In quadrupeds, the thighs are much closer together and more pressed upon the flanks, and, even when they rest on their haunches, they naturally support themselves on their fore legs. This is even seen to a great extent in the apes and monkeys, so difficult is it for them to maintain the centre of gravity in an erect posture. The extensors and flexors of the thigh on the pelvis are also more developed in man, in order to sustain with more firmness the erect posture. Hence the greater breadth of the hip and buttock, and the bulk of the thigh. The breadth of the pelvis also gives a greater leverage to these powerful muscles.

In walking, the human pelvis is thrown alternately, on each side, upwards, forwards, and sideways, as the leg on that side is lifted; the trunk keeping its centre of gravity over the bearing leg by swaying regularly to that side, the pelvic hoop being at the same time drawn over the supporting leg by the powerful abducting muscles, the glutei.

On account of the greater width of the pelvis and trochanters in the female, the centre of gravity oscillates through a greater space, and takes longer time to pass over from one leg to the other, and hence the greater amount of undulation in their gait, especially when running.

Mechanism of the human pelvis in regard to parturition. — As a containing cavity, when completed by its muscular and fascial structures, the pelvis offers a basin-shaped structure with a somewhat triangular superior aperture, the sides of which are formed by the psoæ muscles, and the base by the pubes; and with a moveable floor, formed by fasciæ and the levator ani muscle, and perforated by the rectum and generative organs. Its walls are interrupted laterally by the sacro-sciatic and obturator foramina, which are filled by soft and yielding muscular and ligamentous structures, and give way considerably to pressure from within, enlarging the pelvic diameters opposite to them. They afford, in common with the superior and inferior openings, the outlets for the nerves and vessels passing from the lumbar and sacral plexuses and iliac trunks to the inferior extremities and perineum. The inferior outlet also transmits the external communications of the pelvic viscera. These are, the bladder supported by the pubis; the rectum, supported by the sacrum and coccyx; and the internal organs of generation placed between them.

In the female these internal organs are more bulky than in the male, and consist of the uterus and its ovarian and vaginal appendages. That there is a relation between the greater size and the functions of these organs, and the greater extent of the female diameters, is evident from the consideration of their simultaneous development at the period of puberty, and corresponding increase afterwards.

This relative development of the pelvis seems to extend not only to *sex*, but to the *varieties* of mankind, either as an irrespective consequence of primitive formative type, or in regard to the adaptability of the fœtal head to the pelvis in the processes of parturition. In either case this adaptation is strikingly illustrated by the different pelvic forms prevailing in different races of men, which will be found, when considering that branch of our subject, to be markedly assimilated to the form of the skull.

The pelvic bone, which is of the greatest importance in an obstetric point of view, entering as it does into the formation of both the pelvic brim, cavity, and inferior outlet, is the *pubis*; and deformities of this bone produce the greatest obstacles to parturition. The sub-pubic arch is a peculiarity of the human species, it being only imperfectly developed in the lower animals; and it has an important bearing upon human parturition, in being compensatory for the great curve of the pelvic axis, and the change of direction forward of the inferior from the superior outlet. This curve is dependent upon, and follows the curve of, the sacro-coccygeal column, which, being more acute and directed more forwards below, affords the chief support in the earlier months of pregnancy to the uterus and its contents, which lie in the axis of the superior outlet, which axis, as we have seen, impinges below upon the coccygeal bone. Now, the coccyx, being principally held up in its forward position by the elastic sciatic ligaments and by the resilient ischio-coccygeus and levator ani muscles, affords a resisting support which is at once powerful and yielding, and acts like an elastic spring in supporting the uterus and its delicate contents under the effects of accidental shock. The female coccyx is much more mobile at every age than the male, and when ankylosed to the sacrum it is less favourable both to pregnancy and labour. In the more advanced stages of pregnancy, however, the uterus rises into the abdominal cavity, and rests mainly upon the smooth concave surfaces of the pubes and the soft muscular margins of the pelvic brim, being embraced and supported above and in front by the abdominal muscles. To allow the great expansion of the uterine contents, the broad ventral notch and expanding iliac wings are dispositions of great significance.

During labour, the fœtal head enters the brim of the pelvis in the oblique diameter, which being less encroached on by the muscles is the best adapted to receive it, as well as by its correspondence in form to the brim in that direction. Then traversing the pelvic axis, it passes, first downwards and backwards, and then, being turned forwards by the sacro-coccygeal curve, escapes under the pubic arch and through the inferior outlet. The fœtal occiput is directed generally in the left oblique diameter, towards the left ilio-pubic junction (in 69 per cent. of the cases — Naegele — to 80 per cent. — Boivin), and in its progress is twisted gradually forwards and towards the median line by the impingement of the parietal protuberance upon the inclined plane of the pyriformis muscle and upon the projecting ischial spine, until it emerges under the symphysis pubis, around which it turns vertically as round a centre; the real centre of its motion, however, being, as we have before seen, a little in front of and below the pubis. The more anterior part of the fœtal head, then, traversing the circumference of the sub-pubic circle, extends the coccyx, and passes between the tuber ischii, distending the sacro-sciatic ligaments and perineum, and turning, as it does so, on its own transverse axis.

In a well-formed woman, according to Naegele, the superior plane of the pelvis will be horizontal when the trunk is between the sitting and recumbent positions (*i. e.* when it forms an angle of 30° with the horizon). In such a position traction on the head of the child should be perpendicular.

In sustaining these evolutions, the pelvic circle necessarily is exposed to a force not hitherto considered, viz. pressure from within. In well-formed pelves this pressure will be exerted equally on all parts of the circumference, from the adaptation, before mentioned, of the child's head to the form of the pelvis. The strain, however, will be most evidently exerted upon the *ligaments* of the *pubic* and *sacro-iliac symphyses.*

The question whether these ligaments yielded during labour sufficiently to enlarge materially the diameters of the pelvis, is one which has attracted the attention of anatomists and obstetricians very much, particularly about the latter end of last century, when M. Sigault proposed, in lieu of the Cæsarian section, the section of the symphysis pubis, with a view of affording greater pelvic diameters.

Among the older writers on this subject Mauriceau, Peu, Lamotte, Vesalius, Varandens, Menard, and Voigt *denied* that separation of the pubic bones occurred during labour.

Some believed it to occur only in young primiparous females; others in primiparous females of advanced age; and others again only in pelvic distortions or peculiar circumstances of pregnancy.

Ambrose Parè, Pineus, Bauhineus Riveanus, Diemerbroek, Arniseus, Bianchi, Gregoire Pineau, Duvernay, Bertin, Levret, Santorini, Spigelius, and Smellie, have observed this separation in the *dead* parturient woman; and Guillemeau, Hildanus, Van Solingen, Veslingius, Puzos, Soumain, Bikker, Arnauld, and Morgagni in the *living* subject. Parè and Peu asserted that they had seen cases where the ilia had been separated from the sacrum; and Smellie relates a case where great pain at the sacro-iliac joints rendered this probable.

Of those who admit that relaxation of the ligaments and consequent separation do take place, Boivin, Louis, Severin, Pineau, and Meckel consider it to depend upon softening, thickening, and loosening of a *single* inter-pubic fibro-cartilage, and deposition of fluid in its meshes; Meckel with Antoine Petit, denying the frequent existence of a separation between *two* plates of cartilage. But Tenon found, that although, in most cases, the inter-pubic fibro-cartilage was single in the male, in woman it was generally double, and contained a slit or cavity, with no connecting fibrous tissue between the middle of the plates. And he found this to be the case in the young as well as the old, and before pregnancy as well as after; sometimes the slit was capillary, but in one female, recently delivered, the cavity would admit the forefinger. In none of his examinations did he find any thickening, softening, or laxity of the fibro-cartilage itself, however recent the accouchment, although the external investing ligaments of the joint were relaxed and elongated. He considers, that if in females where but one fibro-cartilaginous plate is present, separation of the bones occurs during labour, it must be by rupture of the fibres of the disc or its separation from the bone. It is, however, difficult to comprehend why elongation of these fibres should not take place as well as of those of the investing ligaments.

Tenon also asserts, that he has observed relaxation of the pubic ligaments, even in the male, during life. Sandifort considered that in women who have borne many children the pelvic ligaments become permanently looser. In a female aged 79, dissected by Cruveilhier, the symphysis pubis was exceedingly moveable, the sub-pubic ligament had disappeared, and a fibrous capsule invested the joint. Sœmmerring believes that separation of the pubes is not rare, even during easy labours, and that they remain permanently loose, and the pelvic diameters larger, after many labours. According to the last author, the sacro-iliac joints have also been found separated by a cavity of the width of an inch in females who have died during parturition. But it is a question, whether this was not caused by disease and deposit of pus. In a woman mentioned by Frank, in *Textors Neuem. Chiron.* (vol. i. p. 261.), the pelvis was so moveable every time she became pregnant, that she could not stand upright. Instances of separation of the pubic joint during labour are also mentioned by Eichelburg in *Rust's Magazine* (vol. xvii. part iii. p. 550.), and by Nicholson in *Trans. of Physic. in Ireland* (vol. iv. 1824). Dr. William Hunter, in his memoir upon this subject, gives two cases of parturient women, in which the fibrous tissue connecting the cartilages was replaced by a cavity lined by a perfect synovial membrane, and forming a perfect arthrodial joint; and he concludes, that a certain relaxation of the pelvic ligaments takes place in the latter months of pregnancy and during labour, allowing of a slight increase of the pelvic capacity, and a yielding to the shape of the fœtal skull.

On examining the pelves of five women who had died soon after delivery, Dr. Knox of Edinburgh found, in all, a remarkable relaxation of all the ligaments of the pelvic joints; in one the bones could be made to slide over each other. This anatomist also inclines to the opinion that this process is a regular and healthy one in the parturient female. This opinion is also supported by the post-mortem researches of the celebrated Rokitansky of Vienna, who considers that, in parturient women, the pelvic ligaments become soft, relaxed, and stretched.

In addition to the testimony on this side of the question, M. Senoir read an essay on the "*Articulations of the Female Pelvis*," at the Academy of Medicine of Paris, on the 1st of April, 1851; in which he concludes, 1st. That the articulations of the pelvis proper should not be considered as *amphiarthroses*, but as *arthroses;* and, 2ndly. That analogy of structure and composition leads him to think that an effusion of synovial fluid from the membrane lining the joints, causes the separation of the bones sometimes observed. (*Bulletin de l'Academie Nation. de Médecine*, t. xvi. No. 13. April 15th, 1851.)

It is, however, considered by Baudelocque, Boyer, Burns, Dewees, Denman, and I think most English writers on Obstetrics of the present day, that, in common cases, *no* sensible relaxation of the pelvic ligaments takes place, and that, when such relaxation does occur, it should be rather considered in the light of a morbid condition, as it adds very little to the diameters, and is attended with severe inconveniences from rupture of the sacro-iliac ligaments.

Notwithstanding, comparative anatomy, particularly in Cows, Seals and Guinea-pigs, to be presently considered, presents us with a strong analogical proof in favour of the doctrine of some parturient relaxation of the pelvic ligaments in women.

Comparative Anatomy of the Pelvis. — In the different races of mankind, the pelvis, as influencing in a very great degree the form of the body, presents considerable varieties.

Camper, and afterwards Sœmmerring, remarked that Negroes had more slender loins and hips than Europeans, consequent upon narrower pelves. Sœmmerring gives a comparative measurement of the diameters of the brim in a Negro and an European of adult size. In the *Negro*, he found 3 in. 11½ lines, long or transverse diameter; in the European, 4 in. 6 lines; in the Negro the short or conjugate diameter was 3 in. 7½ lines, and in the European, 3 in. 11 lines. From Camper's measurements, the long diameter was to the short one as 39 to 27½ in an adult Negro, and as 41 to 27 in an adult European, who, nevertheless, was of much less stature than the Negro.

The measurements in the table on page 151, were taken in the dissecting rooms of King's College, from an adult male Negro 6 feet high. From the measurement of this pelvis, the antero-posterior diameters seem to prevail in the Negro, and the whole pelvis to be smaller than in the European. This is seen remarkably in the limited breadth of the sacrum, (3 in. 9 lines), and in the approximation of the ischial spines (3 in.,) both much lower than the average European; the latter, indeed, less than in the Chimpanzee. In fact, I have never met with an European sacrum so narrow as in the Negro above mentioned, especially in an individual so tall as 6 feet.

This difference is remarkably contrasted in the pelvis of O'Byrne, the Irish giant, in the Hunterian Museum, in which the iliac wings are remarkably large in comparison with the true pelvis, and the sacrum very broad. The superior pelvic outlet is in this skeleton disproportionately larger than the inferior, the ischiadic tuberosities being nearly as close together as in ordinary-sized pelves. This sudden narrowing of the pelvis has evident reference to the better sustaining of the viscera of the pelvis and abdomen.

It is supposed that in Negro women generally, from the easy labours they undergo, there is much more proportionate pelvic capacity.*

The dimensions of the pelvis of a Negress of small stature, contained in Bonn's Museum at Amsterdam, are given by Dr. Hull in his *Second Letter to Simmonds*, as follows: At the *brim*, the conjugate diameter, $4\frac{3}{8}$ inches; the transverse, $4\frac{1}{8}$; the oblique, also $4\frac{1}{8}$ inches. From the inner extremity of the superior pubic ramus, to the sacro-iliac joint of the same side, $4\frac{1}{2}$ inches. At the *outlet*, the antero-posterior diameter (measuring from the apex of the sacrum) was, $4\frac{1}{8}$ inches; the transverse, $3\frac{1}{2}$ inches. The breadth of the sacrum was, $3\frac{1}{2}$ inches, and the length the same. The angle of the sub-pubic arch measured only $67\frac{1}{2}°$. In this pelvis also, although a female, the prevailing size of the antero-posterior diameters, and the limited breadth of the sacrum and transverse diameter of the outlet, as well as the exceedingly small expanse of the sub-pubic arch, are very remarkable, and are hardly accordant with easy labours, unless from the special adaptation of the fœtal head.

Dr. Vrolik of Amsterdam, who devoted much attention to this subject, remarks, that the Negro male pelvis is contrasted widely from the female of the same race, in being strong, dense, and massy, while that of the female is light and delicate in appearance, although not presenting the transparent thin parts that the pelvis of the European female exhibits. But the Negro male pelvis given in the table is remarkably light, slender, and well formed for a man of so considerable a stature, and the centres of the ilia very concave, and as thin as in most pelves I have seen; nor are the ischial tuberosities at all disproportionately large nor turned out, nor the posterior superior iliac spines elevated. Vrolik points out also, as marks of degradation in type in the Negro female pelvis, the vertical direction of the ilia, their elevation at the posterior superior spines, and the approximation of the anterior iliac spines to the cotyloid cavity, together with the narrow transverse and antero-posterior diameters, the anterior sacral projection, the general elongation of the pelvis, and the greater acuteness of the sub-pubic angle. This author considers these peculiarities to resemble the formation of the pelvis in the *Simiæ*. But as far as I have myself seen, there are very few characters indeed, either in the Negro or Bushman pelvis, which assimilate to those of the widely-different pelves of the Chimpanzee or Uran.

* This opinion is given by Mr. White, in his essay "*On the Gradation of the Human Species*," on the authority of surgeons employed in the Guinea trade; but I am informed by Mr. Edwards, a surgeon who has seen much of the West Indian creole negroes, that difficult labours are, on the contrary, *very frequent* among the females of these creoles, who are remarkable, like the males, for the thinness and narrowness of their flanks, and for the steady and easy walk which results from this formation. And he informs me also, that dystochia is not at all unfrequent even in the African negresses.

From the structure of the female *Bushman* pelvis, given by G. Cuvier, in Hist. Nat. des Mammifères, Dr. Vrolik draws the conclusion, that it presents greater animality of composition than even the Negro, as shown in the extreme vertical direction, narrowness, and height of the ilia, and the cylindrical form of the whole pelvis. The height of the ilia was much greater than in European females, while the width between the anterior iliac spines was less than even the smallest Negro pelvis. The spines of the ischia were, however, much wider apart, the sacrum more curved vertically, and the thinness of the iliac centres as little marked as in the Negro. The sacrum projected much forward at the base, and posteriorly was remarkable for the thickness and tuberosity of the lateral parts, and the posterior elevation of the coccygeal articulation, which were supposed to be for the purpose of affording attachment to the large gluteal masses of fat, characteristic of the Bushman race. The thickness, breadth, and posterior elevation of the ischial tuberosities, the posterior inclination of the cotyloid cavities, the prominence of the pubic symphysis, and the greater sub-pubic angle, were also remarked by Vrolik.

In the pelvis of a male Bushman recently added to the Hunterian Museum, I find the iliac wings to be short, broad, not much expanded, but considerably curved antero-posteriorly; with a crest arched, *ƒ*-shaped, and reaching as high as the middle of the fourth lumbar vertebra. The centres of the iliac wings are not thicker than is proportional, and there is a well-formed and deep internal concavity or venter. The pectineal eminence is well marked, but the ischial spines not so, and the ischial tuberosities are small and slender. The sacrum is short, much curved vertically, and elevated inferiorly, so as to project much behind, and diverging widely from the ischia, giving a wide and short appearance to the sacro-sciatic notch. The posterior lateral parts of the sacrum are *not* unusually thickened, but the sacral spinous processes are well marked and proportionally large, the two upper being very distinct, and separated from the crest. The shape of the brim is somewhat oblong and inclined to the Negro type, as may be seen from the measurements in the adjoining comparative table. The whole pelvis has a symmetrical, though a light, slender, and diminutive aspect corresponding to the diminutive stature of the individual. The breadth of the sacrum is even less than in the Negro, being exactly the same as the Uran-utan. The distance between the ischial spines is, however, greater, though that of the ischial tuberosities is less than in the Negro. The pelvi-vertebral angle in this skeleton seems to be less than usual, as far as one may venture to a conclusion from a dried skeleton. In a cast of a female Bojesman recently added to the King's College Museum, however, the vulva seems to be placed unusually far back, which may probably depend upon great obliquity of the pelvis.

The measurements of the *Tahitian* male pelvis, given in the table, corresponds, in the proximity of the ischial spines and narrowness of the sacrum, with the Negro and the Bushman, though its transverse diameters, unlike the Negro, are larger than the antero-posterior. In this respect, the Bushman more nearly approaches the Negro. The great antero-posterior diameter of the cavity shows a great vertical curvature of the sacrum. In the sacro-vertebral and pelvi-vertebral angles, the Bushman and Tahitian are nearly alike.

The pelvis of the female *Australian*, also in the Hunterian Museum, presents a very remarkable shallowness of the true pelvis. Otherwise, it is light and roomy, with well-expanded and very short ilia. The shape of the superior opening is of a perfect oval, with the transverse diameter half an inch larger than the antero-posterior. Though a much larger pelvis than that of the Bushman, its total depth is nearly as limited, and very much more so than in European female pelves of equal horizontal diameters.

In these specimens of races, considered by some to be more nearly related to the apes than the European, an examination of the adjoining table will show a very great pelvic difference between them and the highest apes, in the less proportionate preponderance of the antero-posterior over the transverse diameters, the shortness and expansion of the ilia, the less depth of the true pelvis both in front, sides, and behind, and especially in the more marked *sacro-vertebral angle*.

M. Vrolik describes the pelvis of the *Javanese* as very light in structure, of small size, and of a characteristic *circular* form at the superior opening, the bones being like those of a very young person, and the muscles correspondingly feeble. The small projection of the sacral promontory was also remarkable, as well as the great *inward* projection of the ischial spines, more marked, he says, than in the pelves of any other nation, and quite characteristic.

By the comparative measurement of many human pelves of different races, Professor Weber reduced them to four principal forms, distinguished by the general shape of the pelvic openings.

1st. *The oval form.*—The superior opening of an egg-shaped figure, narrow in front, broadest near the sacro-iliac symphysis, and again narrowing to the sacral promontory. The antero-posterior diameter smaller than the transverse. The ilia moderately distant, and obliquely placed; and the convergence of the walls of the true pelvis downward, also moderate. The sacrum moderate in breadth, length, and vertical curvature. The ischial tuberosities placed rather backward, and the spines widely distant. The subpubic angle neither very acute in the male, nor the arch very prominent in the female. Of this type, he makes two varieties, — viz. the oval or male-oval, and the round-oval or female-oval; the male variety of form being sometimes found in the female. Of this form he gives three specimens :—one of an European male; one, very large, of a Botocundo male; and one of the round or cross-oval form, in an European female pelvis, broad and shallow, with the transverse diameter 5 in., and the conjugate 3 in. 10 lines. The pelvis of the Australian female, given in the table, belongs to the round-oval form, and that of the male Tahitian to the male-oval form.

2nd. *The round form*, distinguished by the round or cross-formed superior opening, by the vertical sides, less anterior direction of pubes, and less projection of sacral promontory, making the conjugate of nearly the same extent as the transverse diameter. Of this form he gives five specimens, all females: — one European, two Negresses, one Hottentot, and one Javanese.

3rd. *The square or four-sided form*, distinguished by the great breadth of sacrum and horizontal flattening of pubes. The transverse diameter greater than the conjugate, but the superior opening forming nearly a square. Of this form are six specimens :— one of an European female ; two of Javanese male, and one of a female of the same race, and two Mestizos.

4th. *The cuneiform, or oblong form.* — Superior opening laterally compressed and oblong; sacrum very narrow; pubis with great anterior direction, so as to unite at an acute angle; with the conjugate greater than the transverse diameter. In the female, this form makes some approach to the oval shape. Of this form he gives eight specimens : — one of an European female, which has this shape very well marked, the conjugate diameter being 4 in. 9 lines ; one of a female Botocundo; one of a Negress ; one of a Negro ; one of a Kaffir ; and three others from Von Sœmmerring's collection. The pelves of the Bushman and Negro, given in the table, belong to this form.

M. Weber's conclusions drawn from these specimens are, that though the oval shape is most common in Europeans, the round shape in the American aborigines, the square shape in the Asiatic or Mongolian races, and the oblong in the Negro races; yet that none of the characters laid down by Vrolik are constant, nor belong exclusively to any particular race, but that deviations from the usual form in any race present characteristics which generally belong to other varieties of the human species.

The coincidence between the prevailing form of the skull and that of the pelvic brim in these classes of the human race is worthy of especial remark, and influences materially, as before mentioned, the adaptation of the fœtal skull to the pelvic passage during labour. After the form of the skull, that of the pelvis is perhaps the most characteristic of race of any in the body, because of its great influence upon the shape of the trunk ; and yet, from Weber's researches, it would appear that it is not sufficiently so to constitute a greater distinction than that of variety, and is not exclusive enough in its peculiarities to establish separate generic classifications of the human species.

In the *Simiæ*, and those even which most

closely approach in osseous conformation the human race, as in the genera *Pithecus* and *Troglodytes*, the form of the pelvis is sufficient, at a glance, to distinguish them even from the Bushman and Australian, which have been seen to present all the pelvic peculiarities of the higher varieties of humanity.

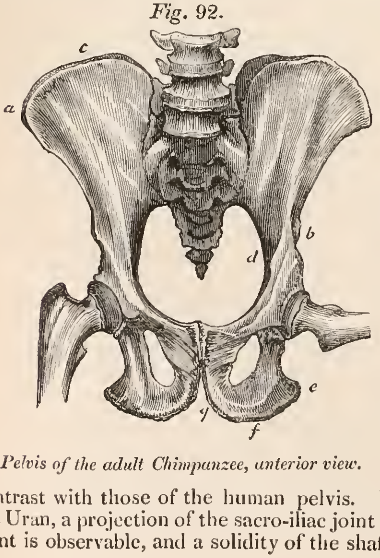
An inspection of the foregoing table will at once show this in the pelvic *diameters*. It will be seen that the antero-posterior diameters in the Chimpanzee, Uran-utan, and Gibbon prevail greatly over the transverse; that the *depth* both of the whole and the true pelvis is much greater than in the human pelvis; and that the sacrum is much narrower, especially in the Chimpanzee, and the ischial spines more closely approximated. The *sacro-vertebral angle*, too, is remarkably increased, especially in the Chimpanzee (160°), the sacrum being placed much more nearly in the direction of the whole spinal column, and having a less vertical, as well as a much less horizontal curvature, with no sacral promontory in the Chimpanzee, and little in the Uran; while the coccyx is straighter, and placed more in the line of the spinal column, and its tip is elevated above the level of the upper border of the symphysis pubis, so that the whole of the sacrum and coccyx is seen in front view. (*See fig.* 92.)

This high position of the coccyx is owing partly to the shortness of the *sacrum*, which is composed of three large flat vertebræ, all entering into the formation of the sacro-iliac joint, and united by ankylosis to two of the four coccygeal pieces in the Uran, and to one only in the Gibbons. In the Chimpanzee, however, there are four sacral vertebræ, *all* articulating laterally with the ilia, and the anterior sacral foramina are very small. The *coccyx* is composed of five vertebræ.

The *ilia* are much longer, thicker, more massive, and narrower, and present no central transparent portion nor internal fossa, being flat anteriorly and concave posteriorly, the reverse of the human ilia, and looking almost directly backwards and forwards, and very little inwards and upwards; so that, in these animals, there cannot be said to be any false pelvic cavity. In the Uran of the Hunterian Museum they are two thirds of the femurs in length, and measure 6 inches, and in the Chimpanzee 7 inches, reaching as high as the third lumbar vertebra. From the limited expansion of the wings, the anterior part seems deficient, the anterior superior spine (*a*) being placed directly over the cotyloid cavity; and the crest (*c*) being, consequently, very short, terminating abruptly at the vertical rib mentioned in the description of the human ilium. The *alæ* are more expanded in the Uran than the Chimpanzee. The crest does not present the lateral *f*-like curvature, and is less arched than in man. The anterior iliac spines are more widely separated, the inferior (*b*) being scarcely discernible, and the border between them thin and concave. The posterior, or iliac tuberosity is even less prominent in these animals than in the lower order of Ruminants. The distance from the cotyloid to the sacro-iliac joint is 3¼ inches in the Hunterian Chimpanzee, and about 3 inches in the Uran, though, from the greater straightness and obliquity of the cotylo-sacral arch (*d*) and the want of the anterior curve, the *direct* horizontal distance between these points is about the same as in man.

In the *Simiæ* generally, the ilia are said to be placed almost in a straight line with the spinal column. Added to the great length of the ilia, this arrangement causes the pelvic brim to be much elongated from before backwards; but much less so, however, than it would be if the pubes and iliac shafts were in the same plane. I have, however, found the *ilio-vertebral angle* in Chimpanzee, Uran, long-armed Gibbon, and brown Baboon to be very little, if at all greater than the human *pelvi-vertebral*, as far as could be ascertained without actual section of the bones. But in the Lemurs the ilia are only 10° from being in the same straight line with the spine; while in the Mandrill and many Monkeys they are almost parallel. This characteristic, heightened by that of the much diminished curve of the lumbar vertebra and the elongation of the iliac shafts in these animals, contributes to form a great

Fig. 92.



Pelvis of the adult Chimpanzee, anterior view.

contrast with those of the human pelvis. In the Uran, a projection of the sacro-iliac joint in front is observable, and a solidity of the shafts of the ilia. Blainville remarks, that the sacro-iliac facet is oval in these animals.

The *ischia*, in common with the whole pelvis, are longer in the Chimpanzee than in the Uran; and the ischial tuberosities (*e*) more turned outwards. In both, however, they are directed much more in the line of the ilia than in the human species, the *ilio-ischial angle* being 165°; and are larger, more flattened, spread, and diverging. The ischial spines in these animals begin to degenerate, and are rather rounded eminences or ridges than true spines; and the inferior rami (*f*) are directed almost horizontally inwards, leaving a large triangular foramen obturatorium, and entering into the formation of the pubic symphysis (*g*), which in the *Simiæ* generally, may be more properly called the *ischio-pubic* symphysis. The whole of the ischial portion of the pelvis has a more anterior position, and a more laterally flattened appearance than in the human pelvis. The cotyloid cavities are small, elongated vertically, and deeper behind than above. The sciatic notches are long and narrow.

One of the most remarkable differences from the human pelvis, however, is the *difference of direction* of the *ilia* and *pubes* with regard to the transverse-vertical plane of the spinal column, an arrangement which bends the plane of the pelvic brim at the ilio-pectineal eminence in different directions. In the Chimpanzee, the antero-posterior *angle*, formed by the superior ramus of the pubis with the cotylo-sacral arch of the ilium, is 120°, and in the Uran 125°; constituting a striking difference from the human pelvis, where the cotylo-sacral and pubic arches are in one plane.

This alteration in the direction of the pubis will be found to be a great characteristic of all quadrupeds, in the prone position of whose bodies the pubis has a tendency to be placed more vertical and more anterior, to be out of the way of the femurs in their angular movements. In the Sloths and Anteaters, the pubis will be seen to be turned in the *opposite direction*, yet still forming an *angle* with the ilium, but with the retiring sides turned backwards. I think, therefore, we may safely take the *ilio-pubic angle* as a general peculiarity of the inferior animals possessing pelves, and one which distinguishes them, as far as I have seen, *universally*, from the human species (see *page* 173. *fig*. 112. 2 —13.).

A remarkable consequence of this more horizontal direction of the pubis in the *Simiæ* is the disappearance of the *angle of the symphysis*, it being quite parallel with the spinal column. And this parallel position is, according to Cuvier, a mark of distinction between all the brute creation and man. In other respects, the pubis of the *Simiæ* is short, little arched, and without marked spine. The inferior outlet of the pelvis is larger than it would otherwise be, from the elevation of the coccyx, and, from the shortness of the sacrum, and length of the ischio-pubic symphysis, its plane is more parallel, and its axis more in a line with those of the brim than in man.

So we see, in these animals, a marked and evident degeneracy of pelvic structure, allying them much more closely to the quadrupeds, especially to the *Carnivora*, than to mankind. And we may remark, more especially, that their fitness for the habitual *erect* position is much diminished by the want of *direct* antero-posterior extension of the pelvis, produced by the flatness of the sacrum and the less marked sacro-vertebral angle, and the shortness and change of direction of the pubis; which renders the arms of the pelvic lever shorter from the cotyloid fulcrum, and the hold of the extensor and flexor muscles of the thigh less powerful in maintaining the standing posture. And, corresponding to this, we see in these animals. great diminution in the bulk of these muscles, particularly in the *glutei* and *gastrocnemii*, the plumpness of which constitute the buttocks and calves characteristic of the human figure From this cause, the gait of these animals in bipedal progression is very unsteady.

The expanded, everted, and large ischial tuberosities, and the strength of the ischio-sacral arch, indicate that the *sitting* posture is more natural to the Simial race; while the greater depth of the posterior than the superior part of the cotyloid brim shows, as well as the marked ilio-pubic angle, a provision for femoral support in a semiflexed, rather than an extended position. In the erect posture, from the flatness of the pelvis, the ischial tuberosities are brought close upon the femurs, and reach nearly half-way down their short shafts, interfering much with their motion.

According to Grant and Wagner, there is no cotyloid notch nor ligamentum teres in the Orangs; but the cotyloid notch is present, though small, in the skeletons I have examined.

In the *Hylobatis Lar*, or long-armed Gibbon, the *iliac* wings are flatter, and directed still more antero-posteriorly, crest rounded, large, and elevated; *ischia* short, in a right line with the ilia, with flattened and expanded tuberosities, spines more distinctly marked, and rami directed, like the elongated *pubes*, more directly inwards. The cotyloid cavities are thus more widely separated, and the superior pelvic outlet has a triangular form, with the small end directed backwards. The *sacrum* is narrow and flat, forming a large angle with the spine, and composed of five vertebræ, of which the three upper, considered by Blainville to be the only true sacral vertebræ, articulate with the ilia. The *coccyx*, consisting, according to Blainville, of seven, according to others, of five vertebræ, is short, there being no tail. The inferior outlet is large, and the true pelvis shallow, from the shortness and expansion of ischia.

The subgenera *Callithrix*, *Cercocebus*, and *Semnopithecus* present an elongation of the *coccyx* into a caudal appendage with prehensile attributes, and perforated for the continuation of the spinal cord, which widens still more the progressive separation from the human type. In the Squirrel Monkey are three *sacral* bones, of which the two upper articulate with the *ilia*, and the broad transverse processes of the last project towards the *ischia*, so as to give a square outline to the inferior outlet. Ischial tuberosities not flattened. In the Capuchin Monkey the *ilia* are parallel with the spine, the *ischia* are inclined forwards to the abdominal surface, and the *pubes* are more oblique. In the *Semnopithecus entellus* the *sacrum* is more arched laterally and broader. The *ilia* are prismatic and long, and project more behind the spinal column. The *ischia* and *pubes* are short, with flattened and expanded tuberosities, and no ischial spine. Ilio-pectineal eminence marked. In these tribes the posterior border of the elongated ilia is the thickest part of the bone, the anterior part being thinned and spread out more or less. The *pubes* are generally placed nearly at *right angles* to the ilia, and the *lumbo-iliac angle* is about 160°.

Of the genus *Cercopithecus*, or Baboon tribe, there is, in the brown Baboon, a well marked *sacro-vertebral angle* (155°); the two upper of the three *sacral* vertebræ only articulate with the ilia. The *caudal* vertebræ are not numerous. The *ilia* are more expanded, but still present the posterior concavity. The *ischia* are short, with very broad and flattened tuberosities. The *pubes* are flattened, with an acute superior border, and rostrated at the symphysis. *Ilio-pubic angle* more marked (110°). In the Mandrill, *Papio Marmon*, the *sacrum* is more arched both vertically and transversely, and the promontory better marked. The *coccygeal* vertebræ are four in number, and there is no tail. The *ilia* are parallel with the spine, directly under which are placed the cotyloid cavities. The *ischia* are short, with much-expanded and flat tubers. The *pubes* are at right angles, both to ilia and spine, and the ischio-pubic symphysis is very little advanced before the plane of the spinal column.

In the *Sapajous*, or American Monkeys, there are three *sacral* vertebræ, of which the first only articulates with the ilia in the *Onistiti*. In the White-bellied *Ateles* the *ilia* are longer and more expanded; *pubes* more oblique; *ischia* short, with no spine, and small tuberosities. In the *Saimiri* there is a very short ilio-ischium.

In the *Lemurs*, or Makis, the *sacrum* is in a right line with the spine. Of the three sacral vertebræ, the first only articulates with the ilia, and the last is not ossified to the second. They differ little from the lumbar vertebræ, except in the thicker transverse processes. *Caudal* vertebræ numerous. The pelvis generally is very weak, narrow, and short. The *ilia* are narrow and almost parallel with the spine, and the ilio-pectineal eminence is unusually well marked; but the *ischial* tuberosities are delicate, indicating the less frequent sitting posture in these animals, and a still greater tendency to quadruped progression. In the *Lemur albifrons*, however, the *sacrum* is broader; *ilia* more expanded; *ischial* tuberosities larger and more expanded; *ilio-pubic angle* 120°. In *L. tardigradus* the *sacrum* is long, narrow, and keeled in the middle, being ankylosed to the last lumbar and three first *coccygeal* vertebræ, as in birds.

The *ilia* are narrow and cylindrical; *pubes* long, large, oblique, with no ilio-pectineal apophysis; *ischia* short, with horizontal rami and tuberosities passing backward to articulate with the transverse processes of the upper coccygeal vertebræ, another bird-like arrangement. In *L. indri* the *sacral* pieces are four, with complete ankylosis, the two or three upper articulating with the ilia. *Ilia* expanded, with extended crest and external fossa, and reaching to the penultimate lumbar vertebræ; *ischia* very short, with more expanded tubers; *pubes* less oblique. In *L. volans*, or *Galeopithecus*, the *sacrum* has five vertebræ, the first only articulating with ilia. *Ilia* small and narrow; *ischia* with large posterior angle; *pubic symphysis* very short. In the subgenus *Sterops*, the slender Loris presents a remarkably elongated and contracted pelvis. The *sacrum* is long and narrow, with the two upper pieces articulating with ilia. *Ilia* slender, long and columnar, and nearly parallel with spinal column; *ischia* small, flattened laterally, placed in a line with the ilia, and very near each other, so that the cotyloid cavities are closely approximated; the lateral diameters very short, and the inferior outlet a mere chink. The *pubes* are long, projecting forwards, downwards, and inwards, being inclined to each other at an angle of 40°, causing the superior outlet to be triangular, with the base at the *inter-cotyloid diameter*, and the apex at the symphysis pubis. This pelvis is also remarkable for the extreme angularity of the pubic portion with the iliac, the *ilio-pubic angle* being 75°, or less than a right angle, the only instance of the kind I have met with. (*See fig.* 93. *a*, *b*, *c*.).

Fig. 93.

Pelvis of the slender Loris, lateral view.

The animals most allied to the preceding order of primates in the form of the pelvis, taken in conjunction with their general structure, are the *Carnivora*. In these, as in most multidigital animals, the pelvis is so contracted that the trunk resembles an inverted pyramid; whereas in man, constructed for an erect posture, the base of the pyramid is in the pelvis. Climbing animals, such as the Apes, Bears, and Sloths, present the nearest approach to the human structure in this particular.

In estimating the *sacro-* and *ilio-vertebral angles* in the succeeding orders of Mammalia, it should be observed that, from the coincidence of the lumbar curve with the great dorsal curvature of the spinal column and the elevation of the neck, the vertebræ cannot be considered as being placed in one general plane, as in man. The line of direction of the lumbar vertebræ has, therefore, been taken for the sacral and iliac angles.

The *sacrum*, in the *Carnivora* (*a*, *fig.* 94.), is narrow, flat, and triangular, with long and distinct spinous processes, and placed almost in a right line with the spine. In the Bear, however, from its climbing habits, the sacrum is broader, larger, and more massy, and the sacro-vertebral angle more marked. The number of sacral vertebræ is three in the great majority of the species, the two upper articulating with the ilia; but in the Hyæna there are but two, in the Tiger four, in the brown Bear five, and in the white Bear as many as seven. The *coccygeal* or caudal vertebræ (*b*) are generally very numerous.

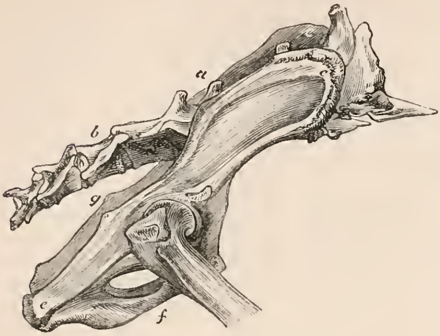
The *ilia* are moderately long, thick, and narrow in their whole extent, and are placed very obliquely upon the lumbar vertebræ, forming with them an angle of about 150° to 160°; but in the Bear and Hyæna 140° only. The external surface of the elongated iliac wing is concave, and the internal flat and turned inwards towards the spine; the crest (*c*) thick, narrow, acutely arched, and projecting backwards beyond the spinal column. The *ischia* are long, strong, prismatic, somewhat expanded posteriorly, and considerably divergent, but directed *in the same antero-posterior plane* with the ilia, forming together a very long ilio-ischion element. This disappearance of the antero-posterior, ilio-ischial angle, which commenced in the Apes, is, in the *Carnivora*, arrived at its greatest extent, and in the Tiger is even *reversed* or bent downwards in the opposite direction about 15° (see *fig.* 112. 5). With the great obliquity of the ilia, this affords, in the quadruped position, a longer and more powerful leverage for the muscles of the hinder extremities to execute their characteristic bounds, and, like the reverse formation of the ilio-pubic angle, it is another great distinction between these and human pelves. The ischial tuberosities (*e*) have an outward direction, as well as the ischia generally, and the spine (*g*) is a mere rudimentary ridge. The *pubes* are short, and the symphysis (*f*) is long, being formed generally both by the ischium and pubis. The *ilio-pubic angle* varies from 110° in the Tiger, to 120° in the Lion and Leopard, and 125° in the Bear and Hyæna.

The anterior pelvic outlet is smaller than the posterior, from the divergence of the ischia posteriorly; and the cotyloid cavities are inclined outwards slightly, so as to overhang the femora in the prone position.

The centre of gravity, in these animals, being placed much nearer the anterior than the posterior extremities, the former bear the most of the weight, while the latter act more as impelling agents in the powerful bounds which they execute.

The *ilia* of the Bear are shorter, thicker, and more massive, with more expanded wings, a better-marked anterior superior spine, and a more marked lumbo-iliac angle; the *ischia* short and widely expanded, and the *pubes* remarkably strong, with a very long symphysis. At the anterior pelvic outlet, the transverse diameter is a little larger than the antero-pos-

Fig. 94.



Pelvis of the Lion, side view.

terior, and the acetabula are large and deep. In the Badger the *ilia* and *ischia* are large, expanded, and curved outwards at their free extremities. The iliac shaft is prismatic, with an *ilio-lumbar angle* of 140°. The *pubes* are rather long, with an elongated symphysis, and form an angle with the ilia of about 130°. The same general conformation is evident in the Racoons and Coatis, the *ilio-ischial angle* being, however, somewhat better marked, and the *ilio-pubic* about 145°. The Coatis have but one sacral vertebra. In the Hyæna, also, the *iliac* wings are considerably spread, with a very pointed anterior spine. In the Dingo the *ischio-pubic* element is very short, the anterior outlet and obturator foramina small, but the posterior outlet larger. The Weasel has a very small pelvis, with but two sacral vertebræ, one only articulating with upper extremities of the long iliac shafts.

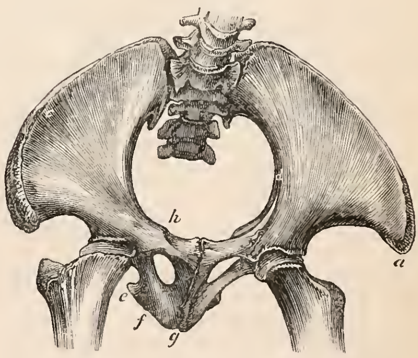
In the *Phocæ* the *sacrum* has four vertebræ, the first only articulating with ilia, and much wider in its transverse processes than the rest; the *ilia* are extremely short, thick, and curved outwards, with very small external fossæ; the *ischia* are long and slender, with small tuberosities almost touching the second coccygeal vertebra, with long rami not forming a symphysis, but directed backward to meet the pubis. The *pubes* are very long, slender, and oblique, with a short symphysis, and including a very large, oval obturator foramen. The pelvis altogether somewhat resembles that of the Badger, with the superior opening much elongated antero-posteriorly, and triangular in shape, with the base at the sacrum. The shortness of the ilia alone indicates the great contraction of the posterior extremities for their swimming requirements. Dr. Knox has observed, in a pregnant female Seal, a separation of the symphysis pubis, and elongation of its ligaments to the extent of nearly 2 inches, such as Le Gallois has described in the Guinea-pig. He found, moreover, that such a separation of the bones produced much more enlargement of diameters in these elongated triangular pelves than in the transverse oval form of the human female.

In the order of pelvic development, the *Pachydermata* occupy a very high place, being characterised by great massiveness, proportionate shallowness, and perpendicularity of pelvis, and large and overhanging acetabula, the better to support the immense weight of these animals, thrown more on the hinder extremities than in the *Carnivora*, from their bulky dorsal structures and abdominal viscera. The ischial spinous ridges and anterior inferior iliac spines are faintly marked or wanting, the sacral spines are coalesced into a continuous crest, and there is little or no sacral promontory.

The *sacrum* of the Elephant (*fig.* 95.) is comparatively very narrow, flat, and short, and placed on the spine at an angle almost imperceptible; the number of vertebræ being four only, according to Cuvier. The *coccygeal* vertebræ are numerous.

The *ilia* are short, broad, massy, fan-shaped, and much expanded, with a large concavity or iliac fossa directed forwards and downwards, the dorsum being alternately concave and convex. The iliac crest (*c*) is large and flat-arched, with the anterior superior spine (*a*) hooked suddenly downwards, and the posterior inferior directed backward from the sacro-iliac joint, to afford leverage to the powerful sacro-iliac ligament. There are no well-marked iliac ribs, except the cotylo-sacral (*d*), which is very strong and massy. The *ischia* are moderately short, and form an *ilio-ischial angle* about 145°, presenting no spine, and having the tuberosities (*e*) directed

Fig. 95.



Pelvis of the Elephant, front view.

dorsally, and the rami (*f*) vertically towards the abdominal surface. The *pubes* are short, and directed almost horizontally inwards, with a well-marked ilio-pectineal spine (*h*). The symphysis (*g*) is parallel to the vertebræ, and very long, including the whole of the short ischial rami as far as the rough portion forming the tuberosity, so that the ischio-pubic symphysis extends as far backwards as the tuberosities. The sciatic notches are wide and open, but the obturator foramina are smaller than the cotyloid fossæ, which are very large and overhang much at the superior or dorsal part. The planes of the acetabula are inclined from the perpendicular about 70° in the elephant, being about 5° more than in the fossil Megatherium and Mylodon. The pelvis of the Elephant is altogether remarkable for its perpendicular position, the *lumbo-iliac angle* being about 120° only, and the pubes being advanced as far forward as the iliac crest, at an angle of 100° with the ilia. Thus the posterior limbs are brought more under the weight of the animal. The superior outlet is roundish, but broader at the pubes than at the sacrum, and the antero-posterior diameter is but little larger than the transverse. In the fossil Elephant, however, the antero-posterior diameter is greater in proportion. The female Elephant has the pelvis more open than the male, and the borders more trenchant, according to Cuvier. Blumenbach states that the round ligament, as well as the cotyloid depression, is wanting in the Elephant.

The pelvis of the fossil Mastodon is much less depressed and expanded than that of the Elephant, according to Cuvier, and its outlets smaller, showing that its abdomen was of less size.

The Rhinoceros has four *sacral* vertebræ, three articulating with the ilia, and supported by articulation with last lumbar transverse processes; and the *caudal* vertebræ numerous.

The *ilia* are large, massy, short, and expanded, though much less so than in the Elephant; with the anterior iliac fossa well marked, and the dorsum also generally concave from side to side, from the backward curvature of the inner border to be applied to the sacrum. The crest is large, and the anterior superior spine turned forwards, as in the Elephant, and forked at the end. The *ischia* are longer than in the Elephant, with thick tuberosities, turned much outwards. *Pubes* long, and united at a sharper angle, with prominent ischio-pubic symphysis. The *lumbo-iliac angle* in the two-horned variety is 125°, the *ilio-ischial* 145°, and the *ilio-pubic* 150°, making the pubis nearly at right angles to the spine. The whole pelvis is shallow, with the ischio-pubic portion placed more backward than in the Elephant. The anterior outlet is large and oval, with the longer diameter antero-posterior. In the fossil variety there is no fork on the anterior superior iliac spine, and the obturator foramina are more elongated.

In the Hippopotamus the *sacrum* is very broad and flat from side to side, though arched considerably longitudinally; with a considerable angle, and articulated with last lumbar transverse processes. The *iliac* wings are almost plane with it, forming a *lumbo-iliac angle* of about 150°, and are less expanded, smaller, and more slightly convex, with the two superior spines directed much dorsally, especially the posterior. The *ischia* are long and comparatively slender, and directed dorsally, forming a large angle with the ilia, and supporting large and massy tuberosities, which are parallel to each other, and project by a prominent tubercle dorsally above the coccygeal vertebræ, a peculiarity which causes this pelvis to look altogether like that of the Ox. The *pubes* are elongated, and the ischio-pubic symphysis also long. The obturator foramen is large, and the plane of the acetabulum looks downwards and outwards, and is placed at an angle of about 50° from the perpendicular, being 20° less than that of the Elephant. The whole pelvis has an open, light, oblique, and flat appearance, with the ischio-pubic portion placed more backwards than either the Elephant or Rhinoceros.

In the Hog the *sacrum* is narrow, the *ilia* and *ischia* more elongated, and the latter closer to each other, with prominent and parallel tuberosities. The whole pelvis is elongated and approaches the *Carnivora* type, as is particularly seen in the *ilio-pubic angle* (120°). The *lumbo-iliac* angle is about 145°.

In the Tapir are three sacral vertebræ, the two upper articulating with ilia, and forming a *sacrum* arched considerably, both transversely and longitudinally, and with an imperceptible angle. The *ilia* are remarkable for their long and somewhat rounded shafts, and the sudden expansion of the wings on each side, so as to form a T shape, of which the branches are directed obliquely antero-posteriorly, the posterior branch being articulated to the sacrum, into which they bite well. The crest is thus made slightly *concave* instead of *convex*. The sacro-iliac facet, which in most mammalia is lunated in shape, with the convexity directed to the acetabulum, and the concavity to the spinal column, is in the Tapir of a peculiar shape, narrowing suddenly between the two sacral vertebra, and then again expanding, forming two distinct sacral "joggles." The *ischia* are long, with tubers projecting dorsally; *pubes* directed inwards. The *lumbo-iliac angle* is comparatively very acute (125°); the *ilio-pubic* large (145°); and the *ilio-ischial* well pronounced (140°). The whole pelvis is very like that of the Horse, but is distinguished by the greater breadth and curves of sacrum, and by more massy proportions, and more distinct T-shaped, and greater expansion of the ilia. The pelvis of the fossil *Paleotherium* has some resemblance to that of the Tapir, but the *ilia* are longer and more prismatic, and the *ischial* tuberosities less developed. That of the *Anoplotherium* is a link between the Tapir and Camel.

The *Solidungula* form a connecting pelvic link between the foregoing and the Ruminants.

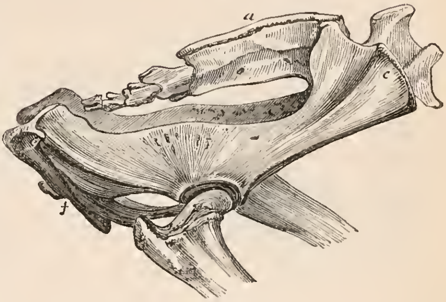
The *sacrum* of the Horse is flat, not curved longitudinally so much as in Ruminants, and placed in the line of the dorsal curve. It is moderately broad between the ilia, but narrows suddenly posteriorly, and reaches as far backwards as the middle of the ischia. This is the same position as in the Pachyderms proper; but in the Ruminants, whose pelves are more oblique, the sacrum scarcely reaches to the symphysis pubis, as is seen in the pelvis of the Ox (*fig.* 97.). The sacral pieces are six in number, two only articulating with the ilia, and the sacral spines are *not* united in a crest. The *ilia* approach in shape to those of the Tapir, being in a less marked degree T-shaped; the posterior limb of the iliac wings projecting inwards as far as the sacral spines; the anterior superior spine often presenting an epiphysis, and the shaft being long and blade-like. The *ischia* are comparatively long, and much more slender than in the Ruminants, being placed nearly parallel with the coccygeal vertebra, and with prolonged tuberosities. The *pubes* are small and short, and directed a little forwards, as well as downward and inward, with a marked ilio-pectineal eminence, and a very long ischio-pubic symphysis. The sciatic notch is wide, and the obturator foramen small. The anterior outlet is large and squarish, and the posterior elongated vertically and somewhat diamond shaped. *Lumbo-iliac angle* rather larger than that of the Tapir, being about 130°; *ilio-ischial*, 145°; and the *ilio-pubic* about 130°; making the *lumbo-pubic* rather less than a right angle.

In the *Ruminantia* the *sacrum* is composed generally of four vertebræ, the two upper articulating with the ilia. In the Gazelle and Antelope, however, there are five, and in the common Stag only three. The sacrum is proportionably broad, and more arched, both longitudinally and laterally, than in the preceding orders. The sacral promontory is also better marked, and the *sacro-lumbar angle* more perceptible. In the Ox, especially, this reaches to about 145° to 150°, and in the Fallow-deer 160°. The sacral spines are coalesced in a perfect crest in the Ox, Fallow-deer, and Stag (*fig.* 96. *a*), and partially in the gigantic Irish deer, Gnu, and Equine antelope; not so in the Giraffe and Camel. The *caudal* vertebræ are numerous.

The *ilia* are long, with the crest (*c*) concave, and the alæ expanding laterally at the top, especially in the heavier Ruminants; being concave internally, and convex externally, and projecting much over the dorsal surface of the spinal column, by the flattened and elongated posterior superior spine (*b*). They form little of the abdominal parietes, and are placed on the spine at an angle of 140° to 150°. The *ischia* are long and large, and placed on the ilia at an angle (*c d e*) of about 150° in the Deer and Sheep tribes, but much less in the heavier animals. This increased length and size of the ischia is particularly marked in the Deer tribe; and, as fulfilling the same mechanical requirements for affording a long and strong hold for the powerful extensor group of pelvic muscles, allies them with the Carnivora, and other *springing* animals afterwards to be considered.

The large and flattened tuberosities (*e*) project much on the dorsal surface of the pelvis. This is especially seen in the Fallow-deer, common Stag, and Ox, with a well-marked lateral tubercle (*g*), which is also present in the Gazelle and Roebuck. They present no ischial spine, except in the Lama, where it is well marked. The *pubes* are very short and slender, and are directed from without almost directly inwards, forming an *ilio-pubic angle* of about 130° to 140°. The

Fig. 96.



Pelvis of the Stag, lateral view.

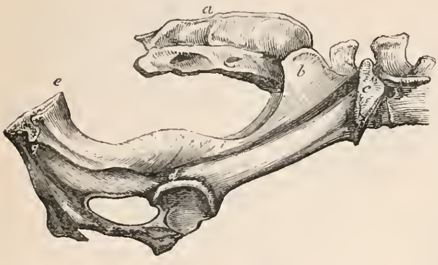
ilio-pectineal spine is much marked in Red deer. Generally the ischia form part of the elongated symphysis (*f*).

In the Ox, the *symphysis* is not placed quite parallel to the spine, as is usually the case in the inferior animals; but is placed *obliquely*, as in the human species, diverging more from the spine at the anterior than at the posterior extremity, and forming with it an angle of about 20°, and causing the anterior opening to be larger than the posterior (see *fig.* 97. *f*). The anterior opening is large and roundish, with a prevalence of the antero-posterior diameter. The posterior opening is more square, but irregular and looking much upwards.

The ischio-pubic portion of the pelvis is altogether very long, and opposed to the coccygeal vertebræ. In Deer, Goats, and Ruminants generally, but especially in the Ox, the gradual upward curve of the ischia, and the well-marked dorsal projection of their tuberosities, cause them to appear prominently on the rump, projecting on each side and above the coccygeal vertebræ (*figs.* 96, and 97. *e*.) In the Ox the *ilio-ischial angle* is as much as 130°; and the *lumbo-iliac angle* being about 150°, the acetabula are thereby placed directly under the last bone of the sacrum, and at the apex of an inverted arch (*c d e*) formed by the ischium and ilium. By this elevation of the ischia, the sacro-sciatic ligaments become a means of support to the sacrum, as well as the sacro-iliac, and thus that bone becomes suspended between two curved springs, formed by the ilio-ischion on each side.

Thus in these animals the sacro-sciatic ligaments resist motion of the sacrum in a direction downwards and forwards, a direction totally contrary to those of the human pelvis, as considered in the section relating to the mechanism of that structure. And this change of function, so simply transitionary, results from the alteration of mechanical requirements in the quadrupedal position of the trunk. About the period of parturition, the sacrum of the Ox is said to sink evidently between the ilia and ischial tuberosities, by relaxation of these ligaments. The elevation of the ischial tuberosities doubtless would make such a change of position more evident in the Ox than in other domestic animals.

Fig. 97.



Pelvis of the Ox, showing the ilio-ischial angle (*c d e*).

It is somewhat interesting, that, in most animals with flat sacral bones, the axes of the anterior and posterior pelvic openings, as well as that of the tubular cavity, coincide in the same straight line. In the Cow, however, and in some other Ruminants, these axes form a considerable angle one with the other, on account of the greater curve of the sacrum. This will, doubtless, have considerable influence in producing the more laborious parturition of these animals, which usually requires artificial assistance.

In the Ox the planes of the acetabula are inclined about 40° from the perpendicular. The pelvis of the gigantic Irish deer also presents markedly this arrangement.

In the American elk, the pelvis is rather elongated and narrow, being small and weak in comparison with the rest of the skeleton. There is the dorsal projection of ischial tuberosities; and the ischio-pubic symphysis is long, and diverges slightly from the spine *posteriorly*.

In the Camel the sacro-vertebral angle is well marked; the sacrum is much curved, and composed of four pieces. The *ilia* are long, strong, and blade-like, with the anterior spine prolonged downwards and the alæ convex anteriorly. The *ischia* are comparatively very short and feeble, set at a larger angle on the ilia, and present a feebly marked spinal ridge, and a well-marked outward projection at the tuberosities. The *pubes* are broad and moderately long, with a better marked *ilio-pubic angle* (120°) than in the preceding, and the ischio-pubic symphysis is long and divergent anteriorly from the spine, as in the Ox, the centre being opposite the last sacral bone. The foramen obturatorium is small, and the anterior outlet large and oval. The *lumbo-iliac* angle is about 140°, and the lumbo-pubic is rather less than a right angle.

In the Giraffe the *sacrum* is narrow, and its angle with the spine indistinct. The *ilia* are not very long, and the crest, unlike most Ruminants, is convex instead of concave, the wings being expanded and concave internally. The *ischia* are long and curved upwards, with everted and laterally flattened tuberosities. The *pubes* short and very thick, with long symphysis, forming a thick tuberosity, and much diverging from spinal column anteriorly. *Ilio-pubic angle* large, 140°; *lumbo-iliac*, 150°.

In Sheep and Goats the *sacrum* is broad, and its angle indistinct. The *ilia* are long and blade-like, with scanty wings; *lumbo-iliac angle*, 145°. *Ischia* broad and short, with large laterally projecting tuberosities; and a rudimentary spine in the Ram. The *pubes* are longer than in Deer, and directed horizontally inwards. The pelvic outlets are large, as also are the sacro-vertebral and ilio-ischial angles.

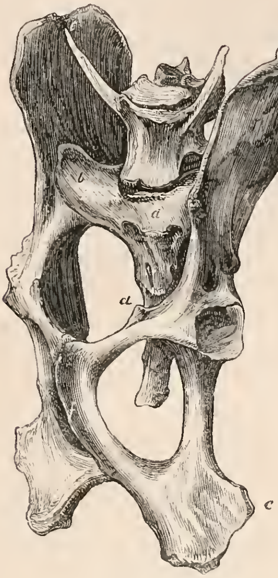
A very distinctive pelvic peculiarity is seen in the *Meminna*, or Pigmy Chevrotain. The *ilia* and *ischia* are, in this curious animal, *ankylosed* to the *sacral* vertebræ. The osseous ridges in the site of the oblique posterior ilio-sacral ligaments are very prominent, and the ossified sacro-sciatic ligaments are distinct and well marked. The sciatic notch is thus converted into a foramen, and the pelvis resembles in this respect that of the Sloth. In the Musk Deer, also, the last sacral transverse processes nearly abut on the short and dorsally projecting ischia. In the heavier Ruminants, as the Camel, gigantic Deer, and Ox, the pelvis has somewhat of the heavy appearance and overhanging acetabula of the Pachyderms, but in the lighter Deer and Goats it becomes gradually more slender and elegant in form, and more oblique in direction.

In the *Rodentia*, the pelvis is largely developed for the support of the powerful hinder extremities in leaping, the most usual mode of progression of the generality of these animals.

The *sacrum* is generally continued in a line with the lumbar curve in the long-tailed species. In Hares and Rabbits, however, the sacrum is considerably arched, longitudinally as well as transversely (*fig.* 98. *a*), and its angle with the spine marked 160°. There are generally four sacral vertebræ, but the first is much larger than the others, especially in its lateral masses (*b*), to articulate with the ilia. The Rabbit and Jerboa, however, present only two; and the common Rat and Beaver three; while the number in the Marmot is as many as six. The spines are not coalesced except in some Rats. The *caudal* vertebræ are more or less numerous, and are remarkable in the Beaver for the great length of the transverse processes and anterior spines, for muscular hold on this its useful appendage. In the Squirrel and Jerboa also, the tail is long and strong, and in the habitual sitting posture of these animals it forms, with the ischia, the third leg of a tripod, on which the body is sustained. In the short-tailed Rodents, the caudal vertebræ are curved dorsally, in an opposite direction to the coccygeal bones in Man and the *Simiæ*.

The *ilia* are long, prismatic, and slender in the shaft, having a central ridge passing upwards from the cotyloid cavity, with a groove on each side of it externally, and continued forward into elongated alæ, little more expanded than the shaft in most of the order. They form with the spine an angle of about

Fig. 98.



Pelvis of the Hare, anterior view.

165° in the Hare, and 150° in the Porcupine. In the Copyrus, Rats, Mice, and Guinea-pig, they are nearly parallel with the spine; but in the Jerboa they *cross* the spine at an angle much less than in others, being about 140°. In the Jerboa the iliac wings are curved outwards superiorly and projected much on the dorsum of the spine, reaching beyond the elongated spines of the last lumbar vertebra. The ilia of the Beaver, and, in a less degree, in the Hare, are expanded, with prolonged and irregularly curved crests (*c*), a little everted at the spinous processes (*g*), and proportionally short in the shaft. The *ischia* in Rodents are generally long, especially in the Beaver and Jerboa. In the latter animal they are directed much outwards, with tuberosities large, much expanded, and everted posteriorly, to give firm attachment to the strong sacro-sciatic ligaments. They are placed in a right line with the ilia, the ilio-ischial angle being wanting as in the *Carnivora* (*see fig.* 112. 8.). In the Hare the tuberosities of the ischia are large, and present well-marked lateral processes (*e*), which are everted, and rise above the level of the coccygeal vertebræ. The *pubes* are long and slender, and generally join with the ischia in a long median symphysis projecting in a sharp, anterior, vertical, ridge (*f*); except in the Porcupines, Rats, and Mice, which have a short symphysis pubis. In the Jerboa there is a slight *pubic spinous process*, very externally placed; this is better marked in Hares (*d*), Rabbits, and Beavers. The *ilio-pubic* angle in Hares and Rabbits is about 120° to 130°. In the Jerboa it is more oblique, 145°; and still more so in Rats and Mice, 150°.

The sciatic notch is generally long and narrow, especially in the Jerboa; and the obturator foramen very large, particularly in the Beaver. The pelvic cavity and outlets are large and capacious, especially in the Jerboa, in which, by the outward direction of the ischia, the posterior outlet is much larger than the anterior. In the Beaver also the transverse pelvic diameter is large, and separates widely the hinder extremities of these animals, to aid their swimming habits. In the Capybara however, the pelvis is of little capacity.

In the Guinea-pig it is compressed so much *laterally*, that the anterior opening is of a triangular shape, with the apex at the pubic symphysis. According to Le Gallois, it measures only 11 millimetres transversely in a full-grown female, while the fœtal head measures 20 millimetres across. Three weeks before labour begins, the elastic ligament uniting the symphysis pubis becomes thick, soft, and moveable; and eight to ten days before, the pubes, turning on the sacro-iliac joints as on a hinge, begin to separate rapidly, till the time of parturition, when they admit one or two fingers between them. After accouchment, the symphysis quickly returns to its original condition, and in a few days presents only a little thickness and mobility, the process being delayed only by age and sickness. Le Gallois found the sacro-iliac symphysis also very moveable, so as to allow of the retreat of the sacrum, and the increase of distance between its extremity and the pubic symphysis when the fœtal head pressed upon it. In this manner the pelvis of the Guinea-pig is widened, during labour, in all its diameters. Its young are produced in a very advanced state of development, and are able to run about and eat as soon as they are born.

In the *Marsupialia* the pelvis is also much developed, both to afford attachment to the powerful muscles of the tail and hinder legs, and, in some of the order, to support the abdominal viscera in their sitting posture and leaping movements. It is remarkable for the development, in most of the genera, of two extra bones (*fig.* 99. *a.*) characteristic of the order, which are attached to the pubes in the site of the crests and spines of these bones in other animals, and support the abdominal pouch peculiar to them and destined for the reception and more mature development of their young, expelled immature from the pelvic cavity. They are directed obliquely forwards and a little outwards, in the direction of the fibres of the aponeurosis of the external oblique muscle of the abdomen; in which, according to Owen and Laurent, these bones are developed by ossification of the fibrous tissue. The free extremities are a little curved, and over them the cremaster muscles in the male animals play. The pelves of the Marsupials differ considerably, according as the mode of progression is quadrupedal, or by a succession of springs from the tail and strong hinder extremities. The Wombat may be taken as an example of the former, and the Kangaroo of the latter pelvic type, which approaches in general form to the pelvis of the Jerboa, just considered.

The *sacrum* of the Wombat is very flat, and strong, and broad, in correspondence with the general squat and massy skeleton of the animal (*see figs.* 102. and 108. Art. *Marsupialia*). Its curve is a continuation of that of the dorsal and lumbar vertebræ. The number of sacral vertebræ is seven, and the transverse processes are separated from each other, the three upper of which are long and strong, and are articulated by their tips to the ilia. The facet on the extremity of the first looks *upward* and outward, and that on the second, on the contrary, *downward* and outward, and form projections which impinge upon the iliac facet. This arrangement in the Wombat like that in the Tapir, is closely analogous to the formation of the sacral "joggles," and the alteration of the inclination of the sacral wedge in Man, at the point of the auricular surface opposite the second sacral piece, substituting for upward, *backwards*, and for downward, *forwards*, a change consequent on the difference between the prone and erect positions. *Caudal* pieces are numerous.

The *ilia* are comparatively short and expanded considerably, and are curved outwards in a remarkably strong, broad, hook-like process at the anterior superior spine. They are placed very obliquely on the spine, being at an angle of 160° with the lumbar portion of the great dorsal curvature. The *ischia* are thick, long, and massy, and in a right line with the ilia. They have curiously bifurcated tuberosities, one tubercular projection turning inward, and the other longer, curving outward, in another remarkable and strong hook-like process, to which formation we have before remarked a tendency in the Hare and other Rodents (*fig.* 98. *e*). These processes, like those on the ilia, afford a powerful hold and leverage to the strong muscles of the hinder extremities, much used by the animal in its burrowing habits. These hook-like processes of the ischia are formed by a Y-shaped apophysis analogous to that of the tuberosity in man. The *pubes* are short and thick ; and the symphysis is parallel to the spine, very long, and joined in very extensively by the vertically directed rami of the ischia.

The *marsupial bones* of the Wombat are long, flat, rounded and expanded at their free extremities, and articulated to the anterior border of the pubes in the position of the crests by two articular facets separated by an arched interval. Ilio-pectineal spines are present, and of large size.

The whole pelvis of the Wombat is large and massy, though the openings and outlets are proportionably very small. It has a flattened appearance antero-posteriorly, so that the anterior outlet has its greatest diameter transversely placed.

In the *Myrmecobius fasciatus* this flattened appearance of the pelvis is still more remarkable.

In the Opossums, *Perameles*, and Phalangers, there is but one sacral vertebra, which, in the *Phalangista Cookii*, is ankylosed to the last lumbar vertebra.

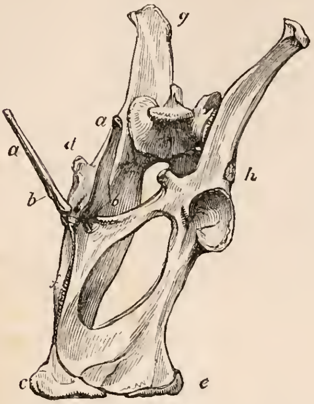
The pelvis of the *Thylacinus Cynocephalus* approaches closely in many respects to the type of the *Carnivora*, like many of the peculiarities of this animal. The *sacrum* presents no angle ; the *ilia* are massy, somewhat short, and less oblique than those of the Wombat : the *ischia* are also short and thick, and are placed at an open angle (170°) with the ilia, while the pubes are short and directed almost horizontally inwards, making an *antero-posterior* angle with the ilia as little as 115°. The whole appearance of the pelvis is massy, with small openings. It has neither the oblique appearance and exaggerated processes of the Wombat, nor the elongation and wide outlets of the Kangaroo, while its well-marked *ilio-pubic angle* contrasts much with both, and shows a strong similarity to the *Carnivora*.

In the Kangaroos, the *sacrum* is in the line of the lumbar curve, and differs in little but size and breadth from the preceding vertebræ. There are two sacral vertebræ, articulating with the ilia, their transverse processes being long and coalesced, but the spinous processes distinct. In the Potoroo there is one only, with large lateral processes. The *caudal* vertebræ are numerous and very strong, and their upper normal spines encroach much on the diameter of the pelvic cavity and posterior outlet. The *ilia* have short, strong, and prismatic shafts as in the Rodents, with alæ of the same shape, much elongated and turned outwards, though in a much less degree than in the Wombat, and terminating in narrow clubbed crests (*fig.* 99. *g*). There is a rudimentary inferior anterior spine (*h*). The upper part of the iliac wing projects much on the dorsal aspect of the spinal column, forming with it an angle of 140° (see *fig.* 112. 9.). The *ischia* are very long, broad, and strong, and have much-expanded tuberosities with an outward curvature (*fig.* 99. *e*). These are united in a median symphysis by a single V-shaped epiphysis (*c*), divided, in the adult, by a suture from the ischia. The tuberosities support also another epiphysis on each side posteriorly at *e*, the anterior ischial rami being almost deficient. The ilia and ischia are very nearly in a direct line. The *pubes* are moderately long, slender, and directed much downward, so as to give to the anterior outlet a triangular shape, with the base at the broad sacrum, and the apex at the pubic symphysis. The *ilio-pubic angle* is 135°.

The *marsupial bones* (*a*, *b*) are smaller, rounder, and more curved externally than in the Wombat. Their free extremities are tuberculated and not flattened, and they are articulated to the pubic crest near the symphysis by a single facet only, the inner, the position of the outer one being marked by a slight tubercle (*b*). The ilio-pectineal spines (*d*) are very large, for the attachment of powerful psoæ muscles.

The direction of the ischio-pubic symphysis (*f*) in the Kangaroo, *Phascogale*, and Potoroo, is not parallel with the spinal column, but

Fig. 99.



Pelvis of the Kangaroo, showing the marsupial bones (a á) and inter-sciatic epiphysis (e).

oblique in the opposite direction to the human symphysis, so that if prolonged forwards the line of direction would cut the spinal column at an obtuse angle. This makes the posterior opening larger in its antero-posterior diameter than it otherwise would be, and allows for the great encroachment of the caudal vertebræ posteriorly. The sciatic notch is long and narrow, corresponding to the great length of the ischia; and the foramen obturatorium is large and elongated antero-posteriorly from the same cause. In the *Dasyurus* and *Petaurists*, the ischio-pubic symphysis is oblique in the opposite direction. The antero-posterior diameter of the anterior outlet in the Kangaroo is greater than the transverse by about half an inch; but at the posterior outlet, the transverse is a little greater, from the projection of the caudal spines before mentioned. The pelvic *cavity* is deep in the *Marsupialia*, and its openings are small in proportion to the size of the animal, since the fœtus is expelled before it is full grown, and placed on the nipples in the marsupial pouch to complete its development into a state of independent existence. But the proportion between the pelvic openings and the size of the fœtal head, at the period of expulsion, is very remote. Even in the *Petaurists*, whose pelves are the smallest, the cavity and openings are six times the size of the fœtal head.

The muscles of the tail and legs attached to the pelvis are, in the Kangaroos, very powerful to perform their prodigious leaps, especially the gracilis and biceps. The glutei, however, are not large, since the trunk is not held erect on the legs by these muscles, but is suspended, as it were, between the femurs, and supported in front by the largely developed psoæ muscles, and behind by the powerful tail, used as a propelling organ by the sudden action of its flexor muscles.

The pelvis of the *Monotremata* resembles in general appearance the reptile type, although in some other respects these curious animals, especially the *Ornithorhyncus*, approach the Birds. The *sacrum* of the *Ornithorhyncus* is composed of two vertebræ, separated, as in the Saurian reptiles, and placed in the line of the lumbar curve, differing little in appearance from the lumbar vertebræ. In the *Echidna* are three sacral vertebræ, also separated and all uniting with the ilia.

The *ilia* are short, thick, and prismatic, and project above the spine at an angle of 140° as high as the sacral spines, and presenting, in the *Ornithorhyncus*, considerable eversion of the alæ, and, in a much less degree, in the *Echidna* also. The *ischia* are short, bent upwards in the former, and project backwards at the tuberosities in an angular spine, most marked in the *Ornithorhyncus*, and giving a reptile-like appearance. The *pubes* are broad and short, placed at a marked angle with the ilia, 110° in the *Echidna hystrix* and 120° in the *Ornithorhyncus*, and uniting by broad plate-like rami with the ischial rami, which form with them a long ischio-pubic symphysis. The ischio-pubic plate thus formed is very like that seen in the reptiles.

The *marsupial* bones are also present, and are very large and strong in this class, although not provided with a pouch. In the *Ornithorhyncus* they are broad and triangular, articulated by the base to the whole length of the pubic crest meeting in the median line, and with their rounded apices directed forwards and outwards. In the *Echidna* they are longer, rounder, more pointed and less everted, with two articular processes at the pubic extremity (*see fig.* 177. Art. *Monotremata*).

The ilio-pectineal spines are also very large in the *Ornithorhyncus*, and in a less degree in the *Echidna*. The obturator foramina are small. The three pelvic bones are united at the cotyloids by bony union in the *Ornithorhyncus*. In the *Echidna hystrix*, the union of these bones is, however, effected by cartilage only, and the acetabula are perforated by a considerable opening into the pelvic cavity, constituting another remarkable reptile-like peculiarity.

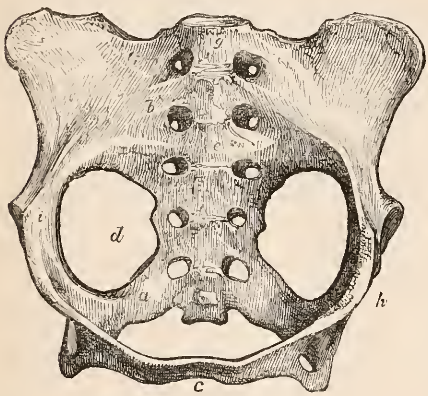
Having traced the Mammalian pelvis to a form presenting somewhat of the reptile type in the Monotremes, we may now recur back to an order of animals which, from their general organisation, are connected closely to the order of primates, and are usually placed much higher in the animal scale than the position here assigned to them.

These are the Sloths or Tardigrades, which form the connecting link between the *Simiæ* and *Edentata* proper. Their pelvic peculiarities, however, ally them more closely to the Birds. The most striking of these is the ossification of the ilia and ischia to the broad sacrum, by transformation of the sacro-iliac and sacro-sciatic ligaments. We have already noticed an exceptional example of this coalescence in the Ruminants, in the *Meminna* or pigmy Chevrotain. But the pelvis of the *Edentata* also presents a diminution of the pubic symphysis, and the absence of the ischia from this junction, a separation which is carried still further in the *Insectivora* and *Cheiroptera*. The increasing obliquity of the pubes also indicates an approach to the Bird type.

The climbing habits of the Sloths produce a habitual vertical position of the trunk, requiring for the support of the abdominal viscera large open pelves.

In the Ai (*Bradypus tridactylus*) the pelvis (*fig*. 100.) is remarkably slender, expanded, shallow and horizontal in direction, the pelvic openings being very large and round, and the antero-posterior diameters little larger than the transverse. The ankylosis of the innominate bones to the sacrum in these animals gives a great firmness to the support of the otherwise feeble hinder extremities, and with the great distance of separation of the acetabula, which are small and shallow, assists to a considerable degree their climbing and holding powers, and to produce that slowness and awkwardness of motion which has given them the name of *Tardigrades*.

Fig. 100.



Pelvis of the Ai, anterior view.

The *sacrum* is large, both in length and breadth, very flat, with large, open foramina, and presenting a flattened surface in place of the posterior spines and tuberosities. It is composed of five vertebræ, of which the three upper (*e*) as well as the last lumbar (*g*) are ankylosed to the ilia (*b*). The union of the last lumbar seems to result from an extension of ossification in the ilio-lumbar ligament (*i*), and contributes much to increase the steadiness of the spinal column on the pelvis. The *coccyx* is triangular, little curved, broad and short, and is composed of six pieces. In some species it is prolonged into a tail.

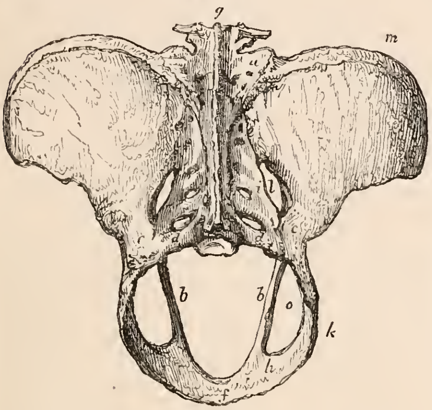
The *ilia* are short and slender, with much-expanded wings, having an anterior concavity and a plane surface posteriorly. They are ossified to the sacrum at an early period. The *ischia* are short and slender, and united to the last sacral vertebra, and more slightly to the two above it, by ossification of the great sacro-sciatic ligament (*a*), which gives to the angle of the bone an expanded appearance, and encloses a round, wide *sacro-sciatic foramen* (*d*), above and behind the cotyloid cavity. The tuberosities are small, and the inferior rami (*f*) are long and slender, enclosing with the pubis a very large obturator foramen, having its long diameter from side to side, and do *not* join in symphysis. The *pubes* (*h*) are long and slender, their rami united in a V shape, with the angles meeting to form a very short symphysis (*c*), which is sometimes ossified, and presenting a very slight ilio-pectineal spine (*i*). The *lumbo-iliac angle* in the adult *Bradypus* is about 145°, and the *ilio-pubic* about 155°, being only about 25° from a right line as in the human pelvis. The *ilio-ischial angle* also approaches the human standard in being diminished to 135°.

This diminution of the *ilio-ischial angle* is still more remarkably shown in the *Mylodon* and *Megatherium* fossil gigantic Sloths, which approach more closely to Man in this respect than any other Mammalian.

The osseous system of the fossil *Mylodon robustus* closely resembles that of the Sloths, differing from them, however, by presenting a continued sacral crest, and more expanded ilia (*fig*. 101.). According to Professor Owen, in his valuable monograph on the specimen in the Hunterian Museum, the *sacrum* really consists of seven vertebræ, but by ankylosis with the three lumbar and last dorsal includes eleven vertebræ, and forms one strong and continuous bony mass along the whole lumbar region (*a*). Its total length is 2 feet 4 inches, and it gradually increases in breadth to the sacro-iliac union (*e*), which is formed by the first, second, and third true sacral vertebræ, and there presents its greatest breadth. It then contracts slightly, and, at the sixth and last, expands again to join the ischia (*d*). It is firmly united by ankylosis both to the ilia and ischia. Its anterior surface is curved both laterally and vertically. The spinal canal is very wide, and the foramina passing from it mark the primary vertebral divisions. The whole of the eleven spinous processes of the ankylosed vertebræ form a remarkable curved crest posteriorly (*g*). There are twenty-one *caudal* vertebræ, which doubtless, in the living animal, contributed to support the body by application to the limbs of the trees upon which it climbed, and were strongly supported by the sacro-sciatic ossification.

The *innominate bones* are very large. The iliac wings are much spread out, widely concave anteriorly, and slightly convex posteriorly, these surfaces being directed forwards and backwards. The iliac crest presents a continuous, well-arched curve, and at the inner part of its centre (*m*) it is prolonged and curved forward in a lip which overhangs the anterior fossa, and contributes to support the bulky viscera. The lips of the crest are remarkably spread. The posterior superior spine is continued by an oblique crest of bone (*a*) to the lateral tubercles of the lower sacral vertebræ, as if from ossification of the oblique sacro-iliac ligament. The posterior inferior spines are continued by a ridge to the borders of the fifth, sixth, and seventh sacral pieces into the bony ankylosis of these with the ischia, which are ankylosed to the same parts, evidently in the position of the sacro-sciatic ligaments (*d*). The *ischia* (*c*) are comparatively short and directed obliquely backwards and downwards, and have remarkably slender tuberosities, as is the general characteristic of the Sloths. The inferior rami (*k*) slope much forwards, and join with the pubis in a plate of bone (*h*) before reaching the symphysis (*f*), which is very narrow and formed by the pubes only. The *pubes* (*b*) of the Mylodon are long and very slender, and form an angle of about 160° with the ilia, the apex of the angle being directed *forwards*, a remarkable peculiarity, by which it differs, in common with the Ant-eaters, from the other Mammalia. The *vertebro-iliac* angle is rather acute, being about 125°, and the *ilio-ischial* is as small as 120°, being very near the human angle.

Fig. 101.



Pelvis of the Mylodon robustus, posterior view; showing the ossification of the sacro-iliac and sciatic ligaments.

The whole pelvis is remarkable for its breadth and shallowness. The anterior outlet is of an oval form, with the long diameters antero-posterior. The posterior opening is somewhat pentagonal, and, from the great antero-posterior direction of the ischial rami and the ossified sacro-sciatic junction, presents a flat level rim. The sacro-sciatic foramen (*l*) is comparatively small, but the obturator foramen (*o*) is large and oval.

The pelvis is one of the most characteristic parts of the fossil *Megatherium*, as forming the fulcrum of muscular forces of unusual vigour. The *sacrum* is very narrow, and shorter proportionably than in the Mylodon, and is composed of five vertebræ, only the last being broader transversely. There is no ankylosis to the last lumbar vertebra.

The *iliac wings* are large and expanded, with a concavity directed forwards, the anterior superior spines overhanging the femurs, and the external border very concave. They are more massy than in the *Mylodon*, and present no hook-like process on the crest. The *ischia* are broad, blade-like, and massy; the tuberosities are not well marked, but rounded and ankylosed to the lower sacral vertebræ, enclosing a small foramen, and contributing, with the ankylosed ilia, to support the weight of the animal. *Ilio-ischial angle* 125°. The *pubes* are slender and very oblique, and form, like the Mylodon, a *reversed ilio-pubic angle* of about 155°. The pubic symphysis is narrow, and presents anteriorly a rostrated projection. The acetabula are large and near to each other; the planes are inclined from the perpendicular about 65°. The anterior outlet is oval, with long diameter antero-posterior. The posterior has the long diameter transverse. The obturator opening is comparatively small. The whole pelvis has a very massive appearance.

The pelvis of the other *Edentata* presents the same general type as that of the Sloths.

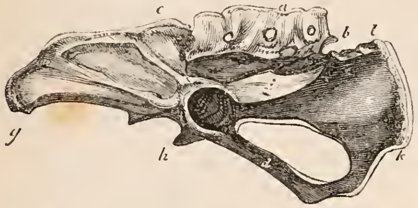
In the Armadillo (*Dasypus longicaudus*) there is a *sacrum* of nine vertebræ, the three upper of which are ankylosed to the ilia, and the sacral spines are coalesced in a crest. The sacrum is narrowed to a remarkable extent between its iliac and its sciatic portions, expanding much in the latter part to meet and coalesce with the ischia, with which it forms a broad osseous plate in the site of the sacro-sciatic ligaments. The oblique sacro-iliac ridge is also well marked. The *caudal* bones are numerous.

The *ilia* are long, strong, broad, and prismatic, and the alæ are prolonged into broad lamellar plates, which are ankylosed continously to the sacrum, and assist to support the carapace. The ilia are much more approximated to each other than the ischia. *Lumbo-iliac angle* 155°. The *ischia* are large, broad, and considerably divergent, with broad tuberosities prolonged dorsally to support the shell; coalescing in a broad plate with the lower sacral pieces, and enclosing a moderately sized *sacro-sciatic foramen*. The rami are at right angles to the body of the ischia. The *ilio-ischial angle* is marked, (145°). The *pubes* are slender and very obliquely directed backwards, making an *ilio-pubic angle* of 150°; and the symphysis is short, especially in the Weasel-headed Armadillo, in which also the *ilio-pubic angle* is smaller. (130°). The posterior pelvic outlet is much larger than the anterior, from the greater eversion of the ischia.

In the Cape Ant-eater (*fig.* 102.) the *sacrum* is composed of six pieces, with the spines (*a*) coalesced, but leaving foramina between them, and the last transverse processes (*b*) elongated. *Caudal* bones numerous (*fig.* 102.).

The *ilia* are very thick and prismatic, and more perpendicular to the spine, with the anterior and posterior borders thickened into a strong ridge. The alæ are concave externally, the posterior superior spines (*c*) prolonged dorsally, and ankylosed to the sacrum, and the anterior superior (*g*), prolonged and curved outwards and downwards. The *ischia* are very long, expanding into a broad plate posteriorly (*e*), but do not touch the last sacral vertebra. The ischial spines (*i*) are marked, and the tuberosities present two tubercular projections, one directed outwards, long and sharp (*k*); and the other thicker, and directed dorsally (*l*). The *pubes* (*d*) are directed obliquely backwards with very short symphysis (*f*), and the ilio-pectineal spine (*h*) is very large. The pelvis is altogether massy and large, with long sciatic notches and considerable obturator foramina.

Fig. 102.



Pelvis of the Cape Ant-eater, side view.

In the great American Ant-eater, both the ilia and ischia abut closely on the sacral transverse processes, presenting a faint suture at the line of junction. The pelvis is proportionately smaller and lighter, and the processes and spines much less marked than in the Cape Ant-eater. The *lumbo-iliac angle* in the Ant-eaters is 140°, the *ilio-ischial* 140° ; and the *ilio-pubic* is *reversed*, and about 155°.

The Manis possess pelves of the same general heavy appearance as the American Ant-eater. The *ilia* and *ischia* are closely approximated, but not ankylosed to the *sacrum*. The symphysis pubis is short and not joined by the ischia, and the pelvic openings comparatively small.

In the foregoing Sloths and *Edentata*, and in some of the Rodents, we have remarked the tendency of the anterior symphysis to become shorter and more imperfect by the absence of median union of the ischia, and that this is accompanied by a corresponding increase of the bond of union between the sacrum and ilio-ischian elements of the pelvis, by a closer approximation or ossification of their uniting ligaments, to give greater firmness to the pelvis as its anterior connection fails.

In the *Insectivora* and Bat tribe, this separation of the innominate bones is increased, and the pubes also fail altogether, in many instances, to meet in the median line. By the classification of animals according to their pelvci development, which is here adopted, these tribes are placed much lower than their general osteology allows, in the general classification commonly given by authors, and are allied more closely to the Bird type in their pelvic formation.

Of the *Insectivora*, the Hedgehog presents the least pelvic departure from the common mammalian type. The *sacrum* is narrow and triangular, and composed of four vertebræ, three of which articulate with the ilia. The *ilia* are thin and elongated, and placed on the spine at an angle of 130°. The *ischia* are slender, projecting above the level of the sacrum, but not touching it ; and the rami are long and slender, and enclose with the pubes large obturator foramina. The *pubes* are long, slender, and obliquely directed, making an *ilio-pubic angle* of about 150°. The symphysis is very short, and the pelvic outlets large, with the long diameters antero-posterior.

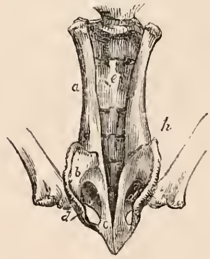
In the *Tupaia*, one *sacral* vertebra only, out of three, unites with the *ilia*, and there is a good sized symphysis pubis, as is also seen in the Tenrecs. In the genus *Desman* two *sacral* vertebræ articulate with the *ilia* and one with the *ischia ;* and the *pubes* are very obliquely placed on the ilia, and, according to Blainville, are placed, anteriorly, rather in contiguity than in symphysis, giving to the pelvis very much of the appearance of that of the Ostrich. In the *Macroscelides* there is a short and rudimentary pubic symphysis.

The Mole (*Talpa*) and the Shrews (*Sorex*) are remarkable for a very narrow *sacrum*, composed, according to Blainville, of four vertebræ, but, according to Cuvier, of seven in the Mole and three in the Shrews. In the Mole the ilia are solidly ankylosed to nearly the whole length of the sacrum. In the Shrews the two first only of the sacral pieces are united with the ilia. The spines in both are coalesced into a prominent sacral crest. *Caudal* pieces numerous.

The *ilia* are cylindrical, much approximated, and parallel to the spinal column. The *ischia* are much elongated, and elevated posteriorly above the sacral vertebræ. The *pubes* are very short and slender, and though they unite with the short ischial rami to enclose a small obturator foramen, do *not* meet in a symphysis, but present an anterior interval, said to be wider in the female than the male, and causing the whole pelvis to assume very much a bird-like appearance. The pelvic cavity and outlets are so strait that the sexual and urinary organs and rectum pass altogether in front of it.

In the Bats (*Cheiroptera*) the *sacrum* (*fig.* 103, *e*), is very narrow, compressed posteriorly into a straight continuous bone, with no lateral foramina, and composed of three to four vertebræ, which are joined by ankylosis to three or four upper coccygeal vertebræ, or to more in the tailed species. There are six to twelve *caudal* bones, sometimes absent, as in *Pteropus* and Vampire.

Fig. 103.



Pelvis of the Ternate Bat (natural size), anterior view ; showing the inter-pubic separation (*d, d'*).

The *ilia* (*a*,) are narrow and subcylindrical, with a thick anterior spine, placed parallel to the vertebral column, and *ankylosed* to the anterior sacral vertebræ. The *ischia* (*c*) are in the same right line with the ilia, and are ankylosed at the tuberosities with the last sacral vertebræ, and, as seen especially in the Ternate Bat, given in the above figure, presenting an appearance as if ankylosed to each other in one mass, from the extreme narrowness of the sacrum at that part, inclosing a small *sacro-sciatic foramen*. The *pubes* (*b*) are thick, short, and very oblique, joining with the short ischial rami at *d*, to form an elongated obturator foramen (*f*). The ilio-pectineal spine (*h*) is very prominent, and recurved almost like a marsupial bone. This is especially seen in the *Vespertilio spectrum*, in which it is considered by Wagner as the first indication of a marsupial bone. The pubic symphysis is totally wanting generally in the Bat tribe, leaving a large interval (*d*, *d′*) ; but, according to Pallas and Schreger, the males of some species possess a symphysis, which is wanting in the female, a peculiarity curiously illustrative of the influence of sex on the pelvis. In a specimen in the Hunterian Museum the symphysis, or a close approximation of the bones, is certainly present, though very short. The cotyloid cavities in the bats are closely approximated, and are directed *backwards* as well as outwards, causing the retroversion of the feet seen in these animals. The pelvic cavity and outlets are much more capacious than in the Mole and Shrew.

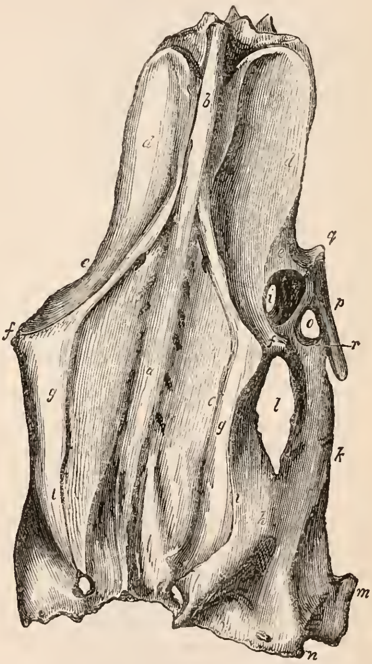
In the *Cetacea*, which are in other respects osteologically allied to the *Pachydermata*, the pelvic development suddenly becomes degenerated into small elongated bones, which may be considered as the homologue of the *pubes*, and which are imbedded in the muscles of the abdomen immediately in front of the ventral opening, and give attachment to the *crura penis*. They differ, only in being thicker and less transparent, from the pelvic bones of the true Fishes, between which and the Mammalia these animals are the connecting link, as the Bats to the Birds, and the *Monotremata* to the Chelonian reptiles.

In the Dolphins these pubic bones are two simple, elongated, flat bones placed on each side of the median line. In some Whales they are connected by a cross piece, and assume a hyoid shape (*see fig.* 257. Art. *Cetacea*). In the Dugong it is a V-shaped bone formed of four pieces, and articulated to one of the vertebræ by its free extremities. In the *Manatus*, according to Carus, they are entirely wanting.

The pelvic structure of *Birds* is characterised by very evident distinctions from the mammalian type, the osseous parts being accumulated, as it were, on the posterior and lateral parts, leaving the anterior parietes deficient, and being also thinner and more spread out, so as to leave smaller foramina.

The *sacrum* (*fig.* 104. *a*) is generally broad and large, consisting of from eight to twenty pieces, being increased forwards by ankylosis to the vertebræ corresponding to the lumbar region of the Mammalia, and which contribute to support the iliac wings. This arrangement, as well as the extensive ankylosis of the ilia and ischia, has an evident relation to their bipedal support, and is compensatory for the deficiency of the pelvic circle anteriorly. It is much more extensive in the *Cursores* and those which use the legs as the most usual instruments of progression. The bodies of the sacral vertebræ are raised in a continuous ridge on the anterior aspect, those immediately between the acetabula being larger and broader than the rest (*fig.* 105. *a*). The first five or six (*s*), which may be considered as the ankylosed lumbar vertebræ, present marked spinous processes united in a high crest which intervenes between, coalesces with, and supports the iliac wings at their inner margins (*fig.* 104. *b*). Their transverse processes, which are also ankylosed to the ilia near their outer borders, are strong and well marked on the ventral surface, and differ from those of the true sacral vertebræ in being more prominently advanced and having a direction more horizontally outwards instead of backwards and upwards (*fig.* 105. *r*), the most posterior being the thickest and placed at the junction of the iliac wing with the shaft. A

Fig. 104.



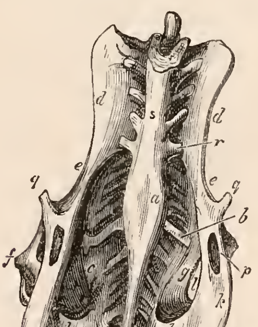
Superior or dorsal aspect of the pelvis of the Duck: *a*, sacrum; *b*, coalesced lumbar spines; *c*, sacral suture; *d*,' ilium; *e*, cotylo-sacral rib; *f*, ischio-sacral buttress; *g*, sacro-iliac plate; *h*, sacro-sciatic plate; *i*, acetabulum; *k*, ischium; *l*, sacro-sciatic foramen; *m*, rudiments of ischial ramus; *n*, spine; *o*, anterior obturator foramen; *p*, pubis; *q*, ilio-pectineal spine; *r*, anterior ischio-pubic union.

little anterior to the acetabula, however, where the true sacral vertebræ may be considered to commence, the spines gradually become less marked as they emerge from between the iliac wings and form a more or less flattened surface (*a*), which is separated from the coalesced transverse processes by two faintly-marked longitudinal grooves. The transverse processes of the true sacral vertebræ present a very prominent framework of ridges anteriorly (*fig.* 105.), which have a direction upwards and backwards as well as outwards, the most strongly marked being opposite the acetabula (*b*). They are coalesced on the superior aspect, by a thin plate of bone only. The sacrum, as seen from above (*fig.* 104.), has a diamond-shaped appearance, and is marked out from the iliac and ischial elements by a faintly-marked suture (*c*). The sacrum in Birds is a continuation of the line of the great dorsal curvature.

The *coccyx* is generally short, composed of from five to nine pieces, generally perforated for the spinal marrow, and curved dorsally, as we have observed before in some Rodents, terminating in a spinous-shaped piece (*see fig.* 107., *a*).

The *ilia* are comparatively short and narrow: with a very short cotylo-sacral rib or shaft (*e*), directed upwards and forwards, and expanding into a wing (*d*), concave or grooved superiorly. *The ala* is prolonged forwards on the posterior surfaces of the ankylosed lumbar vertebræ, coalescing with their spines and transverse processes; and also extends backwards to a less degree, to coalesce with the upper bifurcation of the anterior extremity of the ischium, in a sort of *buttress* (*f*), which projects externally and overhangs the acetabulum posteriorly, presenting, below, a facet, against which rests the trochanter of the femur, and which is apparently a continuation of the articular cotyloid surface. This buttress is continued from the ischium inwards, as a strong ridge, to the extremity of the strongest of the sacral transverse processes before mentioned (*fig.* 105. *b*), opposite the

Fig. 105.



Inferior or ventral view of the pelvis of the Partridge—natural size: *a*, coalesced bodies of sacral vertebræ; *b*, sacral transverse processes; *n*, ischial spine; *r*, lumbar or pseudo-sacral processes; *s*, ankylosed lumbar vertebræ. The remaining letters refer to the same parts as in *fig.* 99.

lateral angles of the diamond-shaped sacral plate, and evidently contributes in the greatest degree to support the trunk upon the femurs in the standing posture. The principal part of the ilium in birds is composed of the alæ, which lie almost altogether on the dorsal aspect of the spinal column. The total axis of the ilium, however, crosses that of the spine at an angle of from 150° to 160°, and does not, strictly speaking, lie parallel to it, as is commonly asserted (*see fig.* 112. 10.).

From the posterior part of the inner border of the iliac wing passes backward a thin *plate of bone* (*g*), along the external borders of the diamond-shaped sacral plate, from which it is marked by a distinct line of suture (*c*). It is continuous, posteriorly and externally, with the sacro-sciatic ossification, to be presently mentioned, from which it is also marked, especially in the Partridge and some other birds, by a raised line of demarcation (*t*). This thin plate is convex above and concave below, and enters into the formation of the pelvic cavity, being much hollowed in the Partridge and the *Gallinaceæ* generally (*fig.* 105. *g*), to receive the pelvic viscera. It seems to result from the ossification of the sacro-iliac oblique ligament, and to form a separate pelvic element which may be called the *sacro-iliac*, or *ilio-sacral*.

The *ischia* of birds (*k*) are long, strong, and divergent posteriorly; and, from the perforation of the cotyloids, appear to be bifurcated at the anterior extremity. The inferior bifurcation is horizontal, coalesces with the ilium and pubis, and separates the acetabulum (*i*) from the obturator foramen (*o*). The superior bifurcation is vertical in direction, separating the acetabulum (*i*) from the sacro-sciatic foramen (*l*), and coalescing above, internally with the long sacral transverse process (*b*) and ilio-sacral bone (*g*), and anteriorly with the ilium in the *ischio-sacral buttress* (*f*), before mentioned, which it principally contributes to support and form, and which may be considered as the homologue of the *ischio-sacral* arch in the human pelvis, separated from the *cotylo-sacral rib* (*e*) by a thin plate of bone above, and by the perforated acetabulum below. The posterior extremity of the ischium is much elongated, and constitutes the bulk of the bone. Its inferior border is spread out into a broad thin plate, slightly prolonged into an anterior process (*m*), which seems to represent the ascending ramus of Mammals, from its frequently uniting with the pubis and forming the posterior boundary of an obturator foramen.

Its superior border is prolonged into a broad thin plate (*h*) hollowed out in the pelvic cavity, and which constitutes the *sacro-sciatic pelvic element*, being evidently formed by ossification of the sacro-sciatic ligaments, from its completing posteriorly the *sacro-sciatic foramen* (*l*), and coalescing with the *sacro-iliac* plate (*g*), before mentioned, and, behind it, with the sacrum. The posterior extremity of the ischium is prolonged generally into a thin angular spinous process (*n*). The *ischia* in Birds generally form a right line with the ilia; but in the *Birds of prey* they constitute a remarkable exception, and make a very marked *ilio-ischial angle* in the reverse direction to that of Mammals generally, *i. e.* with the retiring sides anterior (*see fig.* 107.).

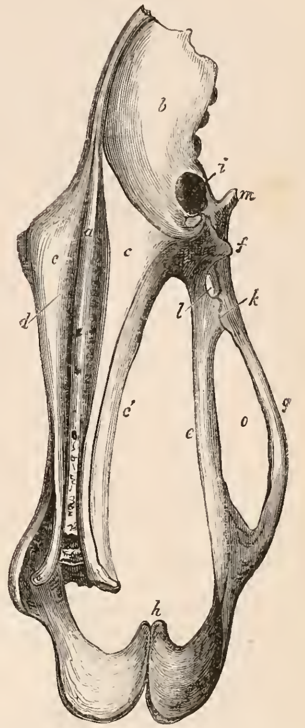
The *pubes* of birds are generally long, slender, rib-like, and divergent, and are composed of a single curved branch (*p*), having no angle, and never forming a true interpubic symphysis, though, in the Ostrich and Falco Fulvus, they are closely approximated at their posterior extremity, and form a sort of symphysis. The *ilio-pubic* angle is very large, from 155° to 160°, except in the birds of prey above alluded to ; and the pubes and ischia are generally almost parallel. Sometimes the posterior extremities of the pubes and ischia unite to form complete elongated obturator foramina ; and they may be united also near their anterior extremities, forming a lesser anterior division of the foramina, as in the *Cursores* (*see fig.* 106. *k*). Very often, the boundaries of the obturator openings are incomplete from the failure of this junction, and the foramina are wanting altogether ; or the anterior union and foramina only may be present, as in the Duck (*fig.* 104. *r*), from deficiency of the pubes posteriorly, or their entire approximation to the ischia. The pelvic cavity is increased in size posteriorly, by the divergence of the pubes and ischia, and is capable of great enlargement by the yielding of their unfixed extremities. The ilio-pectineal eminence is generally present, and often large in size, constituting a spinous process (*q*). The *acetabula* (*i*) are perforated and placed almost close to the borders of the sacrum, and generally much anterior to the centre of the whole pelvic length, that the points of support may be nearer the centre of gravity.

The bird's pelvis thus constitutes a firm, compact, immobile, box-like structure, deficient inferiorly, affording a large and firm hold, by the elongated and strong ischia, for the extensor muscles of the leg ; and, by the large sacrum and ankylosed ilia, for those of the trunk, which is placed almost entirely *in front* of the supporting femora, and always more or less at an angle with them, except in the Grebes and Penguins. The centre of gravity is not, in birds, directly above these supports, as in the true erect position of man, but is placed considerably in advance of the femurs, and necessitates considerable flexion of the lower parts of the legs, and great length of toes, to keep the centre of gravity within the base of support. The long pelvic muscles, the tendons of which reach to the toes, by a constant tendency to flex them, contribute mainly to preserve this semi-erect position, even during sleep, and independently of the will of the animal.

The pelvis of the *Cursores* (*fig.* 106.) approaches most nearly in the massiveness of the bones to the Mammalian type, as well as, in the Ostrich, in the formation of a pubic symphysis.

The *sacrum* (*a*) is very long and narrow, and is composed, according to Cuvier's tables, of twenty pieces in the Ostrich and of nineteen in the Emu and Australian Cassowary. The spinous and transverse processes are distinct, and coalesced only at their ex-

Fig. 106.



Dorsal view of the pelvis of the Ostrich : a, coalesced sacral spines ; *b*, ilium ; *c*, *c'*, sacro-iliac plate ; *d*, sacral chink ; *e*, ischium ; *f*, ischio-sacral buttress ; *g*, pubis ; *h*, symphysis ; *i*, acetabulum ; *k*, anterior ischio-pubic suture ; *l*, anterior obturator opening ; *m*, ilio-pectineal spine ; *o*, posterior or greater obturator hole.

tremities (*a*), in the Ostrich (the former being the only part of the sacrum appearing dorsally), presenting another close approximation to the Mammalian condition.

The *coccyx* is straight, and composed of seven pieces, which are perforated for the termination of the spinal marrow, and end in a conical bone. In the Rhea or American Ostrich, both the sacral and coccygeal bones are much atrophied.

The *ilia* (*b*) are comparatively very short, especially in the Rhea. The alæ are thick, short, and little curved, and lie close to each other at the upper half of their inner borders, by which they are ankylosed to the sacral spines, whose coalesced extremities are seen between them, forming a tent-like eminence above the anterior sacral vertebræ, and supported by their spinous processes in the manner of tent poles. Anteriorly, they overlap the posterior ribs ; and posteriorly, they are prolonged on the sides of the sacrum into a distinct and prominent *ilio-sacral element*.

This is an elongated piece of bone, with a superior (*c*) and a lateral (*c'*) surface, tapering gradually to the posterior extremity of the sacrum, where it terminates in an outward curve; and placed upon the transverse processes, which it encases, like a frame, on each side, and to which it is firmly ankylosed by its inner surface. In the Ostrich, its thick upper surface or border does *not* unite with the similar bone of the opposite side, nor with the sacral crest; but is separated from it by a chink, or oval opening, *d*, gradually narrowing posteriorly, in which the sacral spines (*a*) are seen distinct and separate, and coalesced only at their extremities. Opposite the three last sacral spines, however, the ilio-sacral pieces are ankylosed to the sacral ridge, and terminate posteriorly the oval chink. In the Emu and Rhea, the ilio-sacral pieces are coalesced in their whole length with the extremities of the sacral spines, and a narrow diamond-shaped dorsal plate is formed, composed almost entirely of the united ilio-sacral plates, and having its angles at the massy ischio-sacral buttresses.

The *ischia* (*e*) are very long and thick, and form, by the superior vertical bifurcation of the cotyloid extremity, a very strong *ischio-sacral buttress* (*f*), coalescing at that point with the ilium, sacrum, and ilio-sacral plate. In the Ostrich and Emu the ischia are not connected posteriorly with the sacrum, but a wide and elongated *sacro-sciatic notch* intervenes. In the latter, the ischial extremities are free and tubercular. In the Rhea they are ankylosed, by their posterior four-fifths, not only to the sacrum, but, like the ischia of the Bats, *to each other*, passing in front of the coccyx and greater part of the sacrum, thus excluding them from the pelvic cavity, and enclosing complete *sacro-sciatic foramina*, which open into a sort of posterior pelvic cavity.

The *pubes* (*g*) are long and slender, and are united posteriorly to the ischia in the Ostrich and Rhea, completing the Obturator Foramina; but, in the Cassowary, the pubes, as well as the ischia, are free at their posterior extremities, and the obturator foramina are incomplete, like the sacro-sciatic. In the Rhea and Cassowary they are widely diverging; but in the ostrich they approach each other in a wide curve posteriorly, and unite in a median *interpubic symphysis* (*h*), which curves forward anteriorly in a hook-like process, and completes an oblong anterior pelvic outlet with its longest diameter antero-posterior. The *ilio-pubic* angle is 140° in the Rhea, and 155° in the Ostrich and Cassowary. The ilio-pectineal spines are well marked, especially in the Ostrich (*m*). The *acetabula* (*i*) are perforated, and open partly into the pelvic cavity, and partly upon the sacrum, and are so closely approximated that the bodies of the vertebræ only intervene. Immediately below the acetabula, the ischia and pubes are connected, on each side, by the suture of an ischial apophysis with the pubes (*k*), across the obturator membrane, enclosing a smaller obturator opening (*l*), which transmits the vessels and nerves, and intervenes between the larger obturator opening (*o*) and the acetabulum.

In the *Apteryx* the *ilia* are longer and more concave superiorly, and the *ilio-sacral* prolongation short; and both are separated more distinctly from the opposite ones by the coalesced extremities of the sacral spines, forming an elongated ridge of bone down the middle, and separated from the ilia and ilio-sacral pieces by distinct parallel sutures.

The *ischia*, in this bird, as well as in the fossil gigantic *Dinornis*, or wingless bird of New Holland, are not placed, as in the *Cursores* before mentioned, parallel with the ilia, but form an anteriorly retiring or *reversed ilio-ischial angle* of 140°; and they do not coalesce posteriorly, either with the pubes or the sacrum, but have free truncated extremities, presenting a great general resemblance to the pelvis of the Emu. The *pubes* are parallel to the ischia, and, like them, free and divergent.

In the *Natatores* the pelvis is long and broad, and generally much expanded posteriorly by the divergence of the ischia and large sacro-sciatic ossification, for the attachment of the powerful muscles used in swimming; and the great intercotyloid distance gives to their gait its peculiar waddle (*see fig.* 104.). That of the Loons and Penguins, however, is remarkably contracted, long, and narrow, with little intercotyloid distance.

The usual number of *sacral* vertebræ is fourteen, as in the Swan; the Grebe has thirteen, and the Duck fifteen, and the sea Swallow ten only. The *sacrum* is usually very broad; but in the Penguin and Loon it is unusually narrow, and in the former it is united by ankylosis to the last dorsal vertebra. The *coccyx* is usually composed of eight pieces. The Goose and Pelican have but seven, and the Barnacle Goose nine. In Penguins it is strong, and assists in the support of the body in its usual vertical position. It is usually curved much dorsally, affording a larger posterior pelvic outlet.

The *ilia* are moderately long, and overlap the posterior ribs. In the Penguin they are said, by Wagner, *not* to be ankylosed to the sacrum, but connected only by ligamentous union; thus increasing its loose and waddling gait. The *ischia* are very long, divergent, and largely expanded into a very broad *sacro-sciatic element*, enclosing a small sacro-sciatic foramen. They are prolonged posteriorly into a sort of styliform process in the Auk and Puffin. The *pubes* are very long, slender, and divergent, and are expanded at the extremity, and curved inwards in the Swan, Diver, and Gannett. They do not generally unite with the ischia posteriorly; but, in the Swan, Duck, and Pelican, the obturator foramina are completed by the union of these bones, and are small and elongated.

The *Gallinæ* have large and strong pelves, in correspondence with their powerful legs, used chiefly for progression and scratching up their food.

The *sacrum* is broad, and composed of from ten pieces, as in the Turkey, to fifteen in the Pheasant and common Fowl. The *coccyx* has five pieces in the Pheasant and Turkey, and, in the latter, is said not to be perforated for the spinal chord. In the Peacock there are eight pieces, and the terminal bone is a horizontal oval plate to support the radiating feathers. In the tailless Manx variety of the common Fowl, the coccyx is borted into a single tubercular projection.

The *ilia* and *ilio-sacral ossifications* are broad, and the *ischia* long, divergent, and widely expanded posteriorly into a very broad *sacro-sciatic element*, much hollowed out in the pelvic cavity, and enclosing a large foramen (*see fig.* 105. *l*). This is especially marked in the Crown Pigeon, Bustard, Crested Curassow, and Guan. The *pubes* are long, and generally unite with the ischia to complete an elongated obturator hole (*p*). In the Dove, the pubes and ischia are united in their whole length, and the foramen is obliterated, while in the Crested Guan and Trumpeter it is subdivided into an anterior and posterior portion, as in the Ostrich and Rhea.

In the *Grallatores* the *sacrum* is broad, and composed of from ten to twelve pieces, but in the Oyster Catcher there are fifteen. In the Snipe the transverse processes are more or less separated. The *coccyx* is in seven or eight pieces.

The *ilia* and *ischia* are shorter and broader than in the *Natatores*, the former being placed more parallel to the spine, crossing it at about 165°; and the latter forming an *ilio-ischial angle* of 160°. The inter-cotyloid distance is very great, especially in the gigantic Crane, but in the Stork and Bittern the whole pelvis is smaller and more contracted. The pubes are long, diverging, and parallel to the ischia, especially strong in the *Aptenodytes;* and enclosing often a large obturator foramen by coalescing with the ischia. In the Stork, Ibis, and Flamingo, however, there is no such union.

In the *Scansores*, the *sacrum* of the Parrot is short and very broad, the *ilia* and *ischia* also short and broad, as well as the *ilio-sacral* and *sacro-sciatic* bones, inclosing a small foramen; and the *pubes*, uniting with the ischia in two distinct places, encloses a subdivided obturator foramen. The *coccyx* of the Toucan is long and very flexible.

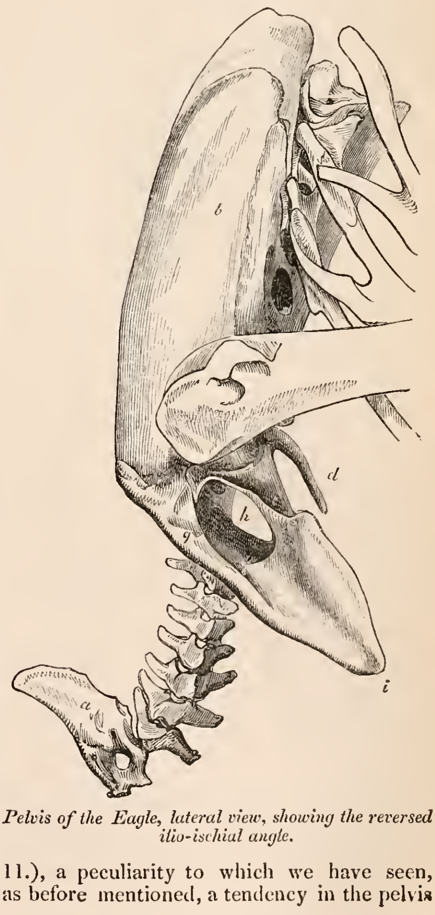
In the *Passeres*, the sacrum is composed of from ten to thirteen pieces; but in the Kingfisher there is but eight. The *coccyx* is in seven to nine pieces, very flexible in the Pies and Swallow; and in the Woodpecker very strong, and supporting on its anterior aspect, near the extremity, a remarkable, round, concave disc, formed by the coalescence and spreading of several of the bones anteriorly. Its use is evidently to support the body by being applied to the stems of the trees to which it clings in the pursuit of its prey and attaching the spreading tail feathers. The *ilia*, *ischia*, and *pubes* are slender in the *Passeres*, and the obturator foramina generally incomplete.

The pelvis of the *Raptores*, or Birds of prey (*fig.* 107.), is narrower, the bones more compact and massy, and less expanded than in the foregoing orders.

The *sacrum* is narrow, and composed generally of eleven bones, which, in the Sparrow-hawk, are ankylosed to the last lumbar vertebra. The *coccyx* is straight, and in seven or eight pieces, with a large and blade-like terminal bone directed dorsally (*a*).

The *ilia* (*b*) are proportionally larger, and project more dorsally than in the other orders, overlapping the spine with elongated wings, concave externally; and a strong tapering *ilio-sacral plate* (*g*), which is directed much downwards, as well as backwards, to unite with the sacro-sciatic plate (*e*) behind the foramen, so as to cross the line of the coccygeal bones almost at a right angle. The *ischia* (*c*) are rather short, strong, and *convergent* posteriorly, where they terminate by a long and pointed spine (*i*), with a strong but narrow *sacro-sciatic ossification* enclosing a small foramen (*h*). The *ischio-sacral* cotyloid buttresses (*f*) are largely developed. The *ilio-ischial angle* is remarkable in being *reversed* or turned forward to a marked extent,—130° in the Eagle, and 145° in the Owl (*see figs.* 107. and 112.

Fig. 107.



Pelvis of the Eagle, lateral view, showing the reversed ilio-ischial angle.

11.), a peculiarity to which we have seen, as before mentioned, a tendency in the pelvis of the Tiger and some *Carnivora*, and which has an evident relation to the increase of leverage for the muscular power of adduction required to grasp their prey, as also has the convergent direction of the ischia just mentioned. The *pubes* (*d*) are long, and are like the ischia, less directed backwards, forming an *ilio-pubic angle* of 125° in the Eagle and 140° in the Owl. They have a great inward convergence in most Vultures and Falcons, and in the Hen Harrier and brown Eagle are closely approximated in the median line and connected by ligaments in a sort of short *symphysis;* generally the ischia and pubes unite posteriorly to enclose a small obturator foramen in the Diurnal birds of prey. In some Falcons and Vultures, however, according to Carus, they are united in their whole extent; while, in the Owls, this union does not take place at all.

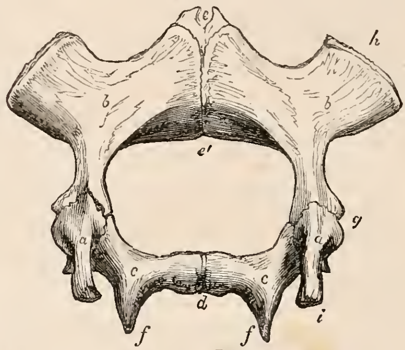
The *Reptile* pelves present some specimens which approach the Mammalian type, in the formation of a perfect pelvic girdle by inter-pubic and inter-ischial symphysis. In these animals, however, the three components of the innominate bones remain separate throughout life, and are connected in the acetabula by ligament only. The manner of articulation of the ilia with the sacrum is also characteristic. We have seen that in Mammals this connection of the ilia takes place about the centre or at the anterior half; and in Birds by the whole length of the alæ. In Reptiles it takes place by the *tip only* of the upper extremity of the ilia, giving much less strength, but far greater mobility to these bones. In the *Chelonian* and *Saurian* reptiles also, the ilia are directed *forwards* and downwards instead of *backwards* and downwards, as in Birds and Mammals, and thus the axis of the anterior pelvic outlet is directed *upwards* and forwards, and the lumbar vertebræ, instead of the coccygeal, form part of the posterior pelvic wall. The pelvic bones are simple, and the sacro-sciatic notch can hardly be said to exist.

In the Ophidians and some Saurians the pelvis, like the corresponding extremities, is totally wanting.

In the *Chelonia*,—the fresh-water, and the mud Tortoise, or *Trionyx*, have a *sacrum* composed of three pieces, soldered, like the dorsal vertebræ, to the back-plate. Their long transverse processes project from it, and unite in a tubercle at their apices, to which the ilia are attached. The *caudal* vertebræ are numerous.

The *ilia* (*fig.* 108. *a.*) are short, thick, curved roundish and clubbed inferiorly, and are directed outwards, forwards, and downwards, extending under the back plate directly between the sacrum (at *i*) and the acetabula. In the Tortoise and Trionyx they are moveable upon the sacrum forwards and backwards. From the acetabula, the *ischia* (*c*), larger than the ilia, pass, almost at a right angle, backwards and inwards, and unite in a *median symphysis* (*d*), forming the real pelvic circle, and presenting a sharp angle posteriorly in the Trionyx (*f*) and fresh-water Turtle. In the land and fresh-water Tortoise this symphysis is continuous anteriorly with the *inter-pubic* (*e*), forming with it a cross-shaped suture, and the obturator foramen on each side is distinct and separate; but, in the Turtle and Trionyx, as in most reptiles, the inter-pubic and inter-ischiatic symphyses are separated and connected by cartilage only, and thus, in the dry bones, the obturator foramina are coalesced in one large opening, and the pubes and ischia have the appearance of large ribs connected at their ventral extremities. The *pubes* (*b*) are the

Fig. 108.



Pelvis of the Trionyx, or Mud Tortoise, superior view.

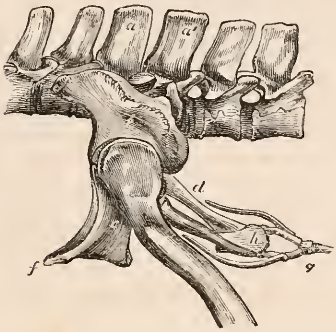
largest of the bones in the reptile pelvis, and, as seen in the Turtle, pass each from the acetabula as a thick bone, which expands as it passes downwards into a broad plate, and divides into an inner portion which unites with its opposite fellow in a *symphysis* (*e*, *e′*) and an outer portion, free and directed externally (*h*). In the *Chelydes* all the pelvic bones are ankylosed to the plastrum or to the back-plate; but in the others, the ischia and pubes are connected to the plastrum by ligaments only. The anterior pelvic opening in the *Chelonia* is directed *upwards* and forwards.

The pelvis of the fossil *Plesiosaurus* is very like that of the Tortoise, with narrow, small, and weak ilia, with the fan-like, spreading ischia, and large square pubes uniting in a common symphysis, by a crucial suture. The pelvic and shoulder bones have a great resemblance in the Chelonian as well as in the Saurian reptiles.

Of the *Saurian* reptiles the Crocodiles have two *sacral* vertebræ with large spines (*fig.* 109. *a*, *a′*), which support the ilia by strong prismatic apophyses, ankylosed together at the ends, and separated by a suture, in the young animals, from the bodies of their vertebræ. The *caudal* bones in all the Saurians, are very numerous.

The *ilia* (*b*) are very short, and in some species almost cuboid, slightly bent, with an inward concavity, and directed downwards and a little forwards, but almost at right angles to the spine, with the superior angle (*c*) projecting backwards. The *ischia* (*c*) are long, and directed, like the sides of an isosceles triangle, downwards and inwards, uniting in a median symphysis (*f*), and much resemble the coracoid bones of the shoulder. The *acetabula* of the crocodile look directly outwards, have strong inter-articular ligaments, and are formed only by the ilia and ischia, the latter presenting, just below the acetabulum, anterior apophyses which support the pubes. The *pubes* (*d*) are directed much forwards, downwards, and towards each other, but do not touch in the median line, being united only by the abdominal aponeu-

Fig. 109.



Pelvis of the Gangetic Crocodile (side view).

rosis (*h*). They are connected by the anterior border with the posterior abdominal ribs (*g*).

The *Lizards* have, like the crocodiles, two sacral bones, as in the Iguana and Great Monitor. In many Lizards the *sacral* transverse processes (*fig*. 110. A, *a*) are very long, and, being articulated by suture to the bodies of the vertebræ, appear, at first sight, like additional ilia. This is particularly the case in a fossil specimen recently discovered by Sir Charles Lyell.* The *ilia* (*b*) are directed forwards and downwards, and the superior extremity projects backwards in a truncated point (*e*). The *ischia* (*c*) are larger, and directed backwards at a great angle with the ilia, uniting in a truncated median symphysis, which is separated from that of the pubes; so that the *obturator foramina* are divided only by ligament (*g*), and communicate in the dry bones. In some Lizards the ischia present posteriorly a spinous projection. The *pubes* participate, with the ilia and ischia, in the formation of the acetabula, present a spine at their cotyloid extremity (*d*), curving downwards and outwards, and unite in a very narrow symphysis; but in the Monitors and Sauve-gardes the pubic symphysis is distinguished by its greater breadth and truncated form (*f*). The *ilio-pubic angle* is about 160°, retiring *posteriorly* in the Great Monitor Lizard, and the *ilio-ischial* angle is very acute, being 60° only (*see fig*. 112. 13.).

In the *Menopoma alleghani* the *sacral* transverse processes are directed backwards, and support apophyses to which the ilia are attached. The *pubes* and *ischia* are short and oblong, and so approximated as to leave no obturator opening.

Upon the pubic spine, in the Cameleon, are two cartilages, which have been stated by Dugès to be of a marsupial character.

Fig. 110.

A, *pelvis of the Great Monitor Lizard.*
B, *ilium, ischio-pubis, and marsupial cartilage of the Salamander (after Dugès), seen from below, and twice the natural size.*

From the pelvis of the fossil *Pterodactyle* Cuvier concludes that the forward direction of the ilia, the anterior position and pointed extremity of the pubis, and the separation of the pubic and ischiatic symphysis, ally this animal to the *Saurian* reptiles.

In the *tailed Batrachia* and *Ichthyic reptiles* there is but one *sacral* vertebra supporting rib-like transverse apophyses which connects them to the ilia. The *ilia* are long and slender, and the *pubes* and *ischia* are blended together in one large, squarish, cartilaginous plate, not perforated, and loosely connected by ligament with the one of the opposite side.

In the *Proteus* the ilia are small, and the whole pelvis very little ossified. In the Salamander, also, the ilia are small (*see fig*. 110. B, *a*). A cartilage, of a Y shape (*d*), is placed at the anterior margin of the ischio-pubic plate (*b*), which Dugès looked upon as marsupial, but which Meckel has considered as part of the sternal elements, and which is a bifurcated prolongation of the cartilaginous ischio-pubic symphysis (*c*). There is also a very small obturator opening in the ischio-pubic plate (*b*). The ossification of the pelvic bones in these animals, according to Dugès, takes place in the same order as in man. The pelvis of the *Axolotl* is, like that of the Salamander, not quite ossified. In the *Siren*, according to Cuvier, there is no vestige of a pelvis. In the *Ophisaurus*, *Cæciliæ*, and *Amphisbæna*, there are only rudimentary vestiges of the ilia and ischia; and in the *apodal Saurians*, as in the *Ophidia*, a single bone only is found, under the skin near the anus. In *Pseudopus anguis* and *Acontia* are simple elongated pelvic bones, articulated by ligament to the last dorsal transverse processes. In *Eryx boa* a pair of elongated bones lie parallel to the rectum, free from the spinal column. They are sometimes found in several distinct pieces.

In the Sauroid reptiles the *acetabula* are directed horizontally outwards, and the inflexions of the feet are made perpendicularly to the rachis or plane of motion, the thigh being

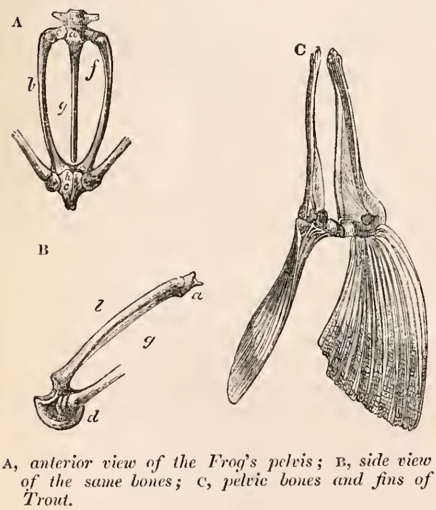
* Lecture at the Royal Institution.

directed outwards, the knee always bent, and the body trailing. They walk on the fore and hinder legs alternately, and leap by a sudden flexion of the body.

The pelvis of the *Anourous Batrachia* is interesting from the changes which affect it, in their transition from the ichthycic to the quadrupedal condition.

The *sacrum* of the Frog (*fig.* 111. A and B) is considered by Dugès to be formed by the last dorsal vertebra, which closely resembles the preceding ones, except in having very long and strong transverse processes (*e*), to the tips of which the ilia are moveably articulated. In the *Rana pipa* and Toad, however, the sacrum presents evident indications of a division into two vertebræ, there being on each side a foramen for nerves, with two prismatic and very rough transverse processes. The *coccyx* of the Frog is composed of two pieces (*f*), which, in the adult state, are ankylosed together and to the sacrum, and considered by some to form part of that bone. They are formed, respectively, from three points of ossification. In addition to these there is a long cylindrical terminal spinous or btyloid process (*g*), which is formed by a single separate ossific point, and becomes ankylosed so the other part at the adult period. This is tonsidered by some to be a second sacrum, end by others a coccyx. It has been supposed ay Dugès to cause, by its progressive ossific development, the mortification and dropping off of the tail at the period of transition from the tadpole condition, and thus closing up the spinal canal posteriorly.

Fig. 111.



A, *anterior view of the Frog's pelvis;* B, *side view of the same bones;* C, *pelvic bones and fins of Trout.*

The *ilia* (*b*) are very long and cylindrical, and directed backwards, becoming almost horizontal in the *Rana pipa*. They suspend between them, by their apices, the long transverse processes and body of the sacrum, like the springs of a coach. At their opposite extremities tney are ankylosed, not only with the ischia and pubes, *but with each other* (*h*) ; and thus the *acetabula*, of which they form the greatest portion, are closely approximated, and the pelvic outlet assumes a V shape with the base at the sacrum and the angle at the coalesced extremities of the ilia. The *pubes* and *ischia* of both sides are coalesced together in an azygos osseous plate (*c*), with a central rounded crest marking the position of the symphysis (*d*), the pubes being the last to ossify. There is no foramen obturatorium. The posterior outlet of the Frog's pelvis looks almost directly upwards, and the anus opens, at the extremity of the coccygeal spine, upon the dorsal aspect of the animal.

In the immature Batrachian a triangular-shaped cartilage intervenes between the opposing ilia and the other pelvic bones in the acetabula, which afterwards becomes obliterated by the ankylosis of the bones. Dugès calls it an "os paracotyleal," analogous to the "paraglenal" bone of the shoulder of the same animal. There are also epiphysial pieces on the ilia and ischia which represent the crest and tuberosity of those bones respectively.

The solidity and firmness of union of the ischio-pubic portion of the pelvis in the frog is a remarkable instance of modification and adaptation of form to meet the requirements for a strong and firm hold for the powerful *triceps cruris*, external obturator, hamstring, and adductor muscles in the thigh of this animal. The single pair of *glutei* also obtain an extensive attachment from the long ilia, and the *pyriformes* from the long coccygeal spine, while the strong abdominal muscles, acting on the moveable ilia, give, as it were, an additional segment to the hinder extremities. In this manner the frog's pelvis is strikingly and directly adapted to its leaping progression.

In the *Fishes* the pelvic structures dwindle to elementary pieces, such as we have mentioned in the bimanal and apodal Reptiles, and finally disappear altogether.

The pelvis is represented in these animals by two bones, sometimes coalesced into an azygos bone, which support the ventral fins. In the *Pisces thoracici* these are suspended by ligament to the coracoids, by which they are advanced anterior to the pectoral fins, and connected to the head; but in the *Pisces abdominales* they are detached from the coracoids, and are suspended in the muscles at the posterior part of the abdomen. They are, however, subject to great diversity of position.

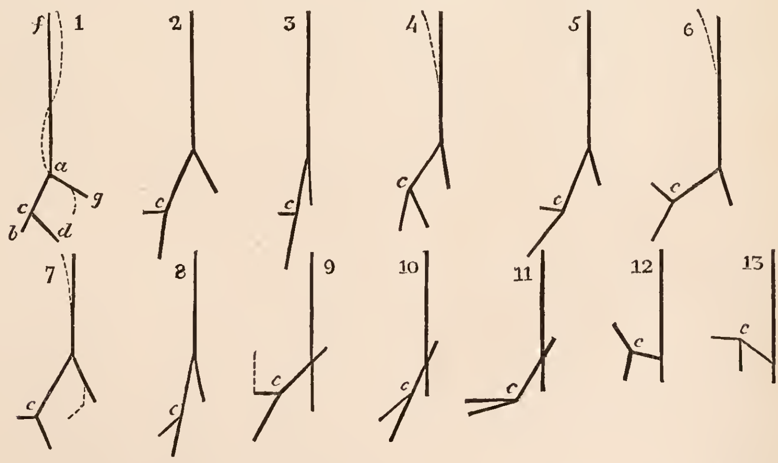
Owen considers the pelvic bones of fishes to be the homologues of the *pubes ;* but, in the opinion of Carus, they are to be considered as *ilia*. Their inferior and ventral position, their occasional union in a symphysis, their frequent coalescence, and their attachment to the generative organs, however, would support rather the conclusion of Professor Owen; the support of the bones of the extremities not being *exclusively* the *iliac* attribute, but also usually contributed to by the pubes and ischia. In Fishes, a supporting arch from the spinal column to the posterior limbs * is not wanted, but rather a free and unimpeded motion for the caudal extremity, used in propelling the body.

In the Angler there are two pelvic bones, each consisting of a vertical portion, which, in this instance, seems to represent the *ilium*, and a horizontal one, which meets in a symphysis with the one on the opposite side, and is the homologue of the pubis, the pectoral rays being attached to the angle of union of the two portions. In the Rays and Sharks, where the pelvic extremities are better developed than in other fishes, the pelvic bones consist of one piece, placed transversely, resembling that which supports the pectoral fins, and suspended loosely, like it, by a ligament to the spine. In the Sharks and *Chimeræ* are found, articulated to it, by means of an intermediate cartilage, two club-shaped bones, called *claspers*, which are used to embrace the female in the generative act. In the *Torpedo*, and also in the *Cyclobates oligodactylus*, an extinct Ray, the pubic bone sends forward two processes, somewhat resembling marsupial bones. In the Sturgeon, the pelvic bones are almost entirely separated from each other, and consist of small triangular pieces, with their apices directed forwards, and supporting the cartilaginous fin rays. In the Cod-fish there are two sub-triangular bifurcated bones, connected to each other by ligament, and suspended from the *coracoids*, the rays of the ventral fins springing directly from them. In the Trout, the pelvic bones are also two in number, flat and of an elongated triangular shape, with the base directed posteriorly, and supporting the ventral fins (see *fig*. 111. c). In the Haddock, there is a single bone, presenting a central oval opening with the shorter diameter transverse. In the *Cyprinus*, *Scomber*, and *Zeus*, they present backward spinous projections. In the *Rhombus* and *Loricaria* there is seen an ankylosis of the anterior caudal vertebræ, forming a sort of *sacrum*, and presenting the first indication of the formation of this bone in the animal kingdom.

Subjoined is a table, showing the comparative pelvic angles in Man and the principal genera of Mammalia, Birds, and Reptiles. The measurements were principally taken, with great care to insure correctness, from the specimens in the Hunterian Museum, through the kindness of Professor Owen. The relative size or total disappearance of the *vertebro-iliac*, *sacro-vertebral*, and the *ilio-pubic* and *ilio-ischial angles* in the different tribes, will be here seen at one view. It may be observed that the two former may vary somewhat through inaccuracies in articulating the skeleton, or with the variations of the vertebral curve, and that the results here given are to be taken in this particular, as approximative only. But the ilio-pubic and ischial angles cannot, from the ossific union of the bones, be subject to such accidental variations.

The accompanying diagram is intended to show the absolute lines of direction or axes of the pelvic bones and spine seen in profile, with the angles above referred to, in the principal pelvic types.

Fig. 112.



Lines of direction and profile angles of the pelvic bones. 1. Human type; *fac*, vertebro-iliac angle; *fag*, sacro-vertebral angle; *acd*, ilio-ischial angle; *acb*, ilio-pubic line, forming *an angle* in all other animals. 2. Orang type. 3. Monkey type, *no* ilio-ischial angle. 4. Edentata type, ilio-pubic angle *reversed*. 5. Carnivora type, ilio-ischial angle *reversed*. 6. Pachyderm type. 7. Ruminant type. 8. Rodent type, *no* ilio-ischial angle. 9. Kangaroo type. 10. Bird type, *no* ilio-ischial angle. 11. Raptores type, ilio-ischial angle *reversed*. 12. Chelonian type. 13. Saurian type, ilio-pubic angle *reversed*, and remarkably *acute* ilio-ischial angle.

Having thus taken a general review of the progressive development of the pelvis, and traced it from its most perfect form in man to its most rudimentary elements in the fishes; we can enter more prepared into the consideration of the *serial homologies* of the pelvis and its ligaments.

SERIAL HOMOLOGIES OF THE PELVIC BONES AND LIGAMENTS.

The *sacrum*, according to Professor Owen, is to be considered as the *centrum* of the pelvic vertebral elements. The ankylosed bodies of the sacral vertebræ, as well as their coalesced laminæ, spinous and articular processes, are sufficiently evident as the representatives of those components of the neural arch in the typical vertebra.* The lateral masses of the sacrum which support the ilia are, however, made up of two elements coalesced together, as is shown in the manner of their development, before described, viz., *first*, of the true transverse processes, or "*diapophyses*," constituting the external row of tubercles seen on the *posterior* surface of the sacrum, and which are ossified, like those of the true vertebræ, by extension from the same points of ossification as the laminæ, and spinous and articular processes; and, *secondly*, of the six *characteristic* sacral ossific points, three on each side of the three upper sacral bodies, which are placed on the *anterior* surface of and below the former, between the sacral foramina, as before described.

These ossific points, as shown in preparations exhibited to the British Association, in 1837, by Mr. Carlyle, were four in number on each side, and very distinct from the true transverse processes; and they were considered by him to represent the necks and heads of four *sacral ribs* on each side. Upon the truncated extremities of these three or four sacral ribs the *auricular facets* are supported. They appear to be similar to the anterior roots of the cervical transverse processes, upon the last of which is occasionally developed, in the human subject, a short costal process. In the nomenclature of Professor Owen, they may be considered the sacral "*parapophyses*," but differ from these processes as seen in the rib-bearing vertebræ of the Crocodile, in being developed by separate and distinct centres. Blainville remarks that the four upper sacral vertebræ, scientifically considered, compose the whole of the true sacral elements; and that the fifth, which he calls "*subsacral*," is an ankylosed coccygeal vertebra. But the lateral epiphysial plates of bone before described — the upper of which forms the auricular facet, opposite the three first, and the lower, the sides of the two last sacral vertebræ — would seem to connect these vertebræ more particularly together, and to be the coalesced serial homologues of the epiphyses forming the articular facets on the *tubercles* of the ribs. In the Saurian reptiles these sacral ribs, two in number on each side, are very distinctly analysed, and have been before mentioned as intervening between the sacrum and the ilia. The anterior of these ribs in the Saurians are said by Mr. Carlyle, to be articulated to the bodies of the last dorsal and first sacral vertebræ, as well as to the intervertebral substance between them; and the posterior, to the last sacral and first caudal vertebræ, and to their intervertebral substance — affording an exact homologue to the true ribs. The ilia in the human fœtus, and for some years after birth, are connected to two only of the sacral vertebræ; but, in the adult state, they

* A remarkable analogous instance of the coalescence of vertebræ to form one solid mass is seen in those of the cervical region of the bottle-nosed Whale.

join three sacral ribs, corresponding, as we have seen, to the three upper sacral vertebræ. Mr. Carlyle has seen them, in the negro, join four sacral ribs, as above stated.

The *sacral element* of the pelvis we have found to be most largely developed in Man, and its angle with the spinal column most marked, in adaptation to his destiny for the erect and bipedal posture. In Birds, also, of bipedal and semi-erect position of body, it is also large, and, in a less degree, in animals whose climbing or sedentary habits require an habitual upright direction of the vertebral column, such as the Apes, Bears, and Sloths; while it is much contracted, both in breadth and length, in most of the animals of true quadrupedal progression. Its spinous processes are long, and sometimes united in a crest, in the springing animals, and those requiring long leverage for the muscles of the back and thigh arising therefrom.

The *coccygeal* pieces are, in the human subject and the higher *Simiæ*, the aborted continuations of the sacral vertebræ, gradually diminishing into their most permanent and principal elements,—the bodies of the vertebræ. The upper ones show also rudimentary transverse processes, and the first presents well marked articular processes to join with those of the sacrum, or sacral horns. Dr. Knox considers the 1st coccygeal vertebra to be the representative, in man, of a class of vertebræ distinct both from the sacral and remaining coccygeal.

In Man these bones are placed very obliquely, to support the pelvic viscera; but in the lower mammals, the Birds, and especially the Reptiles and Fishes, they are placed in the line of the vertebral column, and are developed as caudal vertebræ, in adaptation for their various uses in propulsion or prehension, &c. In many, they present not only a complete neural arch and spine, enclosing the caudal continuation of the spinal chord, but also an anterior or hœmal arch and spine, to enclose and protect the arteries of the tail.

The *ilia* evidently consist of the shafts of the three or four sacral *ribs*, coalesced into one mass of bone on each side, and constitute the homologues of the shafts of the thoracic ribs, termed by Owen the "*pleurapophyses*." The descending branch or body of the ischium is considered by the same writer also to form one of these pleurapophyses. The development of the whole of the *ischium*, as well as the *pubis*, from a single and separate centre; and the connection of both these bones to the ilium in the cotyloid cavity, seems, however, to place the whole of each bone in the same relative position, and to class them both with the chondro-sternal elements, or "*hæmapophyses*" of the thoracic ribs. Professor Owen considers that the pubes and the ascending rami only of the ischia are the homologues of the rib cartilages,—an arrangement that would make a separation of the ischium, which its mode of development from a single centre would hardly justify. The bent and hook-like form of the Mammalian ischia finds a very close counterpart in the *cartilages* of the eighth ribs, in Man, especially when these are ossified, as often occurs; and the manner of its junction with the pubes in the human subject is exactly similar to that of the eighth cartilage with the seventh, before it reached the sternum. In many of the lower Mammalia, especially in the Marsupials and in the Reptiles, we have seen that the ischial ribs reach each other, and are connected, like the pubic, in the median line. The formation of a pubic apophysis or descending ramus to meet the ascending ischium, is a disposition which finds a counterpart in a similar apophysis from the acetabular end of the ischium to support the pubes, which we have seen in the pelvis of the Crocodiles, excluding the latter bone from participating in the formation of the acetabulum, exactly as the ischia in man and some animals are excluded from the formation of the median symphysis. The greatest extent of this ischio-pubic coalescence is seen in the Batrachians and the saltatory *Carnivora*, Ruminants, and Marsupials; its entire absence in some of the Chelonian and in the Saurian reptiles. In the Birds and Bats it is often present even where there is no median symphysis.

The *iliac element* has been seen to be largely developed in its shaft, and placed very obliquely on the lumbar vertebræ in quadrupeds characterised chiefly by saltatory quadrupedal progression, and requiring long hold for the great muscles of the hip, as the *Carnivora*, the Deer tribe, the Monkeys, the Horse, and the Frog,—while it is contracted to a remarkable degree in the Walrus and Seal, which approach in their habits the Cetaceans and Fishes, in whom the iliac element of the pelvis is the first to disappear altogether. Its alæ we see *elongated* behind the sacrum in those animals whose pseudo-sedentary habits require a long leverage for the muscles of the back arising from the iliac crest, such as some of the *Rodentia* and the Kangaroos—and its alæ, on the contrary, to be *expanded* in those requiring support to the abdominal viscera, either from their size, as in the *Pachydermata*, or from the erect or semierect position, as in Man and the Sloths.

The *ischiadic element* has been seen to be adapted—by its large development and direct line with the ilia, for saltatory progression, requiring a long leverage for the flexor muscles of the leg, as in the *Carnivora*, the Deer tribe, the Rodents, the Kangaroos, and the Birds;—or, for the support of the sacrum, by its angularity with the ilium, and by its elongated tuberosities, in the Ox, Hippopotamus, and some others, and by ankylosis with the sacrum, as in the Sloths, Bats, and Birds;—or for the support of a carapace, as in the Armadilloes;—or for the true ischial sedentary support of the body, as in the Apes and Monkeys.

The *pubic element* has been likewise seen to be in a direct line with the iliac shaft in Man *only*, destined to the truly erect posture;—and in those animals formed for quadrupedal progression to be short and placed at a more or less marked ilio-pubic angle, so as to be out of the way of the approximated femurs, in their semi-flexed and angular movements on the pelvis;—but in those habitually requiring a semi-erect position, as the Sloths, to be longer and less angular. It is also unusually long and oblique in the Seal tribe, with reference, probably, to a tapering extremity and fish-like outline.

The *iliac crest* and its *posterior spines* and *tuberosity* are the hypertrophied, coalesced, and spread-out *tubercles* of the sacral ribs, a homologue which will be made more evident by the consideration of the homologues of the pelvic ligaments. The epipleural spines of Fishes, and the costal appendages of Birds, show the serial homology of these processes.

The *Y-shaped epiphysial cotyloid bone* of M Serres has been considered by some to represent a marsupial bone; but, seeing that in the marsupials themselves these Y-shaped bones and the real marsupial bones also, coexist, this opinion cannot be considered as tenable.

In the immature Potoroo, as described by Owen, there is another epiphysial cotyloid bone forming part of the anterior margin of the acetabulum (see *fig.* 110. Art. *Marsupialia*); and one of a similar nature and position is described by Geoffroy St. Hilaire as present in the acetabula of the Rabbit, and is considered by him to be a rudimental marsupial bone. There seems, however, greater reason to suppose that both these cotyloid epiphyses are rather of the nature of those *complementary* ossific points which are seen in the opposed articular surfaces of the bodies of the true vertebræ, and also in the sacral vertebræ, and in the articular ends of some long bones,—as those forming the elbow-joint.

From the position of the *ilio-pectineal eminence* or *spine* at the junction of the ilium and pubes opposite to the superior limb of the cotyloid Y-shaped bone, it would seem as if this process were connected with it by a continuation of its ossification upwards. As this spine is coexistent, as seen particularly in the Monotremes, in a great state of development with the marsupial bone, the opinion that it represents that bone, seems to be quite untenable. We have seen it most developed in those animals whose posture or structure requires largely-developed *psoæ parvæ* muscles, as in the Marsupials and Monotremes; the tendons of those muscles being implanted upon them, presenting a close similarity to the implantation of the *anterior scaleni* muscles into the *scalene tubercle* of the first rib, to which this eminence would be thus homologically related.

The *marsupial bones*, being developed in the tendons of the external oblique muscle, present the greatest homology, both in position and office, with the *spines* of the *pubes* in Man and some animals; and it would appear, from the manner in which the cremaster muscles play over them, as if they were formed by an ossification of that part of the tendon which is called, in human anatomy, the *external pillar* of the ring, or *Poupart's ligament*, and which is implanted upon the pubic spine.* In support of this opinion, it may be stated that, in Poupart's ligament near the spine of the pubis, *cornicles*, similar to those in the stylo-hyoid ligament, are said to have been found in the human subject. The cartilages upon the pubic plate of the Cameleon, before mentioned, are also significantly homologous to these cornicles and to the marsupial bones, as well as that upon the anterior pubic angle in the Salamander, and considered by Dugès as having a marsupial character.

The *epiphysial plates*, forming the articular surfaces of the pubic symphysis in man, are analogous with those which form the *auricular sacral* facets.

In the immature Potoroo, there is a triangular wedge of bone inserted, with its apex forwards, between the pubic bones posteriorly; and, in the adult Kangaroo, we have seen that a single V-shaped epiphysis is placed with the apex upwards, between the ischial bones at the lower part of the ischio-pubic symphysis, and forming a prominent vertical median ridge on its anterior aspect (see *fig.* 99. *c*). These epiphyses appear to result from ossification, by independent centres, of the inter-pubic and inter-ischial fibro-cartilages, and to constitute, in these animals, a serial homology with the *central ossific points* of the *sternum* and *xiphoid appendix*; and they may be considered as represented in the human subject by the *inter-pubic fibro-cartilages*, which are continued along the abdominal walls to their sternal homologues by the *linea alba*; as the pubic and ischial elements themselves are represented by the *lineæ transversæ*, and their cotyloid junction by the external border of the *aponeurosis* of the *external oblique muscle* and the *linea semilunaris*. The *two cartilaginous plates* of the pubic symphysis would seem to be the homological representatives of the *double lateral ossific points*, often found permanently separated by an opening in the lower pieces of the human sternum, and in the bifurcated xiphoid appendage.

We have seen that, while in the Kangaroos and the leaping Rodents, Ruminants, and Carnivora, the *ischial* and *pubic symphyses* are largely developed and coalesced, and seem, in many cases, to be compensatory for the weakness of the sacral portion of the pelvis; in the Sloths and some others the ischial symphysis is entirely wanting; and in the Bats, Shrews, Moles, and Birds, the elements of the pubic symphysis also entirely fail. A congenital and similar deficiency of this symphysis has been observed in some human pelvic malformations, from arrest of development. This deficiency may be well compared to a like congenital absence of the sternum, some instances of which have been recorded.

The loss of pelvic firmness consequent upon this is compensated for, in great part, in the animals just named, by the ossification of another pelvic element, the *sacro-sciatic*.

* Laurent and Owen consider these bones as sesamoid trochlear ossicles. (See Art. *Marsupialia.*)

These are represented in Man and Mammalia generally by the *sacro-sciatic ligaments*, and appear to be ossified by extension from the epiphysis of the ischiadic tuberosity, and from the ischiadic spine. In Birds, they constitute an important element of the pelvis, and are separated, more or less, from the ischium and sacrum by a faintly marked suture, more evident, however, at the sacral extremity. Taken in a scientific point of view they represent two additional pelvic *rib shafts*, or *pleurapophyses*, of the *two last sacral* vertebræ, and are implanted on the sacrum, in the human pelvis, in the site of the two lower lateral epiphysial plates of that bone, exactly as the ilia are articulated upon the three upper. Their extension to the coccyx would also seem to connect them with the elements of the first coccygeal vertebræ; — and their attachment to the ischia would be, in this point of view, a repetition of the kind of union of the latter bones with the descending pubic rami, as the cartilages of the false ribs are connected consecutively to each other in the thorax.

The *obturator* and *sacro-sciatic foramina*, considered in this light, constitute simply consecutive and enlarged *interchondral* and *intercostal spaces* respectively; the lesser sacro-sciatic foramen becoming, in the Sloths, Bats, and Birds, entirely obliterated. This manner of viewing them explains the apparently indifferent way in which the boundaries of these openings, especially the obturator, are left incompleted, or entirely obliterated, in Birds and Reptiles. The *cotyloid notch* may be thus considered as the commencement of the obturator separation, and the formation of two obturator openings, as in the Ostrich, may be readily explained.

The *obturator membrane* may also be thus related to the *anterior intercostal aponeuroses*, and the *membranous expansion* of the upper border of the *great sciatic ligaments* (before mentioned as connected with the fasciæ covering the internal obturator and pyriformes muscles), to the *posterior intercostal ligaments*.

The homologues of the *ligaments* of the *sacro-iliac* articulations are readily found in those connecting the head, neck, and tubercles of the thoracic ribs to the vertebræ.

The *anterior* and *superior sacro-iliac ligaments* are evidently repetitions of the *anterior* or *stellate costo-vertebral*; the superficial fibres of the *posterior sacro-iliac*, repetitions of the *posterior costo-transverse*; the deep fibres, or *interosseous sacro-iliac*, of the *middle* or *interosseous costo-transverse*; and the *ilio-lumbar* and *lumbo-sacral* ligaments, of the *oblique* or *anterior costo-transverse* ligaments of the ribs. The connection of the last-named ligament with the transverse process of the vertebra above, and with the iliac crest below, is very similar to the oblique direction and attachments of the homologous costo-transverse. The ossification of these ligaments in Sloths, Bats, and especially in Birds, gives additional support to their otherwise feebly connected pelves.

The *ligaments* of the *pubic symphysis* find easily their homologues in the *chondro-sternal* ligaments. The *anterior* and *posterior peripheral inter-pubic ligaments* are repetitions of the similarly placed and constituted *chondro-sternal*, which, like them, connect the hæmapophyses together across the interposed elements, as well as directly to the endo-sternal bones and inter-pubic fibro-cartilage. The *superior pubic* ligament finds its homologue in the *inter-clavicular*, and the *sub-pubic*, in the *chondro-xiphoid* and *interchondral* fibres.

It would be easy also to point out the *muscular* homologues of the two regions; but space will not permit more than to mention the evident ones of the *external* and *internal oblique* muscles with the similarly placed and directed *intercostals*; of the *levator ani* with the *diaphragm*; and of the *pyriformes* with the *psoæ* muscles. The *internal obturator muscles* would represent the *triangularis sterni* and *transversalis abdominis*; and the *external*, the *lesser pectoral* and *external oblique muscles*.

The homologues of the *pelvic* bones with those of the *shoulder* are best seen in the Reptiles. According to Dugès, the pelvis of the Salamander has a close resemblance to the shoulder of the Cameleon.

The *ilium* is generally considered to be the homologue of the *scapula*; the *pubis*, of the *clavicle*; and the *ischium*, of the *coracoid bone*. Meckel considers the body of the *ischium* to represent the spine of the *scapula*; while, in the opinion of Oken, the *pubis* represents the *acromion process*, and the *marsupial bones* the *clavicles*.

In the shoulder of the Cameleon, the scapula is longer even than the ilium, and the furcular clavicles and coracoids are ankylosed together like the ischium and pubis. And, in the pelvis of the Crocodile, we have seen that the ischium excludes the pubis from the formation of the acetabulum by an apophysis which overhangs that cavity, somewhat as the human coracoid process intervenes between the glenoid cavity and the clavicle.

The *ascending branch of the ischium* may, further, be taken to represent the *epicoracoid bones* of the Monotremes, Lizards, Batrachians, and some Fishes, as the Cod, Carp, and Perch, In the Cock-fish, Snipe-fish, and Lancet-fish, these bones are joined in a kind of symphysis, forming an independent arch behind the scapular arch.

And those bones of the scapular arch of the Fish, which are considered by Owen to be the *coracoids*, (but by Meckel, Agassiz, Geoffroy, and Spix to be *clavicles*,) unite also in a median symphysis, presenting an homologous affinity to the *ischial symphysis* seen in the Reptiles,—the whole of these symphysial elements being represented, combined, by the elongated *ischio-pubic symphysis* in many Mammalians, but especially in that of the Marsupials and Monotremes.

Pelvis, Abnormal Anatomy of the. — From the close relation of this structure to the processes of child-bearing, the most important of the alterations to which it is liable by disease, are such as produce *deformity* and *obstruction* of the passages, and occurring in the female subject. In the experience of Dr. Robert Lee, about one-sixth of all the cases of difficult parturition in London, depend upon contraction of the pelvis from arrest of development or distortion. In the male subject, they are interesting mainly as to the light they may throw upon the processes and mechanisms of the abnormal changes.

On reviewing a good collection of abnormal pelves, we find them susceptible of the following classification, of which the principal part are interesting chiefly to the obstetrician, but, in a great degree, to the surgeon and general pathologist also.

Pelvic Deformities and Obstructions. — *Deformities* of the pelvis, properly so called, are all such departures from the adult "*standard*," in size, build, and conformation, as are sufficiently *marked* to influence child-bearing.

They have been variously arranged, but seem to fall best under two heads: viz.— 1. *Normal irregularities*—including all those which present the shape and proportions proper to the healthy pelvis at some period of its development; and,—2. *Distortions*,—including all such peculiar alterations of shape and size as are consequent upon disease or injury.

1. *Normal irregularities* may be subdivided into,—*Equable deviations*, in which the general form and appearance are similar, and the diameters *proportionate* to those of the "*standard*" pelvis; and,—*Irregularities from imperfect development*, in which the shape deviates from, and the diameters are *not* in proportion to, those of the "*standard*."

Equable deviations.—"*Pelvis equabiliter justo major.*"—The irregularity in this pelvis consists in all the diameters being in *excess*. It is not uncommon. Burns records one example. Dr. Murphy has another in his possession, and there is in the Museum of King's College a third, the brim of which measures 6 inches transversely, by 5 inches antero-posteriorly. The largest hitherto recorded is one by Giles de la Tournette, who gives

	in.
The distance between iliac crests -	$12\frac{1}{2}$
„ Antero-posterior diam. of *brim* -	$5\frac{1}{2}$
„ Transverse diam. of do. -	$6\frac{1}{2}$
Both the diameters of the *inferior outlet* -	$5\frac{1}{2}$

The *disadvantages* of this pelvis are said to be prolapse and displacement of the viscera, sudden expulsion of the fœtus, inversion of the uterus, and want of the proper impress of rotation on the head. Retroversion of the uterus and its prolapse in the impregnated state, are said by some to be most commonly observed in large pelves.

"*Pelvis equabiliter justo minor.*"— In this pelvis, all the diameters are proportionately *diminished*. The diminution is said, by Churchill, to be generally about one-fourth. Naegele thinks it to be more common than had been supposed by Bandelocque and other writers on midwifery. Velpean gives two cases of "*Etroitesse absolue*" (*Journal Complementaire*), in which the diminution was so great that one woman died undelivered, and the other underwent the Cæsarian operation.

It was considered by Alexander Shaw *, that proportionable contraction of the pelvic diameters is very common in rickety subjects, from want of proper osseous development, and that it is generally accompanied by corresponding diminution of the size of the bones of the lower extremities. The experience of Rokitansky also favours the opinion that this proportionate contraction, without distortion of the pelvis, may be produced by rickets. Naegele, however, records three female pelves affected with this deformity, which presented no appearance whatever of rickety change, neither in strength, weight, nor texture, one being even heavier than usual; nor were there any rickety symptoms in their history. Two of the subjects died after severe instrumental labour; and the third, after one miscarriage, died undelivered of the second conception, from rupture of the uterus; comparison with the child's head afterwards showing, that delivery of a *living* child would have been impossible without the Cæsarian section. The diameters were generally above an *inch* less than the standard measurement. The ages of these subjects were from twenty-three to thirty-two years, showing that the contraction was an adult deformity. They were also about or above the average height. Women of low stature, indeed, have most commonly large pelves as well as large heads, and are not more liable to this deformity than those

* Med. Chirurg. Transactions, vol. xvii.

of taller stature ; the height of the individual being dependent, chiefly, upon the length of the lower extremity and spinal column, which in these cases are disproportionate.

The pelvis of the true dwarf, however, in common with, and in proportion to, the osseous system generally, is contracted and stunted in growth. In the Museum of the Edinburgh Infirmary, is the skeleton of a male adult dwarf, in which the pelvic pieces and epiphyses are not united by bone, but there is no distortion. The jaws are infantile. The pelvic bones in the well-known skeleton of the female dwarf in the Hunterian Museum are in a similar incomplete condition. Sudden and universal "*arrest of development*," is apparently the cause of this curious immature condition.

In Naegele's collection is the pelvis of a female dwarf, aged thirty-one years, whose height was 3 feet 6 inches, the measurements of which are given as a specimen of a distinct kind of "*pelvis equabiliter justo minor*" by that eminent author in the Appendix to his valuable work—" *Das schräg verengte Becken*," as follow —

		in.	line.*
Between the sacral promont. and tip of coccyx	- - - -	3	3
Between the sciatic tuberosity and iliac crest	- - - -	5	5
Between sciatic tuberosity and linea innom.	- - - -	2	7
Superior opening, conjugate diam.	-	3	0
" " transverse do.	-	3	7
Cavity antero-postr. do.	-	3	3½
" transverse do.	-	3	0
Inferior opening, transverse diam.	-	3	0
Length of pubic symphysis	- -	0	11

The pelvis was perfectly regular and normal in symmetry and proportion, presenting all the appearances, in these respects, of the adult "*standard*." The sub-pubic arch, the sacral curves, the direction of the ischia and the curvature of the pectineal line were perfectly regular. The sacral bones, however, and the three pieces of the innominate bones, were united by cartilage only, ossification not having taken place. In this respect only is this pelvis allied to the class of deformities resulting from imperfect development, or to an *immature* pelvis. These peculiarities may possibly be explained by supposing the "*arrest of development*," which dwarfed the woman, to have taken place *after* the age of puberty, and the development of the sexual organs, but *before* the union of the sacral and innominate pieces, that is, between the fourteenth and sixteenth years. This supposition is moreover strengthened by the fact, that the ischio-pubic rami were firmly united, that the woman had menstruated at the proper period, and that all the limbs were in normal proportion to the body. Neither in the history of the case, nor in the appearance of the skeleton, was there any sign of rickets. The woman had become pregnant, and by the advice of the medical attendants, premature labour was induced at the sixth month, and the patient was safely delivered by the forceps, but died ten days afterwards from the consequences of indiscretion in diet.

* Rhineland.

Out of the three cases of *pelvis equabiliter justo minor* given by Professor Busch *, and quoted by Dr. Rigby, there was a fatal termination in two instances. In one case, the pelvic diameters were universally half an inch below the standard size. In another, which resembled that of a child, they were contracted in every direction three quarters of an inch. The last ought, probably, to come under the denomination of an infantile pelvis.

In the above cases, the contraction of the pelvic diameters is marked and *absolute ;* but there is a considerable class of cases, included among the *variations* of measurement of normal pelves, in which the diameters are diminished in a much less degree, and yet their *relative* disproportion to those of a bulky fœtal head may be so great as to call for instrumental aid in parturition. Naegele, however, concludes that the contraction of the pelvis itself (without any complication with unusual bulk of fœtus) should be considered, in most cases, as the cause of the difficulty of labour, and that this kind of faulty pelvis merits the especial attention of the accoucheur as much as others, and the more, that from the absence of evident external symptoms, the difficulty of diagnosis is greater than in rickets or malacosteon.

The *cause* of most of the cases of proportionably contracted and enlarged pelves is only to be looked for among those of Nature's aberrations which result in heads, extremities, &c. disproportionate to the rest of the body. The small pelvis may be considered as one in which the development in *shape* has gone on to completion, but the development in *size* arrested by some cause. This cause has been attributed by Mr. Shaw † to a general rickety disease in many cases.

In addition to its effect in seriously impeding the passage of the fœtal head, a small pelvis of this kind is said by Ramsbotham to cause retroversion of the uterus in some cases.

Irregularities from imperfect development. Infantile pelvis —This form of pelvis is characterised by the persistence of the form of the pelvis which is normally but transitorily present under the age of puberty. Its appearance corresponds, in some degree, with the characters of the infantile pelvis described in the first section of this article, of which, in the respect under consideration, the most important are, the preponderance of the *antero-posterior* diameters, which are *larger* than the *transverse* ; the contraction of the sub-pubic arch ; the shallow and diminished cavity ; the approximation of the ischial tuberosities ; the flat, expanded, shallow, and rounded ilia, and the increased obliquity of the superior plane. The pieces of the sacrum and innominate bones are generally incompletely united by ossification.

In a pelvis described by Naegele ‡, taken from an idiot girl aged twenty-one years, who

* Neue Zeitschrift für Geburtskunde, t. xv. 1837.
† Op. cit. ‡ Op. cit.

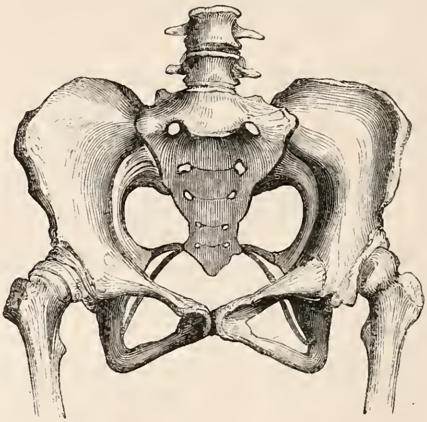
was only 4 feet high, and had never walked nor menstruated, the sacrum and innominate bones were connected by cartilage only, but the ischio-pubic rami were united. It presented, in size as well as form, the characteristics of that of a child of six or seven years old. The conjugate diameter was larger than the transverse, the ilio-pectineal line little curved, and the cavity funnel-shaped, the sub-pubic angle being only 30½°. The bones were not rickety. The organs of generation, both internal and external, were infantile. The measurements and appearance of this pelvis are contrasted by that author with those of the dwarf previously described. The arrest of development seems to have taken place in the present case at a period long before the changes of puberty, as shown by the undeveloped genital organs; so that the cases differ only in the *degree* of immaturity. Such cases as the latter are not likely to require the aid of the accoucheur.

In accouchements at a premature age, however, some of the yet-remaining peculiarities of the infantile pelvis may present difficulties in parturition, among which the contraction of the diameters, if not their want of adult proportions, will be the chief. At the period of puberty, the transverse and oblique diameters enlarge much more rapidly, in the female, than the antero-posterior, and begin to preponderate over them, while, at the same time, and in a great measure in consequence, the pelvis begins to assume its adult "*standard*" appearances. The full development of *size*, however, is somewhat later in being accomplished, and depends upon the completion of the ossification. These changes of the pelvis take place, as explained by Mr. Shaw *, somewhat later than those of the upper parts of the body, in the transition from the infant to the adult state, but proceed to a greater extent, so as to reverse the excess in proportionate size from the upper to the lower extremities. The pelvic growth and the developments of puberty may, according to the same authority, be retarded to a later period than the usual age, fourteen years, by a weakly constitution or rickets; and the female, adult in age, still remains infantile in pelvic development. In a case mentioned by De Fremery †, the three parts of the innominate bone were distinctly separate in a female at so late an age as seventeen years. Some remarkable cases of extreme mobility of the pelvic bones in children are also related by Deventer.

But the development in *size* may proceed to its fullest extent, and yet the development in *shape* and *proportion* be arrested, and the transitional form unchanged. In a specimen given by Dr. Murphy, of a female adult pelvis, the diameters were *above* the standard size, but the antero-posterior diameter was 5½ inches, and longer than the transverse; the transverse of the outlet proportionately diminished; the cavity shallow; and the general form of the pelvis infantile; but the bones perfectly ossified. The pelvis has the shape and proportions of that of a child, and the size of an adult female (*see fig.* 113.). To judge from the appearance of this specimen, as seen in the drawing given by Dr. Murphy, it seems to be a pelvis in which the transverse processes of the last lumbar vertebra are enlarged, ankylosed to the sacrum, and articulated with the ilia, giving the appearance of five sacral holes instead of four. This would account for the increased antero-posterior diameter, and apparent elevation of the sacrum. Cases of this kind are more especially described in the latter part of this article.

Dr. Knox has observed that the male pelvis also sometimes permanently retains the infantile form, to which it is normally more approximated than the female. In one of this kind in his possession, the greatest transverse diameter was nearest the sacrum, and only ⅘ths of an inch larger than the conjugate.

Fig. 113.



Adult pelvis of infantile form. (*After Murphy.*)

Masculine pelvis.—In females of a robust frame and powerful development of muscle, and accustomed to hard masculine labour, the pelvis often presents the character of the male in many important respects. The transverse measurement of the brim is proportionately smaller, the antero-posterior diameter being often increased, and the shape of the brim is thus rendered more oblong; the sacrum is narrower, the pubic symphysis longer, and the cavity deeper, and rendered *funnel-shaped* and less roomy, by the approximation of the ischial tuberosities; by which also the sub-pubic angle is diminished to 60° or 70°. The ischial spines are longer, stronger, and project more inwards; the ilia are less expanded, and the bones larger, more massy, and more marked than in the "*standard*" pelvis.

Dr. Knox is of opinion that in many instances the true pelvis may be of normal size, and yet the haunches be remarkably narrow, owing to a want of proportion of the true and false pelvis; so that while the walls of the latter are flat, upright, and approximated, the true pelvis is of proper dimensions. He adds, moreover, that the opposite dispropor-

* Op. cit.

† Dissertatio de Mutatione Figuræ Pelvis. Leyden, 793, p. 14.

tion sometimes is present, and may mislead the obstetrician by giving an apparent breadth of haunch, while the contraction of the true pelvis may be considerable. He considers it to result from the entirely different and independent development of the false and true pelvis.*

I have met with many specimens of the masculine form of pelvis in the dissecting-rooms, from among the laborious women of this metropolis. In Dr. Murphy's experience it is more common than had been hitherto supposed.

The obstruction in this form of pelvis is met with chiefly in the deep funnel-shaped cavity, at the projecting ischial spines, or at the inferior outlet, under the narrow arch, and between the tuberosities, and is rendered the more serious by the fœtal head in these cases being generally more ossified than usual. The great inward projection of the sciatic spines sometimes affords an obstacle to the passage of the head. The average normal distance between them will be found, on reference to the tables, to be 4 inches. During the turning of the head in the most frequent positions, the inter-temporal and inter-zygomatic diameters of the fœtal head, the former of which is placed by Dr. Murphy at 3 inches, and the latter at $3\frac{1}{2}$ to 4 inches, are placed obliquely between them. In one or two instances I have found the sciatic spines as near to each other as $3\frac{1}{4}$ inches, and in one it was not co-existent with any extraordinary massy or masculine proportions, but simply with small transverse diameters. In the fronto-cotyloid and fronto-pubic positions, or with a large fœtal head, the approximation of the sciatic spines becomes a serious impediment to labour. In this pelvis the sacro-coccygeal articulation is said by Dr. Murphy to be generally less moveable, and the sacro-iliac joints unyielding, and that a bony ridge is often found on the posterior surface of the narrow pubic symphysis.

The *cause* of this form of pelvis seems to be, an advanced condition of ossification in a pelvis which would otherwise have been "*infantile*," brought about by the development of unusual muscularity, corresponding to the laborious employment of the individual. This action of the pelvic muscles will have also the effect of impressing irregularities upon the bones into which they are implanted, or over which they act. The tension of the posterior spinal and abdominal muscles against those of the leg would tend to elongate the pelvis, while the powerful great glutei, much used in supporting or raising heavy weights, will press inwards the ischial tuberosities, and narrow the sub-pubic arch.

Irregularities of the pelvi-vertebral angle.— Too great obliquity of the pelvis has been said to cause "*ante-version*," by throwing the weight of the uterus on the anterior abdominal walls; and too little obliquity to have a tendency to produce prolapsus uteri. Naegele (*Das weibliche Becken*), however, considers many of these supposed consequences are theoretical only; but he observed, both in first, and after many labours, that an approximation of the pelvic plane to the perpendicular caused the fœtal head to be placed so much forward, and the os uteri so high, as to be felt with difficulty; and, on the other hand, in very considerable inclination to the horizon the fœtal head was deep, and not easy to be felt through the uterine neck. In neither condition was there any important deviation from the mechanism of natural parturition.

The alteration of the planes of the pelvic outlets becomes, however, a valuable means of indication of the more important class of pelvic distortions, in which such an alteration is generally effected. In particular, when the tip of the coccyx and pubic symphysis are unusually placed, especial attention to the form and measurements of the pelvis is called for; though, as before seen, an alteration of the pelvic planes alone does not necessarily imply a distorted pelvis.

Dr. Rigby mentions, that the pelvic inclination is generally less in a tall slender person than in a short thick-set woman; and that, in the former case, the hollow of the sacrum is generally small, and in the latter deep.

2. *Distortions* of the pelvis are best arranged into the following practical divisions, according as they affect the *brim*;—the *cavity*;—or the *outlet* only or principally;—or the *whole structure* of the pelvis at the same time.*

Distortions affecting the brim only or principally.— By far the greater majority of these cases consist in an unusually *forward projection* of the *sacral promontory*. This causes the opening to assume a *heart-shape*, diminishes the conjugate diameter, sometimes contracting also the oblique, and increasing the transverse in some degree. At the same time, the promontory of the sacrum is sunk down below its normal altitude, lessening the angle of the superior plane, and making its axis assume a more vertical direction. Most generally the sacral projection deviates from the medium line, and forms the lower extremity of an abnormal curve in the lumbar vertebra, rendering the brim of the pelvis generally unsymmetrical in shape.

This deviation takes place most frequently, according to my own observation, to the *left* side, and appears to be an exaggeration of a very common tendency (which, being seen in the most robust subjects, can scarcely be called abnormal) of the natural curve of the lumbar vertebra towards the left side. This lateral curve is evidently a compensatory one to the very usual and well-known deviation of the

* Med. Gazette, vol. xxxii. pp. 555. and 589.

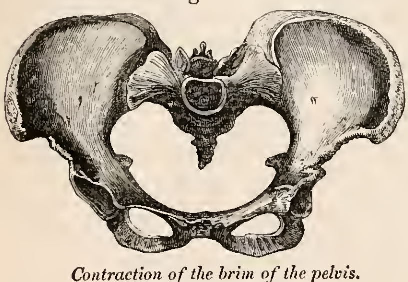
* Osiander enumerates six forms of pelvic deformity, classified without regard to their origin or bearing upon parturition; viz. 1. The *elliptical*, with diminished antero-posterior diameters, and without projection of the sacral promontory; 2. The *reniform*, with a sacral projection; 3. The *hourglass* or 8 *shaped*, from a curve backward at the symphysis pubis; 4. The *oblong*; 5. The *oblique*; and 6. the *angular* or *triangular* form. The method of arrangement I have adopted in the text, seems, however, the best adapted for useful applications.

line of thoracic vertebra to the *right* side, and is calculated to keep the line of the whole spinal column in equivalent relation to the direct and perpendicular line of gravity. It is an interesting question, how far this common tendency of the lumbar curve influences the position of the fœtal head, by affording more room for the sinciput at the right sacro-iliac joint, and determining its long axis in the left oblique diameter, which is generally allowed to be the most frequent presentation. In by far the greater number of all kinds of pelvic deformity that have come under my own observation, the projection of the sacral promontory, when present, has been towards the left side, showing the effect of a natural and previously existing tendency when the supporting structures have been softened by disease. To this subject I shall presently have occasion again to advert.

In these cases of partial distortion of the pelvic brim, the cavity and inferior outlet are generally roomy, shallow, and open. Often the transverse or antero-posterior diameter of the inferior outlet is larger than natural, and the pelvis then approaches the condition of the complete *ovate* deformity. An important practical result of this fact is, that in these deformities of the brim all operations for extraction of the fœtus "*per vias naturales*" are facilitated and rendered more successful. The obstruction being simply and only at the brim, when that is overcome the rest is easy.

Two *examples* of deformity of the brim are recorded by Dr. Ramsbotham. One is preserved in the Museum of the London Hospital (*see fig.* 114.). The conjugate diameter of

Fig. 114.



Contraction of the brim of the pelvis.
(*After Ramsbotham.*)

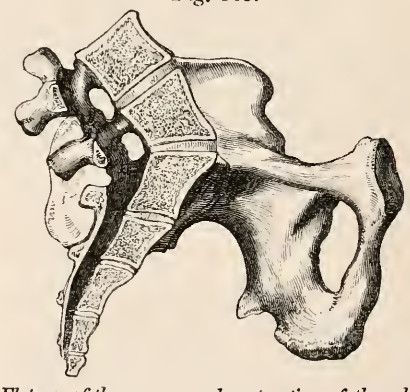
the brim measures $2\frac{3}{4}$ inches; the transverse 5 inches; and the distance from the side of the sacral promontory to the centre of the superior branch of the pubis on each side is equal, and measures also $2\frac{3}{4}$ inches. Dr. Ramsbotham considers this to be just below the smallest space through which the fœtal head could pass entire. The cavity, however, and the sacral curve, are well proportioned, and the distance between the sciatic tuberosities $4\frac{3}{8}$ inches, or a quarter of an inch more than in a healthy pelvis; so that the fœtal head would pass easily, having overcome the obstruction at the brim. The second is the pelvis of a woman who was delivered by craniotomy, which is considerably contracted in all its diameters, but more especially at the brim. The conjugate diameter is $2\frac{1}{4}$ inches only; the transverse $4\frac{3}{4}$ inches; and while the distance from the right side of the sacral promontory to the right pubic ramus is $2\frac{1}{2}$ inches, that on the left side is $2\frac{1}{4}$ inches only. The depth of the cavity posteriorly is only 4 inches; the spines of the ischia project considerably inwards, and the distance between the tuberosities measures only $3\frac{1}{4}$ inches.

This author considers that a proportionate increase in the transverse diameter does not fully compensate for a great contraction in the conjugate, in permitting the passage of the fœtal head. In cases in which the brim is oblong, and presents a preponderance of the antero-posterior diameter, as in the funnel-shaped and masculine pelves, the fœtal head necessarily presents its long antero-posterior diameter to that of the brim, and the case may be one of face presentation.

Distortions affecting the cavity only or principally, and causing obstruction there to the passage of the fœtal head.—These are occasionally seen without particular deformity at the brim or outlet.

Vertical flatness of the *sacrum*, or want of the proper vertical curvature, is occasionally met with, according to Dr. Churchill, after whom the annexed engraving of a specimen of this deformity is taken (*fig.* 115.). This is

Fig. 115.



Flatness of the sacrum, and contraction of the pelvic cavity. (*After Churchill.*)

sometimes accompanied by an increased sacro-vertebral angle. One or two instances I have met with, in which there was a tendency to this peculiarity. It is attended with diminution of the antero-posterior diameter of the cavity, and is most frequently met with in cases of general *ovate* deformity.

The opposition it would offer to the passage and circumvolution of the fœtal head is evident.

An *inward projection* of the *sciatic spines* is often seen in connection with contraction of the transverse diameter of the inferior outlet, without any inordinate massiveness or masculine form of the pelvis, as in the example before mentioned, and is, probably, sometimes dependent on the same cause—viz., the action of the great glutei muscles upon softened ischia. In some instances, however, this length and projection of the spines cannot be thus accounted for. Obstruction may occur before the head reaches the tuberosities in these cases. Their relative positions may be altered also by fracture.

Pelves in which the cavities are contracted at the lower part by *disease*, present the chief obstacles at the inferior outlet, and will be considered under that head.

A variety of the shape of the pelvic cavity is mentioned by Murphy, as forming a contrast to the funnel-shaped masculine pelvis. It is the funnel-shaped *reversed* by the gradual widening of the transverse diameters downward; but, being generally attended by some contraction at the brim, it belongs rather to the classes of deformities before described, and would seem to resemble the first case of Ramsbotham's there cited, and to be the beginning of a more complete ovate deformity, afterwards to be mentioned, as shown by the *widening* of the inferior opening.

Distortions affecting the outlet only or principally. — In these cases the greatest obstruction occurs at the inferior outlet, which, being comparatively independent of the brim and cavity, may be contracted without any important alteration in their shape or size.

Contraction of the *transverse* diameter is the most frequently seen. The ischial tuberosities are approximated, and the space of the sub-pubic arch lessened; and thus, indirectly, the antero-posterior diameter is rendered less effectual. Cases are frequently presented to the obstetrician, and many are on record, in which obstruction has occurred at the sciatic tuberosities, and the use of the forceps been rendered necessary. The normal distance between the centres of these processes is from 4 inches to 4½. In my measurements I have met with as small a distance as 3¾ inches in female pelves, in which the transverse diameters were generally rather small.

The bi-parietal diameter of the fœtal head is said to be 3½ inches, and is placed obliquely between these tuberosities, as the occiput emerges under the sub-pubic arch. The soft parts, besides, will occupy at least three-fourths of an inch. Thus with a large and well-ossified head and contracted intertuberal distance, the impediment is great. The diminished span of the sub-pubic arch, also, pushes back the head upon the coccyx, and renders a greater enlargement than usual of the antero-posterior diameter necessary; while at the same time the great sacro-sciatic ligaments are also approximated and rendered extremely tense, and thus the *oblique* diameter between them and the ischio-pubic rami is also considerably diminished.

The *special cause* of this deformity, when not dependent upon the infantile, masculine, or funnel-shaped pelvis before described, is to be attributed to the action of the great glutei muscles, in standing and walking, pressing upon the ischia partially softened by disease.

Contraction of the *antero-posterior* diameter. This results in most cases from *ankylosis* of the *sacro-coccygeal joint*. The coccyx is rendered immoveable and incapable of yielding to the head of the fœtus, so as to bring about the usual increase in the antero-posterior diameter. In addition, it is usually ankylosed in an almost *horizontal* direction, with its apex directed forwards and its surfaces upwards and downwards, a position which is brought about by the resiliency of the sacro-sciatic ligaments and ischio-coccygeus muscles, and by a continued sitting posture; — and thus the antero-posterior diameter is still more diminished.

The fœtal head is arrested by, and rests on, the coccyx, and the obstruction is only overcome by the giving way of the bone at or near the ankylosed part. The delivery generally requires instrumental aid.

Examples of this condition are numerous. In the practice of Dr. Michaelis of Kiel, a fracture of the parietal bone of the infant was occasioned by an immobility of the coccyx resulting from ankylosis.* Dr. Merriman, in a Letter to Dr. Lee, published in the Med. Gazette (1843, p. 224.), mentions a case in which the point of the coccyx snapped off in three successive labours, and he had observed one or two other cases in which this occurred, and no ill consequences followed. In one, the coccyx was turned upwards, and there was a considerable bulk of ankylosis, produced by a fall. Dr. F. Ramsbotham also mentions three instances in which fracture at or near an ankylosis of the coccyx took place. Dr. Lee relates also a case which occurred in the practice of a country surgeon, in which the lower end of the sacrum curved much forward and was ankylosed to the upper coccygeal bones, the last only being moveable.

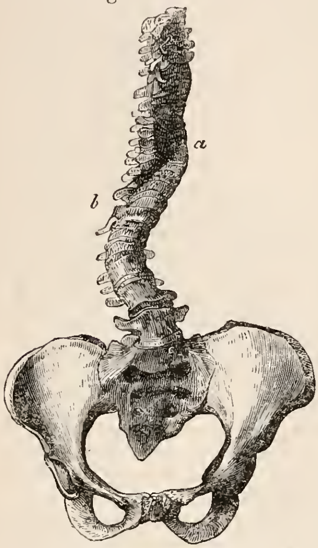
In certain cases the contraction of this diameter is brought about by the *tilting forward* of the lower end of the *sacrum*, with an almost horizontal direction of the lower part of the sacral curve. I have met with two or three pelves in which this condition is present, coexistent with, and evidently caused by, a curvature of the lower dorsal region of the spinal column *backwards*. By such a curvature, the line of gravity of the *trunk* is displaced backwards, passing through the sacrum considerably *behind* its base, and making traction upon it in that direction. The promontory of the sacrum is by this means dragged *backwards* and *upwards*, and the conjugate diameter of the brim increased, so as to be equal to, or greater than, the transverse. The shape of the brim is thus rendered *oblong* or oval in the opposite direction to, and contrasting with, the ovate deformity presently to be described. The axis of the superior plane is rendered more horizontal than normal, by the increase of the pelvi-vertebral angle, the cotylo-sacral arch more open in its curve, and the acetabula in some measure approximated. The cavity of the pelvis is narrowed antero-posteriorly by the gradual advance downwards of the posterior wall, and the vertical curvature

* Neue Zeitschrift für Geburtskunde, t. iv. 1836.

of the sacrum is more open than usual. Thus is constituted another variety of *funnel-shaped* pelvis, caused mainly by the gradually narrowing of *antero-posterior diameters*, instead of the lateral, as in the masculine pelvis before described.

In the King's College Museum are the pelvis and spine of a *female*, well exemplifying this deformity (see *fig*. 116.). The spine is affected by a rickety curve, the greatest extent of which is about the 6th, 7th and 8th dorsal

Fig. 116.



Oblong pelvic deformity. (*From a preparation in the Museum of King's College.*)

vertebræ (*a*), directed *backwards* to a great extent, and somewhat to the left side, with a compensatory curve to the right, at the junction of the lumbar with the dorsal vertebræ (*b*). The lower lumbar vertebræ and sacral promontory are twisted considerably towards the *left* side, and dragged backwards, the sacral promontory being also considerably raised upwards (*c*). The pelvis is of exceedingly large general capacity, and otherwise well formed, showing evidently, by the preponderance of the conjugate diameter and appearance of the sacrum, the effect of the deformed spine upon it. The conjugate diameter of the *brim* measures as much as 5 and a half inches; the transverse $5\frac{1}{8}$ inches. At the *outlet*, the distance between the tuberosities is only $3\frac{7}{8}$ inches, and the sub-pubic angle 75°; but, from an unfortunate deficiency of the lower end of the sacrum, the antero-posterior diameter cannot be measured.

In the same Museum there is a young *male* adult skeleton in which this form of pelvis is also well shown. It, also, is coexistent with, and dependant on, a backward curvature and shortening of the spine, and extensive ankylosis of the vertebræ in the dorsal and lumbar regions. The lumbar vertebræ are inclined much backward, so as to drag in the same direction upon the upper end of the sacrum; while the upper dorsal vertebræ incline forward, so as to bring the 1st dorsal over the centre of the pelvic circle. There is, in this case, no lateral deviation of the spinal column. The tibiæ and fibulæ have an inward curve, indicating the existence of a softened rickety state of the bones at an early period of life.

In the Hunterian collection of pathological specimens is a young adult pelvis, numbered 3420, presenting the same kind of deformity, accompanying the same kind of backward angular curvature and ankylosis of the bodies of the vertebræ at the same place — viz. the junction of the last dorsal and 1st lumbar. The 1st dorsal vertebra, in this skeleton, likewise occupies a position above the centre of the pelvic opening. The upper end of the sacrum is dragged backwards by the inclined lumbar vertebræ so as to increase the conjugate diameter of the brim to $4\frac{1}{2}$ inches. The lower end of the sacrum is tilted forward so as to bring the tip of the coccyx to within a short distance of the ischial spines. The cotylo-sacral arch is stretched out, and the transverse diameter of the brim reduced to 4 inches only. The acetabula are directed more downwards than usual, and the right iliac wing is pressed outwards by the 9th and 10th ribs, which rest on it, and the venter completely flattened out.

I find that Rokitansky has met with instances of this oblong deformity of the pelvis, coexisting with *backward angularity* of the spine.

In cases of backward angular curvature low down the spine, especially where there is no lateral deviation, there will be a tendency to production of this form of pelvis, especially if the bones be somewhat softened, as they usually are in these cases; and although such cases of pelvic distortion are, as far as I have seen, more common in the male, yet the same cause occasionally produces this effect upon the female pelvis, and may produce obstruction during parturition, not only by the contraction of the *antero-posterior diameter* at the *outlet*, but even at the *brim*, by the diminution of its *transverse diameter*.

An acute angle in the lower part of the *sacral curve* may also produce this contraction of the inferior pelvic outlet. When this exists singly, the elevation of the coccyx is more considerable than usual, and the axis of the inferior plane directed more backwards. This bending upwards of the apex of the sacrum is, however, most usually seen in connection with more general pelvic deformity, and is sometimes accompanied by ankylosis of the sacro-coccygeal joint.

In a case recorded by Mr. Bell, the antero-posterior diameter of the inferior outlet was contracted to half-an-inch only, and in one of Naegele's, it was even less than this, in both entirely precluding delivery. In so great a contraction, the sacral bend must have been unusually great, or the lower end of that bone tilted forward in the manner just described.

Distortions affecting the whole pelvis. — In these cases the pubic bones are always more or less extensively implicated in the distortion, and entering, as they do, into the formation of both brim, cavity, and outlet, all these parts of the pelvis are contracted or misproportioned. At the brim, however, the *obstruction* usually takes place, while the operations necessary to procure delivery through the natural passages are rendered more difficult by the distortion of the cavity and inferior opening.

General distortions of the pelvis are commonly divided into three kinds, named, from the shape of the brim, the *ovate* or *elliptical*,— the *cordiform* or *angular*,—and the *obliquely ovate.*

The ovate, elliptical, or reniform pelvis. — In this distortion the *sacrum* is placed almost horizontally, so that the sacral *promontory* projects forward to a great degree, generally at the same time deviating from the median line, and considerably sunk in a direction forwards and downwards, so that the lowest lumbar vertebra forms the most projecting point. The *lateral sacral curve* is diminished, flattened out, and often bent backwards on each side the promontory. The *vertical curvature* is generally diminished and flattened in some degree, and directed more downwards by the more horizontal position of the bone; but occasionally there is an acute bend forwards at the lower part. The *coccyx* is generally bent acutely forwards.

The *ilia* and *ischia* on each side are often removed to a greater lateral distance than normal. The *iliac wings* are flattened and directed more forward; and the *cotylo-sacral arch* is more sharply curved, and often shorter and thicker than normal. The *planes* of the *ischia* diverge instead of slightly converging downward; the *spines* and *tuberosities* being likewise divergent, and the latter directed more outwards and backwards. The *superior rami* of the *pubes* are generally flattened out, having little anterior projection; while the *inferior rami* are widely divergent, affording a wider and shallower expansion of the *sub-pubic arch.* In some cases, however, the sub-pubic arch is little altered.

In some instances the *symphysis* of the *pubis* presents the appearance of being indented or pushed backwards, giving an outline to the brim of an *hour-glass* shape.

The *diameter* principally diminished is the *conjugate* of the *brim,* and often one or other of the *oblique* diameters. In one variety the *transverse* diameter of the brim is also contracted. The transverse diameter is, however, sometimes undiminished, or even increased. The *transverse* diameter of the *inferior outlet* is generally most considerably increased; but the *antero-posterior* diameter is most usually contracted by the bend in the sacrum. In many instances, however, it is considerably enlarged. The *depth* of the true pelvis is generally diminished, and its capacity lessened.

The *sacro-vertebral angle* is generally much diminished, from the backward horizontal direction of the upper end of the sacrum.

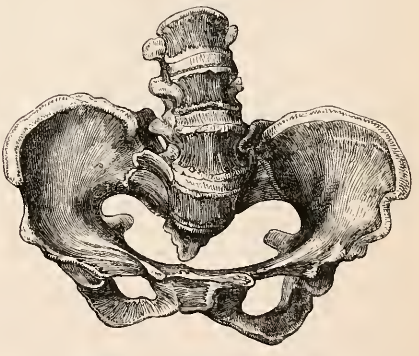
The *inclination* of the *superior plane* is sometimes increased so much as to be vertical; the *axis* of the brim being generally directed more forward than in the "*standard*," and that of the *inferior outlet* more backward. Sometimes, however, they are very little altered.

The *structure* of the bones is light, slender, and fragile, indicating the origin of the distortion in rickety softening.

Examples of this kind of pelvis are numerous. One of the most well-known is that of Elizabeth Sherwood, who was delivered by Dr. Osborne by means of the crochet. The measurements of this pelvis are given as follows:—From the most prominent point of the lumbar vertebra to the upper border of the pubic symphysis, $1\frac{1}{8}$ inch. From the same point on the left side to the left pectineal eminence, $1\frac{6}{8}$ inches. The same measurement on the right side, $1\frac{7}{8}$ inches. From the sacral promontory to the pubic symphysis, $1\frac{1}{4}$ inch. Transverse diameter of *brim*, 5 inches. Left oblique ditto, $4\frac{1}{4}$ inches. Right oblique, $4\frac{1}{2}$ inches. Antero-posterior of *cavity*, $2\frac{1}{4}$ inches. Transverse ditto, 5 inches. Antero-posterior of *outlet*, $2\frac{7}{8}$ inches. Transverse, $4\frac{1}{2}$ inches. Sub-pubic angle, 100°.

The measurements of a very extreme case of this kind of distortion are recorded by Dr. Ramsbotham (see *fig.* 117.) as follows: —

Fig. 117.



Ovate pelvis. (*After Ramsbotham.*)

Conjugate or sacro-pubic diameter of *brim*, $\frac{3}{4}$ of an inch only. From right side of sacral promontory to right pubis, $1\frac{1}{4}$ inch. The same measurement on the left side, $1\frac{5}{8}$ inch. Antero-posterior diameter of *outlet*, 2 inches. Transverse diameter, $4\frac{1}{8}$ inches. The shape of the brim in this pelvis is hour-glass, the pubic symphysis being pushed back. Such a pelvis, in the opinion of the above-named writer, would necessitate the abdominal section.

In a less extreme case, given by the same writer, the sacral promontory and lumbar curve bend much more considerably towards the *left* side. At the *brim*, the conjugate diameter is $1\frac{1}{2}$ inch; the right sacro-pubic, 2 inches; the left, $\frac{3}{4}$ of an inch only. The transverse diameter, measured in the lateral curve of the brim, $6\frac{1}{4}$ inches. At the *inferior outlet*, the antero-posterior, $4\frac{1}{2}$ inches; the transverse, $5\frac{1}{4}$. In the figure of this pelvis given by the author, the long axis of the sacrum is represented as placed obliquely across the median line, its apex inclining to the right side; while the tuberosity of the right ischium is widely divergent, principally causing the increase of the transverse diameter of the outlet. The left ischial tuberosity and acetabulum are brought more under the line of gravity. The left superior pubic ramus is thus pushed nearer to the promontory than the right, causing a slight twist in the pubic symphysis. In this pelvis the author considers that delivery might be effected "per vias naturales," by craniotomy.

In one of Dr. Hull's cases, that of Ann Lee, affected with this deformity, the conjugate diameter was reduced to $1\frac{5}{8}$ inch, and the sacro-cotyloid on each side equal, and measuring $1\frac{9}{16}$ inch. The transverse diameter, in its widest part, amounted to $4\frac{1}{4}$ inches only. There was little flattening of the pubes, the contraction being produced chiefly by the projection of the sacrum, the chief bend being near the sacro-iliac joints. The distance between the antero-superior iliac spines was only $8\frac{1}{2}$ inches, but the dimensions of the cavity and inferior outlet were not materially diminished.

In Mr. Thomson's case of Cæsarian section, the pelvis was affected with this deformity. The normal lumbar curvature was so much increased, together with the pelvic inclination, that the sacrum was placed quite horizontal, and the superior plane directly *vertical*, and its axis consequently parallel with the horizon; but with little or no lateral deviation of the sacral promontory. The legs were crooked, and the acetabula faced directly forwards. The conjugate diameter of the brim was diminished to $\frac{7}{8}$ of an inch; the transverse was about 5 inches, and the intersciatic apparently about $4\frac{1}{2}$.*

Dr. Robert Lee gives the dimensions of a case of ovate deformity in which the patient, after being delivered by craniotomy at an early period of pregnancy in the first labour, died in the second from rupture of the uterus. The conjugate diameter of the *brim* was 2 inches 1 line; the transverse, $5\frac{3}{4}$ inches. At the *outlet* the distance between the sciatic tuberosities was $4\frac{1}{2}$ inches; between the tip of the coccyx and lower border of the pubic symphysis, $3\frac{1}{2}$ inches. This obstetrician considers that if, in this case, premature labour had been induced at or before the fifth, instead of the seventh month, the patient might have been saved.†

It has been said that in pelves presenting the ovate deformity from rickets, the contractions of the diameters of the *brim* are generally accompanied by the *enlargement* of those of the *outlet*, and the numerous examples of enlarged transverse diameters of the outlet, in particular, are adduced.

In an ovately deformed pelvis in the Museum of King's College, however, in which the conjugate diameter of the *brim* is 2 inches, and the transverse also contracted to $4\frac{3}{4}$ inches; at the *outlet* the inter-sciatic diameter is *contracted* to as little as $3\frac{7}{8}$ inches, and with it the subpubic angle is diminished also, while the antero-posterior is *increased* to $4\frac{1}{4}$ inches. This pelvis is remarkable for the great flattening of the sacrum, the anterior surface of which lies almost in a straight line, in which direction the coccyx also is nearly placed. The antero-posterior diameter of the *cavity* is thus reduced to $3\frac{1}{4}$ inches. The distance between the ischial spines is, however, 4 inches. The sacral promontory projects more *forwards* than downwards, and the lumbar curve is inclined to the left side. In this pelvis the brim is contracted considerably in all its diameters, and this contraction is evidently produced by the crushing downwards of the sides of the cotylo-sacral arch. The length of the cotylo-sacral rib on the right side, taken from opposite the ilio-pectineal eminence to the sacro-iliac angle *along the curve*, amounts to only $1\frac{1}{2}$ inch, while the *direct* measurement is reduced to $1\frac{1}{8}$ inch. The rib of bone is at the same time much increased in thickness, presenting an almost cubical mass between the cotyloid and sacro-iliac articulations. On the left side, the *direct* measurement is a little more.

In the table of measurements of diseased pelves given by Dr. Murphy, the transverse diameter of the brim in the five ovate pelves amounts to 5 inches only in two cases, and in a third, it is diminished to $4\frac{5}{8}$ inches. In many of these cases we may conclude that the cotylo-sacral rib was shortened as well as bent backward. The transverse diameter of the inferior opening is not enlarged in all the above-mentioned cases. In one it amounted only to $3\frac{5}{8}$, and the sub-pubic angle (mainly depending on this diameter) is only 70°. The antero-posterior diameter is, in three cases, *increased* to from 4 to $4\frac{5}{8}$ inches, while in the remaining two cases it is diminished to $2\frac{1}{4}$ and $2\frac{7}{8}$. These latter measurements, doubtless, depend in great measure upon the position of the coccyx, or, as in the case above given from the Museum of King's College, upon the flatness of the sacrum, or in its bend. They show, however, that the enlargement of the inferior diameters in not universally characteristic of the general ovate deformity. We may also conclude that the general contraction of the diameters of the brim, which is often found in these pelves, is produced mainly by the *shortening* of the *cotylo-sacral rib* of the ilium in the line of pressure, without any *eversion* of the lower part of the innominate bones.

A singular pelvic deformity, related in some degree to this class, is represented in Moreau's plates, in which, by an anterior

* Med. Observations and Inquiry, vol. iv., with plates.

† Lectures in Med. Gazette, 1843, p. 181.

bend at the lower lumbar vertebræ, the sacrum is placed horizontally backward, and the sacro-vertebral angle diminished to rather less than a right angle. The effect of this is to increase the obliquity of the innominate bones, and the distance from the sacrum to the pubis, to approximate the pubis and coccyx, and to *widen* the transverse diameters. With the exception of the last-named peculiarities, this pelvis presents the condition and appearance of that of a quadruped, in being placed horizontally; the trunk, however, being kept in the vertical position by the remarkable sacro-vertebral bend.

The cordiform or angular pelvis. — This distortion presents wide differences to the kind just described.

The *sacral promontory*, though in some measure projecting forwards, yet is more decidedly sunk down below its proper level into the cavity of the pelvis, with an inclination to one side of the median line, in most cases to the left. The *lateral masses* of the *sacrum* are likewise bent back, altering the outline of the lateral sacral curvature. The *vertical curvature* of the sacrum is also increased to a great degree ; the *hollow* of the sacrum, in many cases, being almost bent double. The *coccyx* is generally placed horizontally.

The *ilia* and *ischia* on each side are pushed together upwards and towards the sacrum, so that the *acetabula* are thereby approximated and placed nearer to the sacral promontory. The *cotylo-sacral arch* presents, in most instances, a very sharp curve near the sacro-iliac joint, and is often bent double, so as to offer a mere chink between the sacral and iliac portions. The *iliac wings* are generally approximated, the *venter* being sometimes doubled into a mere fissure, and the *crest* being curved inwards more than normal, so as to bring the anterior superior iliac spines nearer together ; while the posterior extremity of the crest, or *iliac tuberosity*, is bent inwards and forwards over the sacrum, by the weight of the body, acting through the sacro-iliac ligaments. The *planes*, *spines*, and *tuberosities* of the *ischia* are pushed inwards towards each other, and sometimes turned more upwards, so as to cause a chink or acute bend in the ischial plane, passing downwards and forwards, and which has been compared by Naegele to the fold made by bending pasteboard. The *superior rami* of the *pubes* are directed horizontally forwards, being almost, and, in extreme cases, quite parallel to each other anteriorly.

This alteration in the direction of the pubic bones takes place, in many cases, by an inward curve in the acetabula at the point of junction of the three pieces of the innominate bone, as indicated by the ilio-pectineal eminence, and the form of the brim will then assume the shape of the letter Y when the deformity is great. In many instances, however, the superior pubic rami are bent inwards at an obtuse angle, in the *centre*, just above the obturator foramina, the bones of the opposite sides almost or entirely meeting at the angle, and continuing parallel with each other to their articulation. The form of pelvis resulting from this bend in the superior pubic ramus has received more particularly the name of the *cocked hat* or *rostrated* pelvis; the latter name being applied from the beak-like projection of the pubis at the symphysis. It is markedly distinguished from those angular deformities in which the inward bend of the innominate bones takes place at the acetabular junction of their three component pieces, and is found exemplified in most of the specimens exhibiting the greatest contraction of the diameters.

The *pubic symphysis* is, in every case, more or less folded back, straining upon the anterior ligaments. The bending, however, is seen to occur in the osseous portions of the articulation forming the pubic angles, generally about the position of the pubic spine, and it is much more considerable in the cases where the anterior portions of the pubes are parallel to each other. The *sub-pubic arch* is, in all cases, very considerably narrowed by the parallel position of the superior pubic rami and the approximation of the ischial tuberosities. In many instances, the latter appear to be pushed forwards and upwards, so that the contraction of the sub-pubic arch is greatest at the ischial rami, just above the tuberosities, above which point the sides of the arch bulge outwards. In the *rostrated* pelvis, it is often completely obliterated or transformed into a mere chink. The *acetabula* are elevated and turned more forwards than normal, and in many examples of rostrated pelvis are directed almost quite anteriorly.

The *angles* of both the *superior* and *inferior pelvic planes* with the vertebral column are lessened. In a case given by Naegele, the superior plane was at right angles to the spine. The *axis* of the *brim* is thus rendered more vertical, and that of the *outlet* more forward, than in the standard pelvis. The superior plane is often bent into two by the elevation of the acetabula, but, in some instances, the pubic symphysis is pushed upwards above the acetabula.

The *diameters* are all contracted in a greater or less degree, those of the brim most extensively. In this kind of pelvis occurs the greatest diminution of diameters of all the recorded examples. The diminution, however, is such, that if the irregular form were reshaped, the diameters would be replaced, *i. e.* there is no absolute shortening of the bones, or not so much as in the rickety pelves.

Examples.—The pelvis of Isabel Redman (*fig.* 118.), upon whom hysterotomy was performed by Dr. Hull in 1794, and which is said to present at the brim the most contracted diameters on record, is affected by this deformity in its rostrated form to such an extent, that a ball $1\frac{3}{8}$ inch in diameter would not pass through it at any part.

At the *brim*, the 4th lumbar vertebra was completely sunk into the pelvis, and inclined to the *left* side, and its distance from the pubic symphysis was $2\frac{3}{10}$ inches. The distance between the superior pubic rami at

Fig. 118.

Pelvis o Isabel Redman.

the point of angular bend, was $\frac{7}{8}$ of an inch. From the 4th lumbar vertebra at its upper anterior border, to the left acetabulum, was only $\frac{5}{8}$ of an inch; on the right side $\frac{7}{8}$. The greatest transverse diameter was $5\frac{2}{8}$ inches. At the *outlet*, the distance between the sciatic tuberosities was $3\frac{3}{4}$ inches; between the spines $2\frac{6}{8}$. The greatest contraction of sub-pubic arch was at the sciatic rami, which were only $\frac{7}{10}$ of an inch distant from each other; above this, the arch bellied out. The sacrum was bent double, so that the tip of the coccyx was only $1\frac{1}{10}$ inch from the sacral base. The pelvic bones were quite soft, and lighter than natural.

The measurements of the pelvis of Jane Foster, who was saved by the Cæsarian section by Mr. Barlow, are given as follows:—From the fibrocartilage between the 4th and 5th lumbar vertebræ (which is sunk down so as to occupy the normal position of the sacral promontory), to the outside of the projecting pubic symphysis, is 3 inches. From the same point, to the centre of the superior ramus of right pubes, $\frac{7}{8}$ of an inch, of clear available space. The same measurement on the left side, $1\frac{3}{8}$ inch. From the same point, to the right acetabulum $\frac{3}{4}$ of an inch; to the left acetabulum $1\frac{1}{4}$ inch. The greatest available space is, from the left side of the sacral promontory to the left ilium, and amounts to $1\frac{1}{2}$ inch. The greatest lateral space, following the curve, is $5\frac{3}{8}$ inches. At the *outlet*, the distance between the sciatic tuberosities is $1\frac{1}{2}$ inch. The coccyx and lower part of the sacrum are bent upwards, so as to bring the tip of the coccyx to within $1\frac{1}{2}$ inch of the sacral promontory, and to $2\frac{1}{2}$ inches from the point of contact of the ascending ischial rami, which are so close as to obliterate entirely the sub-pubic arch.

The dimensions of the *rostrated* pelvis of Elizabeth Thomson, who underwent the Cæsarian section at the hands of Mr. Wood of Manchester, and died in consequence, are given by Dr. Murphy, as follows:—From the most projecting point of the sacral promontory to the pubic symphysis, 2 inches. From the same point to the left pectineal eminence, $\frac{5}{8}$ of an inch; to the right pectineal eminence, $\frac{5}{8}$ of an inch. The transverse diameter of the brim, $2\frac{1}{2}$ inches; both the oblique, $3\frac{1}{4}$ inches. *Cavity:*—antero-posterior diameter, $3\frac{1}{8}$ inches; transverse diameter, $2\frac{3}{4}$ inches. *Outlet:*—antero-posterior diameter, $3\frac{1}{2}$ inches; transverse diameter, $2\frac{6}{8}$ inches. The sub-pubic arch measured 10° only.

In a specimen of rostrated pelvis given by Dr. Ramsbotham, the antero-posterior diameter of the *brim* is diminished by the projection of the sacral promontory, and the bend in the pubis, to $1\frac{5}{8}$ inch. The same measurement on the left side of the promontory, $2\frac{3}{8}$ inches; on the right side, $2\frac{1}{2}$ inches. The longest transverse diameter is $4\frac{1}{2}$ inches. At the *outlet*, the nearest points of the ischial tuberosities are as close as $1\frac{3}{4}$ inch; but from the tip of the coccyx to the lower border of the pubic symphysis measures $4\frac{1}{2}$ inches. In the opinion of this author, a fœtus might be extracted from this pelvis by craniotomy.

In Dr. Cooper's case of Cæsarian section, the pelvis was affected with the angular deformity to the extent of reducing the conjugate diameter of the *brim* to $1\frac{1}{4}$ inch.; and the transverse diameter of the *outlet* to $\frac{1}{2}$ an inch only.*

In Dr. Kellie's unsuccessful case of Cæsarian operation, the pelvis was of the *rostrated* kind; the superior pubic rami being as if fractured in the centre, and held only by ligament. The lumbar curve was to the right side, and the 4th vertebra was sunk below the plane of the pelvic brim. The right lumbo-cotyloid diameter was only $\frac{8}{10}$ of an inch; the left, $1\frac{2}{10}$. Between the lumbar vertebra, and the bend of the pubic rami, was only $\frac{8}{10}$ of an inch. At the *outlet*, the intersciatic distance was only $2\frac{7}{10}$; antero-posterior, $3\frac{4}{10}$ inches. The sacrum was doubled, so that the tip of the coccyx was but 1 inch from the sacral base. The pelvic bones were soft; but the joints and cartilages healthy. In this case, the patient was only twenty-seven years old, and had borne four children: the last, three years before her death.

In Dr. Radford's two unsuccessful cases of hysterotomy, the deformities were both from malacosteon, and the form *rostrated*. In one, the circle of space at the brim was only about $\frac{3}{4}$ of an inch in diameter; the opening Y-shaped. The distance between the sciatic tuberosities was $1\frac{1}{2}$ inch, and the sub-pubic arch reduced to a small slit. The subject had previously undergone nine natural deliveries, and one by craniotomy. In the other case, the conjugate diameter was reduced to $\frac{3}{4}$ of an inch; and the superior rami were also bent so as to be parallel anteriorly. The patient had borne seven children with great ease previously; the last case four years before the operation.†

Dr. Hamilton's case was also *rostrated*, the

* Med. Observ. and Inq. vol. v. p. 218.
† Edinburgh Med. and Surg. Journal, vol. lv.

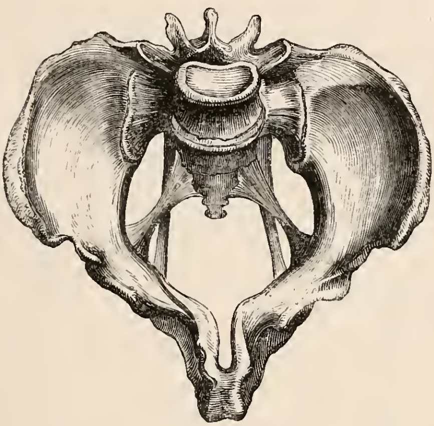
pubic rami being approximated at the angular bend to $\frac{5}{8}$ of an inch.

In a case which was operated on by Dr. Hæbeke, and described in *L'Experience* (No. 140.), the inferior pelvic outlet was nearly closed up entirely, the ischial tuberosities being approximated to within two lines only, and the coccyx and pubes admitting only one finger between them.*

In Mr. Kinder Wood's case, the deformity was *rostrated*, the most available space at the *brim* being a circle of 1 inch diameter to the left of the projecting promontory. The antero-posterior diameter was $1\frac{1}{2}$ inch, but less than $\frac{3}{8}$ of an inch when the soft parts were attached.†

A somewhat remarkable variety of the *rostrated* pelvis is figured by Dr. Churchill (*fig.* 119.). In this pelvis the *superior pubic ramus*

Fig. 119.



Oblong rostrated pelvis. (*After Churchill.*)

is bent at its centre, so as to be nearly approximated to the opposite pubis at that point, and the *symphysis* projects in a rostrum. The upper part of the *sacrum* and the *promontory* is, however, thrown back, the *cotylo-sacral arch* spread out, the *antero-posterior* diameter increased, and the *transverse* lessened, somewhat in the same manner, and, doubtless, by the same mechanical conditions, modified only by the yielding of the pubis, as in the *oblong* pelvis before described. The *acetabula* in this pelvis are directed principally forwards and outwards.

Causes of the foregoing pelvic distortions.—The principal causes of the preceding partial and complete distortions of the pelvis, are two diseases affecting the osseous system; viz. "*rickets*"—and "*mollities ossium*" *or* "*malacosteon*."

Rickets is a very common disease of early life, which is said to be more apt to occur in scrofulous children about the period of dentition, but which may occur even after puberty, according to some authors. It is characterised by a simple deficiency of the earthy matter of the bones—chiefly of phosphate and carbonate of lime; while the animal constituents, although softened, and rendered less elastic, retain nearly their normal composition. The bones thus rendered pliable, which lie in the lines of weight, pressure, or muscular action, yield slowly and give way to the operating forces, bending in such a manner as the resultant direction of pressure and muscular traction, &c., permits them.

We must refer the reader to the Article on the Pathology of Bone (vol. i. p. 440.) for a more detailed account of this disease.

In Rokitansky's Pathological Anatomy, the bones in *Rhachitismus infantalis* are described to present two separate pathological conditions. In one, the bones are very vascular, soft, fragile, and swollen, with enlarged medullary cavities, and the areolar spaces filled with, and often distended by, a pale, reddish jelly, which pressing upon the areolar partitions, produces their absorption, and thus the enlargement of the cavities by coalescence. This jelly is also sometimes found effused under the periosteum. In the second variety, the bone is more or less reduced to its cartilaginous elements, the corpuscles (*lacunæ*) empty, the rays obliterated, and the lamellar structure wanting, or fallen asunder, with corpuscles interposed between the layers. On the last condition the softening of the bones depends. The periosteum is more vascular than normal, tumid, and more closely adherent, so as to tear off with it a portion of the softened adjacent bone. It is said to differ from malacosteon in not being a painful disease, and in being capable of cure, with a subsidence of the swelling and reabsorption of the effused substance. In high degrees of the disease, however, atrophy and fragility remain permanently. The osseous structures affected by rickets are lighter, less marked, thinner, and more porous than normal, or than those affected by mollities ossium, according to Naegele;—appearing as if they had been steeped in weak acid.

The analysis of a rickety humerus and scapula, is given by Rokitansky as follows:

Phosphate of lime and magnesia -	15·60
Carbonate of lime - -	2·66
Soluble salts - - -	0·62
Total of inorganic matter -	18·88
Cartilage, vessels and fat -	81·12
	100·00

In the humerus, also, was found 10·54 per cent. of fat. Specific gravity of the bone, 0·612.

Davy found in 100 parts from the tibia of a rickety child, 74 parts animal and 26 earthy; and Bostock, in a vertebra affected with the same disease, 79·75 animal, and 20·25 earthy, in 100 parts.

When this is contrasted with the norma proportions of the osseous constituents in the child, as given by Schreger—viz. 47·20 parts animal, and 48·48 earthy (or about one half

* Lancet, 1840.

† Med. Chir. Trans. vol. vii. p. 264.

of the weight of the bone) in 100 parts—the great diminution of the earthy matter will be evident.

In *rickets* the bones of the lower extremities first exhibit deformity, which appears chiefly as an aggravation of the natural curves under pressure, and as a yielding in the direction of the lines of muscular motion. The femurs, for instance, are bent, in most cases, with the convexity forwards and a little outwards; the tibiæ and fibulæ generally with the convexity forwards and inwards, so that the knees are bent inwards and the feet thrown outwards and backwards (see *fig.* 122. B and E.) The bones of the pelvis and spine become affected, and those of the upper extremities, ribs, and head afterwards follow.

The spinal column may be extensively deformed, especially at its upper part, without any deformity whatever of the pelvis. An example of this is to be found in the Museum of King's College, and many in the Hunterian Museum. Many others are also recorded. In most of these cases, however, the special curvature results from caries of the vertebræ, or lateral curvature.

Meckel remarks, that spinal curves resulting from general disease of the bones, such as rickets, are usually accompanied by pelvic deformity. The lumbar portion of the spine is curved forwards and sideways, the thoracic portion backwards; and sometimes, the bodies of the vertebræ become affected with caries, and produce angular curvature and ankylosis. The sacrum at the same time sinks under the weight of the spine, and the pelvis becomes impressed, generally, with the complete *ovate distortion*, or one of the partial deformities of brim, cavity, or outlet, which are its commencements. In a good many cases, however, as we shall presently see, the rickety pelvis assumes the *angular* form of distortion; and, in some, the *oblong* form previously described. It is, however, universally shallow, contracted, and of small capacity. The iliac wings are thin, and present a greater central area of translucency than usual; while the columnar masses of bone are shorter, lighter, and less dense, but often present, as we have seen in the *ovate* pelvis with universally diminished diameters, a *thickening* of their bulk, corresponding to the shortening they have experienced by pressure.

Rokitansky mentions that this thickening takes place in common with all the osseous structures abounding in diploetic tissue. In many instances, it evidently depends upon the excess of reparative osseous deposit, described by Stanley as taking place in the lines of the greatest pressure. In all the specimens I have examined, it takes place by far the most considerably in the cotylo-sacral rib, through which the greatest amount of pelvic pressure passes. Shaw pointed out that in most rickety deformed pelves, the contraction of the diameter at the brim is universal as well as disproportionate, from the absolute shortening and *atrophy* of the bones. In fourteen rickety femal adult pelves, he found a general deficiency, in the measurements of the bones, of one quarter of the whole normal size. He also found that the bones of the lower extremity generally are atrophied in this disease more than those of the upper.* Rokitansky also considers rickets to interfere with the general development of the bone.

Mollities ossium or *Malacosteon adultorum* is a disease, not very frequent, affecting the full-grown adult skeleton. It most commonly affects the female sex about the middle period of life, but seldom, according to Rigby, attacks women who have had no children. Three instances in which this disease occurred in the male subject are, however, given by Mr. Curling in the Med. Chir. Trans. (vol. xx. p. 360.). Nor does it seem to be confined to middle age—in Kellies' case, the woman was aged only twenty-seven years—nor to parturient women, as will be seen in Mr. Solly's case.

In many cases, it is said to depend upon the cancerous diathesis, and to result from the dissemination of cancerous matter throughout the system, infecting the nutrition of the animal matter of the bones, and replacing the earthy constituents; thus causing the osseous structures to lose their cohesive power. By far the greater proportion of the complete cases of pelvic deformity, as well as the most extreme and universal contraction of diameters, have resulted from this disease.

For the particular pathological instances of this remarkable disease the reader is referred again to the article on the Pathology of Bone (p. 442. vol. i.) In addition to the cases there described, may be mentioned one which was brought before the Med. Chirurgical Society by Mr. Solly, and published in vol. xxiii. of the Transactions (p. 437.). The subject was a female who had never borne children, and the fragility of the bones appeared at as early an age as twenty-two. She had violent pains in the back, and a white sediment in the urine. At the age of twenty-four, the spine began to yield, and she had rheumatic pains in the head. At thirty-six years, the catamenia ceased, and the patient began to be unable to walk or stand, and had great pain; the greatest deformity being then apparent about the hips and shoulders. The bones of the head then became thickened, and those of the lower extremities more curved, and fractured by the slightest force; but the urine at this time was clear and natural. The patient died, worn out by the disease; and post-mortem examination showed the long bones to be reduced to mere outer shells, which could easily be cracked by pressure with the finger and thumb. The interior was filled with grumous matter, of hues varying from dark blood to light liver-colour. Both the femurs were broken, the tibiæ and fibulæ bent, the spine much curved, and the pelvis extremely reduced in its diameters; but the joints and cartilages were all healthy. The cranial bones were much thickened, and so soft as to be easily cut with a knife. The

* Med. Chir. Trans. vol. xvii. p. 434.

diploe was obliterated, the Haversian canals enormously enlarged, and the osseous corpuscles (*lacunæ*) diminished in quantity. From an analysis made by Dr. Leeson, the fresh bone contained,—in 100 parts; animal matter, 18·75; water, 52·08; phosphate and carbonate of lime, 29·17 parts. The grumous medullary matter contained,—in 100 parts; animal matter, 24·78; water, 73·39; and phosphate and carbonate of lime, 1·83 parts. Under the microscope, Rainey found many granular, roundish bodies, about the size of blood corpuscles, and some fat globules;—Simon, in a different part, could find no new or mature cell formations, but plenty of cytoblasts, and a few young fat cells.

Mr. Curling considers the softening of mollities ossium to be *eccentric; i. e.*, to commence in the centre of the bone, and pass outwards, affecting first the denser parts, and then the areolar extremities of the bone. He looks upon it as the result of defective nutrition, and that both the constituents waste in nearly equal ratio throughout. This author remarks that the pains always *precede* fracture or distortion, and are not the *result* of these conditions. In one case, he observed copious sweats and salivation; in another, a fœtid unctuous exudation from the hands and feet; in a third, fœtid perspiration; in a fourth case, that of an old woman of seventy, who had been bedridden for four years from paraplegin, there were no deposits in the urine. The pelvic bones might be cut with a knife, but the ribs and vertebræ were less affected. The enlarged cavities and areolæ were filled with red patches, resulting from injected vessels, and an oily medulla.*

Rokitansky gives as a characteristic of one form of mollities ossium (to which he applies the names of "*osteo-malachia*" or "*rhachitismus adultorum*"), that it affects principally the bones of the trunk, those of the extremities being affected in a subordinate degree; that it occurs especially in childbed women, and is often associated with cancer of the internal organs. This eminent pathologist also states that, in this disease, the bony corpuscles (*lacunæ*) are found empty, and without *canaliculi*; that the lamellar structure is also lost, and the structure satured with fat. The extract obtained by boiling differs, both from chondrine and from the normal animal matter of bone, a circumstance which he considers to be the most remarkable characteristic of the disease. He states further, that this form of the disease is painful, malignant, and has never been cured. In some cases, the muscles were in a state of fatty degeneration.

Mr. Dalrymple concludes, from microscopical observations of one variety of mollities ossium, that it was a simple fungoid, *malignant* condition of bone. He found the areolar spaces enlarged by the absorption of their partitions, and great increase in the vascularity of the lining membrane. The "lacunæ" were also enlarged, and the "canaliculi" considerably shortened, in the parts most affected. The red, grumous matter contained in the cavities, exhibited a large quantity of blood corpuscles, together with numerous nucleated and nuclear cells, with many cytoblasts, and some few caudate cells. Many oil globules and fat cells were also present. He considers the disease to differ from malignant osteo-sarcoma, in there being no deposit of new bone, and that the caudate cells, instead of increasing, become disintegrated, resolved into granular matter and oil globules, and finally dissolved.*

Professor Paget considers, that there are two kinds of mollities ossium, in one of which he places the *Rhachitismus adultorum*, described by Rokitansky, as well as that just quoted from Mr. Dalrymple, where the bones are reduced to a soft, flexible and cartilaginous condition simply. In the other variety, which he considers to result, like *fragilitas ossium*, from *fatty degeneration* of bone, he would place all the cases which have occurred in this country, including that of Mr. Solly's before described. Of the former variety, this pathologist has never seen a specimen, and he does not, apparently, consider it either a malignant or a frequent condition of the bones. His observations have led him to conclude that the grumous contents of the bony cylinder in this disease, of whatever hue—yellow, pink, crimson or dark red — are composed of disguised fat. In part of a femur presented to the Hunterian Museum by Mr. Tamplin, he found free oil globules in large quantity, fat cells filled with oil, or empty, collapsed, and rolled up, and crystals of margarine contained in or without the fat cells. The colour, which was yellow, pink and crimson, was owing to the hue of the oil globules, nuclei and granules of the collapsed fat cells. There was no excess of blood corpuscles whatever. In a portion of a femur presented by Mr. Howship, there was left, after boiling, only a small quantity of white crystalline matter.†

John Hunter remarked, in a case of mollities ossium, described by Goodwin in the *Med. Observ. and Inquiries*, that the bony structures were spongy, deprived of their earthy matter, and so soaked in soft fat as to resemble a fatty tumour.

In the pelvic bones of a female past the middle age, affected with the *rostrated* variety of *angular* deformity, I found, on making sections, a large quantity of a yellowish fatty matter contained in the areolar structure. This was particularly the case, also, in the head and neck of the femur, which even after long maceration, had entirely a smooth and greasy section. On applying heat to various portions of these bones, in order to ascertain the proportion of earthy constituents, they ignited and burnt with a copious bluish, fatty flame, with much smoke, and continued to burn freely till all the fatty matter was exhausted. The bones, which were very light,

* Med. Chir. Trans. vol. xx. p. 360.

* Dub. Jour. vol. ii. 1846.

† Lectures on Nutrition, Med. Gaz., 1847, p. 234.

even before incineration, left, after exposure to a red heat for some time, a very porous and light inorganic structure. The following results were obtained by thus burning off the organic components—100 *grains of bone*,—

	grs.
From the body of an upper lumbar vertebra left—*of earthy matter* - -	31
„ the last lumbar vertebra - -	27
„ lower end of the sacrum - -	24
„ ilium (cotylo-sacral rib) - -	40
„ ischium (near tuberosity) - -	36
„ pubes (near acetabulum) - -	33
„ head of the femur - - -	22
„ neck of the femur - - -	25
„ shaft of the femur (below trochant)	58

When we compare the foregoing proportions of the two constituents of bone with those given by Schreger, as the normal proportions of adult bone — viz., 20·18 animal, and 74·84 earthy matter—the diminution of the inorganic constituents appears very striking, and still greater when compared with those of aged bone ; although less so than in the results of the analysis of Dr. Leeson, in the extreme case recorded by Mr. Solly before given.

The femurs were perfectly normal in shape, as also were the bones of the lower leg, but the pelvis was a *rostrated* one, the superior pubic rami being bent in the middle nearly at right angles, and much deformed and contracted in all its diameters. It was remarkable, that, at the bend of the superior pubic rami, and at the suture of the ischio-pubic rami, there was a complete deficiency of osseous matter, so that after maceration, the pubes separated at these points ; showing that the connection and continuation of the bone in these places was purely ligamentous, or by organic matter, as if resulting from an ununited fracture.

The sudden diminution of the hard constituents in the head and neck of the femur, as compared with its shaft, is worthy of observation in reference to the bending and fracture of the femoral neck in old people.

The smaller proportion of earthy matter in the pubes, as compared with the ilium, and in the sacrum and lumbar vertebræ, as compared with the femoral shaft and pelvis, will account for the greater yielding and deformity which are observed in these parts in the angular pelvic distortion, especially in the rostrated variety, and will be referred to presently in the consideration of the mechanism of pelvic deformities.

In the analysis made by Dr. Bostock of the dorsal vertebræ of a woman affected by mollities, he found, that the proportion of the earthy constituents amounted to only one-fifth of the whole weight in one part of the bone, and to one-eighth only in another ; while in a healthy bone from the same part, they amounted to more than one half the whole weight.*

In the analysis given, in Rokitansky's work before cited, of a portion of bone affected with this disease we find—in 100 parts :

Phosphate of lime and magnesia -	17·48
Carbonate of lime and soluble salts	6·32
Total of inorganic matter	23·80
Cartilage vessels and fat -	76·20

Specific gravity of the bone 0·721.

Among the reasons adduced in favour of the supposition that this disease is sometimes a malignant one, besides the general and violent pains that usually *precede* the deformity, its incurability and unchecked course towards a fatal termination, have been given. That this result is not invariably the case, the following case quoted from Naegele will show, in the fact that the pelvic bones had *regained* their normal hardness. In the pelvis whence the foregoing analysis was taken, the bones had, most probably, at some former period been much softer than they were at the time of death. Such cases also show, that though very frequently, the pelvic bones distorted by mollities are so soft and pliable as to yield, sometimes considerably, to the fœtal head ; yet that this is by no means always the case, nor should it be taken, as it is by some obstetricians, as a characteristic mark of this disease affecting the pelvis.

A very minutely detailed case of pelvic distortion, resulting clearly from one or other kind of *mollities ossium*, is given by Naegele.* The subject of the case, after having borne six children (five healthy, full sized, and living, and the sixth still born), became affected with this disease, which brought about such extensive pelvic distortion and contraction, that, at the seventh labour, the Cæsarian operation was rendered necessary, from the consequences of which the patient died after the fourth day. The shortness of the time in which the pelvis became so much distorted, together with the extent of the deformity, and the fact that, at the time of the patient's decease, it had *regained* its normal hardness, render the case a very remarkable one. Naegele considered it as the most contracted pelvis that had ever come under his observation.

The anterior wall was pushed upwards and the posterior downwards, the superior plane being bent at the acetabula, so that the upper border of the pubic symphysis was level with the upper surface of the 4th lumbar vertebra ; and a line drawn from one anterior superior iliac spine to the other, cut the upper surface of the 3rd lumbar vertebra at its posterior half. The innominate bones were pushed together, and presented the acute furrow, like cracked pasteboard, on their inner surfaces. The sacrum was bent almost double. The measurements are given by the author, as follow †: —

* Med. Chir. Trans. vol. iv.

* Erfahrungen und Abhandlungen; and Appendix to Das Schräg Verengte Becken.

† The measurements used by Naegele, (Rhineland or Prussian,) are very slightly larger than the corresponding English ones.

From the anterior inferior iliac spine, to the opposite point on the iliac crest posteriorly—on the left side, 2 inches 4 lines; on the right side, 2 inches 6 lines. From the apex to the upper surface of the sacrum, 16 lines only; to the junction of the 1st and 2nd sacral pieces, $10\frac{1}{2}$ lines. From the left superior pubic ramus a little internal to the pectineal eminence, to the body of the 4th lumbar vertebra on the same level, *only* $2\frac{1}{2}$ *lines*. Between the same points on the right side, $6\frac{1}{2}$ lines. The sides of the sub-pubic arch were only 3 lines apart, and more contracted near the sciatic tuberosities than above, by these processes being pushed inwards. The pubes in this pelvis, as represented in the drawings given by the author, are bent in the middle of their superior rami, thus producing the rostrated form.

A like case of progressive pelvic deformity from *mollities ossium* is described by Dr. Cooper.* The patient, Elizabeth Foster, had perfectly easy delivery in her three first labours; before the fourth, she had, while pregnant, rheumatic fever, and afterwards constantly suffered from universal pains of a rheumatic character, followed by gradual spinal distortion. From the fourth to the sixth labours, they were increasingly difficult, and in the seventh and eighth she was obliged to be delivered by craniotomy, the sacro-pubic diameter being reduced to 2 inches. Three years after, she again became pregnant, when the sacro-pubic diameter was found to be reduced to $1\frac{1}{4}$ inch, becoming gradually narrower on each side. Cæsarian section was performed, under which she sank. After death, the sub-pubic arch was found to be so much contracted, that the sciatic rami were little more than $\frac{1}{2}$ an inch apart. The pelvis was so soft and spongy, that the finger could be easily pressed into its substance, and at the place of attachment of some of the muscles, the osseous substance was found raised into eminences, as if pulled out.

Eight similar progressive cases were observed by Barlow. One woman, on whom he performed hysterotomy unsuccessfully, had given birth to two children, and afterwards had become lame and bed-ridden for four years. In another case of Cæsarian section, also resulting from malacosteon, the woman had previously borne children, and been delivered by the crotchet. In this instance, the conjugate diameter was reduced to $1\frac{1}{2}$ inch; the right sacro-cotyloid, to $2\frac{1}{4}$; the left, to $1\frac{1}{4}$ inch. The last lumbar vertebra and sacral promontory formed a great tumour-like curve in the pelvic cavity, which he was able to distinguish from an exostosis only by its yielding easily to the pressure of the fingers, which a tumour of that nature would not do.† Other cases of this progressive kind have been before alluded to.

The question as to whether the *rickety* pelvis ever assumes the *angular* or *cordiform* shape, is one which has occupied considerably the attention of many obstetricians.

* Med. Observations and Inquiries, vol. v.

† Essays, p. 355.

It was very ingeniously advocated by Dr. Hull in his Letters to Symmonds, and laid down by the younger Stein and others on the Continent, that the ovate form of pelvic distortion with contraction of the diameters of the inlet and enlargement of those of the outlet of the pelvis, was the characteristic and invariable form of rickety disease; as that of the angular cordiform shape, with contraction of both outlets, was of *malacosteon;* and the opinion seems to be still frequently held by obstetricians both abroad and in this country.

Dr. Murphy considers that, though the oval pelvis is not the necessary consequence of rickets, nor the cordiform of *mollities ossium*, yet that "of necessity, the softened adult pelvis would take the shape called cordiform, while the infant pelvis would be transversely lengthened;"—unless in the infant, "the spine be softened and bent as well as the pelvis," so as to throw the weight of the body more upon the pelvic cavity, as by a "*backward* curvature" such as he has figured, in which cases he supposes that angular deformity takes place in the child.* This conclusion he draws from the hypothesis that in the child, because of the straightness of the spine, a line passing through the centre of gravity, and consequently the weight of the spine, would fall altogether *in advance* of the pelvic cavity, and that consequently the acetabula would be pressed up behind it, and of necessity, *diverge*, because of the sacrum pressing down between them; while, in the adult, the weight of the body falls within the pelvis and between the acetabula, which consequently would be pressed inwards towards it. In considering the mechanism of these pelvic deformities we shall again have occasion to refer to this explanation. But this author also thinks that a condition of bones identical with or allied to rickets, may be induced in young adult females, whose health is depreciated, and powers of nutrition impaired, by the confined or unhealthy nature of their employment; and that there is thus constituted a special kind of mollities ossium, a *rickets* of *adults*, in which cases the pelvis will assume the cordiform shape. The frequent occurrence of spinal deformities at this age, is an evidence of a deficiency in the supply of osseous material.

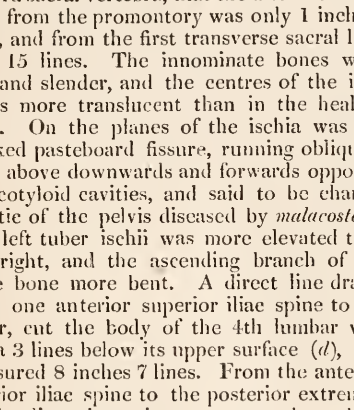
Naegele, who warmly combats the opinion that the infant rickety pelvis is always elliptical, quotes in support of his arguments against it, a case attended by Dr. J. A. Beyerle and Professor Fischer, of Mannheim. The history of the case, and the appearance of the patient herself, and of her father, brothers, and sister, indicated scrofula and extensive rickety deformity existing in the family. The patient had been deformed from the earliest youth, and had not attempted to walk or stand till she was seven years old. She was of very small stature,—4 feet 3 inches, had a projecting sternum, an awkward, shambling, waddling gait, and a remark-

* Lectures on Parturition, p. 32.

able projection of the abdomen, caused by a great increase in the normal forward bend of the lumbar curve; with an equivalent projection of the sacrum posteriorly, from the horizontal position of that bone; so that the plane of the superior pelvic opening was, in the upright position, completely vertical. The lower extremities were not, however, deformed, neither the bones of the upper nor lower leg being bent. About the age of thirty, she became pregant, and died after the necessary performance of the Cæsarian section.

On being examined, the lumbar vertebræ were found much curved forwards, and small, slender, and weak. The sacrum was placed nearly horizontal from before backwards, its posterior part projecting very much behind (see *fig.* 120. *a*). It was sunk so much between the ilia that the centre of the 4th lumbar vertebra was opposite to the upper border of the pubic symphysis, and was bent so much about the 3rd sacral vertebra, that the distance of the apex from the promontory was only 1 inch 9½ lines, and from the first transverse sacral line, only 15 lines. The innominate bones were thin and slender, and the centres of the iliac wings more translucent than in the healthy bone. On the planes of the ischia was the cracked pasteboard fissure, running obliquely from above downwards and forwards opposite the cotyloid cavities, and said to be characteristic of the pelvis diseased by *malacosteon*. The left tuber ischii was more elevated than the right, and the ascending branch of the same bone more bent. A direct line drawn from one anterior superior iliac spine to the other, cut the body of the 4th lumbar vertebra 3 lines below its upper surface (*d*), and measured 8 inches 7 lines. From the anterior inferior iliac spine to the posterior extremity of the linea innominata, measured on both sides, 2 inches. From the ischial tuberosity

Fig. 120.



Angular rickety pelvis. (After Naegele.)

to the most elevated portion of the iliac crest, measured on the right side, 6 inches, on the left, 5 inches 7 lines. From the tuber ischii to the pectineal eminence, measured on the right side, 3 inches; on the left, 2 inches 11 lines. The height of the pubic symphysis was 18 lines.

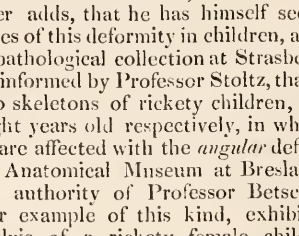
The *superior opening* was angular, with an acute and somewhat symmetrical curve of the cotylo-sacral ribs on each side, and a gradual and equable curve inwards at the union of the ilium and superior pubic rami *at the acetabula* (*b*), which brings the body or acetabular portion of the pubis, to within 5 lines of the body of the 4th lumbar vertebra, the under surface of which is on the same level; the same measurement on the left side being 6½ lines. The distance from the anterior and lower border of the same vertebra to the upper border of the pubic symphysis, was 1 in. 1 line; and from one superior branch of the pubis to the other near the acetabula, 1 in. 7 lines. The pubis presented the usual outward bend at the spines on each side of the symphysis (*c*).—At the *inferior opening*, the distance between the ischial tuberosities was 1 in. 5½ lines only; and the nearest approximation of the ascending branches, 1 in. 1 line.

The shape of this pelvis, of which the author gives three lithographic sketches, had caused it to be frequently mistaken for the results of *mollities ossium*, but the appearance of the bones in texture, lightness, and slenderness, &c., was truly rickety, and with the history of the case, gave no reason whatever for the supposition that malacosteon had ever been present or supervened.

In addition to this case, the same eminent observer adds, that he has himself seen two examples of this deformity in children, and that in the pathological collection at Strasbourg, as he was informed by Professor Stoltz, that there are two skeletons of rickety children, of one and eight years old respectively, in which the pelves are affected with the *angular* deformity. In the Anatomical Museum at Breslau, also, on the authority of Professor Betschler, is another example of this kind, exhibited by the pelvis of a rickety female child aged ten years. Many other similar examples are given by Burns, Otto, Wallach, and Krumbolz. Rokitansky also found the angular deformity in rickety pelves, but in a minor degree of distortion.*

In the Museum of King's College, London, are two rickety pelves of children of about from four to six years old, both of which are affected with angular deformity of the pelvis.

Fig. 121.



Angular child's pelvis from rickets.

A drawing of one of these is given in figure 121. In the larger of the two, the curves of the femurs and leg bones are bent di-

* Pathological Anatomy: Pelvic Abnormalities.

rectly forwards, without any lateral deviation inwards or outwards. In the Hunterian Museum also, there is a rickety skeleton of a child of six years, in which the pelvis presents the angular deformity and approximation of the acetabula. In none of these specimens is there any great backward curvature of the spinal column, though, in the last instance, the sacrum is bent so much forward, that the tip of the coccyx is almost on a level with the superior plane in the centre of the opening.

It is, however, especially remarkable that in *all* these last-mentioned specimens, as well as in that figured by Naegele and just described, the angle of the bend or *culm* of the *lateral curve* produced by the pressure inwards of the heads of the femurs, takes place *in the acetabula* at the line of junction of the two upper pieces of the innominatum, and not in the superior branch of the pubis itself, as in most of the cases resulting from *mollities ossium.* This is evidently produced by the more facile and greater yielding of the as yet unossified cotyloid cartilage, rendered softer and more tardy in ossifying, by the effect of the disease upon its nutrition.

That such a yielding does take place in this cartilage from disease and pressure is shown still more strikingly in another case in the Hunterian Museum (No. 3423.), in which it has bent *outwards*, instead of inwards, and thus is produced an elliptical distortion of the pelvis. This skeleton is from a young subject, in which the pelvic bones had not yet become soldered together. The head and neck of the left femur are nearly destroyed by caries, which doubtless also extends to the acetabulum itself. Both the femurs are extremely flexed and adducted on the pelvis, and seem, especially on the diseased side, to have, by the constancy of this position, pushed upwards and backwards the pubis, so as to cause a distinct bend at the cartilaginous cotyloid line of junction, and an elevation of the pubic symphysis. By this means, the acetabula are pushed outwards, and the superior pelvic opening assumes an elliptical shape; though the cotylo-sacral arch is but slightly spread out, and the ischial tuberosities are normally placed. The lumbar curve and sacral promonotory deviate slightly towards the left side, and the bones are remarkably small and light, showing the prevalence of the rickety tendency.

From these cases, it seems reasonable to draw the conclusion, that the softened infant pelvis does in a great many cases assume the cordiform shape, and that without any *backward* spinal curvature; but, on the contrary, the case quoted by Naegele shows that it is co-existent with excessive *forward* curvature of the lumbar spine, such as would throw the weight of the body entirely in front of the vertically placed pelvic brim; and thus, according to Dr. Murphy's view, of necessity, produce the ovate and not the angular deformity.

We may also conclude that when, by mechanical causes, the *angular* shape is impressed upon the softened infant pelvis, it will yield most readily and extensively at its weakest point — viz. the still cartilaginous line of ilio-pubic junction *in the acetabulum;* and that, as in the instances now given, and indeed in all that I have myself examined, the shape of the angular pelvis resulting from *rickets* in infancy is never *rostrated*, in the sense to which that expression is confined in the present article; but, that this form is usually seen only in the angularly deformed pelvis resulting from the *mollities ossium* of adults, and commencing after the pelvis has attained its adult development and consolidation, when the bend most commonly takes place in the centre of the superior pubic ramus, which, in thickness, and, in some diseased conditions, as the analysis before given shows, in composition also, is the weakest point of the pelvic circle in the adult. This will, I think, be found a general and useful distinguishing mark between the angular pelvis resulting from rickets, and that of the adult *mollities ossium.*

Whether, on the other hand, the adult pelvis, softened by *mollities ossium*, or the rickets of adults, ever assumes the ovate form of distortion, is a question of supposition merely. I have not been able to find any recorded cases of such a result, though there is no evident reason why this should not occur, under certain mechanical conditions. Rokitansky found that the ovate and hour-glass distortions are, almost without exception, the result of infantile rickets.

Mechanism of the preceding Pelvic Distortions.— In considering the forces which operate in producing the two principal varieties of pelvic distortion previously treated of, it is necessary carefully to separate those resulting from mechanical position, from those which arise from muscular action alone. In considering the former, it will be necessary as carefully to separate the idea of the *line of gravity*— i. e. a perpendicular line let fall from the centre of gravity— from that of the *line of pressure*, which must necessarily pass through the osseous supporting structures, whatever disposition they may have.

The *centre of gravity* of the *trunk* itself is that which influences most considerably the form of the softened pelvis in the sitting as well as the upright position. This is placed by Weber in the transverse vertical plane of the spinal column, which here falls considerably in front of the vertebræ, in the thoracic cavity, at the level of the sterno-xiphoid articulation (see *fig.* 122. A, *a*).

In the most easy standing position, this centre of gravity is placed directly above *that of the whole body*, at the sacro-lumbar articulation (A, *c*); so that perpendicular lines let fall from each to the ground will exactly coincide, and (in the well-made subject, after passing through the sacral promontory and the acetabula) fall between the feet as the basis of support. In the sitting posture, it falls a little posterior, between the ischial tuberosities.

To preserve the standing posture, it is

necessary that the line of gravity of the whole body—viz. that from the lower centre—should

Fig. 122.

B. Outline of the lines of pressure in the pelvis and legs in the *ovate rickety* distortion, during the standing posture.—*a b* lines of direction of the pressure of the heads of the femurs in the acetabula,—upwards and *outwards*.

C. Outline of the pelvis and legs in the *angular rostrated* pelvis of the *adult*, resulting from *mollities ossium*. *a b*, *a c*, direction of pressure in the acetabula when the legs are not deformed,—upwards and *inwards*.

D. A similar outline in the *angular rickety* pelvis of the *child*, when the legs are bent *outwards*,—direction of pressure *inwards*.

E. Outline of abnormal antero-posterior curves of the spine, pelvis, and legs. *a b*, direction of the pressure in the acetabula *backwards* increased by the forward curve of the femora. *c d*, line of traction of the psoas muscles increasing the deformity of the pelvis.

fall anywhere between the extent of longitude of the feet (*c d*).

If the trunk, however, bend forward, its centre and line of gravity is advanced beyond that of the whole body, and a share of the support of the trunk, equivalent to the degree of distance of these two lines (*b*, *d*), falls upon the muscles and ligaments of the posterior part of the spine, and a corresponding strain upon their attachments to the sacrum and posterior part of the pelvis. This instance may be taken as an example of many others, in which the mechanical position of the line of gravity influences muscular action, the effects of both falling upon the lines of pressure and support in the pelvis.

For the preservation of the sitting position, it is only necessary that the line of gravity of the trunk (*a b*) should fall within the extent of the basis of support, which is, from more or less of the whole extent of the hams in front to the ischial tuberosities behind. Hence the greater facility with which a person sitting down is pushed backward than forward.

The *line of pressure*, on the other hand, passing down the centre of the bodies of the vertebræ will, in the well-made subject, when standing on both legs or sitting, divide at the sacral promontory, into two equal parts, each of which traverses, first the lateral sacral masses to the sacro-iliac joint; from this point, in the *upright* position, it passes along the cotylo-sacral rib to the heads of the femurs, describing in its course the C-like curve. In the *sitting* posture, it passes down the ischio-sacral buttress to the tuberosities. It will be borne in mind that each of these standing and sitting arches has its tie, which prevents it equally from starting *outwards* or pressing *inwards* at the extremities; that for the cotylo-sacral arch being the united superior pubic rami, and that for the ischio-sacral arch, the united ischio-pubic rami. The cotylo-sacral arch and its pubic tie, united at the acetabula, and placed in the same plane, form in man, as we have seen, a lateral arch made up of the two halves, which supports on its culm the inward pressure of the head of the femur. The cotylo-sacral portion also sustains, in addition, its upward and backward pressure.

The first effect of the softening of the osseous supports in this line of pressure is to increase the natural curves which occur in it. Thus we see an increase in the dorsal, lumbar, and sacral curves, in the cotylo-sacral, femoral, and tibial (*fig.* 122. E). The next effect is to produce lateral curves, which present generally their concavities towards the line of gravity, and are always associated with *compensating curves*, so as to keep the line of gravity within them, about which they produce a wavy line, as is seen in the deformed spine. When this is not the case, the support of the weight falls more upon the tension of the muscles, and ligaments, and parts of bone on the convex side. In the pelvis, and, to some degree, in the bones of the legs, however, these results are modified by the lateral duplication and division of the lines of pressure; and in the pelvic skeleton this effect is still further increased by the circular union of the lateral structures, and by the pressure or traction of the bones of the legs, conjointly or individually.

The alteration of the position of the centre of gravity of the trunk, by deformity of the spine low down, will also have its effect upon the pelvis, by necessitating a constrained and unnatural position to prevent the body falling. Deformities confined to the upper part of the spine are seldom accompanied by deformed pelvis, owing, probably, to the little effect they have in altering the centre of gravity. In addition to these general changes from mechanical pressure, there is, in this softened state of the bones, the powerful effect of combined muscular action.

The influence of *continued posture* on these changes will be found to be the origin of most of the differences of form we have seen in pelvic distortions. Let us consider the effects of mechanical position and muscular action in the *recumbent*,—*sitting*,—and *standing* positions respectively, on the softened pelvis

In *lying upon the back*, the softened pelvis will have a tendency to become flattened antero-posteriorly, by the sinking of the pubic arch, at the same time that the traction of the femurs and muscles of the lower extremities outwards will tend to separate the acetabula and increase the transverse diameters. This I apprehend to be the commencement of the *elliptical* pelvic deformity, which occurs in the majority of the softened pelves of infants, whose most frequent and long-continued position is the dorsal recumbent. The angles of the pelvis with the spine will also have a tendency in this posture to become *increased* by the weight of the inferior extremities. If the softening be great, and the position long-continued, the symphysis pubis would also sink, producing the *hour-glass* form of pelvis; a disposition which would be increased by the traction of the levator ani and weight of the bladder. There would also be a tendency to flattening of the sacrum. In *lying upon the side*, on the other hand, there is a pressure, through the trochanters, upon the acetabula, which, if long and frequently-accustomed, will cause the lateral pelvic arches to yield and bend inwards at the cotyloid line of junction, in children as yet unossified, and produce the first bend or tendency to the *angular* deformity. The effect of these first impressions are, as Dr. Ramsbotham observes, illustrated by making an elbow in a piece of wire subjected to pressure at each extremity. In the undeveloped pelvis also, the facility with which these impressions are made upon the pubic tie is rendered greater by the greater tardiness of its ossification than in the other innominate pieces. In some instances, pelves seem to have been impressed in this manner on *one side only*, so that the two sides present an approach to the two different varieties of deformity, as will be presently alluded to.

In the *sitting* and *standing* positions, a more powerful distorting influence is brought into play—viz. the pressure of the weight of the body on the softened pelvic arches.

The *sitting posture*, when the *elliptical* form has already been impressed upon the pelvis, will still further tend to separate the acetabula by the starting outwards of the lower extremities of the ischio-sacral arch under the pressure of the weight of the trunk on the sacrum; and thus the separation of the tuberosities, the enlargement of the transverse diameter of the outlet, and the spreading out of the subpubic arch take place. At the same time the sacral promontory sinks into the pelvis under the weight of the trunk, while the lower part of the sacrum is kept forwards by the sciatic ligaments, so that a bend takes place in the middle of the bone. This bend will be still further increased by the divergence of the ischial tuberosities, permitting the weight of the spine to be brought to bear upon the coccyx and lower end of the sacrum and against the sitting surface. The total direction of the pressure on the ischial tuberosities being upwards and backwards, the curve of the ischio-sacral arch (coinciding with that of the cotylo-sacral at the top of the sciatic notch) takes place in that direction, and increases the acuteness of the C-like curve.

These effects upon the sacrum and ilia, and pelvis generally, will be increased by the action of the powerful erector spinæ muscles, and psoas and iliacus muscles, exercised in keeping the trunk erect upon the pelvic lever (see *fig.* 122 E, *e d*). These muscles have, in addition, much influence in shortening the spinal column itself, already bending under the weight of the body, and,—following the general tendency of elongated substances yielding to pressure at both ends to twist laterally,—the lumbar curve and sacral promontory become placed on one side the median line. This tendency, from reasons before explained, is generally to the left. Under the increased inclination of the pelvic angle, the abdominal muscles will tend to draw the flattened pubes upwards still nearer the sacral promontory, diminishing the conjugate diameter. In extreme deformity, the iliac wings are pressed still further outwards and everted by the pressure of the lower ribs resting upon them, as we have observed in one of the detailed examples.

But when the lateral pelvic arches are already impressed with the *angular* deformity, the sitting posture has the effect of merely increasing the inward bend, and approximating the acetabula and sciatic tuberosities to the sacrum, pressed down by the superincumbent weight. Dr. Rigby mentions that frequent riding on horseback at an early age will produce contraction of the inferior outlet, even in the healthy pelvis, and that the females of those American nations who ride much bear few children, and are often three or four days in severe labour.

In certain cases, in which the acetabulum on one side only has been pressed inwards by the constant use of the lateral recumbent position, or in which the centre of gravity of the trunk has been permanently shifted to one side by the spinal bend, a habit is acquired of sitting more upon one ischial tuberosity than the other. This unequal pressure produces inequality of distortion, and presses the tuberosity and acetabulum of that side *inwards*, while the opposite one presents the usual *divergence* of the elliptical distortion. This effect is also contributed to in like manner, under the same circumstances, in the standing position, by the pressure being greater and more frequent upon one femur than the other; and thus we have produced a sort of oblique deformity, of which I have seen several specimens.

In the Museum of King's College are three skeletons, all presenting more or less a tendency to this peculiar modification of the ovate deformity. In the Hunterian Museum is another, in an adult female skeleton, still more marked.

It is somewhat remarkable that, in all these examples, the trunk is bent towards the right side, and the lumbar curve and sacral projection towards the left; so that the line of gravity, and consequently the greatest share of supporting the weight of the body, falls nearer the left leg and the left side of the pelvis. The effect is such as to produce great similarity in the form of all these pelves, which vary only in the degree of distortion. The sacral promontory is directed to the left side, while the sacral concavity is more or less twisted so as to face the left acetabulum. The innominate bone of the left side is placed lower and more vertical than that of the right side, which appears longer and less bent; so that the left ischial tuberosity projects lower and more vertically than the right, which is everted and directed outwards. The left acetabulum is brought nearer to, and more directly under, the sacral promontory, the cotylo-sacral arch being more curved than the right; while the right sacro-iliac joint and lateral sacral mass are higher, the cotylo-sacral curve more open, the iliac wing more spread, and directed, like the acetabulum, more forwards, and the ischio-pubic ramus placed more obliquely, than those on the left side.

In the female Hunterian skeleton, the obliquity of the spine and pelvis are so great, that the upper dorsal vertebræ are placed above the right sacro-iliac joint. The femora are shortened, and curved forwards and outwards, and the leg bones forwards and inwards, in compensating curves. The left knee, however, is more under the line of gravity than the right. A tendency to a somewhat similar twist is seen in an adult hydrocephalic skeleton in the same collection.

These pelves present, at first sight, some resemblance to the very different "*obliquely ovate*" pelvis of Naegele. The most characteristic differences are, the presence of other rickety appearances, and the want of the coincidence of lateral deviation of the pubic symphysis with the sacro-iliac ankylosis and malformation of the latter.

Rokitansky includes all the pelves which present a want of symmetry at the sides under the general term of *oblique pelves*, after Osiander's classification, in which he comprehends by far the greatest number of pelvic deformities of all kinds. He gives, as a characteristic of this class,—approximation of the sacral promontory to the pectineal eminence on one side, which side has also a higher level and a less pelvic inclination than the opposite one, originating in a lateral curve and torsion of the sacrum towards the contracted side, —and straightening out of the linea innominata on the opposite side, between the sacro-iliac joint and the acetabulum. It includes the frequent pelvic deviations resulting from lateral curvature of the spine, but most frequently arises from rickets, or displacement of the femur by hip-joint disease or violence.

To a rickety child, who rarely begins to walk till after the usual age, by far the most frequent positions are the two which we have just considered, and the mechanism of these positions, in my own estimation, is quite sufficient to account for the first impression of the most frequent deformity of the rickety pelvis, the *ovate*, as well as for the not uncommon *angular* infantile distortion.

In *standing* and *walking* the supporting pressure on the pelvic structures is sustained, either divided or alternately undivided, between the cotyloid cavities and the sacrum. From the peculiar disposition of the cotyloid articulation, the pressure of the head of the femur is exerted in two directions, 1st, upward and backwards along the cotylo-sacral rib, which is the principal line of pressure, and, 2nd, inwards on the lateral pelvic arch. In the upright position the softened cotylo-sacral rib yields in the direction of its C curve, which becomes more acute as the sacrum sinks. An increased obliquity of the pelvic inclination, such as has been stated to be generally consequent upon the advance of the sacral promontory and increased lumbar curve in the elliptical deformity, will bring the line of gravity, both of the trunk and whole body, in *front* of the acetabular supports, which will cause them to increase the backward curve when pressure is exerted upon them (see *fig.* 122. E, *a b.*), But that such a condition is produced by a greater obliquity of the *normal* infant pelvis than that of the adult, or that this alone is sufficient to account for the elliptical deformity taking place usually in the infant pelvis, by causing divergence of the acetabula under pressure during the upright posture, as asserted by Dr. Murphy, is a conclusion which the results of the observations given in a former section, as well as those of Weber, therein stated, will not at all admit of;—for, as was there seen, the obliquity of the normal infant pelvis is not at all greater, if as great, as that of the adult.

But if the acetabula are already separated by the *elliptical* deformity, or if the leg bones yield *inwards*, so that the pressure on the acetabular articular surface at its upper vaulted part is directed *upwards* and *outwards*, as seen in the accompanying diagram (*fig.* 122. B, *a*, *b*), then the pressure *inwards* of the heads of the femurs upon the lateral pelvic arches is taken off, there is traction instead of pressure on the pubic *tie*, the acetabula become still more widely separated, and the elliptical deformity increased. In such specimens of ovate pelvic deformity as have the leg bones attached, I have found the tibiæ and fibulæ bent much inwards, or the leg bones so disposed by an *inward knee-bend* as to take off the *inward* pressure at the acetabula, and even sometimes by extreme adduction of the femurs, so as to exercise a strain upon the round ligaments of the hip joint and rotator muscles, and thus produce a direct *outward* traction. In this position of the bones, the action of the adult muscles which support the erect posture—viz., the great glutei and psoæ, will be such as to increase the deformity (see *fig.* 122. E, *c d*), as well as those before mentioned which sustain the spine erect.

If the *angular* deformity have been already impressed upon the infant pelvis by the bending of the cartilaginous junction, while the bones of the legs, and in some degree those of the pelvis, retain a sufficient degree of hardness to resist the bending, then the *inward* pressure of the heads of the femurs remains in its full force, associated with the *upward* and *backward* pressure, and the deformity is increased by the upright position (*fig.* 122. C, *a b*, *a c*). The same result is also produced in an increased degree, if the leg bones yield outwards, so as to direct the pressure of the heads of the thigh bones more towards the median line. This will be better understood by referring to the diagram (*fig.* 122. D, *a b*, *a c*).

Naegele observes, that when the lower extremities are curved and distorted the pelvis will generally be deformed; and that such a condition more especially, or where one hip is higher than the other, with an unsteady gait, a projecting abdomen and lower jaw, and retraction of the arms and thorax, diminutive stature, &c., should lead the accoucheur to suspect deformed pelvis.*

The adult pelvis, softened by malacosteon, appears to undergo greater distortion than is proportionate to that of the leg bones. In that upon which the experiments before mentioned, to ascertain the proportions of the osseous constituents, were performed, the bones of the lower extremities were almost entirely symmetrical and well formed, and the proportion of earthy matter contained in the femurs much greater than in the pelvic bones, especially in the pubes (at one point of which it was entirely deficient) and the sacrum. The pubes, as they are also the thinnest pieces of the innominate bones and sustain a great amount of the inward pressure, which exists, in these cases, to its full extent, seem to be the first to give way in the more complete and rapid softening of "*mollities ossium adultorum*." The consequence is, the approximation of the acetabular extremities, and increased curve of the cotylo-sacral arch, so as almost to touch the sunken sacral key-stone; and the starting forward and upwards of the crown of the pubic counter-arch, so as to produce the *rostrated* symphysis.

The muscles before enumerated, which support the erect posture, as they are in the adult more powerful and developed, have a corresponding effect in increasing the contraction of the diameters consequent on the distortion. The bones yield between their contracting distances in the direction already impressed upon them. The acetabula are pressed backward by the psoæ and iliacus muscles, and the ischial tuberosities and trochanters approximated by the pressure of the great glutei, which, aided by the pyriformes, will also draw forward the lower part of the sacrum and coccyx. The powerful influence of the adult muscles upon the pelvic bones partially softened, and especially that of the great glutei upon those bounding the diameters of the inferior outlet, will produce many of the *partial deformities* before treated of, as the influence of mechanical posture in a limited extent, or short duration of the softening disease, will produce others, principally those of the pelvic brim.

* Lehrbuch, § 444.

The peculiar variety of the partial deformity will depend upon the frequency of the use of one particular posture or set of muscles; and this will depend chiefly, in the child, on the concurrent ailments which usually affect it, and in the adult on the nature of his or her habits and employment.

The degree of the backward curvature of the cotylo-sacral arch seems to depend upon the degree of anterior lumbar curvature, which necessitates a forward projection of the femurs to keep the line of gravity between the feet (see *fig.* 122. E, *a b*).

The rostrated pelvis, with *elongated* antero-posterior diameters, apparently results from the coincidence of the softened pubes with the causes of oblong deformity before adverted to, as produced by a *backward* spinal curve, causing the line of gravity to fall considerably *behind* the acetabula, and dragging backwards the superior part of the sacrum.

The mechanism of these important pelvic deformities has been entered into more in detail because of the evident practical inferences which may be drawn from it with regard to the treatment and position of children, especially females, afflicted with rickety disease.

Degree of obstruction. — Pelves affected by the foregoing distortions are usually arranged by British obstetricians, according to the degree of obstruction at the brim, into three classes: —

1st. Those which will suffer the full-sized fœtal head to pass entire.

2nd. Those through which delivery may be accomplished "*per vias naturales*," by means of premature labour, craniotomy, or mutilation of the fœtus.

3rd. Those in which the degree of deformity is so extensive as to call for the Cæsarian section, or the very early induction of abortion.

The limits of the first class have been variously stated by different obstetricians, according to their opinions regarding the obviou variations in size of the fœtal head, and its degree of ossification. The following list conveys the opinions of the most eminent authorities upon the *lowest* limits through which the fœtal head can pass entire: —

	Diameters Conjugate.		Trausverse.
Ramsbotham, Churchill, Lee, and most obstetricians - -	3 ins.	by	4 ins.
Aitken and Osborne - - -	3 „	„	sufficient.
Josh. Clarke - - - - -	3½ „	„	„
Burns, Davis, and Le Roi - -	3¼ „	„	„
Barlow (Essays) - - - -	2¾ „	„	„
Busch (Berlin) - - - -	2½ to 3	„	„
Ritgen - - - - - -	2	„	„

The lowest limits of the second class of pelves involves a great difference of opinion as to the lowest space required for the safe performance of craniotomy: —

	Conjugate.		Transverse.
Ramsbotham - - - - -	1⅜ ins. or	by	3½ ins.
Osborne, Hamilton, and Gardien -	1½ „	„	3 „
Davis and Barlow - - -	1½ „	„	1½ at inf. outlet.
Baudelocque - - - -	1⅔ „	„	„
Burns, Hull, and Churchill -	1¾ „	„	„
Dewees - - - - -	2 „	„	3½ ins.

In these cases, according to Ramsbotham, it is rare that the transverse diameter does not exceed three inches. Less room is required if the brim alone be distorted, according to the same author.

All pelves contracted in their diameters below the measurements given in the last list may undoubtedly be considered to require, for the delivery of a fœtus of viable or full-grown size, the abdominal section.

Dr. Robert Lee, however, advocates strongly, and with great justice, the propriety of inducing abortion in these deplorable cases, as a means of saving the life of the mother. When the sacro-pubic diameter is below 1½ inch at the brim, this author considers that abortion should be induced before the fifth month. According to Ritgen, labour should be induced in the twenty-ninth week, when the sacro-pubic diameter is 2 inches 7 lines; in the thirtieth week, when it is 2 inches 8 lines; in the thirty-first, when 2 inches 9 lines; in the thirty-fifth, when 2 inches 10 lines; in the thirty-sixth, when 2 inches 11 lines; and in the thirty-seventh, when exactly 3 inches. When above 3 inches, the case should be left to nature. Barlow thinks that premature labour should be induced when this diameter is contracted to 2½ or 2¾ inches.*

But in many cases, especially on the Continent, a much less degree of contraction of the conjugate diameter has been thought sufficient to justify the Cæsarian operation. In a table given by Velpeau†, out of sixty-two cases where narrowness of the conjugate diameter was the reason adduced for adopting this operation, in one case it was 1 inch only; in eight cases, 1½ inch; in twenty-three cases, 1½ to 2 inches; in twenty-five cases, 2 to 2½ inches; and in five cases, 2½ to 2¾ inches. These, without doubt, include many which the British practitioner would place in the first of the foregoing classes, and were adopted with a view of saving the child's life, at an additional risk to the mother.

The "pelvis oblique ovata," or obliquely contracted pelvis. — This form of pelvic distortion was first distinguished and accurately described by Naegele, the distinguished Professor of Midwifery at Heidelberg, as possessing the following characteristics (*see fig.* 123.): —

1. Complete ankylosis of one of the sacro-iliac joints, with coalescence of the sacrum and ilium, generally leaving no cicatrix nor line of junction.—2. Arrest of development, contraction of the lateral mass, and diminution of the foramina, on the ankylosed side of the sacrum. —3. Narrowing of the innominate bone of the same side, shortening and also flattening of the linea innominata, contraction of the sacro-sciatic notch by the ankylosis, and contraction of the lateral parts of the sacrum and ilium composing the sacro-iliac junction. —4. Shifting of the sacrum towards the ankylosed side, and twisting of its anterior surface in the same direction, together with removal of the pubic symphysis towards the opposite side, so as to be no longer placed in the median line opposite to the sacral promontory, but obliquely directed towards it; a direct forward line from the promontory falling on the superior pubic ramus, between the symphysis and acetabulum, its distance from the former varying with the degree of distortion. The bodies of the lower lumbar vertebræ are also, more or less, turned towards the ankylosed side.—5 On the ankylosed side, the inner wall of the pelvis, both before and behind, is less excavated and flatter than in the normal pelvis. —6. On the side free from ankylosis also, the form deviates from the normal shape, although at first sight it appears healthy. On placing together the corresponding non-ankylosed sides of two of these pelves, separated at the symphysis and in the median line, in which the right and left sacro-iliac joints respectively were ankylosed, Naegele found the pubic bones widely divergent from each other. So that, on this side also, these pelves are abnormal, not only in direction, but in form also, being curved less behind and more in front, than in the normal pelvis. — 7. From this it follows, that the obliquely deformed pelvis is contracted in the diameter which extends from the normal sacro-iliac joint to the opposite acetabulum; while it is *not* contracted, but sometimes, according to the degree of distortion, even widened in the diameter, from the ankylosed joint to the acetabulum of its opposite side. The superior pelvic aperture thus presents the appearance of an *oblique oval* (or oblong), the longest diameter of which corresponds to one of the oblique pelvic diameters, and the shortest to the other oblique diameter. From this appearance of the brim he was led to apply the name above given. That the sacro-cotyloid distance, and also that between the apex of the sacrum and the sciatic spine, is smaller on the ankylosed side than on the other. That the distances between the sciatic tuberosity of the ankylosed side, and the posterior superior iliac spine of the opposite side, and also between the last lumbar spine and the anterior superior iliac spine of the ankylosed side, are less than the like measurements on the opposite side. That the distance between the lower border of the pubic symphysis and the posterior superior iliac spine, is greater on the ankylosed side than on the other. That the walls of the pelvic cavity converge towards the outlet in some degree in an oblique direction, and the sub-pubic arch is more or less narrowed, and turned towards the thigh of the ankylosed side. That the contraction of the sacro-sciatic notch, and the approximation of the sciatic spines, is proportionate to the degree of distortion. And, lastly, that the acetabulum of the ankylosed side is directed more forward than normal, and the opposite one almost directly outward. In most cases, the sciatic tuberosity, and the acetabulum of the ankylosed side, were more elevated than the

* Essays, p. 354.
† Traité des Accouchements, p. 457.

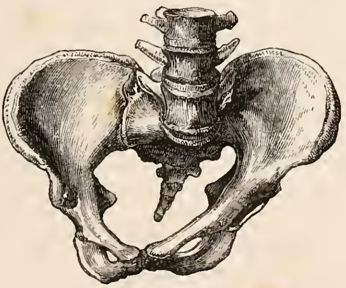
opposing ones; the ankylosed innominate bone appearing as if pushed upwards.

A remarkable peculiarity of this deformity is, that, with the exception of the difference in the side where the ankylosis had taken place, the pelves affected with it were extremely like each other. The strength, texture, and appearance of the bones were perfectly healthy; there was no limping gait observed in the patients affected with it; nor any history of accident, rickets, or malacosteon.

Examples. — Naegele collected, with incredible industry, notes of thirty-five examples of this disease in female pelves, and two in male pelves. Of these, two (one male and the other female) were in the collection of Professor Montgomery, of Dublin, and the others in the various collections of France, Germany, and Italy.

In one case, which was observed during life by the author himself, he observed a slight halt in the gait of the patient, who otherwise was apparently well-built, healthy, and active. In her first labour, at the age of eighteen years, the fœtal head in the early stage was found placed very high, and easily moveable, and the sacral promontory could not be reached by the finger. The patient was delivered, on the third day, with extreme difficulty by the aid of the forceps, and died fifteen days afterwards from puerperal fever. The pelvis was found affected with the oblique deformity, but in strength, weight, and texture perfectly healthy (*fig.* 123.). The sacrum was

Fig. 123.



Pelvis obliquè ovata. (*After Naegele.*)

composed of four pieces only, and measured in length 2 inches 11 lines. The coccyx had six pieces, and measured 1 inch 10 lines. The left sacro-iliac joint was ankylosed, and the same side of the sacrum was shrunk and contracted, so as to measure from the sacral promontory to the usual position of the sacro-iliac joint, only 1 inch 4 lines; whereas the same measurement on the right side amounted to 2 inches 2 lines. The length of the left iliac crest was 3 lines less than that of the right. From the sacral promontory to the left superior anterior iliac spine measured only 3 inches 11½ lines. The same measurement on the right side amounted to 5 inches 4 lines. At the *brim* of the pelvis the measurements were:—

	in.	lines.
From the sacral promontory to the upper border of the obliquely placed symphysis pubis - - - -	3	9
Left oblique diameter -	4	7
Right, ditto, ditto - -	3	5
From the sacral promontory to left acetabulum - -	1	10
From ditto to right acetabulum	3	6

A direct line drawn forward from the sacral promontory cut the left pubis at the junction of its superior and inferior branches, an inch external to the centre of the pubic symphysis. In the pelvic *cavity* the measurements were:—

	in.	lines.
From the centre of the sacrum, to that of pubic symphysis -	4	4
Between the cotyloid walls -	3	11
„ „ ischial spines -	2	11½

At the *outlet*, the measurements were:—

	in.	lines.
Between the sciatic tuberosities	3	0
„ lower border of the pubic symphysis and apex of sacrum	4	4

The lowest oblique diameter in these pelves described by Naegele, was found in one in the Museum of the Hospital of St. Catherine at Milan, in which the left oblique diameter was 2 inches 10 lines only; while the right was 4 inches 6 lines. In the same pelvis, the right sacro-cotyloid measured only 1 inch 8 lines; and the left 3 inches 1 line. In one case, the left, and, in another, the right sacro-cotyloid diameter, was as low as 1 inch 6 lines. In one instance, the distance between the tip of the coccyx and the tuber ischii of the ankyloid side, was only 1 inch. The left side was the one most frequently affected by the ankylosis, but the right side was also found affected in many of the specimens, and, among others, in the pelvis of an Egyptian female mummy.

In addition to the foregoing, three female pelves are described by the same author, in which the oblique deformity was present, but the diminution of the diameters not so great as to produce any great obstacle to parturition.

One of these is in the Museum of St. Bartholomew's Hospital, and is rather above the medium size. The right side of the sacrum is imperfectly developed. The left oblique diameter is nearly 11 lines less than the right; and the right sacro-cotyloid distance, 10½ lines less than the left. A line drawn directly forward from the sacral promontory cuts the right pubis 1 inch external to the centre of the symphysis; and the distance from the sacral promontory to the symphysis is 4 inches 10½ lines. One of them, in Naegele's own collection has six instead of five sacral pieces.

In none of these three pelves, however, is there ankylosis of either of the sacro-iliac joints, although the imperfect development of one side of the sacrum is evident.

In a male pelvis, on the contrary, there was ankylosis of the right sacro-iliac joint, but no atrophy of that side of the sacrum, though the oblique deviation was present in a small degree, the right innominate bone being a little more elevated, contracted, and flattened than the left. The whole appearance of this pelvis bore somewhat a resemblance to that of an animal, and presented on the posterior part of the external surface of each iliac wing a remarkable protuberant growth of bone, as well as an articulation by fibro-cartilage between the left lateral mass of the sacrum and the transverse process of the last lumbar vertebra, which was unusually large.* This last peculiarity was also observed in an obliquely deformed female pelvis in which both the last transverse processes were enlarged and bifurcated; the right being articulated by fibro-cartilage to the corresponding lateral mass of the sacrum, and the left (the side on which the sacro-iliac coalescence existed) similarly articulated to the inner surface of the ilium just above the sacro-iliac junction.†

As a contrast to specimens like the two last, Naegele mentions a well-built female pelvis, in which the left lateral mass or side-piece of the sacrum was, by arrest of development, diminished to the size and appearance of the last lumbar transverse process, but presenting an osseous protuberance, about the size of a bean, as if of the aborted ossific centre, while that on the right side was quite normal in size and appearance.‡

He had seen two others similarly deformed, and mentioned examples in the collections of Sebastian at Groningen, and Vrolik at Amsterdam, and many more in the Pathological Museum at Paris, and others mentioned by Creve and Retzius. Such irregularities of the sacrum are not uncommonly found.

A young female pelvis is described by Dr. Knox § as presenting an example of the obliquely deformed pelvis in an earlier stage. The right half of the sacrum is more than half an inch narrower than the left, the first piece not ossified to the second, and the corresponding half of the pelvic inlet proportionably smaller, the pubic symphysis being opposite the right sacral foramina; but the iliac portion of the innominate bone is tolerably symmetrical, and there is *no* sacro-iliac ankylosis. The lumbar vertebræ present an extensive lateral curve. The same author also mentions that in Dr. Campbell's Museum there is a complete specimen of the obliquely ovate pelvis, deformed on the left side, and presenting a large exostosis on the last lumbar vertebra. In his own possession he has portions of two other pelves, both exhibiting ankylosis of the sacro-iliac joint on the left side, but in one partial only, with twisting of the sacrum and contraction of the ilium, such as would produce, if the specimens were entire, the oblique deformity of M. Naegele. On looking over a collection of human bones taken from an old London graveyard, I have lately met with a well-marked specimen of this disease on the right side, in which there is a line or cicatrix at the sacro-iliac point of coalescence.

From the many specimens which had come under his observation in so short a time, and with but few opportunities of seeing them, Naegele was led to conclude that this deformity occurred pretty frequently.

Its *influence* upon parturition will present an obstacle, not only to the forward progress of the fœtal head, but also to its proper rotation, which will vary with the general extent of the pelvic diameters. If the pelvis be of large size, this deformity, though great, will have less influence than in a smaller pelvis, with a less degree of distortion. The fœtal head may enter the brim with its long diameter in the long oblique diameter of the distorted pelvis; but when in the pelvic cavity it will not be able to make the requisite turn into the antero-posterior diameter of the outlet, and will generally, in the opinion of Naegele, require the use of the forceps to extract it.

The obstruction occurs in the first labours, and its importance may be considered as equal to those resulting from rickets and malacosteon, when it is considered, that in all the cases of labour hitherto published, where this deformity has been present, both mother and child have been lost, although in the hands of the most experienced accoucheurs.

The *diagnosis* of the oblique distortion by the usual measurements is very difficult. It is rendered still more difficult by the absence of any history or peculiar appearance of the patient, indicative of the condition of the pelvis; persons affected with it being usually, in other respects, well built and healthy. The diagnosis, moreover, is usually called for in first labours. The promontory of the sacrum is not to be felt by the finger, an usual indication of plenty of room at the brim; and yet there may be sufficient contraction in the oblique or sacro-cotyloid diameters, to require the Cæsarian section. The antero-posterior diameter, which would show, if a section were made in the centres of the sacral-promontory and pubic symphysis, a clear space of 3½ to 4 inches, may appear, in the living subject, to be contracted to 2½ inches. The contraction of this distortion is as totally unrecognisable by the use of Baudelocque's calipers, which may lead to gross error.

The amount, in the well-formed female, of the measurements instituted by Naegele for the purpose of ascertaining the presence of this deformity upon the living subject, have been given in a former section of this article. The results of the measurements of eight female pelves obliquely deformed, in five of which the ankylosed joint was that of the left side, gave the following *differences* in measurement between the two sides.

* Tafel xi. Das Schräg Verengte Becken.
† Num. 10., tafel iii. Op. cit.
‡ Heidelberg Klin. Annal., vol. x. p. 468.
§ Med. Gazette, vol. xxxii. p. 537.

	Extremes of difference between the two sides.
1. From the sciatic tuberosity of one side to the posterior superior iliac spine of the other	from 1 to 2 inches.
2. From the anterior superior iliac spine of one side to the posterior superior of the other	from 10 lines to 1 in. 11 lin.
3. From the spine of the last lumbar vertebra to the anterior superior iliac spine	from 8 lines to 1 in. 4 lines.
4. From the trochanter major of one side to the posterior superior iliac spine of the other	from 1 in. to 1 in. 7 lines.
5. From the lower border of the pubic symphysis to the posterior superior iliac spine	from 7 lines to 1 inch.

In these measurements it is to be remarked, that the *first* presents the most marked differences on the two sides. This results from the fact that the sciatic tuberosity of the ankylosed side is placed more posteriorly than the opposite one, while the posterior superior iliac spine is lower on the side free from ankylosis. Hence it results that *the ankylosis is always found on that side of which the sciatic tuberosity is nearer to the opposite posterior superior iliac spine.* These two points on a lean subject are easily to be distinguished. On the fat subject, there is, in the position of the iliac spine, a depression caused by the firmer attachment of the integuments to the bone at that place.

Another test of the presence of the oblique deformity practised by Naegele was, to place the patient upright with the back against an even wall, so that the shoulders and nates should equally touch it, and then dropping two plumb-lines, one from the spine of the first sacral or last lumbar vertebra, and the other from the centre of the lower border of the pubic symphysis. In the well-formed pelvis, the plane in which these two lines fall, forms two right angles with the plane of the wall, but in the pelvis obliquely deformed, it is an obtuse angle on the ankylosed side, and an acute angle on the side opposite; the difference between these two angles marking the degree of distortion.

Cause of the obliquely deformed pelvis. — Dr. Naegele was inclined to the opinion that the cause of this peculiar condition of the pelvis was, an *arrest of development* of one side of the sacrum and the corresponding innominate bone; with ossification of the joint instead of its normal development. The following reasons led him to this conclusion. The intimate and complete fusion of the bones into one piece; and the absence of any mark or cicatrix indicating a former separation, except a scarcely perceptible line on the upper aspect of the place of junction; a section of the ankylosis exhibiting an uniform areolar texture in the internal structure. The defective development, *in its whole length*, of the ankylosed side and lateral mass of the sacrum, as well as of the innominate bone in breadth, as particularly exhibited in the narrowing of the sciatic notch; and the analogy herein drawn, from the defective development and fusion of other bones, especially those of the cranium. The great resemblance between the several pelves affected by this disease, which argues identity of cause; original deficiency of development being more likely to produce similarity of results than the accidental and subsequent inflammation. And lastly, the presence of the distortion from the earliest period, together with the youth of the individuals affected, and the total absence of any symptoms whatever, indicating an external cause for the distortion, in the whole course of their history.

In two of the cases of this deformity, there had been present disease of the hip joint, which in one had led to the formation of a false acetabulum; but this was not, in the opinion of the above-named author, the cause of the oblique distortion. He had never seen the distortion coincident with rickets, though he suggests the possibility of such a complication.

Rokitansky also considers this deformity to be a congenital malformation, and not a consequence of fœtal intra-uterine disease.

Dr. Knox adopts the theory that the arrest of development having taken place while the ossification of the sacrum was incomplete, the whole of that side of the pelvis remains thereafter stationary in its fœtal or brute transitional form, while the other advances to complete development; and thus one side is perfect, while the opposite is simply that of an undeveloped pelvis magnified. This anatomist also states, that in the museum of Dr. Outrepont there is a female pelvis presenting the oblique deformity on *both* sides, producing a superior opening of a very elongated shape, with its broadest part towards the sacrum.

The lateral epiphysial sacral pieces, which form the auricular surface, appear in the oblique deformity to have failed in establishing a separate identity, though the presence of the sacral holes and transverse lines and grooves lead to the supposition that the number of the primary ossific points has been normal. Under this supposition, the coalescence of the sacrum and ilium would, probably, take place between the sixth and ninth months of intra-uterine life, (at which time the *characteristic* ossific points of the three first sacral vertebræ begin to appear,) by the prolongation into them of the ossifying process from the ilium or "pleurapophysis," already considerably advanced in its bony development.

Another hypothesis as to the cause of the ankylosis, is found in the occurrence of inflammatory disorganisation, after the complete formation of the sacro-iliac joint, and, as a consequence, oblique deformity of the bones. Dr. Rigby inclines to this theory, and thinks that ulcerative absorption must have existed in the joint, though probably in early life.

Since we know that the fœtus in utero is subject to similar pathological changes to those of childhood, it seems probable that a modification of the two theories may be the true statement of the origin of this formation —viz., an occurrence of inflammation and the pathological changes usually consequent upon this process in joints—such as ankylosis, happening at a period of immaturity, coincident with, or consequent upon, an arrest of development in the structures implicated, and probably having the same ultimate cause. The three cases before quoted from Naegele, in which the deficiency of the sacrum and the oblique deformity existed, but without the ankylosis, and on the other hand, the many cases in which we have ankylosis on one or both sides without the oblique deformity, show that the two conditions may occur separately and independently of each other. These cases also prove beyond a doubt, that the sacro-iliac ankylosis of itself does not produce the deformity; and, moreover, that it is not absolutely an essential, although a frequent accompaniment of this peculiar formation.

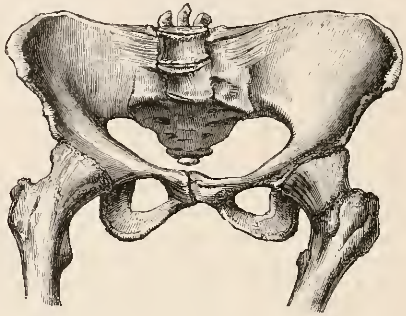
A third supposition alluded to by Naegele, that the ankylosis and oblique distortion is caused by increased pressure from the lateral divergence of the vertebral curve in early youth, seems to be contravened by the fact, that such a pressure does not produce such a result in the many instances of other pelvic deformities. The tendency to an unsymmetrical one-sided distortion in the instances before alluded to, presents many differences to, and more variations of form than, the deformity under consideration.

The *mechanism* of this deformity in respect to the line of gravity of the body falling nearer to the acetabulum of the ankylosed side, and so throwing the weight of the body more on to the corresponding leg than on its fellow, will present some similarities to that of the one-sided pelvis just mentioned; with this exception, that the bones of the obliquely ovate pelvis are healthy and not softened, and that the lateral pelvic arch is, consequently, flattened only, and not indented, the principal yielding and inward bend appearing to take place at the abnormal sacro-iliac junction, and thus the antero-posterior diameter—*i. e.* from the sacral promontory to the pubic symphysis—is increased and not diminished.

Another form of unsymmetrical pelvis is described by Rokitansky, arising from a *coalescence* of the base of the *sacrum* with the body and transverse process of the *last lumbar vertebra, on one side the median line only*, and the participation of the latter in the formation of the sacro-iliac joint on that side. The innominate bone thus obtains a higher degree of elevation, and a greater inclination to the spine, and describes a larger and shallower curve of the "linea innominata" than its fellow. The conjugate diameter is rendered greater, and there is a larger capacity on the abnormal side of the pelvic cavity. There is but slight projection of the sacral promontory, and the lumbar vertebræ are rotated, and their curve inclines to the *opposite* or smaller side, and may thus produce a lateral compensating curve in the thoracic region. In this latter particular, also, this form of pelvic distortion differs from that described by Naegele, in which the lumbar curve is towards the *abnormal* side.

I have met with two pelves presenting this abnormality. In one, that of a *female*, which is in the collection of Dr. A. Farre (*fig.* 124.)

Fig. 124.



Oblique pelvis from sacro-lumbar coalescence.

the *left* half of the sacral base is ankylosed to the corresponding side of the body and transverse process of the last lumbar vertebra, which are flattened and enlarged so as to assume the form of the first sacral, leaving a hole for the transmission of the last lumbar nerve. The lumbar transverse process of the opposite side is bifurcated, the lower division being attached by ligament to the venter ilii; and the corresponding half of the sacro-lumbar fibro cartilage remains unossified. The last lumbar spine and laminæ are connected with the sacrum by very thin plates of bone, but preserve their own distinct outline. There is *no* ankylosis of the sacro-iliac or lumbo-iliac joints. The true sacral promontory projects little, but a prominent false one is formed by the last lumbar vertebra. The sacrum is short and small, but presents four distinct sacral holes, and five pieces. The lower part of the sacrum presents an abrupt forward curve, so as to leave, with the shortness of the whole bone, little room for a fœtal head, which would, probably, require craniotomy in such a pelvis. There is a slight lumbar curve to the right or opposite side to the lumbar abnormality. The pubic symphysis, also, is removed about $\frac{1}{2}$ or $\frac{3}{4}$ of an inch to the *right* of the median line.

The other pelvis is that of a *male*, in the Museum of King's College. In this pelvis, there is complete ankylosis of both the proper sacro-iliac joints, preserving behind pretty much the outline of the sacro-iliac ligaments; and partial ankylosis of the abnormal lumbo-iliac junction, which is also on the left side. The true sacrum is large and well formed, and the posterior crest is connected with the last lumbar spine by a thin plate of bone. There is, apparently, no lateral spinal curve in this specimen.

Whether these pelves and those mentioned by Rokitansky are not similar to those described by Naegele as arrest of development of one side of the first sacral bone, is a question which can only be decided by absolute comparison of the specimens.

A greater or more advanced development of one side of the pelvis than the other is said by Knox, in a memoir "On the Statistics of Hernia," to be frequently seen, and to produce a greater predisposition to hernia on that side. The author considers it as the result of a similar want of balance between the development of the lateral halves of the pelvis to that seen, in a greater degree, in the "*pelvis obliquè ovata*," and which is also often seen between that of the true and false pelvis.

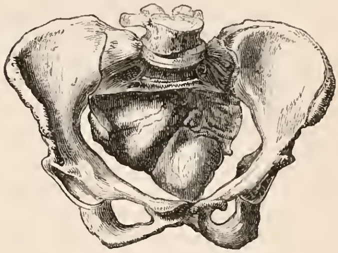
Pelvis obstructed by exostosis.—Exostoses projecting from the pelvic bones most usually proceed from their internal surfaces, in which position they are also of more serious importance in producing obstruction to parturition in the female. According to Ramsbotham, it is a rare condition of the pelvis, he having never seen an instance. Exostoses are most frequently found at the back part of the pelvic cavity, growing from the sacrum, near the sacro-iliac joint, or, according to Lever, at the last sacral piece. They are, however, by no means confined to these positions.

Many instances of this disease have been recorded, in which the diagnosis has not been verified by post-mortem examination; and it is doubtful whether many of them were not projections of the sacral promontory and lumbar vertebræ, as in a case described by Nagel in the *Frankfurter Zeitung* (April, 1778). It has been observed in the male as well as in the female pelvis.

One of the most remarkable cases of *exostosis* of the *sacrum*, producing obstruction to parturition, occurred to Dr. Haber, and is recorded in Naegele's *Inaugural Dissertation*, published at Heidelberg in 1830. The disease was said to have followed a fall while the woman was carrying a load on her head, and which was followed by pains in the back and pelvis. On afterwards becoming pregnant, the whole of the pelvic cavity was found to be filled by a bony tumour growing from the upper part of the sacrum. The Cæsarian section was performed; and the patient died soon afterwards. The tumour was found to be 7 inches long by 6 in. broad, reaching as high as the junction of the 3rd and 4th lumbar vertebræ and as low as from about 2½ lines from the apex of the sacrum. Between it and the posterior surface of the pubes there was a space of 8 or 10 lines in one part, but only a line and a half in another, the mass thus filling up nearly the whole of the pelvic brim. A section of the tumour showed large cells in the interior, communicating freely with the sacral areolæ.

Another remarkable case is recorded in the Edin. Med. and Surg. Journal (April, 1831), for which hysterotomy was performed by Dr. M'Kibbin, Surgeon to the Lying-in Hospital, Belfast. The patient had suffered a fall on the back when about six or eight years of age, which was followed by pains in the sacral region for a short time afterwards. The exostosis was of a conical form, with the base at the sacrum (see *fig.* 125.), and occupying its whole breadth at about the four lower sacral pieces, its apex projecting towards the pubis, and leaving a space of only 1⅛ inch between it and the lower part of the pubic

Fig. 125.



Exostosis of the sacrum.

symphysis. The greatest space was left opposite the superior ramus of the right pubis, where the distance of the tumour from the pubic wall was from 1¼ to 1⅝ inches, but diminished posteriorly. The patient died soon after the operation; nor was the child saved.

A less formidable case came under Dr. Murphy's observation. The tumour was about the size of an orange, and was connected to the sacrum about its middle. It was quite immoveable, and of bony hardness. The patient being in labour, craniotomy was performed; and the case did well. Another case is recorded by Van Doevern, of an osseous tumour, of the size of half a hen's egg, growing from the upper piece of the sacrum, and causing the death of both mother and child.

Dr. Kyle, of Cologne, met with a case of a woman who had borne seven children with great ease; but at the eighth labour the fœtal head became impacted by a hard immoveable tumour, as big as a hen's egg, springing from the upper part of the right *sacro-iliac joint*, being apparently the result of a pelvic abscess after the last delivery, which had, three years before, opened in the groin.

Dr. Lever has seen but one case of pelvic exostosis. It occurred in an unmarried female lunatic, and grew from the posterior surface of the *pubis*, producing retention of urine.* Lassus describes processes of bone, of a styloid shape, projecting from the posterior surface of the pubis towards the bladder.† These resulted, apparently, from ossification of the anterior ligaments of that viscus. Besides these, an exostosis is mentioned by Velpeau (*Tocologie*), protruding from the posterior surface of the right pubis, and of the size of a hen's egg a little flattened; and others by Pinæus, Ruleau, and Portal, from an ankylosed symphysis pubis.

One is alluded to by Naegele, which was as

* Guy's Hospital Reports. No. 14, April, 1842.

† Pathologie Chirurgicale (Paris, 1805, chap. 80.).

large as a filbert, projecting from the *ischium* into the pelvic cavity; and others in the same situation by Dr. Campbell and Otto of Breslau, in which indentation of the fœtal head was produced. Other cases are found in Siebold's *Journal* and Gardien's *Traité*.

Dr. A. Farre informs me that an osseous exudation from the anterior surface of the sacrum, consequent upon disease of that bone, had recently occurred in his practice, and compelled him to have recourse to craniotomy to accomplish delivery. Osseous projections at or near the sacro-iliac joints are also mentioned by Rokitansky, and are to be met with in most museums of pathology. In a large female pelvis, in the King's College museum, is a small exostosis or spinous projection at the angle of the left sacro-iliac joint, in such a position as would produce an impediment to labour in a smaller pelvis. In the Hunterian Museum are two more specimens of this kind, both on the sacro-iliac joint, one in a male, and the other in a female pelvis. Many such exostoses are seen in the subjects brought to the anatomical rooms. They seem to have the same origin as the rheumatic bony projections which are so frequently met with, in old people, in the neighbourhood of the joints, but especially in those of the spine, hip, and shoulder. Rheumatic and gouty patients seem to be predisposed to exostosis.

The *influence* of such exostoses upon parturition approaches closely to that of deformed pelvis, in the contraction of the diameters and the danger or impossibility of their removal.

The difficulty of distinguishing them, when of considerable size, from pelvic deformities, is sometimes very great. Their hardness is not so characteristic as to mark them from the projections of the sacral promontory; their shape, compared with external measurements and the history and appearance of the patient are the chief means of diagnosis.

Osteo-sarcomatous tumours sometimes produce pelvic obstruction, and generally grow from the joints or ligaments. One case occurred to Grimmell of Kisbaden, and is recorded in a letter to Naegele (Dec. 1835). Cæsarian section was performed in consequence of a tumour of this kind, weighing $1\frac{1}{2}$ lb., attached to the periosteum only of the right sciatic spinous process and wall of the corresponding acetabulum. It had followed a fall, which had been succeeded by pains in the sacrum, a sense of weight in the right thigh, and ischuria. Stark performed hysterotomy successfully for a tumour attached to the lower sacral vertebræ and innominate bone. It was immoveable, but *soft* in various parts, as well as could be detected "*per vaginam*."

This characteristic will distinguish these tumours, in diagnosis, from exostosis; their partial hardness, from fibrous tumours; their immobility, from tumours of the soft parts; and their attachments to the side of the pelvis, from the fœtal head.

Obstructions from fibrous tumours attached to the pelvic ligaments. These are of rare occurrence, and have been found chiefly connected with the sacro-sciatic ligaments.

The most remarkable examples are those related by Dr. Drew in the *Edin. Med. and Surg. Journal* for 1805 (vol. i. p. 20). The first of these tumours was taken from the body of a woman, who had died in consequence of its pressure upon the pelvic viscera. It was 16 inches in circumference, of a hard, gristly texture, with no appearance of vascularity, and was attached by a strong root, of the same texture, to the left sacro-sciatic ligaments, and interposed between the bones and viscera, but with no other attachment to the surrounding parts. The second tumour was excised by Dr. Drew, by a formidable operation, from the pelvis of a woman in labour, who was afterwards safely delivered and recovered perfectly well and very speedily. The tumour was 14 inches in circumference, and weighed 2 lbs. 8 ounces. It grew from the right side, and filled the whole cavity of the pelvis so completely as to admit of one finger only being passed between it and the pubis, considerably interfering with the neck of the bladder and urethra. It was separated easily from the circumjacent tissues.

A somewhat similar case is related by Dr. Burns; but, in this instance, the attachments of the tumour were much more extensive; reaching from the pubic symphysis to the sacrum, and adhering intimately to the pelvic brim, being attached also to the obturator internus muscle, urethra, vagina and rectum, and apparently developed in the recto-vesical fascia. It was hard, somewhat irregular, and scarcely moveable. The patient being in labour, Dr. Burns, by a bold operation, in which but little blood was lost, removed the tumour, which required to be almost dissected out. The woman was soon after safely delivered of a still-born child, and, after some peritoneal inflammation, recovered.

Fibrous tumours attached to the pelvic parietes are distinguished from the fœtal head and tumours of the soft parts, by the immobility of their attachments; from exostoses, by their want of bony hardness; and from osteo-sarcomatous tumours, by their uniformity of structure to the sense of touch.

Carcinomatous growths commonly affect the bones of the pelvis, by advancing from the contained viscera, the uterus, rectum or ovaries. Dr. A. Farre mentioned to me a case in which the innominate bones were so much infiltrated by cancerous matter, from a tumour commencing in the uterus, that they could, with great ease, be cut with the knife, presenting a condition very similar to the bones affected with *mollities ossium*.

Pathology of the Pelvic Joints. — The pelvic joints, like all other joints in the body, but much less frequently than many, are subject to inflammation and its consequences in such structures—viz., ulceration, suppuration, and ankylosis. They are also, probably more frequently, subject to original malformation, coalescence, and anomalous constructions of a congenital origin.

Ankylosis is the most frequently seen in the sacro-coccygeal joint. It is also met with in the sacro-iliac, and sometimes, but most rarely, in the pubic symphysis. Ankylosis of the *coccyx* is one cause of pelvic obstruction and protracted labour, and as such has been before adverted to. Meckel describes ankylosis of the coccyx to be more frequent in males than in females, particularly in such as have long-continued equestrian habits.

Coalescence of the bones composing the *sacro-lumbar* articulations have been before described as producing deformed pelvis. This formation almost universally results from an original aberration of development, and not from ankylosis as a subsequent pathological result. Sometimes it occurs on both sides with hypertrophy and transformation of the last lumbar transverse process. In many of the instances recorded of six sacral pieces, and in the pelvis drawn after Murphy (see *fig.* 113.), a complete coalescence of this kind probably existed.

Ossification of the *sacro-iliac* joint has also been referred to in connection with the "*pelvis obliquè ovata.*" It is, however, by no means confined to pelves presenting that deformity.

In the Museum of King's College is a well-formed male pelvis, with ankylosis of the sacro-iliac joint on the left side, the bones presenting no other traces of disease or deformity.

In the experience of Rokitansky, it is rare that the bony union in ankylosis of the pelvic joints extends through the whole of the opposed articulating surfaces, but generally takes place by bridge-like processes, passing from one margin of the joint surface to the opposing margin, so as to enclose the fibro-cartilage in a kind of bony capsule. It is not ascertained whether the fibro-cartilage itself ossifies, or, as he thinks is most likely, becomes absorbed before the ossifying process from the adjacent bones. This author does not mention whether this process takes place without previous inflammation, or follows the analogy of other joints, in which pain, inflammation and absorption of the cartilages, usually precede the ankylosis. The instances of incomplete ossific union mentioned by him to be most common have most probably a *rheumatic* origin, like the smaller exostoses previously referred to, and arise from ossific deposits in the circumferential ligaments, without the interior structures being affected. Meckel describes ossification of the sacro-iliac joints as those most frequently seen, and that it most commonly occurs on the *right* side, and is to be accounted for by the greater pressure borne upon the right leg! He considers, also, that ossifications of this joint usually take place without preceding inflammation, from a gradual change in their substance and in the fibrous tissues around them.

In a specimen of ankylosed *pubic symphysis* described by J. P. Mitchell, and given by Hull in his 2nd Letter, the whole of the fibro-cartilaginous disc was converted into a smooth equable bony substance. A few other cases of complete ankylosis of this symphysis are recorded by Wagner. In a case described and figured by Sandifort*, the pubes were united on their posterior and upper surfaces by an osseous bridge in the position of the ligaments, leaving a chink between the bones in front. In the same pelvis the right *obturator membrane* was also extensively ossified, as well as a considerable portion of the right capsular ligament of the hip joint,—all these circumstances indicating a rheumatic origin. Ossification of the *ligamentum arcuatum* is also mentioned as sometimes interfering with the urethra. Cases of imperfect ankylosis of the pubic joint are also mentioned by Siebold, Voigtel, Walter, and Bonnard.† All writers agree that ankylosis of this joint is rare. Dr. W. Hunter had never seen an instance of it.

Ossification of the *sacro-sciatic ligaments* is mentioned by Meckel as sometimes existing, and even more commonly than that of the pubic symphysis. Such a condition, if present in the female during parturition, would offer great obstruction to the passage of the head through the inferior strait, from its unyielding nature, and resistance to the extension of the coccyx. It is, however, not sufficiently common to be enumerated as one of the ordinary obstacles to parturition.

A different result of inflammatory change in the pelvic joints, is that which gives rise to the *separation* of the bones at their articular surfaces. This, as a pathological process, takes place most frequently by deposits of pus, as a consequence of puerpal fever, which may entirely destroy the joint, and separate the bones. From its more exposed position and more open structure, this change has been most frequently observed in the symphysis pubis. A case of this kind is described by Dr. W. Hunter, and many others have been observed.

A more remarkable separation of the pelvic joints is to be ascribed to a *congenital* origin. It is one in which the pubic bones and with them, in a minor degree, the sacro-iliac auricular surfaces, are separated, more or less widely, and held together by a ligamentous band. Instances in which this occurs to the extent of a third of an inch, are mentioned by Professor Otto, as being pretty frequent.‡

Probably one of the most extreme cases of this kind is seen in a preparation at present in the Hunterian Museum. It is the pelvis of a woman, which was presented, as I am informed, by Mr. Mayo, of Winchester, and taken from a case which died in the infirmary of that town. The pubes are separated to the great distance of 4¾ inches; and connected by a ligamentous band of about the width, in its present dried state, of from ½ to ¾ of an inch. The pubes are more elevated than normal, with their articular extremities turned outward, and the symphy-

* Observ. Anat. Path., b. i. p. 115., tab. 8.

† Journal de Med. de Paris, 1778. t. xxxix. p.433.

‡ Compend. of Human and Comp. Anatomy.

sial surfaces forwards, by the action of the adductors and obturator externus. The lateral curvature of the sacrum is considerably flattened out, and also the cotylo-sacral rib of the ilium. The sacro-iliac joints are each opened in front, for the space of about half an inch, stretching the anterior ligaments. The great space between the pubes is evidently obtained by the flattening of the linea innominata, as well as by the shortening of the innominate bones, in breadth, and their abnormal vertical or wall-sided position. The resulting *diameters* are; — antero-posterior, from the sacral promontory to the inter-pubic ligament, 4 inches; the inter-cotyloid, $6\frac{1}{2}$ inches; and between the sciatic tuberosities, $6\frac{1}{8}$ inches. This condition, according to Meckel, is rarely met with without an analogous congenital fissure in the bladder and walls of the abdomen. Walter, however, mentions one case.*

Other *congenital abnormalities* of the pelvic bones are mentioned by Otto and Rokitansky. In the *siren* formation, the coccyx and lower extremities are entirely wanting, and the lateral parts of the pelvic bones are fused together, the outlet of the pelvis being nearly completely closed, and the parts presenting the appearance of the pelvis as we have seen it in the Cetaceans and Fishes. Their development seems to have been arrested at that period of fœtal life in which this condition is normally, though transitorily, present. In some monstrosities, the sacrum also is wanting, or one or both the innominate bones, with the correspondig lower extremities; or these parts may be stunted or coalesced.

Influence of hip-joint disease upon the pelvis. — Caries and necrosis of the pelvic bones, although sometimes resulting idiopathically, or from bedsores and abscesses in the muscular sheaths or lymphatics, yet chiefly occur as the consequences of *coxalgia*, and have a tubercular origin. The formation of false acetabula and the other pathological results of this disease or accidental malposition belong more especially to the pathology of the Hip-joint.

A preparation of one of these in the Hunterian Museum may be, however, appropriately described in this place, inasmuch as it would produce, if occurring in a parturient female, an obstruction to the fœtal head, analogous to an exostosis. The head of the femur has become displaced into the obturator foramen, and about it an osseous deposit has taken place, apparently in the obturator membrane, which forms a smooth dome-like projection into the pelvic cavity, corresponding in size to the head of the femur. The subject is a male one, and the carious and light condition of the bones and the irregular ossific projections, indicate the results of disease.

An interesting change in the position of the pelvic bones after hip-joint disease, is described by Rokitansky.†

* Von der Spaltung der Schambeine. Berlin, 1782.

† Pathological Anatomy, p. 259. Sydenham Society's translation.

The dislocation of the femur upwards, which is commonly the result of coxalgia, is followed by a wasting of the innominate bones, especially of the ilium. They assume a more vertical direction, and, at the same time, their inclination to the spine, as well as the lumbar curve, is considerably increased.

If this condition be present on both sides, there is general enlargement of the pelvic cavity, due partly—to a general attenuation of the bones, causing the disappearance of the projections at the pectineal eminences, the sacro-iliac joints and the cotyloid walls, and partly to a flattening out of the *linea innominata*. The ischia become dragged outwards and separated, the pelvic cavity shallower, and the sub-pubic angle more obtuse.

The last result is attributed by Hülshof to the dragging of the rotator muscles, from the displaced femur on the sciatic tuberosities, upon which the support of the trunk mainly falls in this condition of the joint. In the pelvis of a woman mentioned by Dr. Hull, however, in whom both the femurs had been dislocated backwards, the transverse diameter of the brim was diminished to $4\frac{1}{2}$ inches, and the antero-posterior diameter of the outlet was diminished to only 2 inches, from the tilting forward of the lower part of the sacrum, or rather probably, from the turning of the lower part of the innominate bones backward by the displaced femurs, acting on the axis of the sacro-iliac joints.

If the disease be one-sided only, as is most commonly the case, and the diseased joint be much used, the *tuber ischii* of that side becomes everted, the innominate bone bent outwards, the distance from the pubic symphysis to the anterior superior iliac spine lessened, and that side of the pelvic cavity enlarged. The pelvic cavity is, on the other hand, contracted on the sound side, towards which also the spinal curvature inclines, from the principal support of the body falling on that side. When ankylosis has taken place, the innominate bone is bent outward at the acetabulum, in the osseous cicatrix; the ilium is placed more inwards and forwards, and the ischium inwards and backwards; and while the pubic symphysis is drawn towards the diseased side, the sacral promontory is turned to the healthy side of the pelvis. In some instances, the pelvic inclination is less, instead of greater, on the diseased side, which is also raised higher than the other. This variation is attributed by Guerin to the action of the psoas and iliacus muscles, which sometimes in these cases impress a deep furrow upon the iliac wings, over the edge of which they play. There is no doubt, that the posture to which the patient may have been most accustomed, has a great effect in producing such differences, as already explained in the foregoing pages.

Fractures and Dislocations *of the pelvic bones.*—The *sacrum*, according to Boyer, is less frequently found fractured than the other pelvic bones, because of its thickness, strength, spongy texture, and deep-seated position. When fractures of this bone do happen, they are most commonly found at the lower part, which is less protected by the above peculiarities. They occur chiefly from direct and great violence, which generally injures also other parts of the pelvis extensively, seriously affecting the nerves of the sacral plexus, so as to produce paraplegia and retention of urine, as well as extensive injury to the soft parts, such as result in effusion of blood, peritonitis, and sloughing of the integuments. Fractures at the lower part are much more easy to diagnose than those of the upper, which are seldom discovered till after death. In the former case, the lower fragment is generally drawn forwards by the action of the great glutei and coccygei muscles, so as to press upon and interfere with the functions of the rectum, through which it may be felt by the finger. It will also produce great pain on moving the legs, which may lead to its discovery, when more serious injury is not present.

The *coccyx* when normally placed is rarely fractured, on account of its great mobility and small size. It always happens by direct violence. When ankylosed, it is more frequently broken, and instances of this have been before mentioned, in relation to the obstruction of the outlet in parturition which it occasions. It is diagnosed by the mobility and grating of the fragments, and by the pain caused by the action of the great glutei muscles. *Dislocation* of the coccyx is said to have occurred backward in difficult labours, and to have been followed by abscess, but these cases have been most probably fractures like those just mentioned.

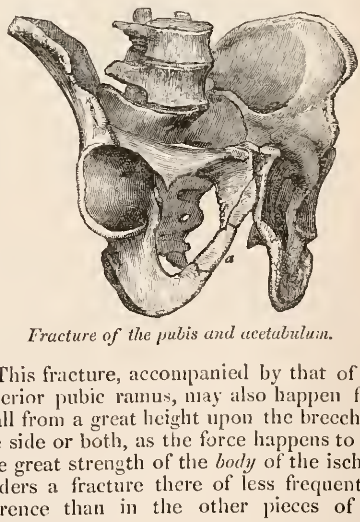
Fractures of the *innominate bone* generally occur on one side only, where the greatest part of the force has fallen, but sometimes on both. They are most frequently found in the ilium—which is most exposed, but often implicate both the ischium and pubes. They may be confined to one part of the bone ; in which case they are found chiefly about the iliac crest and wing. Boyer relates a case in which the inferior anterior iliac spine was broken off by the kick of a horse. Cases are not unfrequently seen where the anterior superior iliac spine and a portion of the crest are broken off. Sometimes they are comminuted in, and radiate from, the cotyloid cavity, such fractures generally resulting from direct violence against the lateral pelvic arch, and acting on the head of the femur so as to drive it inwards through the pelvic wall.

Fractures of the pelvis, like those of the spinal column, are seldom present without *dislocation* also of the sacro-iliac or pubic joints. This results from the circular arrangement of its bones, and from the laws of its mechanism, explained in the first section of this article. Thus, when force is applied so as to compress the pelvic circle from before backward (as commonly the cause of these fractures is such compression by the wheels of a loaded cart or other vehicle), then the cotylo-sacral arch yields inwards at its haunches,—the sacro-iliac joints, the anterior ligaments of which are torn, and the articular surfaces separated in front. At the same time the pubic tie yields either at the symphysis or in the superior rami.

The innominate bone may be entirely dislocated upward or backward, generally on one side only. A case is related by Cloquet, in which this was the case on both sides, the pubic symphysis, at the same time, separated ½ an inch, the pubis and ischio-pubic ramus were broken, and the bladder ruptured. Another case, where the left innominate bone was displaced upwards, was treated successfully by Chaussier.

The ligaments and fibro-cartilage of the symphysis pubis are usually torn, the latter generally carrying with it a portion of one of the bones ; or the superior ramus is broken at its weakest part, above the obturator foramen, or it separates from the other innominate pieces. In most cases the ischio-pubic ramus of the same side also yields at or near the point of suture, which is its thinnest and weakest part, and the obturator foramen is again penetrated. This results from the operation of the force upon the unsupported ischio-sacral arch and its tie, after the other has yielded. A preparation exhibiting such a fracture is found in the King's College Museum. In this case the superior pubic ramus has separated in the acetabulum from the other pieces of the innominatum in the line of the Y-shaped suture, while the fracture through the ischio-pubic ramus extends upwards, along the side, and into the centre of the pubic symphysis (*fig.* 126.).

Fig. 126.



Fracture of the pubis and acetabulum.

This fracture, accompanied by that of the superior pubic ramus, may also happen from a fall from a great height upon the breech, on one side or both, as the force happens to fall. The great strength of the *body* of the ischium renders a fracture there of less frequent occurrence than in the other pieces of the innominatum.

Fractures of the innominate bones seldom occur without *displacement*, produced usually—not by subsequent muscular action, which is kept in check by their balance of power, and by the extensive ligamentous and fascial attachments and the opposing fractured surfaces,—but by the original direct violence.

By such displacement of comminuted and spicular fragments in the true pelvis, the bladder and urethra, particularly if the former be distended at the time of the accident, often suffer great laceration, which may even extend to the peritoneal investments and open the cavity of the abdomen. Such extensive injuries are invariably followed by extravasation of the urine into the pelvic areolar structures or peritoneal sac; and violent peritonitis carries off the patient, even if he survive the first shock of such a formidable accident. The external soft parts, also, generally suffer greatly from the violence, and from the great extravasation of blood which usually takes place from the torn vessels. Gangrene may, in these cases, succeed to a great extent, and destroy the patient. It is these injuries, and their consequences to the soft parts and internal structures, that render fracture of the pelvis, like those of the cranium, so dangerous and fatal to life.

The *diagnosis* is drawn from the pain and difficulty of moving the lower extremities, and from the mobility and crepitus of the fragments, felt on placing the hand on the iliac crest, the pubic spine, and sciatic tuberosity consecutively and moving the leg. The crepitus is most distinctly felt by the hand which rests on the pelvic bones, and scarcely at all by that which moves the leg. This useful comparison will distinguish these fractures from those of the neck of the femur. If one ilium be dislocated upward and backwards on the sacrum, and at the same time separated from the other bones by a fractured acetabulum, the femur is drawn up with the ilium, the trochanter turned forwards, the knee and foot turned inwards, and the whole limb shortened, so as to resemble a dislocation at the hip-joint. Deeply-seated fractures, however, often pass undetected, from the rigid contraction of the muscles, the great pain experienced on motion, and fear of injuring the viscera more extensively. They will be more easy to detect on the thin subject, and on the female.

In one of the cases figured and related by Sir Astley Cooper in his Surgical Essays (plate 2. fig. 6.), the head of the femur had been driven by violence, applied laterally, through into the pelvic cavity, carrying a comminuted portion of the acetabulum with it. The fracture was Y-shaped, and had radiated from the centre of the acetabulum pretty nearly in the line of the suture,—as we have before remarked in fractures here and in the ischio-pubic ramus. A fracture near or in the latter suture also existed. The limb presented the appearance of a dislocation of the femur backwards. In another case, the posterior part of the acetabulum was broken off, the fracture passing across to the pubes, both innominate bones being broken and displaced, and the femur dislocated. The pubic symphysis was separated about an inch, the fibro-cartilage adhering to one bone only. The knee and foot were turned inwards, and the whole limb shortened two inches; but it was more moveable than in a dislocation, and crepitus was felt on cautious extension being made. In a female whose pelvis had been crushed by a cart against a wall, a fracture was found passing through the body of the left pubis and the left ascending ischial ramus. Both the sacro-iliac joints had separated, part of the osseous sacral auricular surface of the right joint having come off with the ligaments. The pubes were separated at the symphysis. Motion and crepitus were felt on applying one hand to the ilium and the other to the pubis, and the posterior superior iliac spine projected upwards considerably. Through the vagina, the pubes were felt projecting into the vaginal cavity. There was much blood effused into the pelvis, and the patient died, sixteen days after, from sloughing of the soft parts.

Otto mentions that, in the Museum of the Veterinary College at Copenhagen, are specimens of horses' pelves, fractured by excessive muscular action.

Sir A. Cooper mentions three cases of fractured innominate bone which had recovered. Two were fractures of the ilium, easily detected by the mobility of the crista and crepitus. The third was a fracture of the ischio-pubic ramus about the suture.

Rokitansky found that fractures of the pelvis rarely united without displacement. One of Mr. Barlow's successful cases of Cæsarian operation was necessitated by the results of a fracture of the left innominate bone, which produced an elevation of the head of the thigh bone, shortening of the limb, and lameness. The contraction of the pelvic diameters resulted mainly from a projection backwards at the symphysis pubis, which was supposed to be caused by ossification of the disarticulated joint, and which reached to within half-an-inch of the sacrum. Burns states that he has seen extensive pointed ossifications projecting nearly 2 inches into the pelvis, in consequence of fractured acetabulum. Naegele also mentions cases in which a bulging of the acetabulum inwards caused obstruction to parturition. Dr. Lever has also seen a bony process, more than an inch long, encroaching upon the pelvic cavity, in a male subject, after fractured acetabulum. Sometimes, after fractures of the pubis, the formation of callus has considerably interfered with the functions of the urethra. When ankylosis takes place at the sacro-iliac joint, after dislocation of the ilium backwards, the pelvis assumes a shape closely resembling the *pelvis obliquè ovata* of Naegele. A preparation of this kind is mentioned by Dr. Ramsbotham, as existing in the Museum of University College.

REPRODUCTION, VEGETABLE. (VEGETABLE OVUM.) Before the microscope was placed in the hands of the vegetable physiologist, the conditions by which he was surrounded in the investigation of the processes by which the embryo is formed, differed widely from those which exist at present. From the absence of means of observation, the phenomena of reproduction could only be studied in the Phanerogamia. Even as regards the highest cryptogamous plants, very little had been ascertained; while the Algæ and Fungi were involved in the most complete obscurity. But in the Phanerogamia it was already known that two kinds of organs were essential to the production of the embryo, and something had also been learnt of the mode of their combination. No sooner were these facts established, than, with a readiness of which innumerable examples present themselves in the history of physiological investigations, they were at once seized upon to serve as the ground of a comparison between the animal and vegetable kingdoms; and naturalists soon passed to the conclusion that the organs in question were of distinct sexes, or, in other words, stood in the same relation to each other as those of animals. The analogy seemed sufficient for the mind to rest upon; and the doctrine derived from it was received as indisputable.

The influence exercised by the state of things we have just described, may be traced in two directions:—In the first place, a strong tendency is even now observable in the minds of naturalists, especially in this country, to approach the subject from the same point of departure as before, when the circumstances were so different. The appearance of greater simplicity among the higher plants, was entirely dependent on conditions belonging exclusively to the observer; that is to say, on the imperfection of the means of observation. Now that so many of these imperfections are removed, to take the Phanerogamia as our starting point in approaching either this or any other general question in vegetable physiology, is evidently unreasonable; we must commence our investigation where there are fewest complications—namely, at the unicellular plants. From this point we must ascend from class to class, following as closely as may be the natural order of complexity of organisation.

A second result of the same causes is the confusion which so frequently arises in the employment of terms which are derived from the animal kingdom, such as "male," "female," "ovum," &c. As our knowledge of the subject becomes more accurate, the grounds upon which the assumed correspondence between the reproductive organs of plants and animals rests appear less substantial. The only analogies, indeed, which can possess any real value are those occurring between the lowest members of the two series. This is the only point at which the two kingdoms are in mutual contact, and consequently it is here only that an actual correspondence can be traced through successive consecutive modifications.

The subject of the following article is the origin and development of the *germ*, or, in other words, the reproduction of plants by means of germs.

Considering it as a conclusion, respecting which there can remain very little doubt in the present state of vegetable physiology, that every existing plant must have originated as a single cell, there are two modes in which this may be supposed to have taken place. In the one case, a cell originally forming a part of the tissue of the parent, and not previously distinguished in any respect from its neighbours, suddenly assumes a new activity which it did not before possess. To this change the term "Verjüngung," or, as it is rendered by Mr. Henfrey, "rejuvenescence," has been applied, and is most expressive of its nature. A cell in which there has previously been a gradual diminution in the intensity of vital manifestations, recovers the capability of development which it possessed when first formed. Now, however, the formative force by virtue of which the whole subjects the development of all its parts to its own, being abated and weakened by age, the rejuvenescent cell becomes individualised and is transformed into the rudiment of a new plant, in accordance with a capability of development, which resides entirely in itself. This process is called gemmation.

In the other case, the cell from which the new plant originates, manifests from the first moment of its existence conformity to law, on the one hand, in its anatomical relations to the organs of the parent upon which it is supported, or within which it is enclosed, on the other, in the mode in which its development commences — its transformation being the result of an activity inherent in it, not as an individual cell, but as being a part of the parent, and still under the control of its formative force. It is to this cell that the name germ is alone applicable in the restricted sense in which it is generally used; namely, as expressing not only that it will, if it live long enough, transform itself into an embryo, but that it presents itself uniformly in the same species under the same anatomical conditions.

The term "vegetable ovum," placed at the head of this article, is employed in order to connect it with the preceding one on the "animal ovum," to which it is intended to form a sequel. In its usual acceptation in vegetable physiology, the word means the generative product of the Phanerogamia only. And even if we were to extend its meaning so far as to include all those varieties of germ, for the development of which two organs mutually dependent on each other for the accomplishment of their reproductive functions are necessary, we should still be obliged to disregard one half of the vegetable kingdom.

Part I.

Algæ, Fungi, and Lichens.

1. *Reproduction by means of Zoospores.*— Among the most simply organised infusory animals are included several genera, which are admitted by all naturalists to present, in the aggregate of their characters, as many points of resemblance with plants as with animals. They agree with plants in their chemical constitution, in the mode in which they react on the atmosphere, and in their green colour. The Euglena viridis, which is so common in all our shady ponds, though in active motion during the greater part of its life, manifests at other periods a condition of plant-like repose. The contractility displayed in its rapid and ever-varying changes of form is a property which, there can be little doubt, manifests itself frequently among undoubted plants;* so that the transition from the Euglenas to many of the forms of the Protococcus-like Algæ is almost insensible. The elaborate researches of Cohn on the so-called Protococcus pluvialis, have unfolded many facts of the greatest importance in relation to this subject. The well-known permanent form of this plant is that of a globular cell, furnished with a distinct colourless membrane, and containing in its interior a semifluid protoplasma, in which numerous green or red granules are embedded. Cohn found that when water is added to Protococci in this condition, they immediately become the subjects of an active reproductive process. In the interior of each cell are formed, by the division of its contents, secondary cell-like bodies, the number of which is always either two, or a power of two. These bodies, which possess no distinct membrane, either give rise to stationary cells similar to their parent, or, as is by far more frequently the case, especially when the number of newly produced individuals is large, they become pear-shaped, fusiform, or oval; at the same time they are endowed with the power of

Fig. 127.

Cell of Protococcus pluvialis, containing moving Zoospores, about 25 diam. (Cohn.)

active motion, and are furnished with a pair of vibratile cilia, emanating from their anterior

Fig. 128.

Free Zoospores of the same. (Cohn.)

extremities. In the course of their further development, these actively moving bodies, which we shall call Zoospores, become invested with a distinct membrane. This seems to be a preparatory step to the cessation of their movements; for shortly afterwards they are observed to lose their vibratile cilia, and assume a form which corresponds more or less completely to that of the mother cell. In many cases, however, before this result is accomplished, a second reproductive process commences in the still ciliated zoospore. A division of its protoplasmic contents, similar to the first, takes place, and a second generation of zoospores is set free, each of which is capable, after exhibiting active motion for a longer or shorter period, of becoming a spherical, motionless cell, in all respects similar to the original parent. Thus an individual Protococcus in its stationary form, may reproduce itself either directly, or with the intervention of a second generation. In the former case, the germ may either become at once an individual similar to its parent, or may pass through a preparatory period, during which it is not only provided with motor organs, but manifests in the protoplasm of which it is formed, a property of contractility resembling that of animals. Facts similar to the above are described by Braun as occurring in another unicellular Alga (Ascidium acuminatum). This species, which is found attached to stones or other objects, resembles the Protococcus pluvialis in its general form. By the division of the protoplasma which lines its cell-wall, numerous zoospores take their origin. These are pear-shaped, and at the apex of each is observed a pair of vibratile cilia.

2. In the above-described plants we have examples of the occurrence of zoosporous reproduction under the most simple condi-

* The presence of contractility of the substance in true plants is still doubted by some physiologists. One of the most accessible proofs of its existence is to be found in the motions of the tapering growing extremities of some species of Oscillatoria. Here we have changes of form of the substance of the plant, rapidly succeeding each other, and developed independently of the action of any external stimulus. These motions may be observed with perfect facility and occur under the most simple conditions.

tions. In the history of their development we have an epitome of that of all the more simple Algæ. In the family of Protococci the type may be said to be included to which all the green and olive-coloured Algæ, with the exception, on the one hand, of the Desmideæ and their allies, on the other of the Fucaceæ, may be referred. Among the Desmideæ, indeed, is placed one genus, that of Pediastrum, in which the zoosporous is the only form of reproduction which has been observed. Pediastrum consists of a disc of cells, which are usually eight in number, and contain a protoplasma, which possesses a generally diffused green colour. The first step in the reproductive process consists in the separation of the protoplasma into a green and a colourless portion. The former, after collecting into a central mass, becomes divided into numerous secondary masses, the number of which is always a power of two. From the latter is formed a transparent gelatine-like investment which lines the parent cell. After the completion of these changes the original cell-wall is ruptured, and the whole contents escape in a mass. No sooner has this taken place than the corpuscles into which the green protoplasma has divided, commence an active motion in the interior of the gelatinous cell in which they are included, and in fact display in every respect the form and peculiarities of zoospores. They are not, however, as in every other example with which we are acquainted, destined to display their activity beyond the narrow limits within which they originate. In a short time their motions become languid, and finally cease, while they arrange themselves in a beautifully regular geometrical order which corresponds exactly to that of the cells that constitute the adult Pediastrum. The next change observed is the disappearance of the gelatinous membrane, and the investment of each of the zoospores with a distinct covering of its own. From this there results a disc-like body, which, in a short time, assumes all the characteristics of the original parent.*

3. Taking these simplest of unicellular plants as our point of departure, we pass to the consideration of the confervoid Algæ, many of which, though they are but little elevated above the Protococci as regards their structural elements, present a general appearance which at first sight recalls that of plants very much higher in the scale of organisation. Thus in Bryopsis and its allies, in which the tubular frond branches in the most complicated manner, the whole consists essentially but of a single cell, the cavity of which is continuous throughout. When the formation of zoospores is about to take place, all that is observed in a Bryopsis is the accumulation of the green granular protoplasma towards the extremities of the tubular branches. In these situations the cavity of the tube becomes completely filled, while at some point in the neighbourhood of each accumulation, the tube membrane becomes sacculated so as to present a nipple-shaped projection. In the meantime the accumulated protoplasma is observed to have given rise, by its division, to numerous green bodies, the forms of which cannot yet be distinguished, owing to the closeness with which they are packed together. No sooner, however, is this process complete, than a remarkable phenomenon, corresponding to that already described in Protococcus, manifests itself. The crowded zoospores, now completely developed, at once commence their characteristic motions. From this results an appearance of confused agitation, to which the term "swarming" has been applied by the Germans. A minute aperture, or pore, is

Fig 129.

a, termination of tubular frond of Bryopsis crowded with zoospores; *b*, the same, after the escape of its contents. Each of these exhibits the lateral pore; *c*, fully formed zoospores in active motion. *a* and *b* 150 diam, *c* 200 diam.

then found at the extremity of the nipple-like projection, apparently in consequence of the absorption of the cell-membrane at its apex. The zoospores now begin to escape, at first one by one, afterwards more rapidly, until at last a few only are left occupying the cavity of the tube.*

4. In the simplest forms of jointed confervoids, the frond consists of a series of cells superposed one upon the other, each of which is capable of producing zoospores independently of the rest. In the vegetative state, each contains only a green protoplasma. The reproductive process is the same in every respect as in the Bryopsideæ, the opening by which the zoospores make their exit, being situated at the upper part of the cell, immediately below the septum, which divides it from its successor. In other cases (as in Microspora), the zoospores escape by a kind of

* The development of Pediastrum has been described by Braun (Die Verjüngung in der Natur) as well as by Caspary (Botanische Zeitung, 1850, S. 786.). The description in the text is after Braun, with whom Caspary agrees in every important particular.

* Thuret, Recherches sur les Zoospores des Algues. Ann. des Sc. Nat. xiv. 217.

dislocation of the tube, each cell dividing into two in a plane parallel to the septa.*

5. The Ulvaceæ, among which the frond has no longer the form of a filament, but assumes that of a membranous expansion of juxtaposed cells, still present the same phenomena to our notice. In the cells set apart for the formation of zoospores, the green protoplasma is increased in quantity, at the same time that it becomes accumulated towards one point of the cell-wall. As the zoospores are formed, they are observed to converge with their apices towards this point. The phenomena attending their escape from the parent cell are similar to those which we have already noticed.

6. In some genera, which seem to be closely related in form and structure to the Bryopsideæ, we observe this important difference, that the zoospores are developed in an organ specially destined to this purpose, which presents peculiarities of form distinguishing it from every other part of the branching tubular frond. Thus in the genus Derbesia distinct spore cases are to be observed, the cavity of which does not communicate with that of the frond. These organs, which are of an oval form, take their origin in the same manner as the ordinary vegetative branches of which they are modifications. A young branch which is destined to become a spore case, instead of elongating indefinitely, begins, after having arrived at a certain length, to swell out into an ovoid vesicle, in the cavity of which a rapid accumulation of protoplasma takes place. The next change which occurs is the separation of this protoplasma from that of the rest of the plant with which it was before continuous, so as to give rise to an oval and opaque mass, which soon becomes surrounded by a distinct membrane. As the result of the division of this mass, a number of pyriform zoospores, each of which is furnished with a crown of cilia, are set free. Many other genera have been described by Derbes and Solier†, in which the relations of the spore cases to the frond are similar to those which exist in Derbesia, although the forms presented by the organs in question are infinitely various.

7. The researches of the authors above alluded to, along with those of M. Thuret, have shown us that in many families of the olive-coloured Algæ, the occurrence of zoosporous reproduction is no less general. The zoospores, however, although they resemble in their general form those of the plants which we have been considering, differ from them not only in respect of their olive colour, but in the arrangement of their cilia. These organs, which are always two in number, are

Fig. 130.

Sporangium of Ectocarpus siliquosus, 240 *diam.*

Ectocarpus is one of the simplest forms of olive-coloured Algæ, consisting of branching, conferva-like filaments. The extremity of any of the branches is capable of being converted into a sporangium by the absorption of the septa of the terminal cells. The zoospores are arranged in regular horizontal layers, the positions of which are indicated in the empty sporangium by faint markings of its membrane.

usually of unequal length, and emanate not from the beak, but from the reddish-coloured point in its neighbourhood. The longest is directed forwards, being closely applied to the colourless beak; while the other, which seems during the motions of the spore to serve as a rudder, assumes an opposite direction. In many genera a peculiarity exists, the signification of which is not yet completely understood—that, namely, of a double fructification. The ovoidal sporangia (*oosporangia*, Thur.), which have been frequently described as single spores, in reality contain numerous zoospores. The other form (*tricho-sporangium*, Thur.) consists of a series of small cells joined together so as to form a narrow and generally short filament. Each of the cells contains a zoospore, which, according to the observations of Thuret, is no less capable of germinating than the one produced by the oosporangium. In the genus Cutleria there is observed, for the first time, another feature of great interest and importance; namely, the appearance of two kinds of organs which seem to be opposed to each other as regards their reproductive functions. The sporangia (trichosporangia) of Cutleria, not only differ from those of other genera, in respect of their greater size, but

* In the genus Œdogonium, the protoplasma of each joint, instead of being converted into a number of zoospores, goes to form but one, which differs from those of other genera, in the first place in being considerably larger, and secondly, in presenting around its rostrum not two, but a number of cilia, which are arranged in the form of a crown. (See Thuret, *l. c.* p. 226.)

† Derbes and Solier, Sur les Organes reproducteurs des Algues. Ann. des Sc. Nat. xiv. 260.

present well-marked distinctive peculiarities of structure. The frond consists of olive-coloured, irregularly divided *flabelli*, on each

Fig. 131.

a, a portion of one of the tufts, or sori, of Cutleria, showing the mode of attachment of the filaments which support the sporangia to the surface of the frond; *s*, a ripe sporangium. Two others, half ripe, are also seen. Each is divided into eight compartments, in each of which is formed a zoospore,—200 diam.; *b*, zoospores; *c*, the same in various stages of germination; the earliest stage to the right, 300 diam.

side of which, tufts (*sori*), consisting of the reproductive organs, intermixed with hair-like bodies, are scattered at irregular intervals. The sporangia, and so-called antheridia, are borne by different individuals, but their positions and arrangements on the frond are identical. The former consist of oblong or club-shaped bodies, which are supported by hyaline pedicles, set into their inferior extremities. The cavity of each sporangium is divided by three transverse partitions into four cavities, each of which is again bisected by a longitudinal median septum. In each of

Fig. 132.

Portion of one of the sori of the male plant of the same.

The ripe sausage-shaped vesicles, which contain antherozoids, are shaded. Others are shown which have already discharged their contents, 180 diam. The transverse markings, much too distinct in the engraving, indicate a tendency to the formation of compartments similar to those which present themselves in the sporangia.

the resulting cavities, zoospores are to be found, which, though they altogether resemble in structure those of the other olive-coloured Algæ, are about three times as large. The supposed antheridia of Cutleria communicate to the tufts of which they form a part, their characteristic orange colour. The organs themselves are elongated, sausage-shaped vesicles: they contain a greyish, granular matter, in which, as the organ becomes ripe, indications may be observed of a division into several concentric layers; the more internal of these layers being distinguished from those next the surface by the greater intensity of the orange colour which they present. After

Fig. 133.

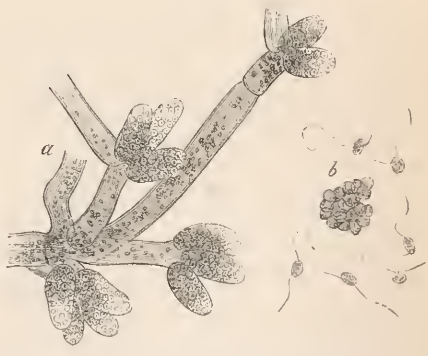
Contents of antheridium of the same, 400 diam.

Each antherozoid is an oval hyaline corpuscle, which moves in the direction of its long axis. It exhibits towards its posterior extremity a coloured granule, from which springs a pair of cilia of unequal length. The longer of the two, which oscillates rapidly, is directed forwards; the shorter, which is motionless, backwards.

the discharge of the contents of the antheridium, it may be observed to consist of a transparent vesicle, which, like the analogous female organ, is divided by transverse and longitudinal septa into eight communicating cavities.

8. With the organs last described we think we need have little hesitation in comparing the structures to which the same name has been applied, as they occur in the Fucaceæ. The fructification of these plants is, as is well

Fig. 134.



a, antheridia from the conceptacle of Halidrys siliquosa, with the filaments on which they are supported, 200 diam.; *b*, antherozoids, 400 diam.

known, enclosed in spherical cavities, situate under the epidermis of the frond, which are called conceptacles, and may be male, female, or hermaphrodite, according to the organs which they contain. The male conceptacles present in their interior an arrangement of branched filaments, or hair-like organs, which, taking their origin from the surrounding cellular tissue, converge towards the pore. At the summits of these filaments, the so-called antheridia are supported, which consist of little ovoid transparent vesicles. They contain, in their early condition, a granular protoplasmic material, but as they approach maturity, the so-called antherozoids make their appearance. These last are hyaline corpuscles, not exceeding about $\frac{1}{5000}$ of an inch in their longest dimension. Each contains a granule of a greyish or reddish orange colour, from which the organs of locomotion emanate. The form of the zoids differs according to the genus. In Fucus, they are bottle-shaped, and each possesses a pair of cilia, one of which, the shortest, is directed forwards from the neck, while the longest emanates from the coloured point and is pointed backwards. In Halidrys, the zoid is ovoid or spherical, and the longest cilium is directed forwards. In Fucus and several other genera, the transparent vesicle in which the zoids are immediately contained, is itself enclosed in a second of similar form. At the period of maturity this last gives way at its apex: the internal sack is expelled, and at once finds its way towards the external opening. In the meantime its delicate membrane disappears, and the liberated zoids commence their active motions.

9. Although the antherozoids of the Fucoideæ differ from the zoospores of the other olive-coloured Algæ, in their not possessing the power of germination, there are yet remarkable points of correspondence between them, in their form, structure, and mode of development. Both are composed of a hyaline protoplasma, and the position of the coloured granule, as well as the arrangement of the cilia, corresponds. They differ, in the first place, in size, and secondly, in respect of the chlorophylle granules, which are present in the zoospore, but absent in the antherozoid. As regards the question of their functional signification, they may be considered, on the one hand, as the elements of a male secretion, and the organs in which they are contained, as antheridia; on the other, we may look upon them as the formal representatives of structures destined in other families to the performance of functions of which they are themselves incapable. In favour of the first of these views we have no direct evidence, and must trust entirely to analogy. We know that in Cutleria and its allies, the zoospores display the power of germinating without the slightest reference to the presence or absence of the secretion of the supposed male organ. Further, if, as all observations which have been hitherto made, tend to prove, the zoospores of all the green Algæ, and of so many of the olive-coloured, normally germinate under the condition of the constant non-existence of such organs, it is difficult to see why an exception should be made in favour of those of other families in which they are present. As regards the Fucoideæ, we have certainly no evidence whatever that the antheridia perform any function, either more or less important in the reproductive process.

10. In the family of Vaucheriaceæ, the zoosporous reproduction is remarkably modified by the substitution of a single multiple zoospore, of large size, for a number of smaller ones. The frond of Vaucheria consists of a branched tube, and much resembles in general form, that of the Bryopsideæ, from which the Vaucheriæ in their vegetative condition differ only in respect of the arrangement of the chlorophylle. The commencement of the formation of zoospores is announced by the condensation of the green protoplasma in the rounded terminations of the branches of the plant. This condensation is accompanied with an enlargement of the cylindrical filament, which soon appears club-shaped, and is completely occupied by a confused and opaque dark-green mass. Shortly afterwards a septum is formed, which limits the terminal portion of the tube. Within the separate cavity thus formed, the mass of protoplasma becomes further condensed; its margin being surrounded by a clear space which intervenes between its external surface and the tube membrane. This body, which possesses an oval form, is the future zoospore. No sooner is it completely developed than the membrane which encloses it gives way at the apex, and it begins to insinuate itself through the resulting narrow opening. Having completely freed itself, it forthwith commences an active progressive motion, which is accompanied by a circumvolution round its axis. The zoospore at this period possesses no distinct or consistent investing membrane, as is evident from the fact, that if, during its escape, it divides accidentally into two — a circumstance which not unfrequently happens, from the relative narrowness of the opening through which it has to pass — each part is complete in itself and capable of germination. Its whole surface is covered with vibratile cilia, which are apparently connected with an epithelium-like structure. In this arrangement there seems to be an indication of a tendency to a division into smaller particles, by the melting together of a number of which the whole may be conceived to be formed. Like all zoospores its period of active motion is short; it soon becomes stationary and begins to germinate.* The zoospores of Vaucheria seem to correspond closely with the motionless spores of the true Dictyotaceæ (Dictyota, Padina, &c.), as well as with those of the Fucaceæ. In the case of the latter, the accuracy with which their structure and germination have been studied, has enabled us to follow out the analogy more closely. In speaking of the an-

* See Thuret, Ann. des Sc. Nat. 2^e S. xix. 269; Vaucher, Hist. des Conferves d'Eau douce, p. 246; Karsten, Die Fortpflanzung der Conferva fontinalis, Bot. Zeit. 5 Stück, 1852.

theridia (§ 8.), we described the general form of the conceptacles. In the monœcious and diœcious Fuci, the female conceptacles are distinguished from the male by their olive colour. The spores are developed each in the interior of a perispore, which is borne on a pedicle emanating from the inner wall of the conceptacle. They make their escape by the rupture of the perispore at its apex. At the moment at which this takes place, the spore is perfectly simple, except that in one or two species the surface is covered with cilia, which seem to resemble those of Vaucheria. Soon afterwards, a remarkable series of changes occurs, consisting in the splitting of the endochrome into a number of masses — usually eight — each of which becomes isolated, and finally assumes the form of a smooth and spheroidal sporule, provided with an investing membrane. About twenty-four hours after the completion of this process, germination commences. It consists in the budding out of the membrane of each sporule, at some point of its surface, into a nipple-shaped projection, which in the following forty-eight hours, elongates into a cylindrical tube; shortly afterwards the whole body of the sporule is converted by repeated division into a mass of cells, in which condition it has been by many writers mistaken for the original spore, and described as such. The Vaucheriæ present the peculiarity of a double mode of reproduction. In the earlier periods of the growth of the plant, there occurs the successive formation of aggregate zoospores of large size at the termination of the branches, as above described. In the older fronds these are no longer observed, their place being taken by organs producing germs which are capable of retaining for a long period their power of development.

11. In that most remarkable plant the Saprolegnia ferox, which is structurally so closely related to Vaucheria, though separated from it by the absence of green colouring matter, we find a corresponding analogy in the history of the development. Its vegetative life is, in fact, divisible into two well-marked periods, each characterised by a special mode of germformation. During the first, the only one with which we have at present to do, swarms of zoospores which rapidly succeed each other, are formed at the closed terminations of the cylindrical filaments. The mode of their origin, agrees with that of the aggregate zoospore of Vaucheria. The protoplasma accumulates in the swollen extremity of the filament, and a septum is formed in exactly the same manner as in that plant; while the mass of protoplasma is now observed to be limited by a distinct surface. At this point the resemblance ceases; the protoplasmic membrane divides, just as in the spore-cases of the zoosporous Algæ, into particles, which, as the period of maturity is approached, become more and more easily distinguishable from each other. These particles are the future zoospores. Soon they detach themselves from their connection with the membrane which encloses them, and with each other, and present the globular or ovoidal form characteristic of their perfect condition. In the meantime the external tube membrane buds out at its apex, so as to form a conical projection; as the zoospores become ripe, a gentle oscillatory motion is seen in the upper part of the spore-case. This is accompanied with a compression of its contents, in consequence of which its membrane gives way at its weakest point,— viz. the apex of the terminal conical projection. In its most perfect condition, the zoospore of *Saprolegnia* consists of a pyriform, protoplasmic, membraneless corpuscle, which is furnished with a pair of *cilia*, emanating from its apex. It is remarkable for the short duration of its motion, the cessation of which is immediately followed by germination.*

Fig. 135.

Sporangium of Saprolegnia ferox, during the expulsion of the zoospores, 200 *diam.*

(All the figures, from 129 to 135 inclusive, are from Thuret.)

* For the history of the second period of the vegetative life of Saprolegnia, see below, § 19. It is only under the most favourable conditions that the zoospores of Saprolegnia assume the form described in the text. Very frequently at the period of their escape, they are spheroidal corpuscles unendowed with the power of motion, if not incapable of germination. In this case, according to Anton de Bary, the completion of their development takes place outside of the spore-case. He describes the accumulation of the escaped, but imperfectly formed, zoospores in rounded heaps (*Köpfchen*), which remain for several hours in contact with the terminations of the tubes from which they have escaped, and finally become invested with a cellulose-membrane. Within this membrane their development is completed; and when they at last escape, they

12. In the process of the formation of zoospores in Saprolegnia, we have an intermediate step between that of the zoosporous Algæ on the one hand, and that of a class of plants which is usually placed among the Fungi on the other. I allude to the Fungi included in the class Cystosporeæ of Leveillé; on the intimate structure of this, as well as of many other allied groups, there are as yet but few researches. We have, however, enough in the beautiful monograph of Cohn, on Pilobolus, to enable us to discover that it is structurally more closely allied to the Algæ than to the Fungi. We shall take Pilobolus as an illustrative example.

13. Pilobolus has an ephemeral existence. The spore germinates about mid-day; the plant grows till evening, ripens during the night. In the morning the spore-case bursts, and the whole disappears, leaving scarcely a trace of its former existence.

In correspondence with the future mode of life of the plant, the spore-cell displays in its germination, a tendency to development in two opposite directions, by the formation of two sacculations, the first, cylindrical — the root; the second, ellipsoidal — the stem. Shortly afterwards the young plant is seen to consist of two cells, of which the inferior is elongated and branched at its lower extremity—root-cell; while the superior is ellipsoid, and acuminated above. The former contains a quantity of protoplasma, which lines, as a distinct layer, the internal surface of its wall. The first change which is observed consists in the accumulation of this protoplasma towards the apex of the cell, at which point the membrane buds out, so as to form a bead-like head. Within the cavity of this organ — the future spore-case, further accumulation takes place, until it is entirely filled with a coloured granular material; while the rest of the cell, from which it is as yet undivided, contains only a clear fluid. The process is completed by the formation of a septum just as in Vaucheria, which takes place early in the morning. This is immediately followed by the "cleaving" of the protoplasma, and its division into numerous small cells, which are the future spores. As the plant reaches the termination of its existence, the cell on which the spore-case is supported, enlarges at its upper part from the increase of its fluid contents; the septum is pushed upwards, and presses on the contents of the spore-case. At last in the course of the forenoon, the tension of the wall of the spore-case becomes so great that it gives way at its junction with the supporting cell with such force, that it is thrown like a miniature bomb for several inches.*

14. The Fungi which agree in their development with the species above described, are limited in number, and belong for the most part to the genera Pilobolus and Ascophora (Mucor). The formation of the spore differs entirely from the process of strangulation, which Schleiden considers as characteristic of the Fungi. On the other hand, the analogies between Pilobolus and Vaucheria are of the closest kind; even the ephemeral periods observed in the development and ripening of the reproductive apparatus, being the same. The root-cell of Pilobolus the inferior of the three of which the whole plant is composed, is as permanent as the tubular frond of a Conferva. From it emanate tubular, unjointed root-like processes, from the upper surface of which spring out at intervals young spore-cases, in every respect similar to the first-formed plant. These creeping rootlets constitute the vegetative system of the plant, which, like that of the Fungi, is perennial.

15. *Reproduction by conjugation.*—From the number of the observations which, during the last few years, have been made on the subject of the phenomena of conjugation, no less than from the variety of the conditions under which they have presented themselves, we are bound to assign them an important place in a systematic description of the reproductive process. Decaisne included in his group Synsporeæ all the Algæ in which the phenomena in question were then known to present themselves — namely, the genus Zygnema and its allies, along with Closterium, which last, for the same reason, he separated from the Desmideæ. The beautiful researches of Mr. Ralfs have taught us that all the genera of the Desmideæ conjugate in the same manner as Closterium. More recently analogous phenomena have been observed in the Vaucheriaceæ, and in that remarkable plant Saprolegnia ferox, which so closely resembles Vaucheria in every respect, except its green colour. We shall describe in succession each of the examples which have been mentioned.

16. Among the Desmideæ, conjugation has been more frequently observed and described, and was known to take place at an earlier period in Closterium, than in any other genus. The earliest description is that of Morren, which is to be found in the Bulletins of the Academy of Brussels, for 1836, and is among the most accurate that we possess. The crescent-shaped cell forming the frond of Closterium is, as in the Desmideæ, composed of two similar halves, to the plane of junction of which its long axis is perpendicular. It differs from other genera in the absence of a median constriction, the junction being only indicated by a faint line in the external mem-

are pear-shaped, and possessed of cilia. These observations I have been altogether unable to confirm, and am inclined to believe that the escape of the zoospores in the spheroidal form is to be attributed to an arrest of development, as in all cases which I have observed, the total disappearance of the spores has supervened shortly afterwards. — Anton de Bary, Beit. z. Kentnisse der Achlya prolifera. Bot. Zeit. 28 St. 1852. For further information on Achlya, see Unger, Linnæa, 1843, p. 129.; Nägeli Zeit. f. wiss. Bot. B. i. H. 1, 2. Pringsheim, Nova Acta Ac. L. C. 1851.

* Cohn, Die Entwickelungsgeschichte des *Pilobolus crystallinus*. Nova Acta Ac. L. C. p. 496. 1851.

brane.* When two fronds are about to conjugate, they place themselves parallel and opposite to each other, with their concave surfaces facing. We next remark that the cell membrane partially gives way at the line above mentioned, the two halves of each Closterium separating slightly on the side opposite its fellow, but remaining in contact on the other side. The openings are soon observed to be occupied by cushion-like projections of the internal membrane, which squeeze out between the valves. From the fact that the cavity of the internal membrane is double, or rather that each half of the Closterium possesses an independent primordial membrane, it follows that each of the projections above mentioned consists of two distinct *sacculi*. Soon the two double cushions come in contact; they are at first perfectly colourless, but shortly afterwards become filled with green granular matter, and press so closely together as to be no longer distinguishable. It is next observed that from the junction of the four sacculi, two canals have resulted, each of which soon swells out in a hemispherical form, corresponding to

Fig. 136.

Conjugation of Closterium.

The two fronds are connected by *two* delicate tubes, each of which contains a hemispherical germ-cell closely invested by its membrane. The two germ-cells, which are in opposition by their flat surfaces, appear as one. About 40 diam.

that of a mass of green granular matter which now occupies its cavity. This mass is soon invested by a delicate membrane, which, in the progress of development, thickens and presents an uneven surface. The two bodies which thus take their origin are the germ cells. They soon become free from the structure in which they were formed, and, according to Morren, display for about fifteen minutes after their escape an active motion. After this period, the motion ceases, and they attach themselves to a foreign body. Morren has observed their germination. The spherical germ lengthens first at one, then at the opposite extremity, so as to assume the characteristic crescentic form of the plant. Its green contents divide into two masses, each of which is invested by a separate primordial membrane, and occupies one of the future segments of the frond. In a short time the young Closterium completely resembles the adult. It is worthy of remark, that in the abnormal cases in which only one germ results from the conjugation of two individuals, only one of the halves of each empties itself, the other remaining unaltered.*

In other families of Desmideæ, the process of conjugation, although variously modified as to its less important details, is essentially the same as that which occurs in Closterium.†

17. In the Zygnemaceæ, confervoid plants, which seem to have a close relation with the Desmideæ, the phenomena of conjugation have been long known. The frond consists of a series of cylindrical cells, which lengthens indefinitely by repeated division of its elements. Here, as in the Desmideæ, it is the last-produced cells in the filament which take part in the process of conjugation. In Spirogyra the union of two cells belonging to opposite filaments takes place by the expansion of one side of each, so as to form a papilla, or short tube with a rounded end. The ends of the two projections then come into contact, become slightly flattened as they are pressed against each other, and unite. The double wall formed by their union, dissolves, or is broken through, so that a free passage is established between the two cell cavities. Upon this, the whole of the chlorophylle previously arranged round the inside of each of the cells, becomes a confused mass, which soon forms itself either in the cavity of one of them, or in the connecting canal, into a globular or oval smooth spore, invested with a colourless cellulose membrane. Having arrived at this condition, it remains several months — from the autumn of one year to the spring of the following,—without undergoing any change of form.‡ During this period two new membranes are produced within the first by the secretion of cellulose on the surface of the primordial utricle. Of these two, the external is of considerable thickness, and of a yellow colour. The internal, which may be considered as the proper membrane of the spore, is delicate and

* Morren, Ann. des Sc. Nat. 1re Ser. p. 325.

* According to Morren, the process above described is not the only one by which the reproduction of Closterium takes place. In the green granular matter contained in a frond, there occur spherical corpuscles which, according to that observer, are capable of reproducing the parent plant. He has described and figured their germination, and it is worthy of remark that his figures of the earliest stages of Closteria thus developed, correspond closely with those of the earliest stages of the plant as observed by Mr. Ralfs, who, however, assigns to them a different origin. (See *British Desmideæ*, tab. xxvii. m.)

† It is clear that if the formation of germs by conjugation were the only provision for the reproduction of the species, in the Closteria and many other families of Desmideæ, its total disappearance must result, inasmuch as the conjugation and consequent destruction of a pair of Closteria can only give rise to an equal or less number of new individuals. But the other mode of reproduction already alluded to as occurring in Closterium, and which has been so well described by Mr. Ralfs in the other Desmideæ, affords an effectual safeguard against their otherwise possible extinction.

‡ Braun has observed the germination of the spores in a specimen of Spyrogyra setiformis which had been collected for eleven months. (Braun, *l. c.* p. 144.)

transparent. Germination consists in the growing out of this membrane at one end of the spore into a many-celled filament, which escapes through a lacerated opening in the external membranes, and gradually assumes the character, and appearance of the parent plant. At the same time a tubular elongation of the same membrane of limited growth is formed in the opposite direction, which is the rudiment of a root.*

18. In a species of Palmelleæ (Palmoglea macrococca) in which the whole individual consists of a single ovoid cell containing green granular matter, and usually multiplying itself by successive division, the phenomena of conjugation present themselves in a somewhat different and very remarkable form. Here two cells, probably the result of a series of divisions, undergo a complete union, affecting not only their contents, but also their membranes. They coalesce as completely at their points of contact, as two contiguous drops of water, the result of their union being a cell which differs in no respect from its predecessors, except in the greater thickness of its walls, and in the complete conversion of the chlorophylle of its contents into oily globules. Like the spore of the *Zygnemaceæ*, it is destined to a long period of inactivity, after which, by the successive division of its contents, it gives rise to a new series of individuals, similar to those that preceded it.

19. We have still to consider the most remarkable condition under which conjugation takes place among the Algæ. The evolution of the aggregate zoospore of Vaucheria has been already described. In the plant which results from its germination, Karsten has observed that along the course of those filaments which come in contact with the atmosphere are formed organs of a peculiar structure. They originate like the ordinary branches, as nipple-shaped buddings out of the cell-wall, which are distributed in pairs along the whole course of the older filaments. In every pair of organs, one elongates so as to form a closed

Fig. 137.

tube, which curves round into a spiral form, like the leaves of a Pilularia, while its fellow soon ceases to grow in length, but swells out into a globular or oval form, about three times as wide as the other. At first both contain chlorophylle, which, in the tubular organ, is soon replaced by colourless globules. In the meantime its fellow, which resembles a dark-green-coloured globe, supported on a short pedicle, alters in form, its cell-wall extending into a nipple-shaped projection on the side next the tubular organ, with which it finally comes in contact. This condition lasts for some time, but it does not appear determined

Fig. 138.

with sufficient distinctness by Karsten's observations, that an actual interchange of the contents takes place. All that we learn as certain is, that after the completion of what he calls the act of fructification, a newly formed cell appears in the cavity of the globular organ, which shortly after separates from the mother plant. In this instance, as in those above described, conjugation is preceded by the conversion of the green granular contents of the conjugating cells into oil globules. The germ thus produced retains its power of development for several months, and gives rise to a new plant resembling its parent in structure.*

20. In Saprolegnia, which is morphologically so closely related to Vaucheria, and like it, in its earliest state of existence, produces zoospores, we obtain, by the germination of these zoospores, plants which produce reproductive organs of an entirely different character. These, when completely formed, consist of spheroidal cells, each supported on a cylindrical pedicle. Each contains in its interior a number of round spores (from five

* Karsten, Die Fortpflanzung der *Conferva fontinalis*. (Bot. Zeit. 1852, 6 Stück.)

The process of which the details have been so well described in the above memoir, was known to Vaucher, and is mentioned by him in his "Histoire des Conferves d'Eau douce" (p. 17.). See also Nægeli (Vergl. Algensyst. p. 175.); Hassall (British Freshwater Algæ. vol. i. p. 175.); and Thuret (Annales des Sc. Nat. 2nd Ser. 1843), who gives a figure illustrative of the conjugation of *Vaucheria hamata*. In *V. polysperma*, a species described and figured by Hassall (*l. c.* Pl. iv. f. 6.), the spore-bearing organs are very much more numerous than the curved tubular organs, a fact for the explanation of which observations are as yet wanting.

or six to forty), which differ from the zoospores, not only in their external form, but in possessing a distinct investing membrane. This complication of structure corresponds with the capability of retaining their vitality for a long period. They may be found in an unaltered condition in the water in which the parent plant has grown for many months after the total destruction of the latter; and it is to them, doubtless, that we must attribute the extraordinary facility with which the Saprolegnia makes its appearance whenever the peculiar conditions it requires present themselves.* On the filaments which produce the above-described spore-cases, there are developed among them, and at the same time with them, slender, worm-like branchlets. These, as they reach the spore-cases, attach themselves firmly to them, and even sometimes wind round them in a regular manner. An actual interchange of contents, however, has not yet been observed.†

21. *Reproductive organs of the red Algæ or Florideæ.*—In this group of plants we unfortunately know too little of the origin and development of the germ-producing organs, to compare them with the forms which prevail in other groups. It is altogether beyond the limits of the present article to describe in detail all the perplexing varieties of structures to be found in the Florideæ which may be supposed to have some relation with the reproductive function. It will be sufficient to mention the three leading forms that are met with, and which may at all times be easily identified, in spite of the innumerable subordinate modifications that they undergo. The first form, to which the term *polyspore* is usually applied, is that of a gelatinous or membranous pericarp or conceptacle, in which an indefinite number of sporidia are contained. This organ may be placed either at the summit or in the axil of a branch, or it may be concealed in or below the cortical layer of the stem. In other cases a number of sporidium-bearing filaments emanate from a kind of placenta at the base of a spheroidal, cellular *perisporangium*, by the rupture of which the sporidia which are formed from the endochromes of the filaments, make their escape. Other forms, which it does not seem necessary to mention, are observed: they all agree in one particular, viz. that the sporidium is developed in the interior of a cell, the wall of which forms its perispore, and the internal protoplasmic membrane (endochrome), the sporidium itself, for the escape of which the perispore ruptures at its apex.

22. The second form is much more simple, and consists of a globular or ovoidal cell, containing in its interior a central granular mass, which, as the organ arrives at maturity, divides into four smaller quadrant-shaped spores, which finally escape by the rupture of the cell-wall. This organ is called a tetraspore; it takes its origin in the cortical layer. The tetraspores are arranged either in an isolated manner along the branches, or in numbers together, surrounded by a whorl of smaller branchlets. In some cases the form of the branches which contain tetraspores is so completely modified by their presence, that they assume the appearance of special organs, which are called *stichidia*, as, for example, in Dasya.*

23. It is with respect to the third kind of reproductive organ, the antheridium, that the greatest differences of opinion exist; all observers, however, agreeing as to the general signification to be attached to it. The antheridia are always produced on different individuals, but in precisely the same situations as the tetraspores and polyspores. They are "agglomerations of little colourless cells either united in a bunch, as in Griffithsia, or enclosed in a transparent cylinder, as in Polysiphonia, or covering a kind of expanded disc of peculiar form, as in Laurencia."† According to the researches of Derbes ‡ and Nägeli §, each of these cellules contains a spermatozoid. Nägeli describes it as a spiral fibre, which, as it escapes, lengthens itself in the form of a screw. Derbes, on the other hand, describes it as "a hyaline globule, furnished with a flagelliform appendage, by means of which it agitates itself with a very active motion, which lasts for some moments." According to M. Thuret, who certainly is to be considered a higher authority than either of the above mentioned, each cell of the antheridium is occupied by a hyaline corpuscle, spherical in Polysiphonia, ovoidal in other genera. These corpuscles, however, whose contents are granular, offer no trace of a spiral filament, but are expelled from the cells by a slow motion, which Thuret compares to that observed in the expulsion of the tetraspores from their theca. The antheridia appear in their most simple form in Calithamnion, being reduced to a mass of cells, composed of numerous little bunches, which are sessile on the bifurcations of the terminal branches. The woodcut represents the antheridium of Griffithsia, in which species, it is produced like the tetraspores, in a sort of lateral involucre of verticillate branchlets. Each of these bifurcates, and bears at the bifurcation a pyramidal antheridium, which

* Pringsheim, *l. c.* N. A. A. L. C. 1851. p. 417. All that is required to obtain a living specimen of this singular plant, is to allow the body of any small animal, such as a fly or spider, to float for a few days in rain water, exposed to the light. By this method a crop of Saprolegnia may be obtained at any season.

a, a kind of involucre is formed by a whorl of six verticillate branchlets, at the points of bifurcation of each of which is borne an antheridium; *b*, terminal tuft from surface of antheridium, along with a few of the hyaline vesicles, 300 diam. (Thuret).

formed of larger cells placed end to end. At the junctions of these, smaller branches are given out, upon which the hyaline cells are sessile. These last possess a diameter of about $\frac{1}{2500}$ of an inch.

From the above details it will be seen that great difficulties lie in the way of a comparison between the reproductive organs of the Florideæ and those of other families. Nägeli considers them to present a strong analogy with those of the Hepaticæ, with which he places the Florideæ in a parallel position. We shall see, as we advance, how little ground there is for such a view.

The Florideæ are triœcious plants: the tetraspores, polyspores, and antheridia being never found together in one individual.

24. *Characeæ.* — Although we are well acquainted with the structure of the reproductive organs of the Characeæ, we are, as yet, able to perceive only subordinate relations between them and those of other plants. These organs are of two kinds; the one being destined to the production of a germ, the other to that of antherozoids. The former is an oblong oval body, which is placed at the junction of two segments of the articulate tubular stem. It consists of an oval germ-cell, invested by two envelopes. The outer of these is remarkable for the arrangement of the five tubular cells of which it is formed, which are twisted spirally round the central parts, and form by their ends, at the summit, a crown of five teeth.

The germination of Chara has been observed and described by Vaucher.* The development of the germ, which ripens in autumn, does not take place until spring. It consists in the budding out of the central cell at its apex so as to form a single tubular stalk, just as in the lower Algæ.

25. The antheridium of Chara is an orange-red, and globular body, which is attached to the stem immediately below the germ-producing organ. It consists of eight concave, rectangular valves, joined at their edges so as to form a hollow sphere. At each suture there is a partition, which is directed to the centre of the sphere; while from the centre of each valve there springs a cylindrical cell, the axis of which is perpendicular to its inner surface, so that each cell approaches the centre of the sphere by its extremity. The whole antheridium is supported by a ninth cylindrical cell, which is inserted by its base into the stem of the plant, and passing up between the corners of the four inferior valves, approaches the other eight cylindrical cells at the centre. From the extremities of the nine cells, there emanate a number of flexible tubes, which are

Fig. 140.

a, flexible tubes from antheridium of Chara. From most of the segments the antherozoids have escaped; two are in the act of escaping: *b*, fully formed antherozoids. 400 diam. (Thuret.)

divided by transverse partitions into a number of segments. In each segment or cavity an antherozoid is contained. Each antherozoid is a spirally coiled fibre endowed with a power of active motion, which is displayed as soon as it is removed from its cell. The motion is of two kinds—of progression, and of revolution round the axis. According to Thuret, two cilia emanate from each antherozoid, a little behind its anterior extremity, and it is to these organs that the motion is to be attributed.*

26. *Summary.*—If we take into consideration only those families of the Algæ in which the phenomena of reproduction have been more or less completely investigated, we shall find that all the instances of the occurrence of bodies to

* Vaucher, Mém. Soc. Hist. Nat. de Genève, tom. i.

* For further information see K. Müller, Die Entwick. der Characeen, Bot. Zeit. 1845, p. 393. Kaulfuss, Die Keimung der Characeen. Leipzig, 1825. Varley, On the Structure of Chara in the Microscropic Journal. Thuret, Ann. des Sc. Nat. xvi. p. 18.

which the term "germ" may be applied in the sense of the definition given at the outset, may be included in one of two classes. The first comprises zoospores and zoosporoid bodies; the second, all those forms of germ which require for their development a previous combination of two parts or organs, complementary to each other as regards their reproductive functions.

27. *Zoospores.*—Of zoospores we recognise two kinds, simple and aggregate. The simple zoospore is a pear-shaped or ovoidal body: it is composed of transparent, colourless homogeneous plasma, throughout the whole of which, with the exception of the smaller end (rostrum), granules of colouring matter are scattered. It possesses no investing membrane, but is provided with a pair of cilia, the directions and positions of which differ according to the class. Every zoospore possesses a single granule of a red or reddish-brown colour, which is always placed in the immediate neighbourhood of the colourless rostrum. Its characteristic *motion* is a constant progression in the direction of its axis, around which the whole zoospore at the same time revolves, the transparent rostrum being always directed forwards. As regards the *chemical composition* of the zoospore, the transparent and colourless plasma is a nitrogenous compound, coloured brown by iodine. The cilia, as far as their reactions can be ascertained, resemble the plasma from which they emanate. As to the constitution of the coloured granules which are scattered throughout the plasma, we have as yet no direct observations; but from the form which they exhibit being that which is always assumed by starch, not only among the Algæ, but also in the green Infusoria, there can be little doubt that they are composed of that principle, in mechanical combination with colouring matter and a fat.

28. In passing from the condition of motion to that of repose, or, in other words, in germinating, the zoospore is not subject to any suspension of its vegetative activity. From the moment that it is set free from the parent plant to that at which it begins to develope from itself a new plant similar to the parent, it continues to grow uninterruptedly.

29. Of the aggregate zoospore, the best-marked example is that which has been fully described in Vaucheria. In comparing the termination of a fructiferous filament of Vaucheria, with the sporangium of Saprolegnia, we can at once satisfy ourselves that these are corresponding structures: the distinctive difference being, that in the one the whole protoplasma contained in the termination of the tube is collected together to form a single large zoospore, while, in the other, it is subdivided so as to form a multitude of small ones. In other words, the single zoospore of Vaucheria takes the place of the collection of zoospores contained in one sporangium of Saprolegnia. This fact is all that we mean to imply by the use of the term aggregate.

30. *Zoosporoid bodies.*—Among these we include the antherozoids of Cutleria, of the Fucaceæ, of the Florideæ, and of the Characeæ. Of the relations of the first two to the true zoospore in form and development, we have already said enough in the preceding pages. Those of the antherozoid of Chara are not so close; and the structure of the organs in which they are developed, differs so essentially from any structure met with in any other family, that it is inexpedient to found any notions of their nature or formal relations upon such slender analogies as may exist. In the case of the Florideæ, the correspondence between the antherozoids and the zoospores of other Algæ, is still less traceable; but the peculiar arrangement of the bodies in question — their being always developed in different individuals, though in similar positions as regards the organs of vegetation— leads us irresistibly to the conclusion that they have a mutual relation, or are in some degree complementary to each other in function; and as we know the production of germs to be the function of the one, it is reasonable to assign their fecundation to the other.

Germs, whose development is dependent on the combination of two organs the reproductive functions of which are complementary each to each.—Of these it is the leading characteristic that they do not necessarily pass at once, as soon as they are set free from the parent, into active development. If the necessary conditions of temperature and moisture are absent, they are capable of remaining in a state of repose, without losing their power of germinating. This state may last for weeks, or even for months. Their second characteristic is connected with the first; viz. that they are always provided with a distinct investing membrane, on the strength of which their power of resistance to external agents may in part depend. This is well seen in the spores of the Desmideæ and Zygnemaceæ.

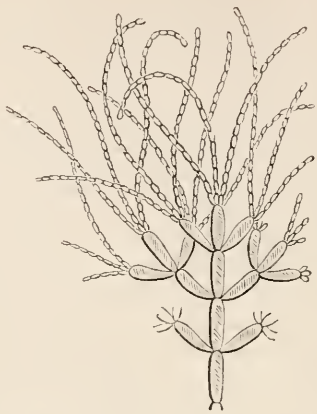
31. There remain a few examples of germ-like bodies of uncertain signification, which are included in neither of the above divisions. Such are the various forms which occur among the Florideæ, the stationary spores of Saprolegnia, and others, of which, as they are still imperfectly known, sufficient has been said in the preceding pages.

32. FUNGI AND LICHENS.—While, on the one hand, the Fungi and Lichens present an endless variety in the organs which constitute their reproductive system (receptacle), their vegetative system (*mycelium*, *stroma*, *flocci*, *hypothallus*, *&c.*), on the other, preserves a remarkable degree of uniformity. It always consists of a network of cylindrical hollow filaments, usually divided at irregular intervals, but sometimes simple. In the latter case the whole network, however complicated it may appear at first sight, is in fact only a ramified cell. This structure, which, in its simplest form is the immediate result of the germination of the spore, is the most permanent portion of the plant, inasmuch as, although every part of it, considered separately, is transitory, the vegetation of the whole is continuous, and its duration unlimited. It is from it that the organs which constitute the reproductive sys-

tem take their origin, and, as its presence is essential to the existence of the plant, it may be considered to represent, functionally, the stem of other vegetables.

33. On the formation and development of the germ in the Fungi, comparatively very few researches have yet been made which are not so deficient either in completeness or accuracy as to be useless. This being the case, the best mode of treating the subject seems to be to select those isolated facts and observations which are most to be depended upon, and arrange them in such a manner as to serve as a foundation for a general view of the subject. The most simply organised Fungi known, are undoubtedly those which belong to the genus Torula. The well-known yeast-plant consists of a single ovoid cell, whose membrane is perfectly simple, and encloses a slightly granular, transparent fluid. It multiplies by the budding out of its membrane at one extremity into a projecting nipple, which soon becomes separated from the original cell by a constriction. As the newly formed germ enlarges, the constriction becomes more complete, and at last separation takes place. After the Torulæ, which are the only examples we are acquainted with of one-celled Fungi, come the innumerable *Hyphomycetes* or thread Fungi, so called because their reproductive, bears so small a proportion to their vegetative system, that it is in many cases altogether overlooked. The growing terminations of the mycelium filaments themselves become individualised, so as to form the germs, which separate from their parent cells by constriction, as above described in Torula. It is this acrogenous mode of spore formation which Schleiden considers as the character which distinguishes the true Fungi from the Lichens*; the latter developing "many spores simultaneously in the interior of a larger parent cell or ascus." Among the higher Hyphomycetes, however, the reproductive system appears in a more distinct and developed form. Thus, in Penicillium it consists of filaments which spring perpendicularly from the stroma, and are formed of elongated, club-shaped cells, joined end to end. These stalk-like filaments branch trichotomously in the most beautiful manner. From their extremities there spring others, which are much more slender, and consist of moniliform series of minute ovoid segments, separated from each other by constrictions, which are indistinct at the base of the filament, but become more and more complete towards its termination. At this point the segments detach themselves, and form the germs of the plant.† In other genera, the perpendicular sporiferous filaments are woven together into more complicated structures, the varieties of which it does not come within our present purpose to describe. As respects their component elements and the mode in which the spores are produced, they do not differ from those noticed above.

Fig. 141.



Branching sporiferous filaments of Penicillium verticillatum, about 150 *diam.* (Corda.)

34. The basidiosporous Fungi are characterised by the presence of a distinct membrane (hymenium), on the surface of which the spores are developed by a mode which, though it is still acrogenous, is considerably more complicated. The hymenium always consists of elongated pouch-like cells, arranged side by side, with their long axes perpendicular to its surface, and in close contact with each other. Some of these cells are longer than their neighbours, and from their free rounded ends, there emanate processes (usually four in number) in the form of pedicles. Upon the extremities of these are borne oval cellules, which, though in their earliest condition they do not exceed their pedicles in width, rapidly enlarge, and finally separate by a kind of constriction. In some basidiosporous Fungi, as in the Agarics, the hymenium is external, and its surface exposed to the atmosphere; while in others, as in the Gasteromycetes, it is internal, the spores being thrown, when detached from their pedicles, into one or more cavities enclosed in the substance of the receptacle. Of the last-mentioned division, we select a well-known genus (Geaster), for the purpose of illustration.

Fig. 142.

A basidium with its four basidospores, along with two other sterile basidia (*Geaster rufescens*), 300 *diam.*

* Schleiden places all the ascophorous Fungi among the Lichens. We shall find, as we proceed, that such an arrangement is altogether inadmissible. (Schleiden, Principles of Scientific Botany, p. 157.)

† Corda, Icones Fungorum, tom. i. p. 21.

35. At the period of the formation of the spores, the receptacle of Geaster (fimbriatus) is a solid body of a depressed spheroidal form. It presents for examination a central mass and a peridium, the tissue of the latter being continuous with that of the former only at the base. The central mass or kernel is originally

Fig. 143.

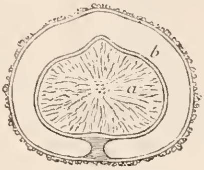


Diagram of receptacle of Geaster fimbriatus.

The kernel, *a*, is surrounded by its reticular membrane, which is indicated by the inner of the two double lines. The outer double line corresponds to the resistant external layer of the peridium. The intervening space, *b*, is occupied by a delicate tissue of spherical cells. At *c*, all these structures are continuous, as well with each other as with the mycelium from which the whole originates.

solid, but when fully developed, presents numerous irregular cavities, which are scattered through its substance. It is entirely composed, when in the solid condition, of delicate filaments similar to those of mycelium, the arrangement of which is as follows:—The superficial filaments are closely woven together, so as to form a delicate reticular membrane, which invests the whole kernel, and from the inner aspect of which a second and very numerous set of filaments passes off towards the centre. It is of these, or of their ramifications, that the corky, semi-elastic substance of the kernel is entirely formed. If we examine the cavities which have been mentioned as existing in the fully developed condition, we find that they are furnished with a

Fig. 144.

Section of a portion of the young receptacle of Geaster rufescens, about 100 *diam.*

The section has passed through one of the cavities, and shows the arrangement of the basidia which form its lining membrane. Some of these bear spores on their summits.

more or less continuous lining of basidia, bearing spores on their summits. These basidia have been shown, by careful observation, to be in fact the swollen terminations of the centripetal branching filaments above mentioned. The peridium it is less necessary to describe, as it has no immediate connection with the spore-bearing organs. It consists of an internal and an external layer, the latter being smooth and very resistant, while the former consists of delicate, transitory, spherical cells. In the ripe condition of the Geaster, the peridium becomes detached, at the same time splitting from apex to base in a remarkable and characteristic manner. Geaster may be considered as the type of a well-known family, including the *Lycoperdons, Bovistæ*, and others, all of which are characterised by the presence of a solid receptacle, furnished with numerous spore-bearing lacunæ. In almost all of these Fungi, the arrangement of the spores with their pedicles in relation to the basidia are the same, four pedicles emanating from each basidium. In the ripe condition the spores are always of a dark-brown colour, frequently approaching to black, and their surfaces are beautifully reticulated with linear furrows, between which there are little conical projections. Each spore possesses an external reticulated, and an internal homogeneous membrane. This last encloses a cavity, which is occupied by a fluid, which contains numerous oleaginous granules. The ripe spores, after their detachment from the basidia, lie loose in the lacunæ of the receptacle from which they are set free by the disintegration of the basidia, as well as of the filament with which they are connected. In this manner, in Geaster, the kernel is converted into a bag, formed of the delicate reticular membrane, described above as its proper investment. This bag contains a dark-brown diffluent mass, composed of the remains of the basidia and filaments along with ripe spores. Finally, the membrane gives way, and the spores are disseminated in the shape of a light, dry-looking powder.

36. We next pass to the consideration of the Fungi, among which the spore, instead of being produced at the summit of a basidium, or at the extremity of a simple filament, is formed in the interior of a vesicle or pouch, which is called a theca or ascus. Of these, the first which we shall mention belong to a group of subterranean plants, of which the truffle is the best-known example. The receptacle of the truffle consists of a fleshy mass, throughout which numerous sinuous cavities are interspersed. Each cavity is partly lined, partly filled with the thecæ and the cells upon which they are supported. This receptacle, like that of all other Fungi with which we are acquainted, originates from a pre-existing mycelium. In its unripe condition it displays on section a number of sinuous empty cavities, which either communicate with each other, or open at one or more points of the external surface. As the truffle advances towards maturity, the cavities are obliterated by the formation of a whitish tissue; so that on section, we observe the whole to consist of two substances—the one translucent, of firm con-

sistence and of a dark-brown colour; the other white and opaque. The former, which cor-

Fig. 145.

a, outer layer of the peridium consisting of a resistant tissue of thick-walled cells; *b*, inner layer of the same, formed of filamentous tissue continuous with that of *v*, one of the venæ internæ, or partitions by which the compartments (originally cavities) of the truffle are bounded. Portions of two of these compartments are seen with the thecæ and septate filaments which they contain.

responds to the partitions which, in the young state of the truffle, separated the cavities, is continuous with the external tissue which composes the envelope or peridium, and constitutes the vena internæ of Vittadini.* The laminæ which it forms, consist of filaments running, for the most part, parallel to each other. The white substance which occupies the original cavities of the tuber, is formed of closed tubes, which are given off in great numbers from the surfaces of the laminæ. These tubes, which are the terminations of the filaments of which the laminæ are composed, are of two kinds. Some are of equal diameter throughout, and divided at intervals by septa; others, much shorter, are dilated at their extremities, and contain spores (thecæ). Each theca is an obovate vesicle, and contains two, three, or more spores, never more than eight. Each spore is invested with a beautifully reticulate, or sometimes warty epispore, within which may be distinguished a smooth inner membrane, immediately enclosing the oleaginous contents.†

37. The ascophorous Fungi are represented in their simplest form by the Uredineæ, a family which has been studied by numerous observers on account of the destructive properties of the plants belonging to it. The mass which is formed by the growth of the reproductive organs of Uredo under the epidermis of the leaves of the plants upon which it grows parasitically, may be aptly compared to a pustule, a grumous-looking substance, occupying, as it were, the place of the pus. On more minute examination of the cavity, we find that it is bounded by a kind of irregular wall or lining of pyriform cells, the smaller ends of which rest upon a reticular cushion of mycelium. These are probably the enlarged extremities of the mycelium filaments, with which many of them can be distinctly traced to be connected. Towards the base of the cavity other cells are developed, resembling those first mentioned in their general form, as well as in their relation to the mycelium. In these, however, the membrane is produced inferiorly, so as to form a tubular pedicle; while in the club-shaped upper extremity it is lined by a considerable deposit of granular protoplasma, so that here the central cavity is very much smaller than that of the external membrane. It is in this cavity that the spore is formed, at first not exceeding it in size, but afterwards increasing at the expense of the protoplasma, so as almost to fill the theca. In other genera, as in Phragmidium, there are pedicled cells of a similar form, and originating in a similar manner, which, however, instead of one spore, develop a number in their interior; these spores are arranged in linear series, and are formed in the same manner. The protoplasma, however, never disappears completely, but remains as a more or less consistent membrane, glueing the ripe spore to the spore-case which encloses it. Some of the Uredineæ possess a cyst which reminds us of the perithecium of the Sphœriaceæ, to which they are evidently closely related. The cyst is formed (Œcidium) of a single layer of roundish cells.*

38. From the Uredineæ we pass by a natural transition to the Discomycetes and Pyrenomycetes. These plants have been investigated with much success by MM. Tulasne, who have shown that they possess the closest relationship not only to the Lichens, but to the most simple thread Fungi. The very remarkable facts which these observers have discovered, render the study of these plants more satisfactory and instructive than that of any other family of the class. The Pyrenomycetes are represented by Sphœria, the receptacle of which consists, as is well known, of a spherical cyst, which is open above. Its wall is frequently prolonged upwards into a tubular beak, which projects beyond the surface of the bark or wood in which the whole plant is embedded. The membrane of the cyst (perithecium) is usually

* Vittadini, Monog. Tuberacearum, p. 2. et seq.

composed of polygonal, tabular cells ; it is lined by an inner layer, formed of the commencements of the paraphyses and thecæ, and of the filaments with which they are connected. The thecæ are obovate cells, the

Fig. 146.

Thecæ and paraphyses of Sphœria, about 300 *diam.*

membrane of which is of extreme delicacy. When fully formed, they contain from three to eight oval spores, the epispores of which are in the early condition delicate and pellucid, but by degrees become brown and opaque.

Fig. 147.

Ripe spores of Cenangium Frangulæ, 350 *diam.*

The contents of the spores, as is observed throughout the higher Fungi, consist of a fluid loaded with oily granules. The thecæ are arranged with their long axes perpendicular to the inner surface of the perithecium from which they spring, and are intermixed with a greater or less number of slender, cylindrical paraphyses. The whole perithecium is usually enveloped in the filamentous stroma or mycelium, from which it takes its origin. The Discomycetes are represented by the Pezizæ; between these and the Sphœriæ there are differences of external form, which, though they strike the superficial observer as important, are in reality trivial. While the receptacle of the Sphœria is a cyst with an apicial aperture, that of the Peziza is a cup-shaped disc, the concave surface of which looks upwards. This surface is lined with an ascophorous membrane, which resembles in every respect that of a Sphœria.

39. Along with the Pezizæ and Sphœriæ and those allied genera which resemble them in producing their spores enclosed in thecæ, there are other forms also included in the Pyrenomycetes and Discomycetes, which, while they resemble those last named in the general outline and structure of their receptacles, differ from them completely in the mode of origin of the spores. The simultaneous occurrence of some of these forms, along with their ascophorous analogues, or, in other instances, the successive development of both kinds of receptacles in the same position, had been frequently observed, and had given rise in the minds of some mycologists to the suspicion of the existence of a relation more close than was generally admitted. This suspicion did not, however, take a sufficiently distinct form to lead to observation until the MM. Tulasne, in a series of researches scarcely completed, showed that the genera in question, hitherto considered as distinct, were in fact identical, and that receptacles containing thecæ and paraphyses, are produced on the same stroma, or, in other words, on the same individual plant, as those which contain acrogenous spores.

40. The earliest researches of MM. Tulasne* were directed to the Pyrenomycetes. In some species of Sphœria, they found not only that the same stroma produces receptacles with acrogenous spores, which are followed by others bearing thecæ; but that, under certain circumstances, it may give rise to spore-bearing organs, of a much simpler character; viz. branching filamentous pedicles, bearing at their terminations single spores, and rising directly from the mycelium filaments, with which they are continuous. In this condition the plant cannot be distinguished from a thread Fungus, and has been hitherto described as such.

41. The later observations of MM. Tulasne † which are much more in detail, refer almost entirely to Discomycetes. In a species of Rhytisma, a genus of Discomycetes, which inhabits the epidermis of the leaves of plants, the stroma at first presents the appearance of a black spot of various extent on the surface of the leaf. In the substance of this stroma the first receptacles are formed ; they are cushion-shaped capsules, furnished with apicial apertures, like those of Sphœria, and are entirely occupied by a pulpy nucleus, which consists of slender branched filaments, often so long as to project considerably beyond the aperture. These filaments bear at their extremities innumerable minute linear sporules, which are enveloped in an abundant mucilage, and are expelled from the ripe capsules in the form of a long cirrhus. After the capsules which are developed during the early summer months have discharged their contents, they are succeeded by the lirelliform discs of the perfect Rhytisma. These do not arrive at maturity until the following spring, and bear

* Notes sur l'Appareil reproducteur dans les Lichens et les Champignons, Ann. des Sc. Nat. 3me. S. t. xv. p. 370.

† Nouvelles Recherches, &c. Comptes rendus, Séance du 13 Dec. 1852.

upon their upper surface thecæ and paraphyses like those of a Peziza. In other genera M M. Tulasne found that the ascophorous receptacles are preceded by capsules which produce, instead of the linear sporules above mentioned, cylindrical spores of a much larger size, each of which is supported at the extremity of a pedicle of its own.

42. Thus in the plants under consideration we find that, without counting the sporules which are produced by filaments rising directly from the stroma, there are no less than three varieties of spore-like structures which can be easily distinguished from each other. All of these may be produced upon the same, individual, and one instance is recorded in which a cupule of a Peziza was found, which bore among the normal thecæ, paraphyses with innumerable, slender, linear sporules at their extremities. As has been already hinted, the capsules which contain acrogenous spores, have been hitherto considered as belonging to genera distinct from those represented by the ascophorous receptacles with which they were found associated. The genus Cytispora is characterised by a structure which corresponds completely with that of the capsules described above in Rhytisma; and other genera as *e. g.* Sporocadus have a similar relation to the capsules, containing the larger variety of pedunculated, cylindrical spores.

43. In order to facilitate the description of these various structures, a nomenclature has been devised by MM. Tulasne, which may be adopted with advantage. The minute, linear sporules, which are produced at the extremities of branched filaments, like the paraphyses of *Sphæria*, are called spermatia. The cylindrical bodies of much larger size, which are borne each at the extremity of a stipitiform cell, are named stylospores; while the term spore is reserved to those which are formed in the interior of a theca.

43. *bis*. In a third "Memoire" which has appeared since the above paragraphs went to press, MM. Tulasne have further prosecuted their researches on this interesting subject. The following is an abstract of their account of the development of a Pyrenomyces (Cenangium), which inhabits the bark of dead branches of the black alder (Rhamnus Frangula). The plant, in its natural position, is represented in *fig.* 148. The mycelium ramifies, in all directions, in the substance of the inner bark of the dead branch. From its filaments there spring, at irregular intervals, the receptacles, which as they develope, burst through the outer bark and epidermis and exhibit the various forms represented. The simplest variety (*fig.* 148. *a*) resembles in structure the organ described in § 49. as occurring in Scutula. In form, it is rounded, but at the same time somewhat conical. The stylospores (*fig.* 149. *a*) which it contains, are curved, crescentic bodies, supported on pedicles, which have an arrangement perfectly similar to that observed in Scutula. The receptacles or cupules in which thecæ are produced are deserving of great attention. In the early condition, their form is cyathoid (*fig.* 148. *c*), and they resemble those described (§ 41.) in Rhytisma. They contain at this time, innumerable spermatia (*fig.* 149. *b*), these being supported on filaments which spring from the inner surface of the cup, as well as of its margin. As the organ grows, it expands, and finally becomes discoid (*fig.* 148. *b*), when it possesses the structure

represented in *fig.* 150. The central portion of the disc is lined by an ascophorous membrane. The overhanging marginal fold still exhibits the filaments bearing spermatia, which characterised the earlier condition of the receptacle. Our authors are inclined to admit that the spermatia are to be considered as a male product, and the whole organ as analogous to a hermaphrodite inflorescence. The relative positions of the spermatia and thecæ seem admirably adapted to insure their contact with each other.

44. We now pass to the Lichens, with respect to which the greater part of our information is again owing to the researches of MM. Tulasne.* In these plants, as in the Fungi, the germination of the spore consists in the emission of a hollow filament from some part of its surface. This filament which is simply an extension of the spore-membrane, branches repeatedly and spreads over the surface, on which the spore has been sown; at the same time it divides by numerous septa, which occur at irregular intervals. By the intertwining of the resulting ramifications, a stroma is formed, to which the term hypothallus is applied, and which constitutes the vegetative system of the future lichen. So far the development is the same as the Fungi. At a longer or shorter period after the formation of the hypothallus, we begin to observe upon its surface a whitish layer of spheroidal cellules, intimately united with each other, as well as with the filaments from which they take their origin. This layer serves as the groundwork for a second formation of globular cells. These are distinguished from their predecessors, as well by the regularity of their form, as by the granules of chlorophylle which they contain. They are called gonidia, and are peculiar to the Lichens, among which their occurrence is almost constant.

45. Such is the origin of the thallus, which, although, at first sight, it appears to constitute the whole plant, forms only a part, and that not the most essential part of its vegetative system. In the Verrucariæ, the most simply organised Lichens with which we are acquainted, it does not attain to any higher development than that above described. The receptacles (apothecia), which closely resemble those of a Sphœria, are formed upon the surface of the hypothallus, which can only be distinguished from the stroma of the Fungus by the presence of scattered collections of gonidia. In the more complicated foliaceous Lichens, such as Parmelia, the mature thallus is formed of two kinds of tissues, the medullary and the cortical. The cortical tissue forms two layers — an inferior and superior — and consists of thick-walled cells intimately adherent to each other, and resembling those of analogous structure, which so often form the peridia of the higher Fungi. From the surface of the inferior layer are given off numerous laminar root-like

Fig. 151.

Vertical section of the apothecium of a Lichen (Parmelia aipolia) and of the subjacent tissue of the thallus, 200 *diam.*

a, Lamina proligera, consisting of thecæ and paraphyses; *b*, tissue of thick-walled cells continuous with the cortical tissue of the thallus. Subjacent to this, but separated by an irregular line of gonidia, is the medullary filamentous layer.

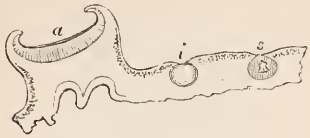
appendages. The medullary substance consists of a filamentous central layer, the elements of which resemble those of the hypothallus, and are directly continuous with them; on either side of this layer, between it and the cortex, or rather embedded in its substance, are the gonidia, which form a green tissue, distinguishable by the naked eye. To these a special function is assigned, which shall be noticed at the conclusion of the article under the head of Gemmation.

46. We have next to describe the receptacles, within or upon which the spores or spore-like organs (spermatia and stylospores) are produced. Of these there are three varieties, to which the terms *apothecia*, *spermogoniæ*, and *pycnides*, have been applied. The most common form of the apothecium is that of a *disc*, which may be plane, convex or cup-shaped. This form is that which characterises the *gymnocarpous* Lichens. In the *Angiocarpeæ*, the organ is closed upwards, its superior surface becoming internal, so as to form a conceptacle like that of the Pyrenomycetes, the form of which is subject to considerable variation. In either case, it is composed of two layers, the inferior or external, being formed of thick-walled cells which are soldered together, and resemble those of the epidermal layers of the thallus. The superior or internal layer is called the *lamina proligera*. It is formed of two kinds

* Mém. pour servir á l'Histoire organographique et physiologique des Lichens, Ann. des Sc Nat. 3me S. t. xvii. pp. 5. and 173.

of elements: first, the *paraphyses*, which are linear, claviform filaments, composed of from

Fig. 152.



Section of fruitful thallus of Sticta pulmonacea, about 20 diam.

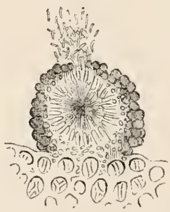
a, discoid apothecium. The vertical lines indicate the lamina proligera; *s*, spermogonia containing spermatia; *i*, empty spermogonia.

six to eight cylindrical cells, joined end to end; and secondly, the *thecæ*, which are obovate vesicles, each containing, almost invariably, eight spores. These elements are arranged side by side, their long diameters being perpendicular to the surface of the apothecium. They appear to be glued together, even in the fully formed apothecia, by an intermediary gelatinous substance, which, however, there is good reason for supposing to be nothing more than a thickening of the external membrane, from which it cannot be distinguished, either in respect of its chemical or other characters. Iodine colours this substance, as well as the external membranes of thecæ and paraphyses, blue, without the addition of sulphuric acid. In the early condition, the cavities of the thecæ are occupied by a yellow, plastic material, out of which the spores are afterwards formed. The thickness of the external starchy membrane is at this period relatively more considerable than later; as the spores increase in size, it gradually diminishes. The structure of the fully formed spore is best observed in those species in which it is largest. The spore-membrane, of considerable proportional thickness, is smooth and semitransparent, wholly unaltered by iodine and sulphuric acid. The contents consist partly of mucous granules, which are coloured brown by iodine, partly of yellowish oil globules. The whole is usually invested, even after its escape from the theca, with the still adherent remains of the inner protoplasmic layer, by which it was immediately surrounded. In form, the spores are most frequently ellipsoid and unilocular. In other instances, however, they are divided by one or more partitions. This division is either complete, so that the spore resembles two obovate cells joined by their larger ends; or incomplete, the septa being in some cases scarcely distinguishable from the protoplasmic contents of the central cavity.

47. The spores are discharged from the thecæ with an elastic force often sufficient to project them to a considerable height above the surface of the apothecium; a fact, which M. Tulasne seems to have shown to be dependent on the great capability of imbibing moisture possessed by the lamina proligera, which much exceeds that of the tissue immediately subjacent. It resembles altogether what is observed in the Pezizas, whose spores, it is well known, are projected with such force as to form a cloud above the receptacle.

48. We have next to notice the remarkable organs which Itzigsohn* described as the antheridia of the Lichens, and to which he was the first to assign a distinct function. They had been previously adverted to by several botanists, and had been usually considered as parasitical Pyrenomycetes, which they closely resemble. They consist of conceptacles embedded below the upper surface of the thallus; their presence is revealed by the appearance of blackish, projecting points, scattered at irregular intervals. The form of these organs,

Fig. 153.



Spermogonia of Scutula Wallrothii, 150 *diam.*

The spermatia are seen escaping in numbers from the apicial aperture of the organ.

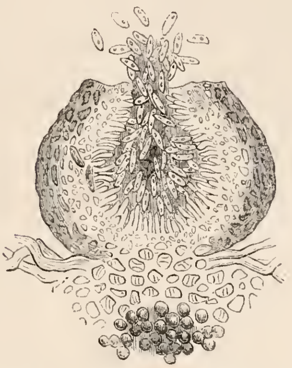
which MM. Tulasne have named spermogoniæ, is globular, ellipsoid, or oblong. Their external envelope is frequently hard and crustaceous, and usually blackish. The cavity may be simple or multiple; in the latter case all the compartments or sinuses open at one ostiole. The whole of the cavity is occupied by a filamentous tissue, which consists of two elements — viz., spermatia and the organs on which they are supported. The latter are simple or branched filaments, which are usually undivided, but occasionally jointed. They originate from the inner surface of the conceptacles. At their summits and articulations, they bear the spermatia, which are straight or curved linear organs of great tenuity, and are motionless. They are coloured brown by iodine; both the spermatia and filaments are embedded in an abundant mucilage; many of the former are sterile, and are so long that they project beyond the opening of the conceptacle like a kind of cirrhus. The whole structure corresponds in every respect with that of the spermatia-bearing conceptacles of the Discomycetes and Pyrenomycetes.

49. To a third variety of conceptacle, M M. Tulasne have assigned the title of pycnidis, This organ, although it has only been observed in two genera, Abrothallus and Scutula,

* Bot. Zeitung. 1850. S. 913.

is no less important, as forming another connecting link between the Lichens and Fungi. The special characteristic of these organs is to be found in their containing, instead of thecæ or paraphyses, stylospores, supported on stipitiform pedicles or basidia. In their

Fig. 154.



Pycnidis of the same, about 150 *diam.*

The stylospores are escaping from the upper orifice of the organ. (The figures from 143 to 154 inclusive, are after Tulasne.)

general form they resemble the spermogoniæ, but their walls are thicker and they are larger. Like them they are provided with a vertical ostiole. The stylospores are oblong, cylindrical bodies, more than twice the length of the spermatia (from $\frac{1}{2000}$ to $\frac{1}{1500}$ of an inch), obtuse at both ends, very slightly curved, colourless, and containing only granular protoplasma. They are supported on pedicles, which have the same arrangements as in the spermogoniæ. They are simple, linear tubular filaments, which taper towards their extremities. Just as the spermogoniæ correspond to the spermatium-bearing organs of the Fungi, the pycnides correspond to those receptacles, containing stylospores, which we have had occasion to describe both in the Discomycetes and Pyrenomycetes.

50. *Summary.*—The reproductive organs of the Fungi and Lichens are of five kinds:—1. Sporules, which are formed by the constriction and subsequent separation of the extremity of a simple cylindrical filament; 2. Spermatia with their supporting pedicles; 3. Stylospores, with their styles; 4. Thecæ or asci; 5. Basidia, with their basidiospores.

Of these the last mentioned are to be found only, as we know at present, in Fungi which are provided with no other reproductive organ. The first four, on the other hand, all of them occur in plants belonging to one family of Fungi—viz. the Disco- and Pyreno-mycetes: they also all occur, with the exception of the first, among the Lichens. They may be arranged, as regards the complexity of their form and structure, in the order in which they are placed above, the simple acrogenous sporule standing first. A similar arrangement may also be adopted in the description of the corresponding varieties in the reproductive phenomena which manifest themselves in connection with each variety of spore-like body. As regards the first of these, nothing further need be said, as the formation of the sporule by division, as described above, constitutes the whole reproductive process. It is exemplified in the stroma of a Sphœria, when in a condition corresponding to that which characterises a Melanconium. The spermatium is found only in a special receptacle, the general form and structure of which remain always the same, as in the Cytispora-like capsule of the Disco- and Pyreno-mycetes and the spermogoniæ of the Lichens. The stylospores are also formed in special organs (pycnides, and the corresponding organs among the Fungi), which differ from the last only as regards the structure of the parts upon which the spore is immediately supported. Lastly, the receptacles which bear thecæ are of larger size, more complicated in their structure, and later in making their appearance than any of the rest, as in the instance of the disc of Peziza, the closed receptacle of Sphœria, and the apothecium of the Lichens.

51. The Pyreno- and Disco-mycetes are, as we have seen, so closely allied to the Lichens as regards their reproductive organs, that the characters of the two families seem in this respect to merge into each other. The distinction is to be sought in the vegetative system. The thallus of the Lichen differs from the thallus-like stroma of the Fungus in its possessing two additional elements, the cortical layer and the gonidia. We observe their first appearance in the most simple form in Verrucaria.

52. There is as yet no sufficient ground for definitively concluding that the reproductive functions of the asci and spermatia are complementary to each other; or, in other words, that these organs are sexual. There is, however, good reason for considering it probable; first, because, when spermatia and asci are produced on the same *mycelium*, the former always precede the latter in their development by a considerable period, just as among the higher Cryptogamia, the antheridia precede the archegonia; and, secondly, because the organs on which the spermatia are supported, and the asci, stand in an anatomical relation to each other, and to the receptacle within or upon which they are formed, which closely resembles those of the antheridia and epispores of the Fuci, or of the antheridia and tetraspores of the Florideæ. We are well aware that these analogies do not afford the slightest proof of an actual correspondence between the organs in question. All more direct evidence, however, is absent; no observations have been made to show that the spermatia or stylospores exercise any influence on the thecæ or their contents, and on these important points, therefore, we must look to further ob-

servations for the grounds on which an opinion may be formed.

53. The fifth and last variety of reproductive organ mentioned above, is the basidium. The Mushrooms, along with another group of Fungi, which is distinguished by the possession of loculate receptacles, each loculus of which is lined with a hymenium, as *e.g.* Lycoperdon, include nearly all of the genera in which it occurs, and form Leveillé's order, Basidiosporeæ. The order is a very natural one, and between it, and any of those which are most closely related to it, we can find no intermediate forms which at present might serve as guides in comparing the reproductive organs of the one with those of the other. The basidiospore is distinguished from all the other acrogenous forms (stylospores, spermatia), by well-marked and easily-defined characters—viz. first, by its much greater complexity of structure; and, secondly, by the very peculiar and uniform arrangement, according to which the spores are developed in fours at the summits of the *basidia*.

Second Part.

Higher Cryptogamia and Phanerogamia.

54. In the attempt which we have made in the preceding sections to discover the order of succession in which nature has arranged the various families included among the Algæ, Fungi, and Lichens, we have encountered difficulties at every step. The extension of the same inquiry to the higher Cryptogamia and Phanerogamia is much more satisfactory in its results. "The comparison of the history of the development of the leafy Mosses and Hepaticæ on the one hand, and of the Equisetaceæ, Rhizocarpeæ, and Lycopodiaceæ on the other," says Hofmeister, "has shown the most complete correspondence of the formation of the fruit of the one with the formation of the embryo of the other. The *archegonium* of the Mosses, the organ within which the rudiment of the fruit (Fruchtanlage) is formed, has a structure altogether similar to that of the archegonium of the Ferns (in the widest sense)—to that part of the prothallium in whose interior the embryo of the frond-bearing plant originates. In both of these large groups of the higher Cryptogamia, we have a single cell, originating freely within the larger central cell of the archegonium, by the constantly repeated divisions of which, in the Mosses, the fruit—in the Ferns, the leafy plant, takes its origin. In both cases the division of this cell fails to take place, and the archegonium aborts, if the spermatic filaments (Saamenfäden) do not reach it at the moment that its summit gives way." *

55. The higher Cryptogamia and Phanerogamia form a series, which, commencing with the frondose or membranous Hepaticæ, ascends through the Jungermanniæ and Marchantiæ to the true Mosses. At this point, the thread is interrupted, but is easily resumed, and followed through the Ferns and Lycopodiaceæ to the Rhizocarpeæ. Between these last and the Phanerogamiæ, there is again an interval of obscurity, which is succeeded in the latter by a new order of phenomena. The plants belonging to the series before us are characterised by their displaying a regular alternation of two generations which differ widely in their organisation. Of these, the first, taking its origin from the germinating spore, develops two kinds of organs, the reproductive functions of which are complementary to each other. One of these (archegonium) is destined for the reception of a germ-cell, while the other (antheridium) sets free a number of corpuscles closely resembling the antherozoids of Chara, which have been already described. It is from this germ-cell that the second generation commences its existence; its development being, as there is now every reason to believe, dependent on the actual contact of the antherozoids. It differs completely in form and structure from its parent, and possesses only one kind of reproductive organ. This organ throws off germs (*spores*), each of which is capable, independently of any external influences, except those of heat and moisture, of transforming itself into a new individual. This in its turn produces *pistillidia* and *antheridia*, and thus forms the starting point of a new development.

56. Supposing the history of the development of the plants under consideration to commence with the germination of the spore, and terminate with its arrival at maturity, it may be divided into two periods. Of these the first is completed in the full development of the archegonia and pistillidia, and the combination of their products, so as to form an embryo; while the second terminates in the full development and distribution of the spores.

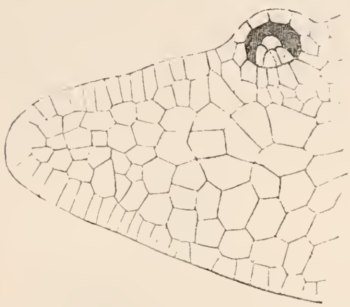
57. Among the lower Hepaticæ, the vegetative system (*frond*) consists of a simple membranous expansion, which may be considered equivalent to what would result from the soldering or fusing together of the leaves and stem of a more highly developed plant. The frond is of various forms—always originally linear, and lengthens at one (the anterior) extremity only. At the other end, which is earliest formed, cessation of vegetation, and marcescence are constantly taking place. The adult plant assumes very various forms, which arise from the repeated bifurcation of the original riband-shaped shoot. In the plant, the development of which we are about to describe (Anthoceros lævis) as one of the most simple of the Hepaticæ in its structures, the fully-formed frond is a lobed expansion of succulent, dark-green parenchyma, the general contour of which is circular. We shall divide the history of its development into two periods, corresponding with those laid down in the last paragraph.

* Hofmeister, Vergleichende Untersuchungen der Keimung, Entfaltung u. Fruchtbildung höherer Cryptogamen. p. 139. Leipzig, 1851.

58. *First period.** — *From the germination of the spore* arises a tubular filament, which is converted directly, by successive divisions, into a simple riband-like frond, with a notch in its anterior margin, containing a young shoot. At whatever age the plant be observed, the actively growing portions are shoots which resemble the spore plant in form and structure, and it is at various points of the upper surface of these shoots that the reproductive organs are developed.

59. *The development of the antheridia* commences in the still very young shoot, by the separation "of a circular group of about sixteen of the superficial layer of cells from those of the tissue below it. There results a small lentil-shaped lacuna in the parenchyma, which

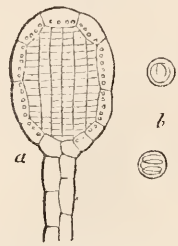
Fig. 155.



Section of young shoot of Anthoceros levis, passing through the lacuna in which the antheridia are developed. The rudiments of the antheridia springing from its floor, project upwards into its cavity. 50 diam.

is filled with watery fluid, and roofed over by the cellular layer above mentioned." Each of the cells forming the floor of the lacuna, is divided by two septa, one parallel to the axis of the frond, and perpendicular to its surface, the other also perpendicular, but cutting the first at right angles. The membrane of each of the resulting small cells buds out upwards, so as to project into the lacuna, and soon after, the upper projecting portion is cut off from the rest by a transverse septum, and becomes the parent cell of the antheridium. A second septum is then formed above the first, and parallel to it. This is succeeded by a third, which is inclined to the horizon at a small angle. Above it is a fourth, similarly inclined, but in the opposite direction; next follows a fifth, parallel to the third, and so on alternately. In this manner is formed a cylindrical papilla, consisting of two vertical series of cells, each of which is a segment of a cylinder. Each is next bisected by a radiating vertical septum, so that the papilla is now formed of four instead of two vertical columns. The penultimate cell of one of these columns next divides by a vertical septum, parallel to a plane touching the centre of its outer surface. This meets the perpendicular wall last formed at 45°, and divides the cell into an external tetrahedral, and an internal three-sided compartment. The latter divides twice by septa, which cross each other at right angles, so as to form a central group, which, as it rapidly enlarges, causes the four less actively growing cells by which it is surrounded to assume a tabular form. In its further development it is converted into a mass of very numerous and minute regularly-arranged tessellar cells, in each of which is found "a lentil-shaped vesicle which occupies the greater part of its cavity." Shortly before the antheridium arrives at maturity, the membrane of the cells disappears; the vesicles float free, and there is now found rolled up in each, a spiral fibre of from 2½ to 3 coils, which is coloured yellow by iodine. The ripe antheridium presents the general form and appearance shown in fig. 156. The cellular mem-

Fig. 156.



a, diagram of antheridium of the same, 250 diam.; *b*, lenticular cellules containing antherozoids, 600 diam.

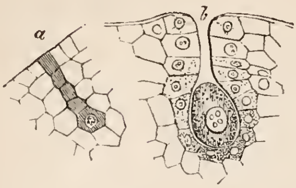
brane, resulting from successive division of the four cells, which originally surrounded the central mass, gives way at the apex of the organ. In the meantime, the layer of cells which roofed over the lacuna has split open. The escaped spiral filaments (antherozoids), as seen under the microscope, soon after lose the vesicles in which they were enclosed; "each slowly revolving round its own axis, lazily progresses in the surrounding water."

60. *The development of the archegonia* in Anthoceros differs from that of all other Hepaticæ in its much greater simplicity. A single row of cells commencing at the upper surface of the young shoot, and directed towards its interior, becomes distinguished from those surrounding it by the quantity of granular mucus which it contains. The lowest cell of the series becomes larger than the rest. In its interior a daughter cell (germ-cell) which nearly occupies its cavity, is formed around a pre-existing central nucleus. The contiguous walls of the cells forming the remainder of the series are absorbed. Hence results a canal which leads from the surface to the cavity of the basal cell. It is difficult to believe that an arrangement so remarkable can have any

* The following description is abridged from Hofmeister in *loc. cit.* pp. 4—9.

other object than the admission of the antherozoids.

Fig. 157.

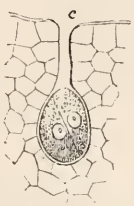


Archegonium of the same, 300 *diam.*

a, origin of the archegonium; the shaded vertical row of cells constitutes the rudiment of the organ; *b*, archegonium immediately before impregnation.

61. *Second period.—Fructification of the archegonia.* In the greater number of archegonia, development ceases at the point above described. In those in which the germ-cell has received the influences necessary for its fructification, this last-named body enlarges rapidly, and very soon divides by a slightly

Fig. 158.



Archegonium of the same immediately after impregnation. The germ-cell has divided by an oblique septum.

oblique septum, which is followed by a number of others, alternately inclined in opposite directions. This results in an egg-shaped body, perfectly separable from the surrounding tissues. The last-formed summit-cell now divides by a septum which is inclined not in the opposite direction, but in a direction at right angles to that of its predecessor. This is followed by a second in the same relation; that by a third, and so on continuously. The cylindrical rudiment now consists of four columns of cells, each of which is divided symmetrically by a vertical septum, into an external trapezoid and an internal three-sided cell. The former again divides, first, by a vertical, then by a horizontal septum, both of them perpendicular to the surface of the rudiment, which now consists of four central cellular columns, which are enclosed in eight others formed of trapezoidal cells. These last divide by vertical septa, alternately parallel and perpendicular to the external surface, by means of which the rudiment gradually thickens. This process goes on much more actively at the lower than at the upper or middle portion, in consequence of which it becomes club-shaped; its swollen base being embedded in the parenchyma of the stem of the parent, and causes absorption of its cells. The cells in the neighbourhood of the originally six-sided canal leading to the germ, have in the meantime rapidly multiplied. The upper part of the canal now encloses the growing extremity of the rudiment, which, however, is separated from it by a quantity of fluid. It opens at the apex of a nipple-shaped projection of the upper surface of the frond, by a narrow aperture through which the conical upper extremity of the rudiment protrudes, and, as it rises, usually carries with it the remains of the cells immediately surrounding the narrow channel through which it has forced its way. It now presents the horn-like form, characteristic of the mature fruit, from which the generic name of Anthoceros is derived.

62. *Changes preparatory to the development of the spores.*—An axile cylindrical column, consisting of four cellular piles, becomes distinguished from those surrounding it by the cessation of the division of its cells by horizontal septa. In the layer which immediately surrounds it, on the contrary, division by horizontal septa occurs twice as frequently as in any other portion of the fruit. The hitherto homogeneous parenchyma becomes in con-

Fig. 159.

The axile column of elongated cells is the columella. Next to it are two dark spaces corresponding to a cavity, which contains at its upper part parent cells of spores and elaters,—inferiorly the tubular cells from which they originate; *a*, capsule.

sequence distinguishable into three portions — an external, of about five concentric layers of trapezoidal cells (the future capsule), an axile portion of elongated columnar cells (the future columella), and, interposed between these, a single layer of tabular cells, whose greater surfaces are horizontal (the cells from which are formed the spores and elaters).

63. *Development of the spores.*—Those of the cells last mentioned, which are destined to become the mother-cells of spores, soon become detached from their neighbours, and assume a spherical form. Each at first contains a large central nucleolated nucleus, and

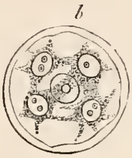
a quantity of granular mucus. Soon this last arranges itself in two masses, at opposite

Fig. 160.

Original parent-cell of spores of the same, 500 *diam.*

sides of the central nucleus. Each of these masses is transformed into a new nucleus, from which radiating threads of mucus stretch to the internal surface of the corresponding half of the cell. Each new nucleus is, when fully formed, vesicular, possessing a membrane of extreme delicacy, and is surrounded by a layer of protoplasma. At a later period its contour becomes cloudy and indistinct; this change being preparatory to a second division, which results in the formation of four new nuclei similar to the first two; these

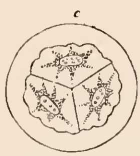
Fig. 161.



The same, containing four vesicular nuclei,

soon place themselves in such a manner, that each would occupy one angle of a regular tetrahedron contained in the parent cell. Up to this point the original central nucleus has remained; it now disappears, and six septa are formed simultaneously, which radiate from the centre to the circumference, one between every two nuclei, in such a manner as to divide the parent cell into four compartments, which are the special parent cells of the spores.

Fig. 162.



The same, divided into four compartments.

(The above, from 155 to 162, inclusive, are after Hofmeister.)

In each new cell, after this wall has become thickened by the deposition of a gelatinous material on its inner surface, a spore is formed, which, even at the first appearance of its membrane, occupies the whole cavity. As it approaches maturity, it assumes a brownish yellow colour, its external surface remaining perfectly smooth. In those of the cells of the middle layer of the half-ripe fruit, which are destined to the formation of the so-called elaters, the tubular form is permanent. In each cell the nucleus disappears, and is replaced by two others, between which a perpendicular septum is formed. From a repetition of the same process, there results a cylindrical body consisting of a series of four cells, the fully formed elater.

64. No sooner are the spores of the upper part of the capsule ripe, than it splits into two valves; dehiscence commences at the apex, leaving, as it proceeds, the columella with the loosely attached spores and elaters.

65. *Jungermanniæ frondosæ.*—From Anthoceros we pass to a group of plants, which, while they resemble it in their mode of growth, differ from it considerably in the form of their antheridia and archegonia, and still more in that of the organs in which they are contained. Here as in Anthoceros we follow the description of Hofmeister (Pellia epiphylla).*

66. *First period.—Germination of the spores.*—The spore is an ovoid cell, divided into four by three transverse septa, and enclosed in a finely granular external membrane. Of the four cavities, one of the terminal ones distinguishes itself from the rest by the small quantity of chorophylle which it contains. This cavity, or rather the cell which it represents, develops in germination, to the first hair-like roots; while the others, by successive divisions by septa in the direction of the long axis of the spore, form the rudimentary flattened stem of the young plant.

67. *The antheridia.* — The rudiments of the antheridia make their appearance as club-shaped projections of the upper surface of the young spring shoots. Each such projection originates from a single cell of the superficial layer by a mode of division which corresponds in every respect with that described in Anthoceros (§ 59). The completely formed antheridium consists of a globular mass of very small four-sided tessellar cells, which is surrounded by an outer layer of about twenty flattened cells, containing chlorophylle granules in contact with each other by their margins; the whole is supported on a very short stalk, consisting of only four cells. Each of the small cells contains a lentil-shaped vesicle, within which a spiral fibre is rolled up. This fibre moves with great activity for about ten minutes after its escape, revolving round its own axis, and at the same time progressing rapidly. The posterior extremity is slightly thickened, while from the anterior which tapers off gradually to a point, there emanate two long and delicate cilia, like those of the antherozoids of Chara. These, as well as the slender prolongation of the tail, manifest an active "winding screw-like" motion. These phenomena remain in perfection only for about ten minutes after the escape of the filament.

68. *Archegonia.*— The rudiments of the archegonia make their appearance as oval cellular bodies (from four to twelve in number) in the notch, which in Pellia, as in other frondose Hepaticæ, is found in the anterior margin

* Hofmeister, *loc. cit.* pp. 10—20.

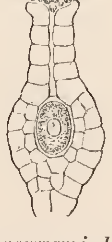
of the young shoot. Soon after their origin, there is formed, by the continued growth of

Fig. 163.

Antherozoids of Pellia, 400 *diam.* (Thuret.)

the shoot below them, a thin laminar prolongation upon the surface of which they are supported. By a process of cell-division resembling that observed in the development of the antheridia of Anthoceros, each rudiment is converted into a cylinder, rounded above and consisting of a single central cellular column, surrounded by a single layer, which is formed of four perpendicular series of flattened cells in contact with each other by their edges. The cells of the central column contain granular mucus, in which vesicular nuclei are embedded. As the archegonium becomes fully formed, the lowest cell in the series, as well as its nucleus, enlarges, and the cells of the outer wall in its neighbourhood rapidly multiply, so that the organ becomes swollen out at its lower part. The development is completed by the disappearance of the transverse septa, which separate the cavities of the cells forming the central column. In this manner is produced an axile channel, closed above, and terminating below in a flask-shaped dilatation, in which

Fig. 164.



Archegonium of Jungermannia bivaricata at period of impregnation, 400 *diam.*

Cellules containing antherozoids are observed at the entrance of the canal.

the enlarged nucleus of the basal cell (germ-cell) is contained. Soon the cells forming the summit of the archegonium give way, so as to open a communication between its cavity and the external atmosphere.

69. *Second period.—Development of the embryo.*—In consequence, as there is every reason to believe, of the entrance of the spiral filaments into the cavity of the archegonium, the germ-cell is divided by a tranverse septum into a larger inferior and smaller superior (hemispherical) portion. This last next divides by two perpendicular septa crossing each other at right angles, which are succeeded by a third, which is horizontal. This is succeeded by others parallel to it, each new septum being placed immediately above its predecessor. Hence results a cellular cylinder, the rounded summit of which always consists of four cells, divided from each other by crucial septa. By successive cell-divisions, this body becomes a pear-shaped cellular mass. Afterward by the lengthening of its middle third, the cylindrical stalk of the perfect fruit is formed, and still later from the lower third springs a cup-shaped sheath, the margin of which reaches to about a third of the length attained by the stalk of the fruit before it has escaped from its calyptra.

70. *Changes preparatory to the development of the spores.*—At an early period, when the young fruit is still pear-shaped, its rounded upper end (the future capsule) manifests peculiarities in its intimate structure. The cells of its superficial layer are divided repeatedly by septa perpendicular to the surface, while those which they enclose gradually enlarge without dividing. The result of this process is the formation of a central mass of large dodecahedral cells (parent cells of the spores and elaters), which is surrounded by a single layer of tabular cells of not more than a quarter their breadth (the future wall of the capsule). As the development proceeds, the walls of the central cells become thickened by the deposit of a gelatinous material on their internal surfaces. This material, which is coloured violet by iodine, swells out, and finally dissolves, on the addition of water, the globular primordial vesicle, which occupies the centre of the cells, being brought into view. Still later both the cell membranes and their gelatinous linings disappear, and the primordial membranes are left, lying in the cavity of the young capsule. Soon after they clothe themselves with new membranes of cellulose, and assume forms, which differ according as they are destined to become parent cells of spores or elaters. Those of the newly formed cells which are to be elaters, assume the form of spindles. They are found partly grouped round the axis of the capsule, partly in series which radiate from it towards the circumference. The future parent cells retain only for a short time their globular contour: soon four projections of the membrane of each cell become visible, each of which would correspond in position to one of the angles of a regular tetrahedron contained in the parent cell. These projections increase so rapidly, that in a short time the whole presents the appearance of four egg-shaped

sacculi blended together by their smaller ends in such a manner that their axes meet at a central point, each forming with all the rest angles of 120°. The cell-wall now becomes thickened by the deposition of a granular material on its inner surface, which takes place most rapidly along the linear ridges which separate the sacculi. In this manner six imperfect dissepiments are formed, which stretch from the ridges towards the centre, and encroach so far on the central cavity, that it now communicates with the cavities of the sacculi only by four narrow circular channels. These changes are followed by the formation in each sacculus of a delicate vesicle (the spore) completely filling the cavity of each. No sooner has this taken place than those portions of the parent cell which correspond to the sacculi dissolve and disappear, the four oval spores remaining attached for several days to the still permanent tetrahedral central portion, which consists of vitreous cellulose. The central nucleus of each spore now disappears, and is replaced by two others, around which the mucous and chlorophylle granules group themselves. A septum is soon after formed between them, dividing the spore into two halves, in each of which the process is repeated. In the meantime the coloured external membrane is secreted on its external surface. The ripening of the capsule and consequent scattering of the spores takes place in spring, a year after the development of the archegonium within which the fruit originated.

71. Our limits will not permit us to enter upon the history of the development in other families of Hepaticæ. In the higher Jungermanniæ, which are provided with a distinct stem, as well as with regularly formed and symmetrically arranged leaves, it closely corresponds to that of Pellia. In the Marchantias, in which we have again a frondose stem, we have considerable differences. The antheridia are found on special receptacles of various forms, sometimes stalked capitula, concave superiorly, like the stalked apothecia of some Lichens (Marchantia polymorpha), sometimes sessile. However much the general form may vary, they agree in their relation to the antheridia. These last are flask-shaped bags, and always completely immersed in the parenchyma subjacent to the upper surface of the receptacle. This surface is always found to be scattered over with nipple-shaped elevations. At the summit of each an aperture is observable—the termination of the long and narrow neck by which the cavity of the antheridium communicates with the surrounding medium. The fully formed antheridium consists of a central mass of quadrangular cells, which, surrounded by a single layer of others much larger and of a tabular form, is continued upwards so as to form the narrow neck; the whole being closely invested by the parenchyma of the receptacle. Within each of the central cells is found a lentil-shaped vesicle containing a spiral filament, which only differs from those described already, in its greater minuteness. The archegonia of Marchantia are produced on the under surface of a somewhat umbrella-shaped, deeply lobed, stalked receptacle. This body corresponds in the mode in which it takes its origin from the notch in the anterior margin of the frond, with the ordinary vegetative shoot, of which it is obviously a modification. Its development has been well described by M. Mirbel.* The structure of the archegonium, and the commencement of the development of the fruit, correspond very closely with what has been described in Pellia. The mode of formation of the spores and elaters differs, however, considerably. The latter, which in the last-named plant, are nothing more than fusiform septate cells, attain in Marchantia, as well as in many Jungermanniæ, a more complicated structure. Their development has been described in an admirable contribution by Mr. Henfrey, who finds that the young elaters are, like those of Pellia, elongated fusiform tubes, and contain at first only colourless protoplasma.† Soon after starch granules are deposited in their interior, and they are converted by a growth which is much more rapid in length than in breadth, into very slender, hollow filaments, attenuated at each closed extremity. Still later, the starch and protoplasma disappear, and at length faint streaks, denoting the nascent fibres, are to be perceived upon the walls. These become gradually more and more distinct, till, in the mature elaters, they present themselves as strong flattened bands. In Marchantia there are two fibres, which coil in opposite directions, and are confluent by their ends at the extremities of the tubes in which they are contained. At the time of the scattering of the spores the cell-membrane gives way, and the elastic fibre rapidly uncoils, at the same time lengthening considerably. The parent cells of the spores in Marchantia are also, at an early period, fusiform. They are arranged side by side with the young elaters, from which they differ in being very much broader. Each of these cells is converted, by the formation of transverse septa, into a series of four, which afterwards separate from each other. In each of the new cells, the protoplasma increases in quantity and assumes a yellow colour. Still later it begins to accumulate into four distinct masses, each of which becomes invested in a cellulose membrane, and, after the solution of the membrane of the parent cell, assumes the structure and appearance of the ripe spore.

72. *Mosses.*—The Mosses are distinguished from the leafy Hepaticæ, first, by differences in the structure and arrangement of the stem and leaves, involving greater complexity; secondly, by the fact that the leafy axis is not developed directly from the spore, but, with the intervention of a confervoid structure (proto-

* Recherches Anat. et Phys. sur le Marchantia, Mém. de l'Acad. v. xiii. p. 380.

† Transactions of Linnæan Society, vol. xxi. p. 106.

nema),* resembling in all its relations to the future plant, the mycelium of the Fungi and Lichens.

73. *First period.—Germination of the spore.*† —The spore of the Mosses is a nucleated cell, the solid contents of which are granular, and consist of protein compounds, starch and dextrine. From the budding out of its membrane, results a hollow filament, which, as it lengthens, divides by a succession of transverse septa. It then begins to branch in all directions, each branch resembling the parent, and ramifying in the same manner. Hence results an entangled network of filaments of a brilliant green colour, which spreads over the moist surface on which the spores have been sown. At length some of the filaments are observed to give off lateral branches which differ from those previously formed in being more slender and containing less chlorophylle. In some of these the terminal cell, after dividing four or five times, becomes globular, and is transformed into the rudiment of a leafy axis.

74. *Development of the antheridia and archegonia.* — These organs are usually found in groups, which are situated either at the termination of the stem or branches, or in the axils of the leaves. In either case they are surrounded (with the exception, in many genera, of the axillary antheridia) by special arrangements of modified leaves (involucres). Those involucres which surround the antheridia are called perigonia, and are composed of leaves much smaller than the ordinary leaves of the stem. Those leaves which enclose the archegonia, small at first, attain a large size as the fruit approaches maturity. In some (hermaphrodite) mosses, both antheridia and archegonia are contained in one involucre.

75. In the very diminutive plants belonging to the genus Phascum, which we select as examples on account of their great simplicity of structure, the groups of archegonia are terminal, those of antheridia usually axillary. The growing extremity of the stem (terminal bud) or axillary bud, when destined to bear reproductive organs, instead of developing to a new axis, becomes flattened in such a manner as to present a slightly convex disc, which takes the place of its conical growing extremity. It is upon the surface of this disc that the rudiments, whether of antheridia or of archegonia, originate, by a process precisely similar to that which we have described in the commencing development of the antheridia of Anthoceros. The rudiment consists, as in Anthoceros, of four columns of cells, combined so as to form a cylindrical club-shaped body. The development and ultimate form of the archegonium corresponds so completely with what has been described in the Jungermanniæ, that it is unnecessary to describe it. The fully formed antheridium of Phascum is a club-

Fig. 165.

Section of termination of fruitful stem of Phascum cuspidatum, 50 *diam.*

On the right a female, on the left a male inflorescence. From the slightly convex surface which forms the summit of the stem, spring in the one case the archegonia, in the other the antheridia, along with numerous jointed filaments.

shaped body of about the same length as the archegonium, and consists of a central mass of minute quadrangular cells, which is enclosed by a single layer of tabular cells, in contact with each other by their edges. Shortly before the antheridium arrives at maturity, the quadrangular cells, each of which contains a spiral filament enclosed in a lentil-shaped vesicle, are dislocated. This is followed by the total disappearance of their membranes, so that the vesicles float free in the cavity of the now ripe antheridium. No sooner is this the case than the organ gives way at its summit, and discharges its contents in the form of an intestine-like coil of mucus, consisting of the lenticular vesicles with their contents. Soon after, this is dissolved, and the spiral filaments commence their active motions.

76. *Development of the fruit.* — The early stages correspond with those described in Pellia. At a period when the lower dilated portion of the archegonium is about five times its original length, the young fruit, which is a fusiform cellular body, does not occupy more than its upper half. In the meantime the cells forming the tissue subjacent to, or in the immediate neighbourhood of, the base of the fructified archegonium, have multiplied with such activity, that the end of the stem has again assumed the form of a cone, on the summit of which the fruit is borne, while the aborted archegonia are scattered round its sides. In its further development, the fruit grows much more rapidly in length than in breadth, and in consequence of its extension upwards being opposed by the resistant structure of the canal of the archegonium, its lower end presses downwards in such a manner as to cause the absorption, not only of the cellular tissue of the archegonium, which is subjacent to it, but of that of the conical summit of the stem. In

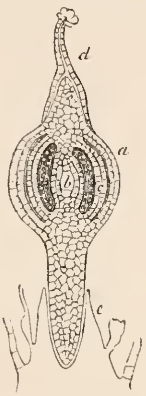
* From the very recent observations of Grönland (Mém. sur la Germination des Spores de quelques Hepatiques, Ann. des Sc. Nat. 3me. S. xx.), it appears that among the higher Hepaticæ with cut leaves, the first result of germination is always a branched and septate filamentous protonema, resembling that of the Mosses in its relation to the leafy stem.

† Hofmeister, *loc. cit.* pp. 65—71.; Bruch & Schimper, Bryologia Europæa, Fasc. i. p. 5.

this manner it becomes firmly implanted, the tissue which surrounds it assuming the form of a sheath, and receiving the name of vaginula. During this process, the dilated portion of the archegonium has increased in size, and has now attained about ten times its original length. Finally, it gives way at its line of junction with the vaginula, and is carried upwards on the summit of the still lengthening fruit.

77. *Development of the spores.* — The upper portion of the cylindrical fruit, which is destined to become the capsule, begins, some time after the calyptra has given way, to dilate rapidly. Soon after there is formed, by the separation of the external and superficial lay-

Fig. 166.



Section of half-ripe fruit of the same, 50 *diam.*

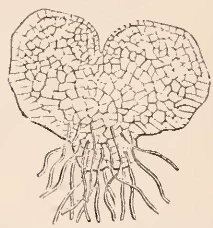
The globular dilatation exhibits the following parts: — *a*, the capsule. Within this, and separating it from the central portion, is a dark space, which corresponds to a cavity of the form of a hollow cylinder; *b*, columella; *c*, superficial layer of central portion; *d*, remains of archegonium; *e*, vaginula. (From fig. 164 to 166 from Hofmeister.)

ers of cells from the central portion, a cavity of the form of a hollow cylinder, the axis of which coincides with that of the fruit. At this stage, the central portion consists of an axile column of large cells, closely invested by a single layer of smaller ones (the columella); a superficial layer of cells, about four times as large as those last mentioned; and lastly, between the two, a layer of nucleated cells, with granular contents, the primary parent cells of the spores. The development of these last consists in the disappearance of the nucleus of each, and the substitution for it of two others; this being accompanied or followed by the division of the primordial membrane into two new vesicles, each of which encloses a nucleus. A cellulose membrane is now formed at the surface of contact of the two vesicles by which the original cavity is bisected. In the cavity of each of the resulting nucleated cells, two new ones make their appearance, apparently by contraction of the primordial membrane, either before or immediately after its division into two halves. On the surface of each half cellulose is secreted, so that the spherical cells which are thus formed possess a delicate cellulose external, and a very distinct inner membrane (primordial vesicle.) This last divides into four portions (the young spores), each of which becomes invested with a layer of cellulose. The ripe spore has been already described. The capsule now gives way at the line of its insertion on the pedicle which supports it. It is by the opening thus produced that the spores make their escape after the dislocation of the layers of cells immediately surrounding them. Phascum differs from all other genera in the absence of all trace of an operculum.

78. *Ferns.*—No two plants could be found which differ more completely from each other in the appearance which they present to the ordinary observer, than a Hepatica and a Fern, at the moment that the spores of each arrive at maturity; yet, in the history of their organisation and development a very close correspondence exists. The immediate result of the germination of the spore of a Fern is a frond similar to that of the simpler forms of Hepatica; on this frond antheridia and archegonia are formed. In each fructified archegonium, a central germ-cell is developed to a new individual, widely different in organisation from the parent. It, in its turn, produces spores, the germination of each of which is the commencement of a new circle of phenomena similar to the one which precedes it. Dividing this circle into two periods, as before, we have the following stages in the development.

79. *First period.** —*Germination of the spore.* — The mature fern-spore consists of a delicate transparent vesicle, which is invested in a brown resistant external membrane. Germination consists in the budding out of the transparent vesicle so as to form a nipple-shaped projection, which penetrates the external membrane. The projecting part divides repeatedly by transverse septa. About the same time a second budding out takes place in the opposite direction, which is destined to the formation of a root. By the further growth of new cells, a flattened two-lobed organ is formed — the Prothallium.

Fig. 167.



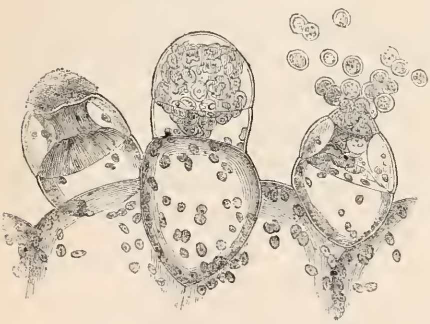
Early condition of prothallium of Gymnogramma chrysophylla, about 20 *diam.* (Henfrey.)

80. *The antheridia.*—The antheridia are situate on the under surface of the prothallium,

* Hofmeister, *l. c.* pp. 78—82.

and take their origin as follows. A hemispherical projecting portion of one of the superficial cells is cut off from the rest by a horizontal septum as in Anthoceros. This is divided by a single transverse septum. In the resulting terminal cell a second septum is formed, inclined to the horizon at a small angle, which is followed by a third, inclined in the opposite direction. Both of the cells resulting from these divisions, and subjacent to the last-formed septa, are again divided by perpendicular septa coinciding with the axis of the papilliform rudiment. In one of the resulting cells there is then formed a perpendicular septum, which meets its predecessor at an angle of 45.° Hence results a club-shaped body, consisting of a four-sided central cell, filled with granular mucus, and enclosed by six others, having the following arrangement. Four of the form of segments of a hollow cylinder, which are in contact by their edges, surround the central cell on all sides. It is surmounted by a fifth, which is hemispherical (the terminal cell last formed). A sixth, the cell resulting from the first division by a horizontal septum, is cylindrical, and serves as a pedicle on which the whole is supported. The central cell is converted by a successive division into a round group of dice-shaped cellules, in the interior of each of which a delicate lenticular vesicle is formed, which contains, rolled up in its interior, a spiral filament. The ripe antheridium bursts at its summit, and the escape of its contents is, as in the preceding cases, followed by the bursting of the vesicles, and the commencement of the active motions of the spiral

Fig. 168.



Antheridia of Pteris aquilina, 260 *diam.*

On the right is seen an antheridium from which cells containing antherozoids are escaping; in the centre another, which has not yet burst; on the left a third, which has already discharged its contents. (Thuret).

filaments (antherozoids.) In each filament the extremity which is directed forwards during motion, is broader than any other part, while the opposite extremity (posterior) tapers off into a long filament. The anterior coil of the spiral bears on the surface furthest from its axis a number of delicate cilia. The motion of the antherozoid is of two kinds—of progression and of revolution round the axis of the spiral.

81. *The archegonia.* — At a period somewhat later than that at which the rudiments of the antheridia begin to appear, there commences on the inferior aspect of the prothallium, and in the immediate neighbourhood of the notch by which its anterior margin is bisected so as to form two lobes, an active development of new cells. The result of this is the formation of a cushion-like projection of the surface bordering the notch above mentioned, upon the anterior aspect of which the archegonia are formed.

82. Each archegonium takes its origin from a cell, which is distinguished from those surrounding it by the comparative abundance of granular mucus which it contains, and by the presence of a distinct central vesicular nucleus. This cell divides by a horizontal septum into a superior and an inferior portion. It is from the latter, which is hemispherical, that the papilla which forms the rudiment of the projecting portion of the organs is formed. It consists, as in the Hepaticæ and Mosses, of four contiguous columns of cells, each of which is a half segment of a cylinder, the whole being surmounted by a hemispherical terminal cell. In the further development, varieties are often observed, even on the same prothallium. This is dependent on the mode in which the canal occupying the axis of the mature archegonium is produced. Most frequently a central column of cells is formed in exactly the same manner as an Anthoceros. The cells forming it are afterwards absorbed and disappear, leaving a four-sided canal. In the other case, the canal results simply from the separation of the four piles of cells along their common line of contact. This is the arrange-

Fig. 169.

Archegonium of Asplenium septentrionale, 250 *diam.*

a, germ-cell enclosed in its parent-cell; the membrane of the latter is still perfect, and separates its cavity from *b*, the axial canal. (Hofmeister.)

ment which occurs constantly among the Equisetaceæ, Lycopodiaceæ, and Rhizocarpeæ. In reference to the mode of origin of the germ-cell, there is some difference of opinion. According to Hofmeister,* the cell which contains it originates by the formation of a tangental septum in the lowest of the cells, constituting one of the four columns of

* *Loc. cit.* p. 80.

which the rudiment is composed. According to Mr. Henfrey*, on the other hand, the germ-cell is contained in the superior, and consequently deeper, of the two portions into which the primary nucleated parent cell of the organ divides by a horizontal septum; and is distinguishable before the formation of the papilla-like structure has commenced. This account of the matter is not only supported by analogy, but, as it appears to us, in a very marked manner by Hofmeister's own drawings.

83. *The embryo.*—Immediately after the entrance of the spiral filaments into the cavity of the archegonium, the cells which immediately surround it multiply rapidly, in consequence of which the cushion-like projection of the inferior surface of the prothallium increases in size. At the same time the germ-cell is transformed into an irregularly egg-shaped body, which consists of minute cellules, and may be considered as the primary axis of the future fern. It originates in the same manner as the rudiment of the fruit of the Mosses and Hepaticæ, and elongates by repeated divisions of a terminal cell by septa, inclined alternately in opposite directions. It consequently presents but one growing point, which is directed, not towards the orifice of the archegonium, but, on the contrary, towards the centre of the cushion-like mass, by the cells of which it is surrounded. Soon after, however, there appears on the side of the egg-shaped embryo, which is directed towards the notch in the anterior margin of the prothallium, a second growing projection of its surface. This projection, at first conical, becomes, as it enlarges, compressed from above downwards. No sooner is this the case, than it bursts through the superficial cellular layer of the prothallium, at a point which is invariably a little anterior to the base of the archegonium—between it and the angle of the notch. It now assumes the form of a symmetrical leaf-like organ, and begins to project beyond the notch of the prothallium. The further development consists in the appearance in the axil of this primordial leaf, of a new axis, the permanent stem of the young plant. From this axis all the succeeding leaves take their origin, each diverging from its immediate predecessor at an angle of 60°.

84. *Sporangia and spores.*—At a point of the surface of the frond, which always corresponds to the termination of a vascular bundle, a lacuna is formed under the epidermal layer, by the separation of that structure from the subjacent tissue. The floor of this cavity consists of a pavement of tessellar cells, some of which grow out into nipple-shaped projections. In each of these, the projecting portion is separated from the rest by a horizontal septum, which is soon followed by several others superior and parallel to it. The last-formed terminal cell now enlarges, and assumes a globular form, and is converted by a process similar to that to be described below in the rudimentary sporangium of Equisetum, into a central mass of nucleated cells, with grumous contents (parent cells), enclosed in a capsule formed of a single layer of others, which are tabular. In each parent cell, the central nucleus afterwards disappears, and is replaced by four others. This is followed by the division of the primordial sac into four portions, around each of which a cellulose membrane is formed. This membrane becomes the epispore; a second (endospore), which is distinguished by its greater delicacy, being subsequently formed within it.*

85. *Equisetaceæ.*—The history of the development of the Equisetaceæ corresponds in most respects with that of the Ferns.

86. *First period.*†—*Germination of the spore.* — The spore of Equisetum consists, in its ripe condition, of a delicate, colourless internal vesicle, which is surrounded by a more or less resistant granular membrane, and contains a central nucleus, and a yellowish grumous fluid, in which swim oil and chlorophylle granules. The first change observed in germination consists in the division of the nucleus into two, and the subsequent formation of a septum between the two corresponding halves of the spore-cell. Of these halves, the larger contains nearly all the chlorophylle, and is developed to the stem; the smaller, the contents of which are almost colourless, is the commencement of the root. The prothallium, which results from repeated cell-division of the larger half, is an irregularly riband-shaped expansion, growing and branching repeatedly at the extremity furthest from its point of origin, and consisting of large, delicate-walled cells, containing much chlorophylle. One of the branches is usually observed to be larger than the rest, and it is upon it that the reproductive organs are formed.

87. *Antheridium.*—The rudimentary antheridium of Equisetum consists, like that of preceding families, of a papilla, composed of four conjoined vertical piles of cells, each pair slightly overlapping the pair preceding it. In each of the cells constituting this rudiment a tangential wall is formed, dividing it into an inner three-sided, and an outer tabular cell. The inner cells, which form a central oval mass, are soon observed to be filled with finely granular mucus; the tabular cells, on the contrary, contain chlorophylle, and form the wall of the future antheridium. The further development of the central mass corresponds entirely with what has been described in other families. The antherozoa are larger in Equisetum than in any other known example. They originate by the deposition of a gelatinous linear thickening, in the form of an imperfect ring, parallel to the plane surfaces of the discoid vesicles in which they are enclosed. When fully formed, they resemble, in almost

* On the Development of Ferns from their Spores' Trans. of Linnæan Society, vol. xxi. p. 135.

every respect, those of the Ferns. The antheridia of the Equisetaceæ are placed, not upon

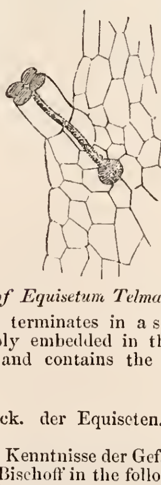
the inferior surface, but along each margin of the principal branch of the prothallium.

88. *Archegonium.* — The archegonia were first discovered and figured by Milde* in Equisetum Telmateia, and have been since more completely described by Hofmeister† and Bischoff‡ in two other species. The projecting papilliform portion consists, according to the last-mentioned observer, of eight cells, of which the four lower, in apposition to each other, have the general form of truncated cones, each presenting two flattened surfaces by which it is united to its two neighbours. The upper, in the same relation to each other, are nearly cylindrical, but are slightly rounded at their summits. The axis of the organ is occupied by a quadrilateral intercellular passage. The whole is supported on a base, which consists of two or three rows of cells

Fig. 171.



Archegonium of Equisetum Telmateia, 200 *diam.*

The axial canal terminates in a spherical cavity, which is deeply embedded in the tissue of the prothallium, and contains the germ-cell. (Bischoff.)

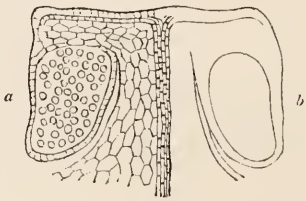
superimposed upon each other, which combine to form a circular wall round a central cavity, which contains the germ, and is the termination of the quadrilateral canal. On the transformation of the germ-cell into the embryo, observations are as yet wanting.

89. *Spores and sporangia.*—The organs upon which the spore-cases are supported are arranged in whorls round the upper part of the fruit-bearing stem. They seem to be modifications of the ordinary stem-leaves, on which account they have received the name of *sporophylla*. In its earliest condition, the sporophyllum is a cellular projection of the surface; but, as it advances towards maturity, it assumes the form of a hexagonal disc

Fig. 172.

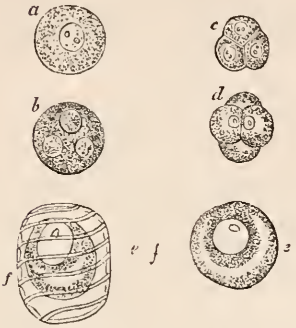


Vertical section of one of the sporophylla of Equisetum limosum, 100 *diam.*

a, mature sporangium; *b*, another in outline. The capsule of the sporangium is composed, when ripe, of the external layer of cells only, in consequence of the absorption of the two inner layers, which resemble in their structure those described more at length in the sporangium of Selaginella (§ 94.), and seem destined to afford the materials for the rapid growth and development of the mother cells of the spores.

attached by a pedicle at its centre. Upon the surface of the disc which faces the stem, the spore-cases are formed. Each spore-case originates as a little papilla, and consists of a large central cell, which is invested by a single layer of others of smaller size. As the organ enlarges, these last are transformed into a capsule consisting of three concentric layers, within which is enclosed a mass of cells exhibiting large central nuclei and grumous contents. In each of these cells the nucleus is afterwards replaced by two others similar to it, which almost fill the cavity. These, however, soon disappear, and now four globular nuclei, much smaller than their predecessors, present themselves, and are arranged, as in the Hepaticæ, towards the four angles of a regular tetrahedron. Around each nucleus a tetrahedral cell is formed, within which, after it has become detached from its fellows, there is deposited on the inner surface of its membrane, a gelatinous transparent layer. Within this layer, and immediately surrounding the nucleus, may be distinguished the primordial vesicle, on the surface of which the cellulose membrane of the future spore is secreted, as well as the two parallel, elastic fibres by which it is surrounded. When the spore is ripe, these last, which are external to the spore membrane, and consequently formed before it, line the inner surface of the parent

Fig. 173.



Development of parent cells of the spores of the same.

a, one of the nucleated cells which constitute the central mass of the young sporangium; *b*, the central nucleus has disappeared, and is replaced by four others, one of which is out of focus; *c*, the cell is divided by six septa into four somewhat tetrahedral compartments. This object has by mistake been represented relatively smaller than the rest; *d*, the four compartments (special parent cells of the spores), are about to separate from each other: *e*, mature special parent cell. In its interior we observe the nucleated spore, and between it and the membrane of the parent-cell, the coils of the two elastic fibres; *f*, the free spore; the spiral fibres, which remain for a short time after its escape from the parent-cell, attached by their middle points to its membrane, have disappeared.

cell, from which the gelatinous thickening has now disappeared. Soon after, springing asunder from each other, they tear the membrane of the parent cell, retaining, however, their central attachment to the surface of the spore.

90. *Lycopodiaceæ.**—The large spore (macrospore) of Selaginella, consists, when ripe, of an internal spherical vesicle of delicate structure (endospore), which is enclosed in a resistant epispore. The endospore contains a fluid, in which float mucous and oleaginous granules only, its nucleus having disappeared. On its surface are observed three linear projections, all of which converge towards one point, the summit of the spore. The epispore, a structure of later formation, is composed of two layers, the internal of which is distinguished from the other by its remarkable transparency. The external surface is scattered over with acuminated projections, which are connected with each other by a network of minute ridges.

91. The development of the prothallium commences (usually several months after the macrospore has been sown) by the deposition of several cells on the internal surface of the proper spore membrane, at a point subjacent to that towards which the three external ridges converge. Whether these cells are originally developed *in situ*, from a single parent, or existed before, lying free in the cavity of the spore, is uncertain. Hofmeister inclines to the latter opinion. At first the prothallium is a cellular expansion of circular form, which enlarges by growth at its periphery, and lines the upper part of the proper membrane of the spore. At its centre it is of considerable thickness, and is composed of several layers of cells. Towards its margin it becomes gradually thinner and thinner, its two surfaces at last converging at a very acute angle, so as to become continuous with those of the spore membrane.

* Hofmeister, *l. c.* pp. 118—124.

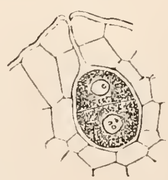
92. *Archegonia.*—The first-formed archegonium is always found to occupy the centre of the upper surface of the prothallium; its successors surrounding it at various distances. A superficial cell, distinguished from its neighbours by the quantity of granules which it contains, is divided into two by a transverse septum. From the upper of the resulting compartments is developed a papilliform projection, which is composed, as in the Equisetaceæ, of two double pairs of cylindrical cells, surrounding an axial intercellular canal. In

Fig. 174.

Section of unimpregnated archegonium of Selaginella denticulata, containing the granular germ-cell, 400 *diam.*

the lower is contained a vesicular nucleus, the germ-cell of the fully formed archegonium. Its cavity becomes continuous with the axial canal by the solution of its membrane.

Fig. 175.



Archegonium of the same immediately after impregnation, 600 *diam.*

The germ-cell has enlarged considerably, and divided by a transverse septum.

93. *The embryo.*—About the time that the formation of archegonia is completed on the upper surface of the prothallium, there is developed, on its inferior aspect, a tissue composed of cells much larger than any of those previously existing. This tissue projects, in the form of a cushion, into the cavity of the spore. In general one only of the many archegonia receives the necessary fructifying influence. In this the germ-cell divides repeatedly by transverse septa, as the result

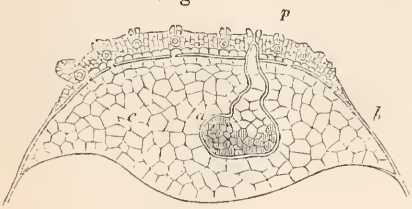
of which a structure is formed composed of a series of cylindrical cells placed end to end. The growing extremity of this body, the so-called *suspensor*, penetrates the single layer of cells which separate it from the inferior surface of the prothallium, and buries itself in the cushion-like mass. A new development now commences in the terminal cell, which is divided by a succession of septa inclined alternately in opposite directions.

Fig. 176.

Egg-shaped rudiment of embryo of the same attached to the suspensor, from the terminal cell of which it has originated, 300 *diam.*

From this results an egg-shaped body, the primary axis of the embryo, which, as it enlarges, causes the absorption of the cells by which it is immediately surrounded. Soon after a new (secondary) axis is developed,

Fig. 177.



Section of contents of upper part of macrospore of the same, 120 *diam.*

a, prothallium, continuous at its periphery with *b*, the original inner membrane of the spore; *c*, cellular body subjacent to prothallium, which projects into the cavity of the spore; *a*, commencement of secondary axis of growth of the embryo; below *p* are observed the remains of the archegonium within which the embryo originated. Several other unfructified archegonia are seen in section.

the direction of which (obliquely upward), is nearly opposite to that of its predecessor. It finally makes its escape from the cavity of the spore by penetrating the prothallium near its centre, bearing upon its summit the first pair of leaves of the young plant.

94. *Sporangia and spores.* — The sporangia of Selaginella denticulata are formed in the axils of the leaves of the fertile branch, in the following manner. A superficial cell of the stem, the position of which is always immediately above the middle of the line of insertion of the leaf, is developed to a nipple-shaped projection. The centre of this body is occupied by a large cell, which is enclosed by a single layer of others, and supported

Fig. 178.

Two germ plants of Selaginella Martensi, which have taken their origin from a single macrospore, 5 *diam.*

on a short pedicle. As it advances towards maturity, the spore-case consists of a capsule of three layers. Of these the external or epidermic, is composed of narrow prismatic cellules containing only a transparent fluid. The cells of the middle layer are tabular, and contain starch granules, while those most internal are narrow and somewhat columnar, with very delicate walls. Within this capsule is enclosed a central mass of larger cells, which exhibit central nuclei and granular contents. These, which are the parent cells of the spores, are at first intimately united, but afterwards lie loose in the cavity of the spore-case. Up to this point the development of all the sporangia is uniform. In those in which macrospores are to be produced (oophoridia), one of the parent cells, in no respect different from its fellows in structure, continues to increase in size while they disappear. Its nucleus is soon replaced by four others, which arrange themselves, as in Equisetum, towards the four angles of a regular tetrahedron. Septa are afterwards formed, which divide the cell into four compartments, in each of which a spore is developed. The spore at first exhibits only a delicate membrane, but as it approaches maturity the three converging ridges, and, finally, the external tegument, the structure of which has been already described, are formed upon its surface. No sooner is this process completed than the membrane of the parent cell disappears, the four spores retaining their relative position, however, to each other, apparently attached by the remainder of the septa. It is at the point at which the spores are in relation with the centre of the mother cells, that the three ridges converge, as well as the three lines by which the valves of the external tegument give way to allow of the growth of the prothallium.

95. In those sporangia in which microspores are to be formed, *all* of the original parent cells exhibit a development which corresponds with that which is above described as occurring in *one* only in the *oophoridium*, with this exception, that they do not attain the same dimensions. Hence results a large number of microspores which resemble the macrospores in the structure of their internal membrane, and external three-valved tegument, but differ

completely in their mode of germination. After lying a certain time on a damp surface, their inner cavities are found to be occupied by a number of small spherical cellules, each of which contains in its interior a spirally coiled fibre (antherozoid). By the dehiscence of the valves of the external tegument,

Fig. 179.

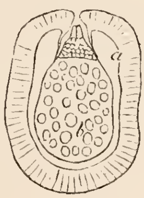
Valvate dehiscence of microspore of Selaginella helvetica, six months after sowing, showing escape of antherozoids, 300 *diam.*

the antherozoa are set free; and it is presumed, that it is by their agency that the archegonium is fructified, after the prothallium has been laid bare by the bursting of the macrospore at its apex.

96. *Rhizocarpeæ.*—In describing the mode of reproduction of the Rhizocarpeæ, we shall confine our attention to the genus Pilularia, respecting which the most exact researches have been made.

97. The macrospore of Pilularia is an egg-shaped body, presenting an equatorial constriction. It consists of an internal proper membrane (endospore), the so-called embryo sac,

Fig. 180.



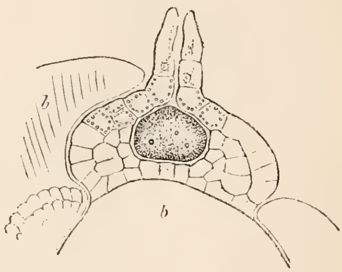
Section of macrospore of Pilularia some time after germination, 50 *diam.*

a, two layers of the exospore, the outer, vertically striated, the inner, homogeneous; *b*, cavity of endospore bounded superiorly by the prothallium, the papillæform summit of which projects through the canal of the exospore.

which is surrounded by a white coriaceous exospore. This last exhibits two distinct layers, of which the internal is colourless and vitreous, without trace of structure; while the external appears to be formed of prismatic columns fitting closely together, which are more distinct at the lower end of the spore, while they disappear entirely towards its smaller end or apex, at which point the exospore forms a papilliform projection open at its summit. From this arrangement there results a canal, which is immediately surrounded by the thickened and dentate margin of the vitreous layer, and leads to the apex of the endospore.

98. *The prothallium.*—The first indication of the commencement of the germination of the macrospore is the formation of a lenticular accumulation of granular plasma, at the summit of the endospore, which had previously contained only starchy, mucous, or oleaginous granules. Soon after there appears in the same position a delicate cell of similar form, the upper surface of which is in contact with the endosporal membrane, and is immediately subjacent to the aperture in the exospore. It is in all probability from this cell, although the earlier stages of the development have not been clearly made out, that the prothallium takes its origin. A day or two after germination it consists of a central cell, which is surrounded by a single layer of others of smaller dimensions. Four of these last are invariably found interposed between the upper surface of the large cell and the spore membrane; the septa by which they are separated being perpendicular, and at right angles to each other. Soon after the central cell itself divides by a transverse septum into two; of these the upper, of globular form, contains a large vesicular nucleus, the future germ-cell. The lower, which is tabular, divides repeatedly by vertical septa, so as to form a single layer of cells which intervenes between the cavity of the archegonium and that of the spore. In the meantime the four cells which surmount

Fig. 181.



Vertical section of prothallium of the same at the period of impregnation, which passes through the axial canal of the archegonium, and exposes

a, the germ-cell; *b*, cavity of macrospore; *b*, outer, and *c*, inner layer of exospore, the apicial canal of which (§ 97.), it completely occupies.

the germ-cell extend upwards in the form of four papillæ, separated from each other by an axial canal, which burst through the proper spore membrane, and finally project beyond the aperture of the exospore. By the absorption of the central cell, its cavity becomes continuous with that of the vertical quadrilateral canal above mentioned.

99. *The embryo.*—In consequence of the presumed entrance of the antherozoids into the cavity of the archegonium, the germ-cell enlarges, and is transformed by repeated division into an embryo, which is at first a somewhat meniscus-shaped body, formed of minute cellules. Soon after, a conical projection of its upper surface presents itself, which rapidly

increases by the repeated division of a terminal cell by alternately inclined septa. The

Fig. 182.

a, remains of papilla of archegonium with its canal; *b*, first root; *c*, first leaf; *d*, primary axis; *e*, cavity of macrospore.

and soon after, as a lateral development from this last, the second leaf. In the meantime the first root makes its appearance as a rounded projection, which grows from the upper surface of the embryo, in a direction opposite to that of the first leaf. Both of the last-mentioned organs finally burst through the remains of the prothallium, and become free.

100. *Sporangia and spores.*—The organ in which the sporangia of Pilularia are contained is an egg-shaped body, supported on a short, curved pedicle, which springs directly from the creeping stem, in the axil of one of the awl-shaped leaves. It presents a tough, coriaceous, cellular coat, which encloses a cavity, which is divided into four compartments by vertical septa, and subsequently dehisces in four valves. The middle of the internal surface of each valve is, from the first, marked by a ridge of gelatinous cellular tissue, from which the sporangia take their origin as a vertical series of projections. Their development remains up to a certain time the same, whether they are to produce large or small spores. All are found to exhibit at this period a central mass of cells, containing nuclei and grumous fluid, which is surrounded by a double capsular layer. In each of the central cells, the nucleus soon after is replaced by four others of smaller size, around which are formed four tetrahedral secondary cells, which are the immediate parents of the spores. In the lowest of the vertical series of sporangia which corresponds to each valve, one only of the original central cells continues its development, the rest becoming abortive, and finally disappearing. The four spores, which are formed just as in Selaginella, at length become free by the absorption of the cell in which they are enclosed, and for a time continue to enlarge equally, while their walls are thickened by internal gelatinous deposition. Soon, however, one begins to exceed the rest in growth, and finally occupies the whole cavity of the sporangium, which is subsequently burst by the swelling of the exospore, which is produced when it is subjected to the influence of moisture.

101. The microspores are developed precisely as in Selaginella. The exosporal membrane

Fig. 184.

Microspore of the same, 600 *diam.*

The inner membrane projects through the outer, which has given way. A few of the cellules containing spermatozoids have escaped.

dehisces in three valves, the proper membrane of the spore at the same time giving way irregularly, to allow the escape of numerous little globular cellules. These cellules contain, in addition to starchy and mucous granules, parietal lenticular vesicles, each of which encloses a delicate, spirally coiled antherozoid, which moves actively in water.

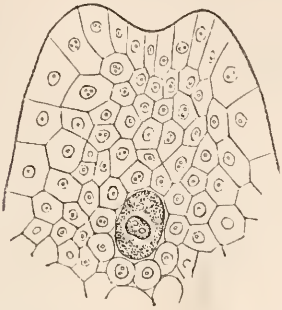
102. *Phanerogamia.*—Between the higher vascular Cryptogamia, and the simplest forms of flowering plants, there exists, as has been already noticed, a wide chasm of obscurity. The researches, however, of Hofmeister, have shown that in the Coniferæ the embryo is formed upon a plan which presents the most striking analogies to what is observed among the Rhizocarpeæ and Lycopodiaceæ; and that, in fact, their development stands intermediate between that of the plants just mentioned and the angiospermous Phanerogamia.

103. *Phanerogamia gymnospermia.*—Following the same plan of description that we have adopted in the previous section, we shall confine our attention to the Abietineæ, of the development of which Hofmeister has furnished us with a most complete account. The so-called ovule consists, at the time of the scattering of the pollen, of a short and thick nucleus of delicate cellular tissue, which is enclosed in a single, somewhat fleshy integument, leaving open a wide micropyle canal.* In the centre

* For the origin and signification of botanical terms in common use we refer the reader to any of the elementary works on Botany.

of the nucleus there exists an ovoidal embryo-sac, which owes it origin to the coalescence of a vertical and axial series of cells. At this period it contains only granules of starch and

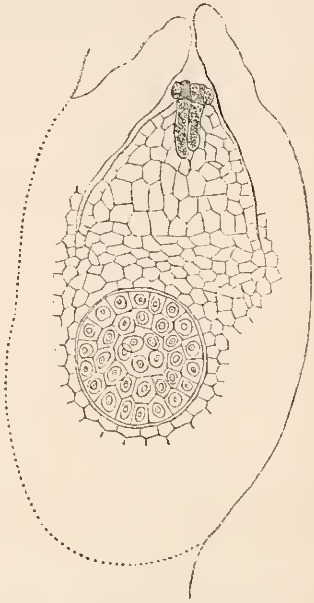
Fig. 185.



Section of nucleus of ovule of Pinus Austriaca, in the centre of which is observed the young embryo-sac, 150 *diam.*

mucus, the nucleus which it at first contained having disappeared. It corresponds, as will be seen as we proceed, to the internal membrane of the ripe macrospore of the Rhizocarpeæ and Lycopodiaceæ. The pollen grain in the Coniferæ generally itself reaches the summit of the nucleus by means of the wide micropyle. From each grain emanates a tube, which penetrates for a short distance into the tissue of the nucleus; not, however, until it has remained for some time upon its summit. In the meantime numerous free nuclei have become visible in the embryo-sac, which immediately afterwards "presents itself filled with a large number of radially elongated cells, which are arranged in a concentric layer." These continue to multiply by septa in all three directions, until the beginning of winter, at which period the wall of the embryo-sac is so delicate as to be indistinguishable. During the winter months these cells undergo no further change, except that their walls are thickened by internal gelatinous deposition. In the beginning of March of the second year, both the gelatinous material and the cell-wall disappear, the primordial sacs lying free in the cavity of the embryo-sac, each containing a large globular nucleus. Shortly after, the nucleus of each cell disappears, and is replaced by two or four smaller ones, round each of which new spherical secondary cells are formed. The parent cell is dissolved, and immediately after, the same process is repeated in the secondary cells. While this is taking place, the embryo-sac has increased to twenty times its former volume; its membrane has become resistant and vitreous, while throughout the whole ovule, with the exception of its summit, an active cell growth has taken place. Towards the middle of May the permanent cellular body which afterwards fills the whole embryo-sac, originates by the application, in successive layers, of the cells contained previously in its cavity, to its membrane. By the continuation of this process, the sac becomes a second time filled with cellular tissue.* Two or three of the cells subjacent to the micropyle end of the embryo-

Fig. 186.



Section of naked ovule of Pinus maritima, as observed in January of the second year, 150 *diam.*

The spherical embryo-sac is filled with cells, the walls of which are already thickened by gelatinous deposition. Two pollen grains occupy the funnel-shaped space between the wide micropyle and the summit of the nucleus. The cellular tissue of the latter is penetrated by two tubes emanating from the pollen grains. At the dotted line the tissue of the ovule becomes continuous with that of the spermophore.

sac now become larger than the rest, and are destined to contain the germs of the future embryos. As their development proceeds, these bodies, the so-called corpuscula, assume an elongated, oval form, and the space intervening between their summits and the membrane of the embryo-sac is occupied by four small cells on the same level, which are

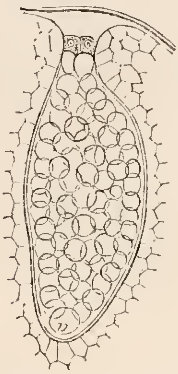
Fig. 187.

Four cells which surmount the corpusculum of Pinus sylvestris, seen from above, 200 *diam.*

* To this tissue is commonly applied the term "albuminous body." It corresponds in its mode of origin with the "endosperm" (§ 106.) of other Phanerogamia.

separated from each other by as many vertical septa, meeting at right angles. Each corpusculum is likewise surrounded on all sides by a single layer of cellules resembling pavement epithelium, and exhibits in its interior a nucleus which is usually placed at its superior extremity. After some time the nucleus disappears, and now a number of transparent vesicles become visible, which accumulate for the most part towards the extremities of the corpusculum.

Fig. 188.

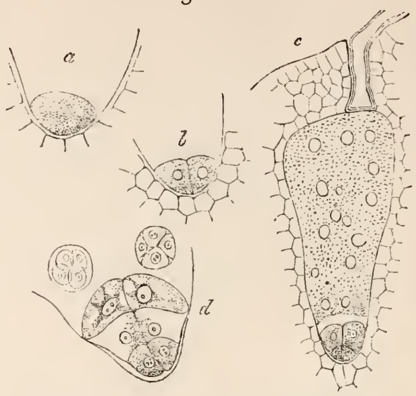


Corpusculum of the same in section, immediately before impregnation, 200 *diam.*

Its cavity is filled with transparent vesicles, and bounded superiorly by four granular cells, the position and relations of which recal very forcibly the arrangement which presents itself in the rudimentary archegonium among the higher Cryptogamia.

104. The growth of the pollen tube, which has been for many months arrested, at last recommences ; the membrane of the summit of the embryo-sac at the same time becomes attenuated, and immediately after is penetrated by the narrowed end of the pollen tube, which is brought into immediate contact with the summit of the corpusculum, the four cells which previously surmounted it having disappeared. At this time, the corpusculum exhibits in its interior, at the end opposite the pollen tube, a single vesicle, much larger than those by which it is surrounded, within which is afterwards developed a secondary cell, occupying more than half its cavity. This cell, which is convex above, is applied by a flattened inferior surface against the wall of the corpusculum. It soon divides by a longitudinal septum into two, each of which is nucleated. These two cells, which occur throughout the Coniferae, form the commencement of the suspensor. They next divide by a second pair of vertical septa, at right angles to the first ; and in each of the four cells which result, a succession of horizontal septa are formed, by which they are converted into four vertical columns intimately united to each other. The suspensor lengthens in one direction only, partly by the repeated division of the four inferior terminal cells, partly by the interstitial growth of those first formed. Soon it bursts through the

Fig. 189.



Corpusculum of the same, 120 *diam.*

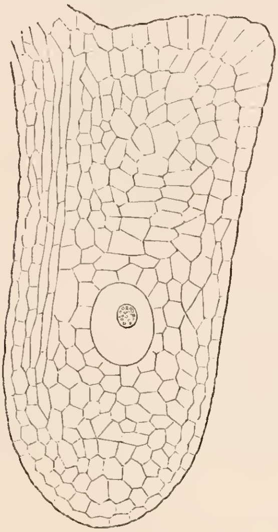
The four cells by which it is bounded superiorly have disappeared. The pollen tube is still in contact, by its flattened extremity with the corpusculum, and by the rest of its surface with the cells of the albuminous body. *a*, 300 diam. Earlier stage of development of lower end of the same. A single germ-cell is applied to its wall. *b*, 300 diam. Division of germ-cell into four by two vertical septa, of which one only can be seen on section. *c* and *d*, 250 diam. Division of the four resulting cells by a succession of transverse septa. Above *d* are two of the numerous complexes of cells, which at this time float in numbers in the corpusculum. (From fig. 172 to 189 inclusive, are after Hofmeister).

membrane of the corpusculum at its lower end, and becomes immersed in the tissue which occupies the embryo sac, the cells of which, at the same time, become less intimately united than before. The four series of cells of which the suspensor is formed, now separate, and, from the terminal cell of each, the rudiment of an embryo takes its origin. Its development commences, like that of the embryos of the Hepaticæ and of the first leaves of the Ferns and Equisetaceæ, by the repeated formation of alternately inclined septa in a terminal cell ; these being followed by vertical septa radiating from the axis, and, subsequently by others parallel to the external surface. Of the four embryos thus formed, one only advances to vigorous maturity.

105. *Phanerogamia angiospermia.*—The observations on record relating to the origin and development of the embryo among these plants are now so numerous, that although the conditions are much more complicated, and the difficulties in themselves much greater, we are, notwithstanding, more competent to draw our conclusions with confidence than we have found ourselves to be in our previous study of the Cryptogamia. Among the many examples at our disposal, we select two of the simplest, between which, at the same time, great differences present themselves in those respects in which the development is variable.

106. *Hippuris vulgaris.**—The already anatropous ovule of this plant consists of a cylindrical nucleus of delicate cellular tissue, along one side of which is observed a longitudinal fleshy ridge, terminating above in a short funiculus, by which the ovule is suspended from the apex of the one-celled ovary. One of the central cells of this nucleus becomes larger

Fig. 190.



Section of naked nucleus of Hippuris vulgaris at an early stage, about 150 diam.

The embryo-sac is seen as a large central nucleated cell. (Unger.)

than the rest, from which it is further distinguished by its containing a free vesicular nucleolated cell-nucleus and granular fluid. This cell, the embryo sac, rapidly enlarges, and at the same time assumes an elongated oval form. A number of vesicles of various size are developed at the same time, at its micropyle extremity, all of which disappear some time before the scattering of the pollen. Shortly after this has taken place several new cells are formed, one of which, situated towards the upper end of the sac, begins at once to lengthen, and is finally converted into a tube closed at both extremities (germ-cell). The rest arrange themselves in vertical series, so as to form a continuous tissue (the endosperm), which completely occupies the lower part of the sac. *After* this, in consequence, as may be presumed, of the contact of the pollen tube with the membrane of the sac, the germ-cell is divided by a transverse septum into a tubular superior, and a spheroidal and much smaller inferior compartment. The

Fig. 191.

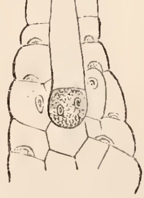
The tubular germ-cell, the lower end of which is embedded in the nucleated cells of the endosperm, occupies its axis.

latter, which is the parent cell of the embryo, is divided by a vertical septum into two hemispheres. In these two new septa are formed, also vertical, but at right angles to

Fig. 192.



The same immediatety after impregnation.

The germ-cell is now divided by a transverse septum into two compartments, the inferior of which is the parent-cell of the embryo. 250 diam.

the last. In the meantime, several new vesicles make their appearance in the upper tubular compartment of the germ-cell, which eventually become cylindrical, and arrange themselves, end to end, in its interior. The four cells of the embryo now divide by horizontal septa, which are succeeded by others parallel to its surface, and meeting their predecessors at angles of 45°. The globular body which is thus formed, consists of six-

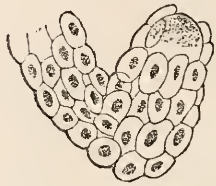
Isolated sixteen-celled embryo of the same, with its filamentous prolongation, about 150 *diam.*

its globular form, until it is transformed into an embryo, the direction of growth of the axis of which is downwards.

107, *Orchis Morio.*— In the Orchideæ the structure of the ovule is remarkably simple. The following description of the mode of origin and early development of the embryo, in Orchis Morio, all the stages of which we have ourselves followed, is taken from Mr. Henfrey's paper on Vegetable Reproduction, in the Annals of Natural History: — "The ovule springs from the placental surface as a single projecting cell, which, by subdivision, soon becomes a cellular papilla (the nucleus), composed of a central cell (the embryo-sac), surrounded by a simple cellular layer. The two coats gradually grow up over this, and by the greater elongation of one side the ovule becomes anatropous. The nucleus meanwhile loses its cellular coat, apparently by absorption, and appears as a large oval sac enclosed in the coats, consisting in fact merely

Fig. 195.



Early condition of ovule of Orchis mascula.

The embryo-sac is exposed in consequence of the absorption of the cells which previously surrounded it, 180 diam.

of an embryo sac. In the apex of this, about the epoch when the pollen falls upon the stigma, three cellules (embryonal vesicles), make their appearance at the upper end of

Fig. 196.

Isolated embryo-sac of the same immediately before impregnation, containing three embryonal vesicles, 180 *diam.*

the embryo sac, formed apparently by free cell-formation around a globule of protoplasm. The pollen masses on the stigma send down pollen tubes, which traverse the conducting tissue of the style, and make their way to the placentas, where they enter, ordinarily, singly (sometimes more than one) into the micropyle canals of the ovules, and come in contact with the outside of the apex of the embryo sac, immediately above where the embryonal vesicles lie; but the pollen tube does not penetrate the embryo sac. Soon after the pollen tube has reached the embryo sac, one (very rarely two) of the embryonal vesicles begins to swell, becomes divided by a cross septum into two cells, and while the upper one grows out in a filamentous form through the micropyle, by a continued process of cell-division, the lower cell enlarges, and divides repeatedly so as to form a cellular globule—the embryo, which in this plant does not go on to produce a cotyledon and radicle, as in most other cases. The filamentous prolongation, the use of which is not evident, but which seems analogous to the suspensor, presently to be mentioned, meanwhile decays away."*

Fig. 197.

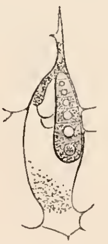
x, the external integument; *c*, the internal, which immediately surrounds *e*, the embryo-sac. The pollen tube *p*, after passing the wide exostome becomes sensibly narrowed as it penetrates the canal leading to the embryo-sac, with the outside of which its termination is in contact. 180 diam.

108. *The anther and the pollen cell.*—The history of the development of the anther is remarkably uniform among the different families

Fig. 198.

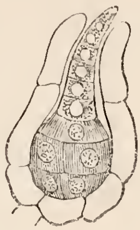


The same, some time after impregnation.

The remains of the pollen tube are observed to be still adherent to the sac. The rudiment of the embryo exhibits itself as a somewhat pear-shaped cell, divided towards its upper part by a succession of transverse septa, into numerous compartments. The lowest of these, larger and more granular than the rest, is the parent-cell of the embryo. 180 diam. (The above, from 191 to 198 inclusive, are original.)

of Phanerogamia. It at first appears in the young flower-bud as a cellular papilla, which grows out laterally from the floral axis. By continuous cell multiplication an organ is formed, in which may be distinguished a

Fig. 199.



Further developed embryo. (*Orchis Morio.*)

The embryo-sac is no longer distinguishable. The spheroidal embryo which completely occupies the cavity of the ovule is surmounted by a filamentous prolongation, which projects through the micropyle. 150 diam. (Henfrey.)

central cylindrical column (connective), along the antero-lateral aspects of which are attached two larger cellular masses; the outer surface of each is marked by a vertical furrow, indicating its division into two halves, which are the rudiments of the future *loculi*. In each half a single axile vertical column of cells soon becomes distinguished from those surrounding them by their greater size and granular contents. In each of these cells the nucleus disappears, and is replaced by two others, this being followed by a division of the cell contents (primordial membrane), which results in the formation of a new cell round each nucleus. By the repetition of this process a mass of cells — the parent-cells of the spores—is formed, which occupies the centre of each rudimentary loculus. The next change observed is the thickening of the walls of the parent-cells by gelatinous deposition on the interior surfaces. This is followed in all of them by disappearance of the nucleus, and consequent division of the contents of the cell (primordial membrane) into two portions, each surrounding a new nucleus. These, however, are only transitory formations, and are soon succeeded by four permanent nuclei, which are placed towards the four angles of a regular tetrahedron, each invested with a primordial sac containing a granular mucus, on the surface of which is soon secreted a gelatinous layer. In this manner the parent cell is divided into four compartments — the so-called special parent cells of the pollen grains. Within each compartment is now formed a new cellulose membrane on the surface of the primordial utricle. This is transformed into a resistant and coloured tegument, which is the outer membrane of the pollen grain, and exhibits various projections of its surface, which differ according to the species.

109. While these changes are taking place in the central mass of each loculus, the tissue forming its wall is transformed into a capsule of three distinct cellular layers. The inner

* Henfrey, On the Reproduction of the higher Cryptogamia, and the Phanerogamia. Annals of Nat. Hist., June, 1852.

layer consists of radiating prismatic cells, and is soon absorbed. The cells of the second layer are distinguished by their containing at first numerous starch granules, and afterwards by the deposition of spiral fibres on the inner surfaces of their walls. These are usually dice-shaped cells arranged in concentric layers. The external or epidermic layer consists of tabular cells in contact by their edges.*

110. *Review of the analogies which present themselves in the history of the development of the reproductive organs of the higher Cryptogamia and of the Phanerogamia.*—The families in question are distinguished by the presence of what is called "sexual reproduction" from all others. It is true that among the Characeæ, Conjugatæ, Vaucheriaceæ, and Desmideæ, the concurrence of two dissimilar parts is necessary for the development of the germ; but in them the phenomena do not present themselves in such strict conformity to law, and the anatomical relations of the germ to the organ which contains it are not nearly so complicated as in the plants under our consideration. Taking the sexual germ as our starting point, in comparing the history of the development of the phanerogamous with that of the cryptogamous plant, the following analogies present themselves:—

111.—1. *Analogies existing between the ovule, the anther, and the sporangium* — In Zostera marina the termination of a stem destined to bear reproductive organs, is broadened out in the form of a spatula, concave on one side, convex on the other. On the concave surface are observed, early in the development, two vertical series of papillæ—one on each side of the middle line—which are the rudiments of the organs which support the ovules and anthers. In each series, the two kinds of rudiments are arranged alternately in such a manner, that an ovule in one series is always on the same level with an anther in the other. The rudimentary organ which is destined to contain the ovule, commences as an imperfect ring of cellular tissue, on the inside of which is seen a little round projection—a bud in the axil of a leaf. From this projection is developed the ovule, with its tegments, just as described in Orchis Morio. The axis of its nucleus is occupied by a vertical series of cells. Of these the uppermost enlarges, and becomes detached from its neighbours, so as to form the embryo-sac.† If we compare this process with what occurs in Selaginella, we find in each case, a cell belonging to the stem in the axil of a modified leaf, which transforms itself into an axial organ. In each case one of the central cells enlarges and becomes detached—in Selaginella, to form the mother cell of four spores—in the phanerogamous plant, to become the embryo-sac.

112. The exact correspondence, step for step, which exists between the development of the anther, and that of the sporangium, will be best seen by successively comparing the descriptions contained in § 89 and § 108. It is rendered still more striking when we consider the very remarkable variations which present themselves in the structure of the anther among the Phanerogamia themselves; as *e. g.* in Zostera, among the Orchidaceæ, and other examples for the description of which space is wanting. The contemplation of these analogies leads us to remark how little relation there seems to be as respects the organs under consideration between the morphological import of the rudiment and its development. The ovule of Zostera is an axial organ, originating in the axil of a modified leaf; its analogue in development, the anther, is itself a bilateral foliar organ. The sporangium of Equisetum seems to originate as a leaf,—that of Selaginella, as an axis in the axil of a leaf.

113.—2. *Analogy between the embryo-sac, the pollen cell, and the parent cell of four spores* — In approaching this, the most difficult part of our inquiry, we must refer to the Coniferæ, as holding in so many respects an intermediate position. Of those stages of the development which *precede the act of impregnation* in Selaginella, the first, namely, the division of the parent cell into four compartments, and the formation of a spore in each, is entirely wanting in the Coniferæ. The prothallium—understanding by the term the organ of which the archegonia form a part—is represented by the corpuscula, between which and the archegonia, the resemblance in structure is very striking.—The difference in the mode of origin of the germ-cell, on the other hand, is no less remarkable. "Among the Cryptogamia there is," says Hofmeister, "only one germ-cell which completely fills the central cell of the archegonium, while in the Coniferæ, very numerous germ-cells swim in the central cell of the corpusculum, of which one only, applied against its lower end, is fecundated." In the gymnospermous Phanerogamia, all the steps of development which intervene between the parent cell and the germ, disappear; the latter originating altogether independently at the upper end of the embryo-sac. As the transformation of the germ-cell is the most important element in the process of development, it presents the greatest degree of constancy. It always commences by the formation of one or more septa, the direction of which, in relation to that of the first axis of growth, is transverse or nearly so.

114. In the Hepaticæ and Mosses one septum is formed, the inferior of the two resulting cells undergoing no further development, while the superior is transformed into the primary axis of the fruit. This fruit-axis, the apex of which is converted into a sporangium, is normally a leafless one. In the Mosses, how-

* Nägeli, Zur Entwick. des Pollens, &c. Zürich, 1842; Wimmel, Zur Entwick. des Pollens, &c. Bot. Zeit. 1850, S. 225.

† Hofmeister, Entwick. der Zostera. Bot. Zeit. 1851; Grönland, Beitrag. zur Kennt. der Zostera marina, &c. Bot. Zeitung, St. 10. 1851.

ever, examples frequently occur, in which its development is changed, under the influence of peculiar external circumstances, in such a manner that, instead of producing a sporangium it lengthens considerably, and bears symmetrically arranged leaves. Such a condition makes it more easy to compare the fruit of the Mosses and the leafy stems of the higher plants. In the Ferns and Equisetaceæ, again, only one transverse septum is formed; but here, it is the inferior secondary cell which is developed to the embryo, the direction of the first axis of growth being opposite to that of the archegonium. In Selaginella, a succession of transverse septa are formed, whence results a conferva-like filament, which lengthens downwards by repeated division of a terminal cell. At length the youngest cell is transformed into an embryo. Among the Coniferæ, the same process presents itself, with this important difference, that before it commences, the germ divides by two crucial vertical septa into four cells, which correspond to the four embryos which are afterwards formed. In all the Phanerogamia, probably without exception, the germ-cell divides, in the first instance, by a transverse septum into two cells, of which the upper is the larger. In some cases the lower cell is developed directly to a spherical cellular mass (as in Hippuris and Orchis Morio). Much more frequently, however, it is transformed into a conferva-like filament (suspensor) which lengthens by repeated division of an inferior terminal cell. At length the youngest cell, instead of lengthening, becomes spherical, and gives rise to the embryo by a process similar to that described above in Hippuris.

115. The organ to which the name suspensor is applied by Mr. Henfrey in Orchis Morio, differs materially from that of Selaginella, the Coniferæ, or from that described in the preceding paragraph. Its formation does not, like that of the true suspensor, precede, but follows the origin of the embryo. In Hippuris, it appears to result from endogenous cell-formation in the lengthened upper compartment of the original germ-cell.

116. The difference between the development of the pollen grain, and that of the microspore of Selaginella and of the Rhizocarpeæ, is no less remarkable. Among the Phanerogamia, after the pollen grain has remained for some time in contact with the stigma, its inner membrane grows out at one point of its periphery into a filiform cell; this lengthens more or less rapidly until it reaches the micropyle of the ovule, which it enters, and at last comes into contact with the embryo sac. The sac usually resists it strongly; sometimes it is bulged in, but is very rarely perforated. In consequence of this act the transformation of the germ-cell commences. The absence of moving filaments among the higher plants stands connected with the intervention of a second membrane (that of the embryo sac) between the two fluids, the union of which seems to constitute the essential condition of fecundation.

117. In comparing the development of the microspore with that of the spore of the Ferns with which the plants among which it presents itself are so closely allied, the difference is even more striking. In Selaginella all the steps intervening in the Fern between the spore and the tessellar cells of the antheridium have disappeared.

118. Direct observations relating to the act of impregnation among the Cryptogamia, are for the most part wanting. The presence of antherozoids in the cavities of the archegonia of the Ferns has been witnessed only by Suminski and Mercklin. Among the Hepaticæ and Mosses, Hofmeister observed within the involucre of *Jungermannia bivaricata*, antherozoa "which moved rapidly and played livelily round the archegonia."* In this species, as well as in *J. bicrenata* and *bicuspidata*, the same observer found a mucous substance of glass-like transparency, occupying the mouths of the archegonia. In this substance were embedded numerous curled fibres, which he considered to be dead antherozoids. Evidence more to be depended upon is that of the concurrent testimony of all observers that, among the diœcious mosses and liverworts, wherever plants bearing archegonia grow in the neighbourhood of those bearing antheridia, fruits are almost always produced; while in the contrary case, the archegonia are abortive.

119. *Origin and development of germ-cells in special organs destined for their reception, which are capable of transformation into rudiments of new plants, without the concurrence of two organs of opposite functions.*— Of this, distinct examples occur only among the Hepaticæ; viz. among the leafy Jungermanniæ, and the Marchantiæ. In one of the latter, the *Lunularia vulgaris*, there is formed by the doubling in of the epidermal layer of the upper surface of the frond, immediately behind the notch in the anterior margin, a crescentic pouch, which extends backwards for about a line under the surface. Its cavity is bounded by an inferior and a superior wall, whose concave surfaces unite in a sharp margin, the plane of which inclines slightly backwards and downwards. The upper wall is formed by the double epidermal membrane; the lower by a membrane which is intimately united with the parenchyma of the frond, in its relations to which it resembles the tissue which lines the subepidermal air cavities. It consists originally of a single layer of tessellar cells, much smaller than those upon which they are supported. A number of these grow out into papilliform projections, in each of which the projecting hemispherical portion is soon separated by a transverse septum. A second is then formed above the first, and parallel to it. The highest cell next divides by a vertical septum parallel

* Hofmeister, Vergleichende Untersuchungen, &c. S. 38. *Vide supra, Fig.* 164.

to the axis of the frond. This is followed on each side by transverse, and afterwards by

Fig. 200.

The club-shaped rudiments of the gems are attached by their bases to the superficial layer of cells, which are much smaller than those upon which they are supported.

vertical septa, which last are parallel to it. Hence results a bilateral organ, the surfaces of

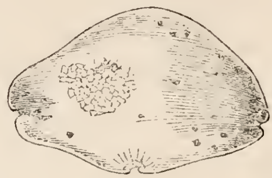
a flattened rudiment of the gem viewed laterally. Division of the second cell of the rudiment by a vertical septum, on each side of which the commencements of several transverse septa are modelled out in the protoplasma. 400 diam.
b, the same at a later stage, 250 diam.

club: afterwards, as it becomes larger, two notches are formed on each of its *lateral* margins, which exactly resemble those of the *anterior* margin of the young frond. As soon as its development is completed—that is, when it has attained a length of about $\frac{1}{3}$ of a line, it is pushed out of the receptacle by its rapidly growing successors. If, after its expulsion, it is sown on a damp surface, a new growth at once commences in two opposite directions, in a line which is at right angles to its axis. At the same time the cells of the inferior surface grow out into nipple-shaped projections, which soon become filamentous roots, and the whole is transformed into a riband-shaped frond. The organ, the development of which is de-

Fig. 203.



Outline of gem as observed two or three days after it has been sown, 50 diam.

In its inferior margin is a notch which indicates its point of attachment to the floor of the gem-pouch. The other two notches, one on each side, are the points of growth of the young plant into which the gem is transformed: they resemble those which are described (§ 58.) in the margins of the young frond of Anthoceros. It is remarkable that the line of direction of growth of the young plant is at right angles both to that of the gem itself, and to that of the parent plant.

scribed above, receives, in common with others of a different nature, the name of "gem." The whole process differs widely from that of true gemmation or "rejuvenescence" of an old cell, in order that its primordial vesicle may be transformed into an embryo. This distinction is well illustrated in the gemmation of Anthoceros; the primordial sac of a cell of the parenchyma of the frond, the position of which is undetermined, contracts and secretes on its surface a new cellulose membrane. The new cell is converted by repeated division into the rudiment of a young frond, which, as it grows, breaks through the tissue of the parent. In Jungermannia bivaricata, we have observed a similar process. A single cell of the leaf of a marcescent, last year's stem, is seen still to contain a primordial vesicle, lined with green protoplasm. This forms around itself a new cell, which divides by a septum, the direction of which is transverse in relation to that of the first growth. One of the resulting cells grows out so as to project through, or carry before it, the membrane of the old cell. This divides by a septum inclined obliquely to the former, which is succeeded by another, inclined in the opposite direction, and so on alternately. Hence results the rudimentary stem of a new plant. Both of the preceding are examples of gemmation.

The very distinct analogies in development (homologies) which present themselves among the higher plants, are exhibited in the following table. The six last vertical columns represent the principal groups, which follow each other in the same order as in the preceding pages. In the two first columns are indicated those more partial analogies which may be traced between the higher plants, on the one hand, and the Algæ, Fungi, and Lichens on the other.

* According to the researches of Dr. Reissek "Uber die selbständige Entwickelung der Pollenzelle zur keimtragenden Pflanze," (Nova Acta Ac. Cæs. *l. c.* t. xxi. p. 468.) the tube which is emitted by the pollen grain of many Phanerogamia, when sown on a moist surface under suitable conditions, develops a new plant, which not only vegetates independently, but bears acrogenous spores at the termination of the filaments of which it is composed. Reissek describes a fungus which results from what he calls the germination of the pollen cell of Caltha palustris, which resembles in every respect a Botrytes.

† The Lichens in general, and especially the gelatinous Lichens (Gallert-flechten, Byssaceæ of Leveillé) exhibit several very remarkable points of resemblance to the Fuci. The structure and arrangement of parts in the conceptacles of the latter, correspond closely with those met with in the apothecia of the former. The large spores of Fucus with the smaller masses (usually eight in number) into which its endochrome is divided previously to its germination, may be compared to the ascus of the Lichen with its eight spores; while the filament bearing Antheridia are represented by similar filaments bearing spermatia.

‡ In some species of mosses, if the plant is transferred into an unusually moist atmosphere shortly after the commencement of the development of the fruit, this last is transformed into a stem bearing symmetrically arranged leaves, thus manifesting a tendency to the higher vegetative development which presents itself in the spore-bearing plant among the ferns.

§ The endospermal tissue of the Phanerogamia appears to us to exhibit a much more distinct resemblance in its mode of origin and formation to the tissue which occupies the cavity of the spore in the Lycopodiaceæ, than to the prothallium itself, which last structure seems to be unrepresented among the higher plants. Hofmeister having taken the opposite view, we express an opinion on the point with hesitation.

‖ The existence of antheridia among phanerogamous plants has been asserted by Grisebach, who has described as such certain bodies occurring in the leaf-buds of various species of Rhamnus. On this subject, see the author's "Note on the supposed Antheridia of Rhamnus," in the Annals of Nat. Hist. for August and September, 1851.

Appendix. — *On the relations which exist between the animal and vegetable kingdoms, as regards the function of reproduction.* In the introduction to the foregoing article, it was observed that, if any analogies in development may be supposed to exist between plants and animals, they are to be sought between the lowest members of the two series. Whether we conclude that it is or is not possible to mark out the limit which separates the one kingdom from the other, it is not to be overlooked that the phenomena of reproduction, and consequently the whole circle of the development, of the zoosporous Algæ resemble more those which present themselves on the other side of the disputed territory, than those which occur among the higher plants. Let us compare the development of a unicellular Alga, with that of one of the simplest Infusoria. An egg-shaped body composed of a homogeneous and contractile substance — as regards its chemical constitution nitrogenous — displays active motions, and exhibits two locomotive organs springing from its smaller end. Soon, however, its motions become languid; a newly formed cellulose membrane, which is not contractile, encloses it, and now it undergoes a kind of cleavage, which results in the formation of a number of new bodies. In each of these, as soon as they escape from the parent, the same transformation is repeated.

In the other case, taking the development of Vorticella as an illustration (in the description of which we follow Stein*), we find that a disc-shaped mass of homogeneous contractile substance (a monad), is transformed into a stalked and ciliated Vorticella. After having been for a time endowed with active motion, and with a power of ingesting food, the Vorticella enters into a state of repose, and at the same time is enclosed in a flexible membrane or cyst. The interior of the cyst is now occupied by a mass of protoplasma, which is no longer contractile, and presents no trace of the structure of the former Vorticella. By a process similar to that which occurs in the plant, this plasma divides into a number of disc-shaped bodies, resembling that from which the parent originated.

Between the Protozoon and the Protophyton, there is an intermediate group, of which the Englena viridis, alluded to in § 1., may be considered as the representative. The Euglena after actively moving for a time, enters into the condition of repose, becoming at the same time enclosed in a new membrane. What follows this change, however, has not been as yet ascertained.

* Stein, Wiegmann's Archiv. für Naturgesch. 1849. Bd. i. p. 92.

The phenomenon of conjugation, also, while it is without parallel among the higher plants, presents itself under nearly similar conditions among the Infusoria. According to the observations of Stein, the circle of changes described in the preceding paragraph, is not the only one by which in Vorticella the specific form is reproduced. A Vorticella enters into a state of rest, and becomes encysted; it is not now, however, converted into a mass of homogeneous protoplasma as in the former case. The cyst membrane changes into a thin walled vesicle, while from the body of the enclosed Vorticella, which has assumed a spherical form, there emanate a number of contractile radiating processes. It is now a Protozoon, identical with that to which has been given the name Actinophrys. Now in Actinophrys, the occurrence of conjugation has been recorded by several trustworthy observers. It was first described by Kölliker*, afterwards by Siebold †, and finally by Cohn. ‡ According to the last-mentioned author, two neighbouring individuals after approaching more and more closely to each other, emit from their opposite surfaces, vesicular processes, which finally unite. As the union becomes more complete, the two seem to form but a single animal. As to what are the results of this remarkable conjugation, neither Cohn, nor, as far as we know, any other observer, is able as yet to speak positively. Every fully formed Actinophrys exhibits embedded in its substance a central nucleus-like body; this nucleus, according to Stein, is sooner or later transformed into an egg-shaped animal, which grows at the expense of the parent, and finally becomes endowed with active motion. At the smaller end is formed a crown of cilia, at the larger an oral depression, and soon there presents itself a perfect Vorticella. It is, at least, extremely probable that this development is the result of the previous conjugation of two Actinophries.

The analogies which have been under our consideration in the preceding paragraphs, may be placed in a clearer point of view, by exhibiting them in a tabular form. Referring the reader to the description contained in §18. of the most simple form of unicellular conjugating Algæ (Palmoglœa macrococca), we shall contrast the circle of development, as it presents itself in Palmoglœa and Protococcus on the one hand, with that of Vorticella on the other, as follows:—

* Das Sonnenthierchen. Zeitschrift für Wiss. Zool. i. p. 198.

† Ueber die Conjugation des Diplozoon paradoxum, u. s. w. *loc. cit.* iii. p. 62, 1851.

Zoosporous Unicellular Alga.	Conjugating Unicellular Alga.	Protozoon.*
Production of a series of *Zoospores.*	Production of a series of sterile *Podophryæ.*	Production of a series *Monads,* which are transformed into Vorticellæ.
Cessation of motion.		Cessation of motion. Transformation of Vorticellæ into sexual Actinophries.
	Conjugation of two Podophryæ. Cessation of growth.	Conjugation followed by Cessation of growth.

* In the zoosporous Algæ, constantly recurring series of unisexual generations are produced indefinitely. In Vorticella the production of Monads may also recur repeatedly, without the intervention of any sexual stage. So long as this is the case the two developments correspond completely.

Here it may be observed that in the stage of cessation of growth, which, in the Protozoon, as well as in the Protophyton, follows the act of conjugation, we have a condition which corresponds to that of the ovum of the higher animals. The ovum after passing through a period of repose, resembling that which presents itself in Podophrya, exhibits a series of transformations, which correspond to the later steps of the developments under our consideration. This correspondence is, as might be expected, more distinctly seen in the lower than in the higher animals. Thus for example, in the development of a Trematode Worm (Distomum pacificum), the mass of the yolk is transformed into a locomotive rudiment resembling an infusory animal. Within this originates an asexual, but fertile nurse, the homologue of the Vorticella, in the interior of which is formed a second and numerous generation of animals endowed with locomotion (Cercariæ). In these, after a time, the locomotive power is lost, and each finally becomes a sexual Distomum.*

Although the foregoing homologies are founded on observations the details of which are as yet imperfectly worked out (on which account it may seem somewhat premature to draw attention to them), they are not open to the objections which may be urged to homologies supposed to exist between the highest members of the two series. There, the connecting links are wanting; here, we pass through closely related intermediate forms, from the Alga to the Protozoon, and from the Protozoon to the Trematode Worm. Hence, while we are not justified in applying the term ovum to the generative product of the phanerogamous plant, the present state of our knowledge allows us with propriety to compare with the ovum the result of conjugation as it occurs among the Algæ.

The differences in chemical composition which exist between the Algæ and the Protozoa will not serve as a ground of distinction. Euglena is invested during its period of repose with a cellulose membrane and contains granules of chlorophylle. In Polytoma uvella we find, on the one hand, the contractile vesicles of the infusory animal, on the other, starch in the granular form, so characteristic of the plant.†

RESPIRATION.—ORGANS OF. I. *Human and Mammalian.*—The respiratory system of organs in man and mammalia comprehends the larynx, the trachea, and the lungs: embryologically, the thyroid and thymus glands should be included in this category. The embryonic apparatus of the branchial arches falls under the same denomination. In this article the trachea, bronchi and lungs only will be studied, in their general and minute anatomy. These parts in the human subject will be described at length. In mammalia the prominent varieties of structure occurring in some of the commoner genera will be incidentally noticed.

The Lungs (πνεύμων, Gr.; *Pulmo*, Lat.; *Poumon*, Fr.; *Lungen*, Germ.; *Lungs or Lights*, Engl.) coincide typically in structure with the compound grape-like glands. The lobules and air-cells constitute the glandular parenchyma. The larynx, trachea and bronchi represent the excretory apparatus. They differ from all other glands, however, in the mechanism of their action. They simultaneously eliminate and absorb. In the lungs two diametrically opposed functions proceed in the same place at the same time. This mechanical paradox occurs in the example of no other gland. Secretion and excretion are successive steps of the same process. They are not contrary functions. The whole mass of the blood passes through the lungs: other glands receive only a part. The air-passages and cells are far more capacious than the corresponding parts of other glands. This characteristic results from the aeriform nature of the compounds emitted and received. Aeriform bodies are subject to rapid variations of bulk; fluids undergo no material changes of volume, through fluctuations of temperature; thence, in the instance of the lungs, results the necessity for mechanical provisions, which in ordinary glands would exist to no purpose. The elastic tissue and resilient cartilages so abundantly introduced into the structure of the air-passages and cells realise the required provision. The excretory ducts of all other glands are membranous, the opposite sides of which are capable of collapsing into contact. Fluid in motion readily forces its way through a collapsed tube: air can only traverse a patulous channel.

In man the lungs are two in number. They are contained in the cavity of the thorax, one on either side of the spine, and embraced by, but still exterior to the pleura. The *pleura pulmonalis* and *pleura parietalis* are everywhere and always in actual contact. It follows that the space of the thorax must be at all times perfectly filled by the lungs and other organs. In figure each lung is conical. The right is wider and shorter than the left, a difference which results from the position of the liver on the right side and the heart on the left. The right lung is cut by deep fissures into three *lobes;* the left only into two. The base of each lung presents downwards, and rests on the diaphragm; that of the right is more concave than that of the left. On the right side the liver bulges upwards, encroaching upon the chest. The anterior edge of the right lung slopes off obliquely downwards and backwards, so that it projects much lower by its posterior than by its anterior border. On the left side the heart occupies the space which, in the absence from this place of this organ, might have been engaged by a third lobe.

The *apices* of the lungs project above the level of the first rib. The right is higher than the left. The dorsal aspect of the lungs, thick, round, and vertical, is received into the hollow of the ribs near the vertebræ.

It is longer than the anterior. The posterior and inferior margins descend into the angular space between the ribs and the diaphragm. The anterior border is thin, irregular, and oblique. That of the left extends forwards over the pericardium. The inner surface of each lung presents towards the mediastinum. That of the left is hollowed out to receive the heart. The *root* of each lung is attached to the *posterior* edge of its inner surface. Each lung is divided into lobes by fissures, which commence near the apices, and descend obliquely forwards, to end in the anterior border near the base. The fissure divides the lung, on either side, into an upper small lobe and a lower large one. In the right lung a second small fissure is directed downwards and backwards from the anterior margin, to end in the great fissure—it cuts off a small triangular piece from the upper lobe, and gives three lobes to the right lung.*

From Malpighi to Reisseissen, comprehending the first historical period of Anatomical Science, the structure of the lungs formed a constant ground of controversy. From Reisseissen (1803) to Rainey, Addison, Rossignol, Schultze, Moleschott, and Adriani, the most recent authors, differences on this subject have continued to divide the opinions of anatomists. This question, which involves so much that is historically interesting in anatomical science, divides itself naturally into two primary departments: 1st, *the descriptive and structural;* and 2nd, *the historical bibliography.*

The Trachea in man extends from the larynx† to the bifurcation of the tube into the right and left bronchi; its first superior ring, which is attached to the cricoid cartilage, coincides with the upper border of the body of the fifth cervical vertebra: the point of its bifurcation in the thorax is level with the superior edge of the body of the third dorsal vertebra: it averages in internal diameter from $\frac{3}{4}$ of an inch to 1 inch, and in length from 4 inches to $4\frac{1}{2}$ inches.‡ Variations in the length of the trachea are due to the great

* For a full account of the relations of the lungs to the thorax and to the neighbouring viscera, see art. Thorax.

† See Art. Larynx.

‡ "Trachea, $3\frac{1}{2}''$—$4\frac{1}{2}''$ longa, $8'''$—$12'''$ lata, et e pariete anteriore ad posteriorem, $7'''$—$9'''$ ampla est."—Disquisitiones de Structura et Textura Canalium aeriferum. Scripsit Ernestus Schultze. Mitaviæ et Lipsiæ, 1850.

range of motion within which the larynx is capable of changing place. The diameter of this tube is greater in the male than in the female, at the lower than the upper extremity; it is nearly cylindrical in figure, and permanently patulous. It is composed in the human subject generally of about eighteen cartilaginous rings; of these rings the posterior fourth is deficient; the circle is completed at this interval by a musculo-membranous structure. The tracheal muscle stretches from one extremity of each cartilaginous ring to the other: the trachea is therefore contracted in diameter by muscular action, and enlarged by the elasticity of the ring-cartilages. The rebounding property of these cartilages results physically from their ring-like figure: they tend constantly to straighten themselves; this perpetually acting force preserves the patency of the tube. The convexity of the tracheal rings is directed forwards, the membranous interval being placed posteriorly: by this arrangement the exemption of an important organ from external injury is secured. Against the accident of occlusion during the movements of the neck artful provision is made in the flexible and elastic nature of the structures by which the rings are tied together.

The trachea externally is everywhere embraced in loose areolar tissue: upon this circumstance depends the great range of its longitudinal mobility. Its posterior aspect is in contact with the œsophagus, which is interposed between it and the vertebral column. The recurrent laryngeal nerve, ascending to the larynx, is placed in the interval between these tubes.

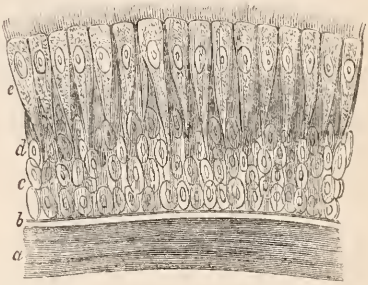
In front of the trachea are situated the sterno-thyroid and sterno-hyoid muscles, which leave an interval in the median line, through which the deep cervical fascia enters to embrace the windpipe. The brachio-cephalic and left carotid arteries, leaving the chest through the episternal notch, lie on the trachea near the top of the sternum: above this limit is observed the plexus of the inferior thyroid veins, and near the larynx it is crossed by the isthmus of the thyroid body: on either side and parallel to it are the carotid vessels and the lobes of the thyroid gland. Entering the limits of the thorax, the trachea is in relation anteriorly with the first piece of the sternum, and the sternal extremities of the sterno-hyoid and thyroid, and to the left, in a descending order, with the innominate vein, the commencement of the innominate and left carotid arteries, which tend towards the sides of the tube, with the arch of the aorta and the deep plexus of nerves, and at the point of its bifurcation it is in contact with the pulmonary artery at the place at which this vessel subdivides into branches. Lying between the two pleuræ, the trachea is contained in the posterior mediastinum; on its right side it is in relation with the pleura and pneumogastric nerve, and on its left, with the carotid artery, the pneumogastric, recurrent and cardiac nerves.

Structural anatomy of the trachea.— The trachea is constructed of cartilage, yellow and white fibrous tissue, muscular fibres, blood-vessels, lymphatics, and glandules, the whole being internally lined by a dense stratum of ciliated epithelium.

These parts may best be described from within outwards.

The tracheal mucous membrane is a development of the pharyngeal. (Henle). It forms a

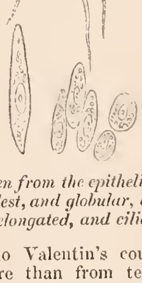
Fig. 204.



Vertical cutting through the epithelial and sub-epithelial layer of the trachea. (After Kölliker.)
a, *b*, basement or homogeneous membrane; *c*, the first race or growth of epithelial cells; *c*, *d*, the last, further evolved; *e*, the adult, surface, ciliated cells.

layer of 0·024—0·04‴ in thickness; it resolves itself into two distinct layers, including severally two equally distinct orders of cells; the undermost, resting immediately on the basement membrane, is composed of orbicular and fusiform particles, measuring from 0·004 to 0·005‴, and bearing a clear conspicuous nucleus of from 0·0025 to 0·003.‴ The superficial stratum is constituted of the adult cells; they consist of club-shaped bodies, armed at the free outermost end with cilia (each single cell carrying about 50 cilia)*, and elongated at the proximal end into a long tapering tail: in length these cells average

Fig. 205.



Separate cells taken from the epithelium of the trachea, the lowest, smallest, and globular, being the youngest; the uppermost, elongated, and ciliated, the oldest.

* According to Valentin's counting, each cell supports no more than from ten to twenty-two cilia; but I have often reckoned many more.

from 0·015 to 0·02‴, and in breadth from 0·0025 to 0·004‴, according to the measurements of Kölliker.* This order of ciliated cells is disposed upon a bed of cytoblasts in a double stratum of about 0·006 to 0·01‴, in thickness: they differ from ordinary cylinder epithelia in the remarkable length to which the attached extremity is prolonged; the tail of each cell exhibits quite the character of a yellow filament, and measures from 0·024 to 0·027‴ in length.

In the centre of the broad end of each of these cells is contained, without exception, a clear, bright, oblong nucleus, of from 0·003 to 0·0045‴ in length; and, further, each nucleus bears a very visible nucleolus (*e*, *fig.* 204.). The cell contents consist of minute granules and fat molecules. Valentin describes a double nucleus in many of these cells.

The *cilia* attached to the tracheal epithelium are clear, fine continuations of the cell-membrane: they measure 0·0016 to 0·0022‴ in length: each cilium tapers to its free extremity, that is, it is broader at its base than at its apex. The cilia of the tracheal epithelium are longer and more conspicuous in the embryo than in the adult: the current excited by their vibration tends in the direction of the laryngeal outlet of the tube. Proofs will be afterwards adduced that these motive organules enact no part in the office of respiration: they subserve a merely mechanical purpose in the process of mucous excretion. These epithelia swell in water, while chromic acid restores them to their original characters (*Hannover*). By Biermer and Gosselin †, the tracheal cilia have been detected in motion 78 hours after death in man. Under normal circumstances no *shedding* occurs in the epithelium of the air-passages.

In disease, however, these cells abundantly desquamate. (See Pathological Anatomy of the Lungs).

It thus appears that the cells of the tracheal epithelium proceed from the basement membrane (*b*, *fig.* 204.) in the direction of the surface in successive generations, the youngest (cytoblasts) being the deepest and the next to the blood-supply, and the oldest, the highest and cilia-bearing. It is stated by Hannover ‡, that this epithelium may be indefinitely preserved in chromic acid.

The tracheal glands are productions of the mucous membrane of the trachea. The largest and most numerous are situated in the posterior wall of the tube, and possess long excretory ducts (*i*, *fig.* 206.), which traverse the whole thickness of the muscular and elastic layers. The glandules themselves are best examined from the outside, and rest on the posterior surface of the trachealis muscle; they exhibit a slightly reddish colour, and belong to the compound order of glands (*f*); they do not all belong to the same variety; some coincide in structure with the salivary glands, others with the sudoriferous. Those which are found over the cartilaginous anterior three fourths of the tracheal walls, are thinly distributed, and penetrate into intervals between the ring-cartilages. This class of glands measures from $\frac{1}{10}$ to $\frac{1}{4}$ of an inch: they are smaller than those which cluster on the posterior surface of the tracheal muscle and which measure from $\frac{1}{4}$ of an inch to an inch. In external characters these glands correspond with the grape-like compound glands: from the latter, however, they differ in some particulars. It is only the larger variety of these glands which is lined at the terminal gland-vesicles, with globular epithelium, the ducts being clothed with the cylinder variety. The smaller sort, conforming in this respect with ordinary sudoriferous follicles, are lined throughout with cylinder epithelium. In these latter there is no distinction (*except that of size*) between the epithelium which clothes the blind extremities of the follicles and that which covers the ducts. These follicles fork at their cœcal extremes, each branch measuring from 0·02 to 0·03‴ in

‡ Müller's Archiv, 1840.

diameter, the parietes of which are composed almost exclusively of fine small cylinder epithelium.

The cylinder epithelium of the ducts of these glands bears no cilia; a character in which it differs from that of the mucous membrane of the trachea in general. The ciliated variety ceases at the orifices of the ducts. The secretion of these glands is a limpid, non-corpusculated fluid. Here it is certain that the act of secretion is not synonymous with that of the shedding of the epithelium. Under certain pathological conditions the tracheal glands augment in size, and become choked with epithelial cells.*

Fibrous Structures. — In the order from within outwards is next observed a remarkable layer of elastic tissue. It lies immediately underneath the mucous membrane (*a, fig.* 204. ; *e, fig.* 206.). It consists of two varieties of fibre, the yellow and the white. The former lies chiefly on the posterior wall, over the trachealis muscles. Its fibres are here disposed in a regular longitudinal direction. They are gathered into thick bundles readily seen with the naked eye, even through the mucous membrane, of $\frac{1}{12}$ of an inch in thickness. They descend in a serpentine manner along the posterior aspect of the trachea, and will be afterwards traced on the bronchi. They frequently anastomose. Smaller fibres, forming a thinner layer of the same tissue, are distributed over the anterior walls of the trachea; like the former portion, running under the mucous membrane and preserving uniformly a longitudinal course. Another order of elastic tissue lies between the ring-cartilages, tying them together cylindrically. Of this tissue the fibres are more slender than those of the former, and belong to the white variety (Bowman). It is to the elastic property of this tissue that the trachea owes its power of lengthening and shortening, a power which in birds is more remarkable than in mammalia.

The *tracheal cartilaginous rings* come next to be described. Each cartilage forms a little more than three quarters of a circle (*e, fig.* 207.). It embraces the anterior three-fourths of the tracheal tube. The deficient portion, comprising the remaining fourth of the circle, is completed by muscle and membrane and elastic tissue (*k, fig.* 207.). This description applies only to the case of the human subject. In the sheep the posterior

ends of the tracheal cartilages meet, to project behind as spinous processes, thus concealing the trachealis muscle. In the horse the same parts of the ring cartilages overlap. This arrangement prevails also in the dog. In the ox the posterior ends of the tracheal rings are everted. Each cartilage is embraced in a fibrous perichondrium (*f, fig.* 207.) which is intimately united to the inter-annular fibrous tissue.

In ultimate structure these cartilages are chiefly composed of cells interspersed through a fibrous basis (*b, c, d, c, b, fig.* 206.). The cells are largest and doubly nucleated in the centre of each cartilage (*d*). At the inner and outer surface these cells become flattened and elongated (*b, b*). In different parts of a vertical section of the cartilage they present different directions as regards their long axes (*d*). They are charged, in addition to the nucleus, with minute fat molecules. The first and last rings of the trachea are figured differently from the rest. The first constitutes a complete ring of cartilage, and is frequently anchylosed to the cricoid. The last is prolonged backwards over the membranous interval ; consisting of more than one piece, it arches over the angle where the trachea bifurcates into the primary bronchi. By such skilful adaptation of these elastic rings, the occlusion of the air-tube is prevented during the varied motions of the neck and chest. Unlike the laryngeal cartilages, the tracheal manifest no disposition to ossify. They amount, in man, to from 16 to 20 in number, and measure each in width, from above downwards, about one line and a half. They frequently fork at their posterior

* "Die Drüsen des Kehlkopfs und der Luftwege überhaupt werden bei Catarrhen häufig verändert, so dass ihre Bläschen bis 0·08 selbst 0·15‴ messen und mit kleinen rundlichen Zellen erfült sind, die wohl den auf Schleimhautoberflächen sich bildenden Schleimkörperchen sich vergleichen lassen."—Kölliker, Anat. Mik., p. 452.

"Interdum hæ cryptæ mucosæ amplificatæ, ita ut pæne 1‴ latæ sint, et sinubus secundariis instructæ reperiuntur. In hoc casu illæ sæpe usque in regionem plexuum vasorum postea et porriguntur. In preparatis per longum tempus in spiritu vini asservatis aperturæ harum cryptarum mucosarum nudis oculis optime cerni poterant, atque imprimis numerosæ in parietis anterioris interstitiis non cartilagineis et in pariete posteriore animadvertebantur."—Disq. de Struc. et Text. Canal. aerif. S. E. Schultze, 1850.

extremities, and sometimes two or more become united. The internal aspect of each ring is thickened into a rounded form. This disposition of material exhibits an advantageous mechanical adaptation to the chief purpose which these cartilages are designed to fulfil. It confers upon them a powerful *straightening* tendency. To this continuously-acting mechanical force the trachea owes its patency. If the membranous interval of the tube be suddenly cut longitudinally, the rings will rebound almost into straight lines.

The *tracheal muscles* (*k*, *fig*. 207.) extend transversely between the free ends of the ring-cartilages, and also in part *between* these rings in form of oblique fasciculi, a disposition which enables them to influence both the transverse and longitudinal movements of the tube. The fibres of each muscle do not extend in a regularly parallel direction from one extremity of the ring-cartilage to the other. They interweave frequently and irregularly. They are also intermixed with elastic tissue. They form a layer of 0·3′′′ in thickness. The elements of each fascicle are 0·03′′′ long, and from 0·002 to 0·004′′′ broad. Along the course of the fibres, at long intervals, are observed nuclei of very elongated figure.

The tendon of each muscle is attached to the internal surface of the ring cartilage, at some distance inwards from its extremities. This arrangement confers upon the muscle great mechanical advantage in the act of narrowing the tube. In the horse, this disposition of the tendons is still more marked. In man and mammalia the tracheal muscles belong to the *unstriped* variety. In birds they are striated: this is also the case in the muscles of the snake. The layer formed by these muscles is perforated by the ducts of the tracheal glands, which are thickly distributed over its posterior surface in form of reddish granules (*l*, *fig*. 207.).

The musculo-membranous portion of the trachea in man is narrower at the laryngeal end of the tube than at the thoracic. Above, *less* than one third of the circumference of the cylinder is membranous; below, *more*, except at the actual point of bifurcation. The tracheal glands are more numerous at the thoracic than at the laryngeal end. At the former point, both the vascularity and sensibility of the tube are greater than at the latter. It is the innermost and immediate inlet into the organs of breathing. Here, in man and mammalia, the excitability and high organisation of the larynx are repeated, and in birds a second larynx is developed. The presence of mucus at this point excites immediate cough. The trachea is to the lungs as the apex of a rapidly-expanding cone is to its base.

The *arteries* (*i*, *fig*. 207.) of the trachea are chiefly derived from the inferior thyroid, and the *nerves* from the sympathetic and the recurrent of the pneumogastric. By injection it is easy to demonstrate the existence of a submucous capillary plexus.

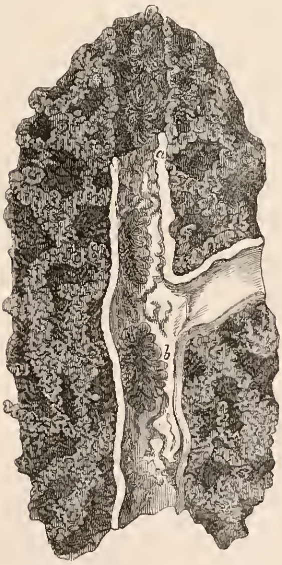
The meshes of the web are considerably larger than those of the true pulmonary plexus. A network of lymphatics also exists in the submucous tissue of the trachea. The meshes of this web are larger and more round-angled than those formed by the blood-vessels.

The *Bronchi* are the primary divisions of the trachea. They consist of two single tubes, one on either side, leading to either lung. Immediately on entering the substance of the lung, they undergo divisions into as many branches as there are lobes. The bronchus on both sides is posterior to the vessels at the root of the lung, and is surrounded by the bronchial vessels and glands and by the pulmonary nerves. The right bronchus presents a greater diameter than the left; it is shorter than the latter, and passes almost horizontally outwards above the right pulmonary artery, and the vena azygos arches over its upper part. The left bronchus, nearly double the length of the right, passes obliquely downwards through the arch of the aorta, and, in its extension to the lung, lies on the œsophagus, thoracic duct, and descending aorta, being below the level of the pulmonary artery. The right and left bronchi, *before* they penetrate the pulmonary substance, exhibit the same structure as the trachea. The cartilaginous rings are imperfect behind, like those of the trachea; the interval being completed by a musculo-membranous structure. These cartilages on the right bronchus vary from six to eight in number, being shorter and narrower than those of the trachea. Those of the left amount to from nine to twelve. The membranous posterior space is thickly interspersed with glands like those of the trachea. *After* entering into the substance of the lungs, the bronchial tubes become modified in structure. The cartilages are no longer parallelly disposed semi-rings. They are arranged in irregular curved pieces over every point of the circumference of the tubes. They do not exist in the corresponding part of the bird's lungs. Thus the bronchi may be classified as the *extra* and *intra* pulmonary.* Compressed at every point of their circumference by the surrounding pulmonary substance, it is evident that the tubes *within* the lungs should be constructed such as to be capable of resisting external pressure. This provision is adroitly realised in the manner in which the cartilaginous pieces are disposed over the walls of the tubes. Each piece of cartilage, having a main circular arrangement, is a small segment of a large circle. They are tied together by muscular and elastic fibres. Thus they form a patch-work, cylindrical frame. The diameter of the tubes is diminished by the approximation of the separate pieces under muscular agency. The patency of *these* tubes, unlike that of *those* of which the walls are exclusively membranous,

* By some authors the air-tubes within the lungs are distinguished as the *bronchia* and *bronchiola*, after Haller, who thus alludes to them:—"Eos ramos Veteres *bronchia* syringes et aortas dixerunt."—Elem. Phys.

is not the result of atmospheric pressure, nor of the action of the thoracic inspiratory muscles: it is due to the elastic property of the cartilaginous pieces. A "membranous interval" in the walls of the intra-pulmonary bronchi would obviously expose the air-passages to injurious pressure. The muscular fibres which always belong to the unstriped kind in this class of bronchial tube are arranged chiefly circularly, but partly longitudinally. They are thus enabled, not only to contract the calibre, but *to diminish the length*, acting, therefore, as important expiratory powers. As the dissector advances towards the branches of the "bronchial tree," the cartilaginous fragments in the walls of the tubes become thinner and smaller, and more and more distantly placed, until eventually they cease altogether, the walls of the tubes being composed of nothing but fibro-membrane. Here the tubes are maintained in the open state in part by the expansive force of the contained column of air. The collapse of these passages leads to the *ataleclasis* of that portion of the lung to which they lead. At this point the gravest impediment to respiration, in *bronchitis*, occurs; here also is chiefly seated the obstacle to expiration in some forms of emphysema; and these musculo-membranous tubules are the scene of spasm during the paroxysms of spasmodic asthma. The parietes of the bronchial tubes

Fig. 208.



A section of a minutely injected piece of human lung. (After Rainey.)

The section cuts longitudinally a branching bronchial tube. At *a*, the ciliated *epithelium* of this tube is seen to terminate by an abruptly defined border, illustrating the doctrine held by Mr. Rainey, which contends for the complete absence of *all* epithelium from all parts of the lung beyond this limit. *b* marks the sudden manner in which the intercellular passages arise from the extreme bronchi.

within the substance of the lungs bear glands like those of the trachea, and, like the latter, they are lined internally by a ciliated cylinder epithelium. *This* epithelium terminates, by abruptly-defined borders, at the commencement of the true pulmonary tissue. (*a*) This fact was first shown by Mr. Rainey*: subsequent observers have, however, proved, contrary to the opinion of Mr. Rainey, that the epithelial layer does *not wholly cease* at these points (*b*). It is prolonged over the respiratory segment under the character of pavement-epithelium.

The true bronchi, in every part of the lung, are distinguished by their tubular form and smooth walls (*a*, *b*) — characters in which they contrast with the loculated aspect of the intercellular passages.

The walls of the minutest bronchi are composed of three coats: a mucous, a muscular, and fibrous. Schroeder van der Kolk has proved that unstriped muscular fibres are contained in the parietes of the smallest of these tubes. The illustrations which accom-

Fig. 209.

pany the theses of Adrius Adriani are drawn by S. van der Kolk himself, from his own microscopic dissections. In the whale, the structural elements of the walls of the smallest bronchial tubes are of very large dimensions, and therefore readily to be detected.

The muscular fibrillæ are principally disposed circularly (*b*, *c*, *b*, *c*); and the elastic (*a*, *a*, *a*), longitudinally.

During the *ingress* of the respiratory column of air into the lungs, both these orders of fibres must be stretched; during the egress of the air, the one must actively contract, the other must passively recoil. This constitutes an expiratory force. It is important to remember that these two elements continue to prevail in the parietes of the bronchi as long as they retain the character of bronchi properly so called — in other words, to the limits everywhere which denote the origins of the intercellular passages. At this point the muscular element ceases altogether; so also does the *ciliated* epithelium; but the elastic

* Med. Chir. Trans. vol. xxviii., 1845.

fibres proceed, under a modified form however, over the walls of the intercellular passages and air-cells. The muscular and fibrous structures are discoverable in the walls of the bronchi *after* these latter have penetrated within the bounds of the lobuli; but never the cartilaginous. This latter element, however, exists in the walls of the smallest of the extra-lobular bronchi.

The extreme end of each bronchus is the common mouth of the *infundibulum* of Rossignol; the peduncle of the pulmonary vesicles of Reisseissen; the origin of the interlobular passages of Addison.

The *bronchi divide on no constant or regular plan.* — Small branches sometimes proceed from a large stem, at different angles, from every point of its circumference.

Fig. 210.

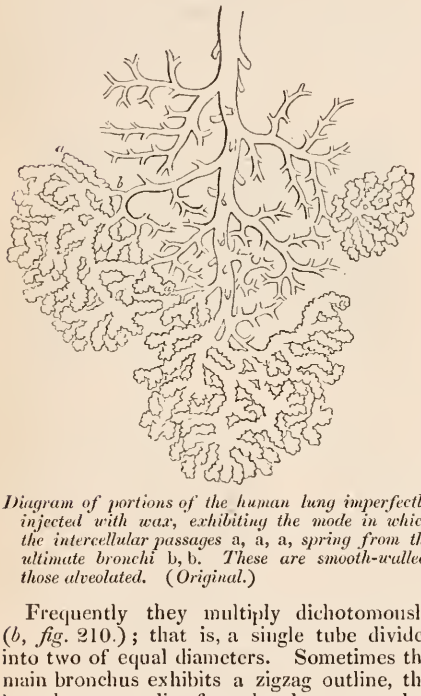

Diagram of portions of the human lung imperfectly injected with wax, exhibiting the mode in which the intercellular passages a, a, a, *spring from the ultimate bronchi* b, b. *These are smooth-walled, those alveolated.* (*Original.*)

Frequently they multiply dichotomously (*b*, *fig.* 210.); that is, a single tube divides into two of equal diameters. Sometimes the main bronchus exhibits a zigzag outline, the branches proceeding from the alternate angles. This latter method obtains with great constancy in the case of the intralobular bronchi. The number of branches *within* the lobule into which a bronchus subdivides bears a general proportion to the size of that lobule. In the smallest, the intercellular passages begin from two or three bronchial peduncles; in the largest, from eight or ten. In some instances a second or supplementary bronchus enters a lobule at the side. It is, however, the rule, that each lobule is supplied only with a single central bronchus. The point of attachment of the bronchus is the *apex* (*a*) of the lobule (*b*); the opposite point being the base. The angle of division in the bronchial tree is, for the most part, the *obtuse.* This disposition of the tubes favours, mechanically, both the ingressing and the egressing column of air.*

It has been maintained by Dr. Radcliffe Hall†, that the contractility of the bronchial tubes is called into action rhythmically in each expiratory movement, to assist in emptying the lungs. But no evidence has been adduced in support of this doctrine. If the contraction of the bronchial tube, through muscular or any other force, occurred at the first stage of the act of expiration, it is obvious that it would arrest rather than favour the egress of the air. It is not, however, improbable, that a certain *regulated* power over the outgoing column of air is exerted by the parietes of the bronchial tubes. This is more likely to consist in a shortening and lengthening of the tubes. They may also serve to regulate the supply of air to the lobules, in accordance with the wants of the system, just as the contractility of the minute arteries regulates the supply of blood to the organs to which they proceed. ‡ It may possibly be through this channel that the remarkable variation is effected in the amount of respiration which adapts the quantity of heat produced to the depression of the external temperature. It has been further suggested by Dr. W. Gairdner § that the contractility of the smaller bronchi may serve to expel collections of mucus which may accumulate within them, and which neither ciliary action nor the ordinary expiratory efforts suffice to displace.

Ultimate pulmonary tissue. — Lobules. — Historical bibliography. — From the dawn of anatomy to the present age, "the structure of the lungs" has proved a fertile theme for disputation. Anterior to the era of Malpighi, anatomists were wont to regard the lungs as consisting of "a spumous tissue," in which air and blood became directly intermixed. Malpighi ‖ first demonstrated the untenableness of this view. He placed the fact beyond doubt, that the air and the blood were contained in *separate* channels.¶ He described the air-cells, and contended that they communicated among themselves, but not with the blood passages.

In the year 1665, Bartholin wrote to de-

* "Rien n'est plus varié que la longueur de ces rameaux, le mode de ramification qu'ils subissent, le nombre de leurs subdivisions et la direction que celles-ci affectent. On peut cependant les rapporter à deux types principaux: le premier comprend les tubes aériens qui sont soumis au mode de division par ramifications alternes; le second, ceux qui subissent la loi de dichotomie ou de trichotomie."—Recherches sur la Structure intime du Poumon de l'Homme, &c. par M. Rossignol. Bruxelles, 1846.

fend the theory of Malpighi.* Willis † came next in the list of disputants. By him it was argued, that the extreme bronchi deprived of their cartilages *bulged on all sides* into the "vesicles" described by Malpighi, and that they communicated among themselves. After Willis came Borel ‡, and Duverney. § By the former it was denied that muscular fibres exist in the walls of the vesicles; by the latter it was maintained that the extremities of the bronchi in man's lungs, as in that of the bird, communicated amongst themselves.

Helvetius (1718) ‖ now sought to modify the views of Malpighi as developed by Bartholin and Duverney. He also admits that the pulmonary tissue consists of a cellular or spongy tissue, of which the cells open the one into the other.

Haller ¶ now entered the arena. This illustrious anatomist doubted the existence of a system of air-cells in the lungs, because he could not see that those of one *lobule* were connected with those of the adjacent. Haller, at this period, was followed by Hales, Volelfart, Hamberger, Hildebrand, each in his turn advocating some modification of the opinions already stated.

A new epoch now occurred in the history of this controversy by the publication of the far-famed "*Dissertation*" of Reisseissen.** In the judgment of the Berlin academicians the researches of Reisseissen overthrew, by undeniable fact and experiment, the theories of Willis, Malpighi, and antiquity. It was taught by Reisseissen, that the air-cells form the real terminal extremities of the bronchial tubes, each vesicle being independent of the others, and having its own separate bronchial peduncle.††

In 1825, Magendie published opinions with reference to the structure of the lungs, which were essentially a reproduction of the views of Helvetius.‡‡ The facts adduced by Magendie did not, however, satisfactorily overthrow the theory of Reisseissen. In England, Home and Bauer §§, attempted at this period to show that the pulmonary vesicles did not consist of dilated air-tubes, as supposed by Willis and Reisseissen, but of polygonal cells of determinate form. They declared a preference for the theory of Malpighi. M. Bazin, in the year 1832 *, reproduced the opinions of Reisseissen. In 1839, M. Sereboullet † followed on the same side. About this period, M. Bourgery in France, and Dr. W. Addison in England, combated severally the views of Willis and Reisseissen. To the theories of these anatomists, more especial reference will be afterwards made. Dr. Addison ‡, from a repetition of the method adopted by Reisseissen, concludes, "that the bronchial tubes, after dividing into a multitude of minute branches, which take their course in the cellular interstices of the lobules, terminate in their interior in branched air-passages and freely communicating air-cells." Mr. Rainey, whose excellent memoirs have rendered great service to the cause of the minute anatomy of the lungs, more clearly defines the distinction between the inter-cellular passages (the *lobular passages* of Drs. Todd and Addison) and the true bronchi.§ M. Hüschke ‖ in 1844 published researches which tended to support the views of M. Bourgery. At this time Dr. Eichholtz ¶ contributed to anatomy the results of careful investigations into the structure of the lungs. The dissertation of Dr. Moleschott ** was also added to the rich list of works on the organisation of these parts. The views of this excellent writer differ in no essential respects from those of M. Rossignol ††, who describes the extreme bronchi as terminating in *infundibula*, which sacculate into *lateral* and *terminal alveoli* (air-cells). In the year 1848, Adrius Adriani ‡‡ published a dissertation of considerable value. It is illustrated by drawings taken from their own preparations by Schrœder van der Kolk and Harting. To this admirable essay, special allusions will be afterwards made. An inaugural dissertation, also, by Ernest Schultz §§, devoted chiefly to questions of structural anatomy, now appeared to enrich the literature of this subject.

The standard writings of the English anatomists issued at this period express chiefly the views of the continental authors above quoted. In Carpenter's Principles of Human Physiology, and Messrs. Todd and Bowman's Physiological Anatomy, excellent chapters

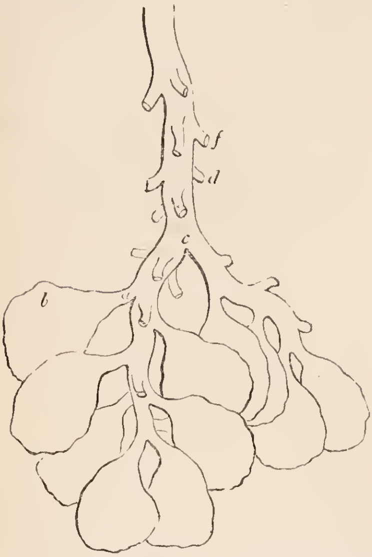
will be found on the structure of the lungs. The works of the Würzburg Professor (Kölliker) contain the most recent, and probably the most conclusive and important, researches upon this subject.* In the details which are now to follow reference will be frequently made to the views taught by this distinguished anatomist.

Fig. 211.

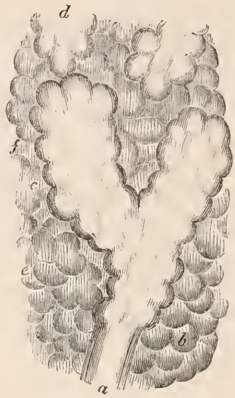


A group of lobules loosened from their mutual attachments, indicating the mode in which each lobule (b) *receives a single bronchial tube* (a). (*Original.*)

At *c* is represented the dichotomous manner in which the primary and secondary orders divide; at *c*, *d*, and *f*, is shown the irregular arborescent method in which the terminal lobular bronchi project from every side and point of the circumference of the secondary bronchial tubes.

Minute Anatomy of the Lobule.—The proper pulmonary tissue (*b*, *fig.* 211.) begins where the bronchial tubes (*a*, *fig.* 211.) end. The latter are convective channels, and fulfil only a mechanical purpose; the former is the immediate seat of the respiratory process. These two parts differ no less in anatomical structure than in mechanical conformation. The bronchi terminate in the "intralobular bronchial ramifications" (Addison); "lobular passages" (Todd); "intercellular 'passages" (Rainey); "mouths of the infundibula" (Rossignol). These are different designations only for one and the same thing. The passages in which the bronchi end are greater in diameter than the bronchi themselves. Their sides are at first *smooth* (*a*), like those of the bronchial tubes; they become afterwards loculated (*c*) with cells or alveoli, like the terminal air-cells (*e*, *b*) (*vesiculæ* s. *cellulæ aëreæ* s. *Malpighianæ*, *alveoli pulmonum* Rossignol. *Luftzellen oder Lungenbläschen* of the German writers). *Looking down* along a section through one of these passages, it is perfectly easy to define either an "infundibulum," or a broad-based passage bounded by *Malpighian* cells. It is, however, perfectly certain that Rossignol has given in his illustrations far more regularity of outline to these

Fig. 212.



(*After Harting.*)

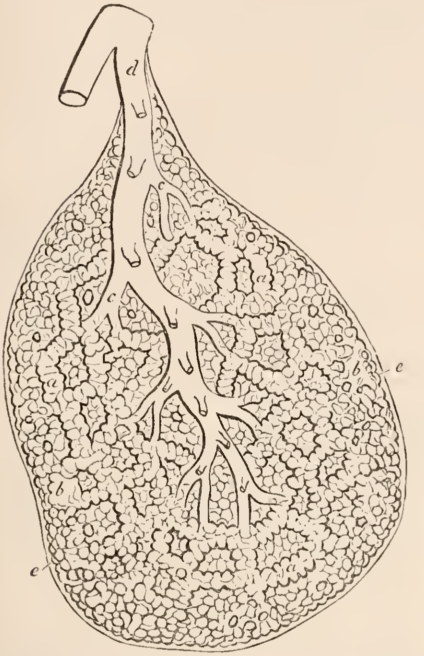
a is the termination of a bronchial tube properly so called, ending abruptly in an intercellular passage marked by its cellulated parietes. *b*, *e*, cell-tissue.

parts than they present in the actual preparation. The intercellular passages (Rainey), then, are those *continuous* channels in the lobule which are laterally sacculated by cells. They conduct the air to and from every part of the lobule. They give rise to secondary passages (*b*, *e*, *fig.* 208.), which again lead to a third, &c., all communicating with a group of air-cells. Each of these passages with its appended system of cells, if bounded by an *imaginary* outline, *may* certainly be called an "infundibulum." The intercellular passages *unite* and *divide* (*a*, *fig.* 210.). They thus intercommunicate. In this particular they are distinguished from the bronchial tubes (*b*, *fig.* 210.; *c*, *fig.* 212.), which never inosculate. The latter are merely convective passages; the former are expressly organised for the office of respiration. The bronchi diminish in calibre as they divide; the intercellular passages rather enlarge in diameter (*f*, *fig.* 213.). The former preserve in their branchings one main direction; the latter run through the lobule at every angle. They are perforated at every point by secondary passages (*a*, *b*, *e*, *fig.* 212.) of varying lengths and directions: sometimes only by a deeper cell than ordinary. M. Bourgery saw in this arrangement only a "labyrinth of canals" (*canaux ramifiés bronchiques.*) Home and Bauer, mistaking the intercellular passages for the bronchi, remark, "the cells of the human lungs are not dilatations of the bronchial tubes, but are regular cells in which the

* Mikroscopisch-Anatomie, Sweiterbund, Leipsic, 1850, and Handbuch der Gewebelehre des Menschen, von Kölliker, Leipsic, 1852.

tubes terminate." This really coincides with the supposition of Reisseissen: — "tracheæ ramos ita per pulmones distribui, ut facta partitione multiplici, singuli quique cœcis nec ampliatis terminentur finibus, quibus vesiculæ aëriferæ constituantur." Moleschott has slightly modified the views of Reisseissen: — "Jam singulos ductus aeriferos, non uti

Fig. 213.



An imaginary section of a lobule of the human lung, carried parallel with the plane of distribution of the chief interlobular divisions of the bronchi. The latter are observed to multiply both on the dichotomous and arborescent plan. (*Original.*)

c, c, denote the smallest of the true bronchi which contrast by their smooth walls the alveolated intercellular passages *a, a, a*. The latter exceed the extreme bronchules slightly in diameter. Unlike these bronchules (*c*), which never inosculate, the intercellular passages (*a*), ramify in every direction and at every plane, and frequently open into one another, establishing thus a free communication for the air between all parts of the lobule. *b, b, b*, indicate the ultimate air-cells of the lungs. They correspond in size with the alveoli (themselves true cells) on the walls of the intercellular passages. *e, e*, bottom of the sub-pleural or most superficial air-cells.

Reisseissen voluit, cœcis nec ampliatis finibus terminari dicit, verum ad latera parietalibus vesiculis instructos esse testatur." Kölliker adopts the views of Rossignol, and constructs an illustration which expresses more perfectly the views of the latter author. *

If a series of hollow cells were disposed linearly, the points of contact being converted into foramina, as represented in this diagram, they would accurately answer to the description of the "intercellular passages" (*'a'*, *fig.* 210.; *'a'*, *fig.* 212.). It is, therefore, obvious that two different minds, contemplating the same

Fig. 214.

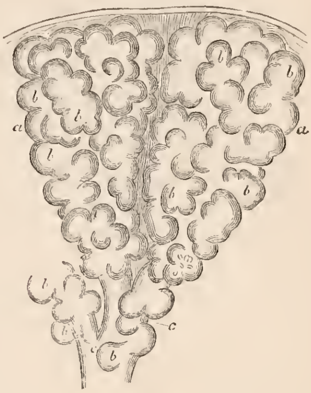


Diagram of two lobules a, a, *of the human lung.* (*After Kölliker.*)

b, b, b, b, ultimate air-cells; *c, c*, the finest bronchial tubes. (Magnified 25 diameters.)

objects under two different preconceptions, would see in them "passages" or "*infundibula*." A lung injected with wax readily misleads to the

Fig. 215.

(*After Rossignol.*)

b, extreme bronchial tube of the human lung terminating in the "infundibula;" *a, a*, infundibula multiplied into cells on their parietes.

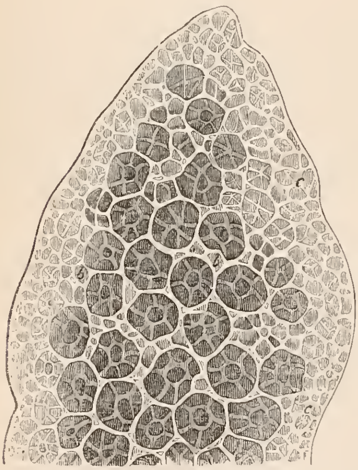
error committed by Reisseissen of supposing each cell to be the separate termination of a separate bronchial branch. But it is certain

* "Mit denselben stehen dann die letzen Elemente der Luftwege, die Luftzellen oder Lungen bläschen, in Verbindung, doch nicht so, wie man früher glaubte, dass jedes feinste Bronchialästchen *terminal* in ein einziges Bläschen ausgeht, sondern in dem dieselben immer mit einer ganzen Gruppe von Bläschen sich vereinen. Diese Bläschengruppen entsprechen den kleinsten Läppchen traubenförmiger Drüsen, und es ist daher nicht die geringste Nöthigung vorhanden, dieselben mit einem andern Namen zu bezeichnen, wie *Rossignol* der sie *infundibula* nennt, wenn auch zuzugeben ist, dass ihr Bau in manchen eigenthümlich sich verhält. Während namlich in andern Drüsen die Drüsenbläschen, wenn sie auch nicht so isolirt für sich bestehen, wie man bisher angenommen hat, doch eine gewisse Selbständigheit haben sind, die ihnen entsprechen Elemente in den Lungen, die Luftzellen, in bedeuten Grade untereinander verschmolzen, so dass alle einem Läppchen angehörigen Bläschen nicht in Abzweigungen der zu demselben tretenden feinsten Bronchialästchen, sondern in einem gemeinsamen Hohlraum einmünden aus dem dann erst das Luftgefäss sich entwickelt." —Mic. Anat., Zweiten Hälfe, p. 309.

that Reisseissen mistook the *infundibula* of Rossignol which are loculated with the ultimate cells, both terminally and laterally, for the separate ends of separate bronchial tubes. It is no less certain that Rossignol has disposed with unnatural precision the "cells" and "passages" of which the lobule is composed. Schultz, again, has erred in viewing the intercellular passages in the light of "bronchial petioles:"—Bronchiolorum continuationes ita constructas causis supra dictis commotus appellaverim petiolos, atque hanc denominationem novam commendo, fines autem eorum amplificatos nomine jam antea ipsis indito infundibula voco; eos denique alveolos, qui in petiolis reperiuntur alveolos parietales, omnes vero, qui in infundibulis occurrunt, alveolos terminales nomino."*

Professors Schröder Van der Kolk, Harting, Promotor, and their pupil Adrius Adriani, adopt the opinions of Rossignöl in relation to the disposition of the air-cells and passages within the lobuli. Whether the intercellular passages be distinguished by that name or by that of the *infundibula*, it is certain that they differ both from bronchial tubes and from the ultimate air-cells by *a greater diameter*. The nearer they are to the point of their attachment to the bronchial tubes, the more tubular or cylindrical their figure or outline; the further, the more irregular and inosculating, until

Fig. 216.



A section at right angle to the axes of the "infundibula," showing the alveoli (b, c). (*After Rossignol.*)

finally they terminate in air-cells; not after the manner supposed by Reisseissen in form of a Florence flask; for the extreme cell has the same diameter as the tube itself. From the accompanying diagram, constructed by the author, the relation between the bronchi, intercellular passages, and air-cells will be readily understood.

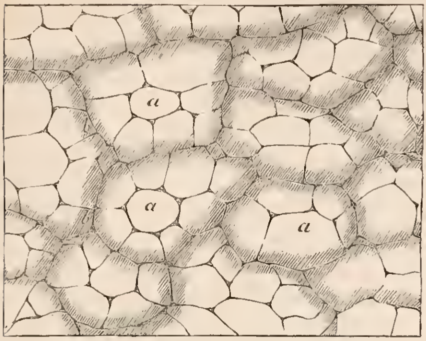
It is, then, important to remember that the intercellular passages are open spaces between the ultimate cells, their walls being constituted of these latter. Like the ultimate cells, therefore, they participate *actively* in the process of respiration. They are not *merely* convective conduits. Since they proceed at every plane and angle from the centre of the lobule, a section of the latter in *any* direction will cut these passages both transversely and longitudinally.

Ultimate Air-Cells of the Lungs.—Vesiculæ, s. cellulæ aëreæ, s. Malpighianæ, alveoli pulmonum; Rossignol.—An air-cell in the human and mammalian lung is a space circumscribed by a single wall of reticulated capillaries, and varying infinitely in figure, and presenting in different parts of the lung numerous varieties of size; each cell having *an opening* embracing a section, more or less considerable, of its circumference. The cells on the walls of the intercellular passages (the sides of the infundibulum of Rossignol) may be defined as mere cup-shaped depressions, sometimes perforated at the bottom by a large foramen opening into one or more cells. Under the pleura the air-cell occurs as a four or six-sided chamber, of which the bottom, presenting under the pleural membrane, is rounded, and might readily be mistaken for the fundus of a pear-shaped vesicle, the apex running into a bronchial tubule. If a cell, situated in the central parts of a lobule, be selected for examination, it will be found as a polyhëdral alveolus, one or two or more of whose sides are deficient or converted into a *foramina*, through which its enclosed space communicates with those of contiguous cells. No cell is a perfect geometrical figure—such, that is, as would be formed by regular plane sides; because ridges and partial partitions, from the encroachment of the angles of neighbouring cells, project into and multiply its interior. It is not often that the eye falls upon a unilocular cell having only one opening: they occur most frequently as irregular, angular spaces, with one or more imperfect sides, *fig.* 219. Those cells which communicate directly with the bronchial tubes and intercellular passages open into them by large circular apertures; and they are themselves similarly perforated, to communicate with other vesicles, which again open into others beyond them; so that each of the openings in the air-passage leads to a *series* of cells, extending from it to the surface of the lobule. The vesicles which communicate directly with the air-passages are more minute, and have a closer vascular network than those which lie nearer to the surface of the lobule; an arrangement which is in beautiful harmony with the relative facility by which the air in them respectively is renovated. The diameter of the human air-cells is about twenty times greater than that of the capillaries which are distributed upon their parietes, varying, according to the measurement of

* Disq. de Struc. et Text. Canal. aërif. Scripsit Ernest Schultz, Lypsiæ, 1850, p. 34.

Weber, from the $\frac{1}{200}$ to the $\frac{1}{70}$ of an inch. It has been calculated by M. Rochoux that

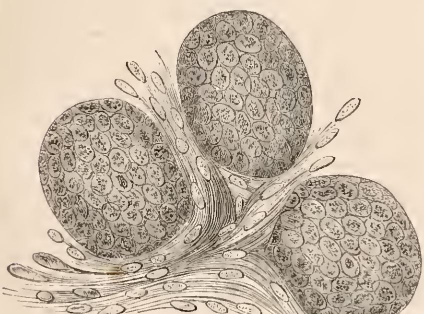
Fig. 217.



Pleural surface of the human lung, indicating the lobules in shaded outline, and the air-cells a, a. (*After Adriani.*)

as many as 17,790 air-cells are grouped round each terminal bronchus; and that their total number in the lungs amounts to no less than *six millions*. The dimensions of the air-cells given by M. Moleschot*, are very much less than those of Rainey and Kölliker. According to the former observer, they range from $\frac{1}{120}$th to $\frac{1}{1200}$th of an inch: those of Carpenter and Kölliker correspond with those of Weber already stated. They continue to increase in size from birth to old age, and present in man a greater capacity than in woman. Dr. W. Addison supposed that the air-cells did not exist *before* birth, that they were mechanically formed by the first act of inspiration, and that the foramina between the cells were really ruptured partitions caused by the pressure of the atmosphere.

Fig. 218.



Ultimate pulmonary tissue from a fœtus three months old. (*After Harting, quoted by Adriani.*)

a, a, a, primitive "infundibula," of which the parietes are as yet composed only of minute oval cells (*c*); *b, b, b,* elastic tissue occupying the intervals between the infundibula, exhibiting the nuclei of its cells.

* Op. cit.

It was, however, first proved by Mr. Rainey, and by Professor Harting more lately, that they exist nearly as perfect in contour before as after birth. Neither the form, the number, nor the disposition of the air-passages and cells can any longer be held as the offspring of chance, but as the nicely adjusted products of marvellous foresight and design.

The preceding statement will enable the reader to understand the sources of the differences by which the views of different writers upon the structure of the lungs are marked. It is easy to make a "labyrinth," a "passage," or a "group of vesicles," or "a funnel-shaped arrangement of cells," out of the complex appearance which a section of an inflated and dried lung presents. It is important to observe that the classification of the cells into the *parietal* and *terminal*, as suggested by Rossignol, is calculated to lead to a false idea as to the real arrangement of the air-cells within the lobule. The capsule of the *lobule* encloses a pear-shaped space; but this is not the infundibulum of Rossignol. This ingenious author applies this term to those parts which Mr. Rainey and Dr. W. Addison have distinguished as the air-passages surrounded and terminated by secondary passages and air-cells. The *septa* bearing *alveoli* which project everywhere into the funnel of Rossignol, render the word *parietal*, as applied to them, altogether unmeaning. Every recent observer admits that the air-cells open everywhere into one another, such that the air entering one intercellular passage at one part of the lobule would traverse its entire extent through the intervening labyrinth of cells, and return through another air-passage into the same peduncular bronchus.

When *two sides* of two contiguous air-passages or cells come into opposition, the resulting partition is not composed of *two* layers, but *one*. If the cells were *formed* by the protrusive force of the air in entering in the first act of inspiration, such partitions would, of mechanical necessity, consist of *two* layers: they are, however, formed by an act of *organisation*. This curious and distinctive fact in the history of the human and the mammal lung will be again referred to. As the partitions of the cells are organised *before* birth, it follows that the geometrical outline of each cell must be determined before the first act of inspiration. The same argument applies to the *foramina* between the cells. They are not accidental perforations; they are definitively and designedly organised orifices, and are sustained in a permanently patulous state by an arch-like arrangement of elastic fibres, which will be afterwards described.

As the air-cells of the lungs of mammals generally bear no proportion in size to that of the body of the animal, so in the human subject there is no relation between the dimensions of these cells and the stature of the body; and it is probable that no estimate can be formed of the vital capacity of the lungs from a calculation of the individual dimensions of the air-cells. It should be observed that the orifices, by which one cell communicates with another, are of the same shape and dimensions as those which exist between the first set of cells and the bronchial tubes; they can be very distinctly seen by looking down upon the air-cells from the intercellular passages, focussing the microscope at the same time. Since these openings are not necessarily in a straight line, the exact number of cells which communicate cannot in this manner be determined; but the number will depend upon the distance which intervenes between any given part of the bronchial passage and the surface of the lobule: so that when a bronchial passage arrives nearest the surface it will be separated from it only by a single terminal cell. The dimensions of the cells in different animals present many diversities. In the lung of the kangaroo, especially in those parts remote from the surface, the air-cells are very small, and disposed with the greatest irregularity. The lining membrane is also proportionally imperfect, being perforated in many places opposite the areolæ of the plexuses, so as to admit the air passing through them to come into contact with the coats of the vessels, as in the lung of the bird. In this mammal the minuteness of the air-cell is such, that it is too small to contain a *single ciliated* epithelium (*Rainey*). In the lung of the rat and mouse the air-cells are still more minute, and certainly many of them are not of a sufficient size to receive even an individual particle of the dimensions of the bronchial ciliated epithelium. The air-cells are disposed with the same kind of irregularity, and the pulmonary membrane is deficient, as in the lung of the kangaroo. In the lung of the hare, the air-cells are very small, but perhaps not so much so as in the preceding species. The lung of the rabbit resembles that of the hare, but its air-cells are rather larger. In the lung of the dog the air-cells are larger than in the rabbit; but still in the more central parts of the lung they are very minute, too minute, indeed, to be capable of having a lining of *ciliated* epithelium without being wholly unfitted for the purposes of respiration. In the monkey, the air-cells are large, and resemble those in the human lung. In the lung of the sheep and ox they are, upon the whole, about the same size, and very minute in both.*

The diameter of one of the intercellular passages ranges from $\frac{1}{100}$ to $\frac{1}{200}$ of an inch, and that of the cells from $\frac{1}{200}$ to $\frac{1}{300}$ (*Todd* and *Bowman*). In the lung of the calf these cells do not exceed $\frac{1}{600}$ By Dr. W. Addison they are stated, in the human lung, to measure from $\frac{1}{200}$ to $\frac{1}{500}$ of an inch.

Minute Structure of the Air-Cells. — Three anatomical elements enter into the composition of the air-cells: the epithelium, the blood-plexus, and the elastic tissue. The interlobular tissue is not here considered.

1st. *The Epithelium of the Air-Passages and Cells.* — It was first surmised by Dr. Thomas Addison, from the phenomena of the difference between pneumonia and bronchitis, that the air-cells of the lungs must be destitute of epithelium. Dr. W. Addison contends that the air-cells "possess an epithelium in form of large round nucleated scales, and from one to fifteen or more nuclei may be counted in a single scale. A great many nuclei without any epithelial envelope may be seen upon them; but I have never satisfied myself that they possess the ciliated cylinder epithelium so abundant in the trachea and bronchi."*

Mr. Rainey denies the presence of epithelium of *any description* on the interior of the air-cells, the vascular plexus being *lined* only by a "pulmonary membrane." Rossignol is the only subsequent writer who has supported this view: — "Neither does the ciliated epithelium lining the bronchial tubes extend into the intercellular passages, and from thence into the air-cells, or rather air-spaces (speaking of the bird's lung), but it ceases where the bronchial membrane terminates. In the mammal, but especially in man, in whom the air-cells are very large, *the fact of their having no epithelial lining* can only be proved by a careful examination of the parts with the microscope, and therefore, with no other means than those of deciding this question, it might always remain *sub judice*, so long as persons are found who are more ready to confide in the assertions of others than submit to the pains and difficulty of examining the point for themselves."† Rossignol says: "Les parois alvéolaires sont formées: 1° par une charpente de fibres qui laissent entre elles des espaces vides ou aréoles; 2° par *une membrane transparente*, qui n'offre aucune trace de fibres, qui recouvre la charpente précédente, et remplit les espaces vides." In this passage M. Rossignol has evidently adopted without inquiry the conclusion of Mr. Rainey, with whose writings he seems well acquainted. The opinion of all German and English anatomists is now finally formed with reference to this

* As the following passage expresses the views of S. van der Kolk, Harting, Kölliker, as well as that of the writer, Adriani, I append it here at length: —

"Has cavitates antea cellulas dictas, nunc Dr. Rossignol alveolos nuncupavit, quod admitti potest, si nemo tantum huic nomini regularitatem mathematicam adjungat, quæ in alveolario apium invenitur; in pluribus locis enim alveoli infundibulorum aut rotundi sunt, aut magis polygonam figuram referunt; eorum parietes vasis cinguntur minutissimis, confertissimis, sæpe optimè materia colorata impletis, et tunc rete subtilissimum constituentibus. Fibræ autem elasticæ potissimum ad margines septorum, quibus alveoli constituuntur, decurrunt, tamen uti jam monuimus, nonnullæ per parietes ipsos etiam decurrunt. Vasa capillaria majora hac tela sustinentur. In ipsis parietibus infundibulorum alveoli inveniuntur, in ipsos bronchiolorum ramos sese ostendentes; Rossignol, qui etiam illos vidit, eos alveolos parietales vocavit; nos autem, antequam ejus commentatio fuerat edita, *cellulas* parietales vocavimus."—P. 43. Op. cit.

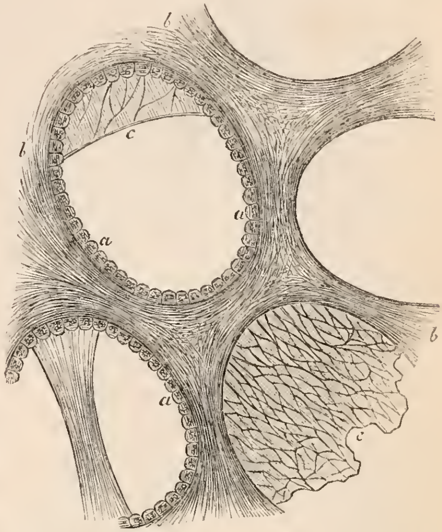
point. Carpenter, Quain and Sharpey, Kirkes and Paget, Kölliker, S. Van der Kolk, Harting, Adriani, and Schultz *describe a pavement epithelium on the interior of the air-cells of the lungs;* and the author who has devoted many special examinations to this particular point is now convinced that a fine pavement epithelium *does* cover these parts which he proposes to distinguish as the "*hyaline epithelium.*"* Messrs. Todd and Bowman, like Rossignol, adopt the views of Mr. Rainey, and teach that the air-cells have no epithelium of *any kind.* The adjoined is the illustration of the epithelium given by Schroeder Van der Kolk in Adriani's Essay.†

Fig. 219.

Ultimate cells of the human lung, showing the trabicular framework formed by the elastic fibres of the walls, and the hyaline pavement epithelium which lines the interior of the air-cells. (After Schroeder Van der Kolk, quoted by Adriani.)

By this distinguished observer it is represented under the character of transparent pavement epithelium, the cells of which are furnished with a nucleus and *minute* granules They are adjusted accurately, as a single layer, edge to edge. The description given by Kölliker coincides with the preceding.*

Fig. 220.



A thin section of a few air-cells from the human lung, viewed by transmitted light. (After Kölliker.)

a, epithelium lining the air-cells; *b*, elastic tissue arching over and between the cells; *c*, the flat wall of a cell, showing the scanty distribution of elastic fibres over this part of the cell.

By Kölliker the cells of this epithelium (*a*, *fig.* 220.) are stated to consist of polygonal particles of from 1—1600th to 1—2250th of an inch in diameter, and from 1—2800th to 1—3800th of an inch in thickness. They repose immediately upon the fibrous layer. They are normally *shed;* though not readily detected in health, it is easy to discover these epithelia in disease. This epithelium lines every part of the air-passages and cells *except* the bronchi. These latter tubes are furnished with a thick layer of *ciliated* epithelium, which, as formerly stated, terminates abruptly at the commencement of the intercellular passages. It may

* In suggesting the word *hyaline* as a distinctive epithet for this variety of epithelium, I do not wish to be understood as denying, in its component scales, the existence of every form of visible element. The word should be accepted in a comparative sense, as signifying that their nuclei and granules are less declared than those of any other description of epithelium.

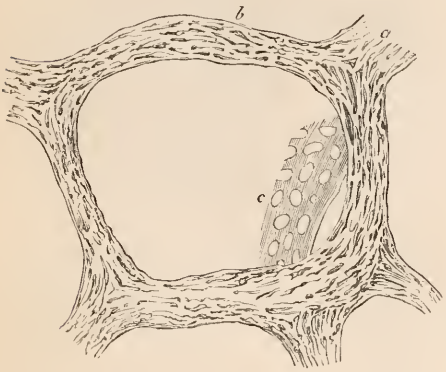
† This figure is thus described by Adriani:— "Alveoli constant membrana subtilissima structura carente, quæ autem membrana mucosa tegitur epithelio pavimentoso (*plaat epithelium*) admodum pellucido, in quo potissimum ope acidi acetici nuclei conspiciuntur; propter singularem autem pelluciditatem sæpe difficile est, illud epithelium rite distinguere; vid. fig. 12. nostram, ubi ad alveolorum parietes conspicitur. Cellulæ conicæ ciliatæ quæ in bronchiolis minutis adhuc conspiciuntur, in alveolis penitus deficiunt; hæc membrana cum epithelio pavimentoso obtegit vasa sanguifera per alveolorum parietes ducta; propter singularem tenuitatem imbibitio atque absorptio per hanc membranulam facillime perfici posse facile intelligitur."—Op. cit. p. 61.

* The following passage in the Microscopic Anatomy of Kölliker refers to the figure cited in the text. "Das Epithelium der Lungenbläschen ist kein flimmerndes, wie man früher ziemlich allgemeine annahm, sondern ein gewöhnliches Pflasterepithelium, das mit polygonalem Zellen von 0·005—0·007‴ Durchmesser und 0·003—0·004‴ Dicke in einfacher Lage unmittelbar auf der Faserhaut der Luftbläschen aufsitzt. Die Zellen sind alle kernhaltig, und haben meist ausserdem der *Trachea* und der Bronchien anzunehmen, dagegen können allerdings mehr zufällig oder dann in Krankheiten der Luftwege einzelne Elemente desselben dem Bronchialschleime sich beimengen. Beim Menschen fallen diese Zellen ungemein leicht ab und liegen dan frei in den Luftbläschen und feinsten Bronchien, doch kann man fast in jeder Lunge, wenigstens in einzelnen Alveolen dieselben noch *in situ* sehen und bei eben getödteten Thieren bietet bei Beobachtung der Lagerung derselben nicht die geringsten Schwierigkeiten dar."—Op. cit., p. 315.

then be accepted as a fixed conclusion in the histology of the lungs that the air-cells are lined internally by a single layer of "*hyaline epithelium*." This conclusion is corroborated by the minute structure of the respiratory organs in *all animals*. In *none* are the vessels absolutely naked.

Elastic Tissue of the Air-Cells.—The existence of this tissue is admitted by every anatomist who has studied the subject. Its disposition amid the air-cells is less known. It fulfils a part, though mechanical, of the highest consequence to the movement of the lungs in respiration. The fibres of this tissue belong to the yellow variety. They resist both the action of acetic acid and liquor potassæ. They are most visible in the lungs of the cetacei. They are readily detected in those of all mammals.

Fig. 221.



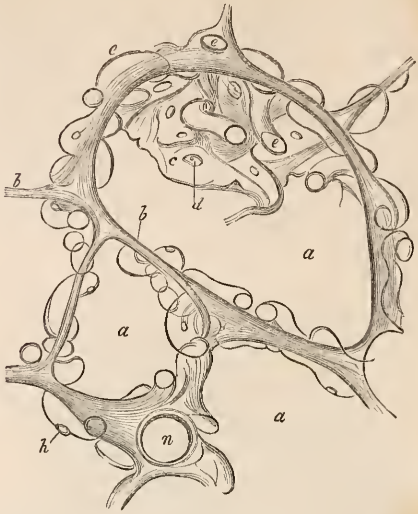
(*After S. Van der Kolk.*)

a, *b*, elastic tissue (with thick yellow fibres) bounding an air-cell in the lung of the whale; *c*, a small portion of the wall of the same, showing the capillary web injected.

They are limited chiefly, in distribution, to the edges and margins of cells. They encircle foramina, and maintain them by their elasticity, in a patulous state. They not unfrequently arch over the roof of the air-cells, constituting to the latter true *trabeculæ*. They pass from cell to cell, and form an important connecting tissue. They are everywhere arranged in bands or fascicles, or in a large meshed network of single fibres, as shown in the adjoined figure.

When they are distributed over the flat surface of an air-cell, they are situated immediately under the epithelium. As there are two epithelial surfaces to each cell-wall, the intermediate vascular plexus being single, it follows that the elastic fibres must run over and between this plexus on both of its surfaces. A real framework is thus constructed which is well adapted to support the capillary layer; and this is an important function, which devolves on the elastic tissue. The framework formed by this tissue over the walls of the air-cells is so large-meshed that it does not obstruct the contact between the air and the blood. These two elements are separated only by a slender hyaline lamina

Fig. 222.



View of a thin section of the lung of a Cat, which had been injected by the pulmonary artery with gelatine, so as to fill blood-vessels and air-cells, and had been sliced when cold. (After Todd and Bowman.)

a, *a*, *a*, air-cells and lobular passage in section; *b*, *b*, their fibrous wall in section; *c*, their wall in face; *d*, extremely faint nucleus in the same; *e*, *e*, capillaries; *h*, nucleus in wall of capillary; *n*, small pulmonary artery, or vein with simple wall. (Magnified 250 diameters.)

of epithelium and the coats of the blood-vessels. At the edges, angles, margins of cells and the foramina between the latter, the fibres of this tissue are gathered into dense and strong bands having an arched and circular disposition. It is suspected by Kölliker that there may be muscular fibre-cells among this tissue in the air-cells, like those already described in the walls of the bronchial tubes. But the long nuclei which occur in the walls of the air-cells, seen also by Mr. Rainey and frequently by the author, are situated in *the substance* of the tunics of capillary blood-vessels. They are neither so large nor so long as the unstriped muscle *nucleus*. In the walls of the bronchi the elastic fibres were described as denser and stronger than those of the walls of the air-cells, and as observing almost exclusively a longitudinal arrangement, the muscular fibres being disposed circularly. Among the air-cells they exhibit that order and plan which fit them best to subserve the mechanical exigencies of the part. Harting, S. Van der Kolk, and Promotor have detected these fibres in the sputum of phthisis, which they regard as characteristic of the existence of a vomica. A failure in the mechanical property (elasticity) of this tissue amid the air-cells is probably one of the conditions of emphysema.

Vascular System of the Lungs.—The blood-system of the lungs constitutes a separate system: "the second, pulmonary, or small circulation." The nutrition of some parts of these organs is sustained by another order of vessels, distinct from these.

The *pulmonary artery*, conducting venous blood, and proceeding from the right ventricle, is the channel by which the blood destined to be arterialised is conveyed to the lungs. It is circumscribed in its distribution to the area of the true pulmonary tissue as distinguished from the bronchial. The plexus formed by its branches is emphatically the *rete mirabile*. The branches of the pulmonary artery follow those of the bronchi as far as the origin of the intercellular passages; a point at which they assume an irregular course over and between the cells. A lobule of the lung receives, with great regularity, only a *single* ramusculus from the pulmonary artery. It is not so large in size as the bronchial tube which it accompanies. Within the lobule, the artery coincides with the tube in its divisions, which are here more intimately bound together than at the extralobular stages of their course. It was supposed by Bourgery that the artery formed a framework of vessels around the tube. This is not the case. Of course, many of the branches of the pulmonary artery course between the lobules in order to reach others more distantly situated. Reisseissen conceived that he had traced a ramuscule of the pulmonary artery to the root of each "vesicle," describing a venule on the other side. Krause supposed that each individual cell, with unvarying constancy, had its artery and vein, and intermediate plexus.* Berres believed that each cellule presented, on its circumference, a great many facets, like the eyes of insects, each facet having its own plexus. Rossignol † embraces the views of Krause which assign a separate arteriole and venule to each cell. In the accompanying figure, taken from the essay of Adriani, and drawn from a preparation by Schroeder van der Kolk himself, the branches of the pulmonary artery are seen to run, not only between the ultimate air-cells, but in many instances through the very centre of the walls.

With this view the exact description of Mr. Rainey coincides:—"In the mammal the number of capillary plexuses is not, as some have supposed, the same as that of the air-cells; that is to say, a terminal artery does not divide into a plexus at any particular part of a cell, its branches uniting for the commencement of a vein on the opposite part. On the contrary, one plexus passes between and supplies several cells. In the interior of the lung the exact extent of an individual plexus cannot be determined, in consequence of the removal of some part of it by the section necessary for its exhibition. But, on the surface of the lung, where the extent of these plexuses, in relation to the cells over which they ramify, can be easily made out, an individual plexus may be seen to spread over an area of ten or twelve cells in some parts and in fewer on others, the exact num-

Fig. 223.

A thin slice (near the pleural surface) of the lung of the Cow, with the pulmonary artery (a), *and pulmonary vein* (c), *injected.* (*After Schroeder Van der Kolk.*)

a, large arterial trunk terminating abruptly in small branches (*b*, *b*, *b*), which travel between and along the borders of the air-cells, and in the ultimate capillaries *e*, *e*, by short trunks as shown at *d*; *f*, *f*, foramina arising from the sections of intercellular passages; *g*, fibrous trabeculæ, supporting by their elasticity the cells, and preserving their wall at a regulated tension.

ber depending in some measure upon the size of the cells." *

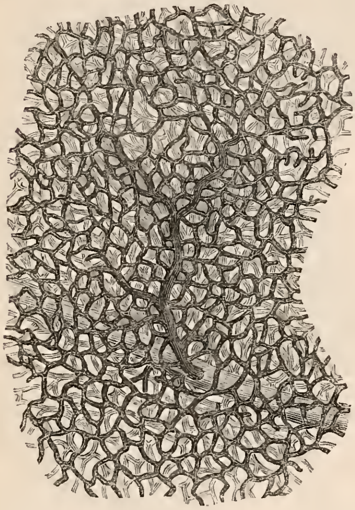
Around the foramina and margins of the cells very frequent anastomosis takes place between the minute branches of the pulmonary artery. With reference to this artery, it should, however, be stated, that it differs from all other arteries in the extremely *infrequent inosculations* which occur between its secondary and tertiary branches—and that its blood mingles with that of no other vessel; it is poured entire into the pulmonary veins. "The trunk" of a vessel is most certainly very seldom seen

* Huschke, Encycl. Anat. Splanchnologie, p. 233.
† Op. cit. p. 56.

* Op. cit. p. 7.

on the flat expansion of a cell-wall. But it is quite an error to suppose that each cellule has its own separate arterial ramuscule. Professors Harting and S. Van der Kolk's injections place this point beyond doubt: — "quod ad divisionem ramorum arteriarum attinet, animadvertendum est, non alveolum quemque singulum ramulum accipere, quum hoc tantum valeat de infundibulis, ita ut lobulus, infundibula continens, accipiat truncum arteriæ, ille truncus ad numerum infundibulorum dividatur et iterum subdividatur." (Adriani). From this description it results that the capillary *web* without an intervening trunk stretches from cell to cell. One more important fact remains to be stated with reference to the capillary plexus. *It is nowhere doubled upon itself,* as it is in the lung of the reptile. Every cell-wall and every partition between the cells bears only a *single* layer of vessels. The opposed sides of such a layer must therefore bound two different cells, and the current of blood by which it is traversed must be subjected on *both* its flat sides to the action of air contained in the cells. If this plexus were double, only *one* side could receive the influence of the atmosphere. *This* type is exemplified in the reptilian lung. All other things being equal the respiration of the mammal and man must be twice in amount that of the reptile. But this anatomical fact has also an interesting pathological bearing. When the capillary layer, or rather the blood borne by it, is the seat of disease, the products of that disease must be poured into the two contiguous cells, between which it is interposed, at the same time and in the same amount. This accounts for the rapidity with which pneumonic infiltration occurs. In the most injected preparation the diameter of the capillary vessels of the *rete mirabile* exceeds that of the meshes. This, however, is not an exact expression of their proportions in the living state. The diameter of a single capillary, measured in the injected state on the wall of an air-cell, does not exceed $\frac{1}{1800}$ (Todd and Bowman.) The human red blood corpuscle ranges, in the same drop of blood, from $\frac{1}{4000}$ to $\frac{1}{2800}$ of an inch in diameter, the average being from $\frac{1}{3500}$ to $\frac{1}{3200}$. Then *two* red-corpuscles may traverse any single capillary abreast? When allowance is made for the difference between the internal and external diameters of the vessel, it will appear very probable that in man and mammals only a *single* row of red-corpuscles traverse the pulmonary capillaries at a time. In the lung of the reptile it is to be proved by observation of the living circulation, that a double row of corpuscles really does move along the vessels. This fact must reduce the amount of oxygenation which in a given time a single corpuscle receives.

Fig. 224.



Injected preparation of a single arterial twig and the attendant vein, showing a single plane *of capillaries overlying the air-cells. The pleural capillary system is distinguished from that of the true pulmonary tissue by the greater denseness of the vascular web and greater minuteness of the meshes in the latter situation.* (*After Kolliker.*)

The *pulmonary Veins* convey the blood, arterialised in the plexus just described, to the left auricle. The distribution of the pulmonary veins differs strikingly from that of the artery and bronchia. Each lobule has its separate arterial and bronchial branch. This regularity does not obtain with respect to the veins. The pulmonary veins arise in the form of minute radicles in the capillary plexus of the air-cells. Now although, as formerly stated, the individual air-cells are not furnished with a separate arteriole and venule, the extreme branches of the pulmonary artery and the incipient venules are separated in different parts of the lung by *areas* of similar dimensions. It follows, therefore, that the *time* during which a globule of blood in different parts of the lung is exposed to the agency of the air is equal; in other words, every drop of blood which enters the lung is arterialised to the *same* amount from the equality of the areas of exposure over which it passes. It should also be observed that as the capillary web is spread over *several* cells, every particle of blood *in transitu* from artery to vein traverses the circumferences of *several* cells. This is a beautiful provision for securing *certainty* to a vital process. The minute venules unite to form visible trunks, which course irregularly over and between the cells and intercellular passages. They observe a general diagonal direction, the bronchia and artery occupying with great constancy the geometrical axes of the lobule. They emerge out of this lobular space not at its apex, in company with the air-tube and artery, but at every or any point of its circumference. This is more obviously the case as regards the lobular veins along the surface of the lung. Those more centrally situated follow the bronchia more closely. This explains why Reisseissen, Cruveilhier, and others have expressed very opposite opinions upon this point. In the intralobular spaces the veins proceeding from several lobules unite together into a trunk common to them all. The larger trunks, resulting from the confluence of the smaller, converge towards the roots of the lungs, but by a route different from that of the bronchia and arteries. Thus the general mass of the lung may be regarded as containing two series of ramified canals; one transmitting the bronchial tubes, the nerves and pulmonary artery, the other the pulmonary veins. This interesting fact was well described by Dr. Addison of Guy's Hospital in a paper in the Medico Chirurgical Transactions in 1840. At the root of the lungs four pulmonary veins result, which discharge their blood into the left auricle. "The cause of the separate course of the pulmonary arteries and veins is to be found in the opposite position of their radicles in regard to the capillary net-work of the lobules, it being a convenient arrangement for the terminal arterial and venous twigs to hold alternate positions among the capillary net-work, so that each arterial twig dispenses its blood in all directions, and each venous radicle collects it from all sides." *

The Bronchial System of Vessels consists of arteries and veins. The bronchial arteries are commonly described as the nutrient vessels of the bronchial tubes. They arise from the front of the descending or thoracic aorta. They are, however, variable in number as well as in place of origin. They are commonly described as the inferior and superior.

The *superior*, two usually in number, arise either separately or by a common trunk from the front of the aorta, opposite the third or the fourth dorsal vertebra, and one directed to each side adheres to the posterior surface of the bronchial tube, on which it divides into branches, and passes into the interior of the lung.

The *inferior*, two or more in number, arise lower down than the preceding, and are distributed, like them, on the bronchus of each lung: these small arteries give branches to the œsophagus, bronchial glands and pericardium. The superior bronchial artery of the left side may arise from the superior intercostal artery. Every successful injection exhibits large and long branches from these vessels, leaving the tracks of the bronchi, and entering into the inter-lobular tissue and sub-pleural tissue. †

The *bronchial Veins* accompany the arteries, and the branches unite one for each side; the right opens into the azygos vein, and the left into the superior intercostal vein. Many branches may be traced also to the œsophageal veins, and those of the posterior mediastinum. Numerous branches of these veins may be observed to wander under the pleura, in the sub-pleural tissue.

Anastomoses between the Bronchial and Pulmonary Systems of Vessels. — Since the days of Ruysch, Haller, Soemmering, and Reisseissen, this has proved a vexed question in anatomy. One point in this controversy has been overlooked. The bronchial arteries are said to be the nutrient vessels, not of the *lungs*, but of the *bronchi.* The tissue composing the structure of the air-cells and intercellular passages of the lungs is nourished by the blood of the *pulmonary* system. In the lungs of Reptiles there exists no bronchial system of vessels. The solid walls of these organs are occupied exclusively by the *pulmonary* system. It is upon the latter, therefore, that the function of *nourishing* the substance, the *parenchyma*, of these organs *must* devolve in these animals. Thus is proved the *capacity* of this blood. The epithelial particles and elastic fibres of the air-cells derive the materials of their nutrition from the blood of the plexus (the true pulmonary) on which they immediately lie. It is indisputable, therefore, that the afferent blood of the lungs, like that of every other gland, discharges a twofold office,—that proper to the gland, and that of nourishing its tissue. *Two systems* or layers of capillary plexuses are discoverable on the walls of the bronchial tubes; one lies immediately underneath the mucous membrane, and exhibits extended oblong meshes, which run parallel with the yellow elastic fibres; the other lies on the *outside* of the circular muscular layer, so that the stratum of muscles is interposed between the two systems of vessels. This outer layer of vessels, its trunks and capillaries, run circularly with the fibres of the muscles and at right angles with those of the submucous layer. The blood of the former empties itself into the pulmonary vessels; that of the latter (the outer) returns by means of the bronchial veins. This, in brief, is the result of the author's investigations. They are confirmatory of those of Adriani. The *mode* in which the bronchial and pulmonary vessels communicate is stated differently by different authors. Some suppose that the blood of the bronchial arteries is poured directly into the pulmonary *artery*, with the venous blood of which it admixes, and like which, traversing the respiratory plexus, becomes arterialised before it reaches the left auricle. On this supposition the blood entering the left auricle would be purely and exclusively arterial. By other anatomists — of these Rossignöl is the most prominent * — it is contended that the bronchia

* Physiol. Anat. by Todd and Bowman, p. 393. vol. ii.

† In an excellent paper recently read before the Royal Society (June 9th, 1853), Dr. Heale states this fact still more strongly. He denies that the vascular plexus, distributed over the walls of the bronchial tubes, is derived at all from this system of vessels, but from the pulmonary *rete*. I have repeatedly remarked, that the *bronchial* plexus cannot be injected from *the aorta*. I ascribed the circumstance always to some imperfection in the attempt. It will be seen in the text further on, however, that my injections prove the presence of a *bronchial* plexus on the *exterior* of the bronchial tubes, though not on the *interior*.

* "Dans les injections faites par les artères bronchiques, le liquide revenait en abondance par les veines pulmonaires, en bien moindre quantité par les veines bronchiques, et on n'en retrouvait aucune trace dans les rameaux de l'artère pulmonaire."

blood is poured into the pulmonary system at the *left* side of the respiratory *rete*. The current, therefore, entering the left auricle is not *pure* arterial blood: it is alloyed by the venous rivulet received from the bronchial system,— a reptilian characteristic traceable in human organisation.

By a third class of observers it is said, that the *capillaries* of the pulmonary and those of the bronchial system of vessels intimately inosculate. The precise solution of this question is difficult, in consequence of the readiness with which an injection thrown into one vessel will pass into another by *extravasation*. Other anatomists suppose that the three above-described modes of communication actually exist. It is certain that these two systems *do* communicate, and that only *a part* of the blood of the bronchial arteries returns by the bronchial veins. More recently, a new aspect has been given to this controversy by the statements of Dr. Heale, to the effect that the bronchial and the pulmonary systems of vessels do *not in any manner or degree* communicate. He maintains, on the evidence afforded by his injections, that the vascular web of the air-cells *extends*, and is prolonged over the internal surfaces of the bronchial tubes. Dr. Heale assigns to this *extension* of the *rete mirabile* the power of prolonging the aëration of the blood. This is impossible. The bronchial tubes, the minutest, are internally lined by a dense ciliated epithelium. Such epithelium does *not* exist on the true *capillary* parts of the lungs of any vertebrated animal. Where there is *ciliated* epithelium, a universal principle of structure requires in the *higher vertebrated* animals that the function of breathing should be suppressed. This principle, however, does not obtain in respiratory organs of the invertebrata, and in the bronchial organs of lower vertebrata.

Respiratory Organs of Birds.

The lungs of birds are two in number, symmetrically developed, flattened, and irregularly triangular in figure. They are fixed, by means of areolar tissue, to the ribs and vertebral column, from the inequalities of which they receive deep impressions. They extend from the second dorsal vertebra as far as the kidneys, and laterally to the junction of the vertebral with the sternal ribs. In their fixed position under the back and near the centre of gravity, they contrast strikingly with the lungs of mammals, which float loosely in the thoracic chamber. In colour they are blood-red, and in general texture they are more fragile than the lungs of mammals. They are not divided by deep fissures into lobes, like the mammalian lung; lobuli, however, exist, although more lengthened in form than those of the mammal lung. In the former, as in the latter, a

Fig. 225.

a, a, a, primary bronchi maintaining a uniformity of diameter and terminating cœcally; *b, b, b,* secondary bronchi, maintaining also a regularity of diameter and opening into a dense cubic labyrinth of blood-vessels *c, c.*

B. *A small piece of the ultimate portion of the lung, representing the arrangement of the ultimate respiratory capillaries.*

lobule is a smaller lung. All its parts are complete. The lobuli are embraced and isolated by membranes of areolar elastic tissue. A pleural investment embraces their sternal aspects, and an aponeurosis, proceeding from the diaphragmatic muscles below, blends its fibres with those of this covering. The trachea, after a course in the neck varying with the length of this part, at its entrance into the lungs, divides into two primary bronchi, one for each lung. At the place of this bifurcation there exists, in most birds, a complex mechanism of bones and cartilages, moved by appropriate muscles, and constituting the true organ of voice. This part is known as the inferior larynx.* The trachea is composed of rings of cartilage which are *not* deficient at the posterior third of the circle, as in quadrupeds. The successive rings are linked together into a cylindrical form by means of a highly extensile and elastic membrane. The whole cylinder is embraced in a second concentric cylinder of muscular fibre which belongs to the voluntary or striped variety. In this particular it differs from the trachea of mammals. In the latter, only the deficient portion of the rings is composed of

" Par les artères pulmonaires, l'injection revenait en entier par les veines correspondantes et *jamais* par les artères bronchiques."

" Enfin, l'injection poussée par les veines pulmonaires remplissait tous les autres vaisseaux sanguins du poumon, c'est-à-dire, l'artère pulmonaire, les artères et les veines bronchiques."—Rossignol, Op. cit. p. 64.

* See arts. LARYNX, VOICE, and art. AVES.

muscular fibre, and that too of the involuntary or unstriped kind. This muscular layer in birds extends from the superior larynx to the commencement of the bronchi : these latter are, however, unsupplied by muscular fibres. They are exclusively membranous.* The bronchi in the case of birds, on entering the substance of the lungs, divide and subdivide without decreasing in diameter (*a*, *a*, *a*, *fig.* 225.) Patches of cartilage appear in the parietes only of the largest order of these tubes. They are distinguishable into two principal classes: those, first, which course superficially along the inferior or sternal surface, and which terminate by wide openings in the thoracic and abdominal air-receptacles. This class of tubes is perforated by the inter-cellular passages only on one side, the other being strengthened by cartilaginous semi-rings. The deep bronchi, resembling cylindrical tubes, traverse the lungs in many directions, and freely communicate with each other, not, however, to form a network, for they run in nearly parallel directions. These tubes are always patulous on dissection, and seem incapable of contraction and dilatation. They are lined internally by a well-marked ciliated epithelium. The submucous tissue in the true bronchi is strong and dense, composed chiefly of elastic fibres, *none* of a muscular character. It constitutes a distinct fibrous layer, like that which lines the trachea of quadrupeds. Those bronchi which do not end in open orifices on the surface of the lung terminate cœcally. These cœcal extremities are perfectly defined by a prominent lining of fibrous and mucous membrane. It was first proved by Mr. Rainey that in the lungs of birds the mucous membrane does not extend inwards in the direction of the interior of the lungs beyond the limits of the bronchi. By the words *mucous membrane* Mr. Rainey desires to indicate that flocculent covering which is so well seen in his *injected* preparations. By this observer it is maintained that all parts of the lungs of birds *beyond* the extremes of the bronchi are literally devoid of all epithelial covering whatever, the extreme capillary vessels being included in nothing but their own proper tunics. It has been already shown that Mr. Rainey has mistaken the cessation of the *ciliated* epithelium at the ends of the bronchi for the termination of all the other elements of this covering. The *apparently* naked vessels of the air-cells are *really* invested by a hyaline epithelium, coinciding with that which, in the instance of reptiles, will afterwards be described. The abrupt termination of the bronchial tubes marks the abrupt commencement of the intercellular passages. These passages contrast remarkably in structure with the bronchi. The membranous walls of these parts are reduced to the utmost state of thinness; those of the former are furnished with cylindrical epithelium and a dense fibrous coat. But, what is extraordinary, the dense mass of vessels which bound these passages are *not* joined together into a continuous partition. Each vessel is separate from and unconnected with those adjacent. "A wall" thus constructed is at every point *between* the vessels permeable to air. These "intercellular passages" (*b*, *b*, *b*, *fig.* 225.) arise, with singular uniformity, from the sides of the bronchi, at right angles to the axes of the latter. This is so constant as to become a characteristic point of structure in the bird's lung.

* See art. AVES, by Prof. Owen.

The "spaces" between the vessels forming the walls of the intercellular passages lead to no definitely bounded *cells* or chambers. They lead only to the *interval* which divides the contiguous bronchi from each other (*c*, *c*). This *interval* is filled densely with the ultimate pulmonary vessels. (B, *fig.* 225.) It was first determined by Mr. Rainey that these vessels, in the bird's lung, are arranged in a peculiar manner. They do not form *plane* reticular definitively bounded air-chambers. Each ultimate capillary crosses an air-space of its own. It is thus *surrounded* by air. The ultimate vessels interlace and interloop in every direction, forming a *cubic* mass of capillaries *permeated everywhere by the air.* The apparently naked loops of the ultimate vessels may be seen projecting into the areas of the intercellular passages. Nothing can be conceived more mechanically perfect than this arrangement of the vessels for the exposure of the blood to the operation of the air. The latter is in immediate contact with each individual vessel (B, *fig.* 226.) It *surrounds* the blood-current borne

Fig. 226.

a, cavity of the tube; *b*, its lining membrane, containing blood-vessels with large areolæ; *c*, *c*, perforations in this membrane, where it ceases at the orifices of the lobular passages (*d*, *d*); *e*, *e*, spaces between contiguous lobules, containing the terminal pulmonary arteries and veins supplying the capillary plexus (*f*, *f*) to the meshes of which the air gains access by the lobular passages.

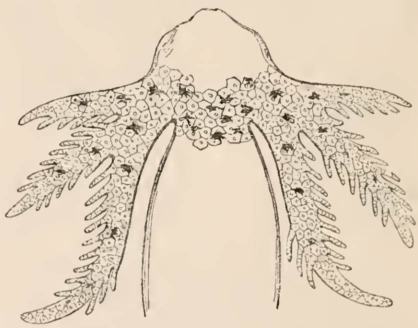
by the latter. Every part of the circumference of this current, less than $\frac{1}{9600}$ of an inch, is under the *direct* agency of the aerating *element*. In the bird's lung there exist, therefore, no *air-cells*.

It is argued by Mr. Rainey that the *ultimate vessels* in the bird's lung, as in the mammal's, are literally *naked;* that is, that they have no other covering whatever than their own proper coats, of which at irregular intervals the cell-nuclei may be distinguished. In other words, that the epithelium, so perceptible on the bronchi, is *not under any shape* continued beyond the termination of these tubes. To this view it has already been objected that it is at variance with all analogy; the branchial and pulmonary vessels of fishes and amphibia are provided, as will be subsequently shown, with pavement epithelium, the scales of which may be seen to be continuous with those of the ciliated division of the membrane; that a law of anatomical structure applying to the respiratory organs of the lower vertebrata must also govern that of the higher. It *is* impossible to demonstrate on the *injected vessels of the bird's lung* the presence of a separate investment of epithelium. The vessels *do* appear to be literally naked. But in the recent structure, in their sections through the bronchi and intercellular passages, it is perfectly easy to the practised eye to trace the epithelium of the bronchi over the larger vessels amid the intercellular passages just before the former break into the mass of the ultimate capillaries. The continuity of the *pavement* epithelium of the larger vessels with the *cylindrical* of the bronchi may be undoubtedly traced by the eye. Now, what is true of the larger vessels is very probably true also of the smaller. Although, therefore, it cannot be directly *proved* at present that in the bird's lung the ultimate capillaries, as in the branchiæ of fishes and the saccular lungs of amphibia, are invested by a separate epithelium, the conclusion first stated appears at present to be most reasonable and most in accordance with analogy. In these examinations it is important not to mistake the *outline* of the red corpuscles in the vessels for that of the epithelial scales on their parietes. According to the measurements of Mr. Rainey the *areolæ* between the capillary vessels, which in the bird's lung are the real air-spaces, — equivalent to air-cells, — are generally smaller in diameter than the capillaries themselves, and average in diameter about $\frac{1}{9600}$ of an inch. An epithelial cell taken from the lining membrane of the bronchi in a pigeon measures in length $\frac{1}{800}$, and in breadth $\frac{1}{3300}$. It is therefore certain that, as Mr. Rainey contends, epithelium of *such* magnitude *could* not, by physical possibility, line spaces the diameter of which did not exceed $\frac{1}{9600}$ of an inch. The error here committed consists in overlooking the difference between the dimensions of the *cylinder* epithelium which lines the bronchi, and those of the wondrously attenuated hyaline epithelium which belongs to the true respiratory, capillary, areas of the lungs of birds, reptiles, and mammalia. A similar distinction between the epithelium which lines the cæcal *extremities* of glandular ducts, and that covering the merely convective or excretory stages of the *same* ducts, obtains in nearly all the simple and compound glands of the animal body. How singular if a principle so wide-spread should be violated in the instance of the lungs!

Respiratory Organs of Reptiles.

Temporary branchiæ of Amphibia. — In the life of all batrachian reptiles, the period which immediately follows the emergence of the young from the ovum is remarkable for the existence of organs capacitating the animal to live in water. In different genera these organs vary in duration of existence. The larvæ of the frog retain the external branchiæ only for a few days, after which these organs become internal. Those of the toad remain in the egg state for a longer, and in that of the fish condition for a shorter, time than those of the frog. The tadpoles of the terrestrial salamanders of this country retain the external gills only for a brief interval, early assuming an exclusively atmospheric life. Those of the aquatic species, exemplified in the familiar tritons of our pools, carry the external branchiæ for a much longer period, affording thus, an opportunity for the study of the structure

Fig. 227.



Head and branchial appendages of the larva of the Water-newt (Triton aquaticus vulgaris). (Orig.)

The branchiæ are enveloped in a prolongation of the general cuticle of the body. The cells of the epithelium covering the gills are, however, reduced to a state of great attenuation, compressed into scales, and polygonal in outline. The nearer the period of transition from the larva to the perfect reptilian type, the more intimate the resemblance between the epithelium of the branchiæ and that of the general body. For some time before their obliteration, the branchiæ cease to be distinguished by ciliary vibration. This results from the change which gradually occurs in the anatomical characters of the component cells. The branchiæ in the larva of the newt consist of a trilobed extension of the cuticle at either side of the head, the two posterior lobes, which, in figure, resemble compressed finger-like processes, presenting on either side secondary projections, by which the respiratory area is multiplied. In relation to the size of the body, they are larger than those of the larva of the frog.

and function of these appendages. The genera *syren*, *proteus*, and *menobranchus* are those only in which the external gills are persistent throughout the whole term of adult life. Whether temporary, as in the caducibranchiate, or persistent, as in the perennibranchiate genera, the branchial organs of amphibia are supported by no skeletal framework analogous to that which sustains the soft parts of the breathing apparatus of fishes. They are, essentially, only "productions," under a modified form, of cutaneous structures. Contemplated only as a mechanical contrivance, whether provisional or permanent, upon which devolves the most important function in the animal economy, it demands a more minute investigation than it has hitherto received at the hands of anatomists.

The cartilaginous arches erected on the hyoid bone do not entirely disappear until the *internal* gills have ceased to be distinguishable. The circulating system of the decidual branchiæ consists, in its earliest stage, of a simple artery and vein; that is, a loop of one vessel. As the larva grows these two vessels become separated by an intermediate system of capillaries. In the latter phase they offer no remote analogy to the vascular apparatus of the branchiæ of fishes. The cardiac centres are composed only of a right auricle and one undivided ventricle; the left or pulmonary auricle remains unevolved until the organic necessities attendant on growth create a necessity in the system for the exercise of the pulmonary functions. The left auricle is then superadded, and the chamber of the ventricle is partially divided by a median partition, and the embryonic organism reaches the maximum limit of development. The pulseless ventral artery, the resultant of the united afferent vessels of the branchiæ, undergoes obliteration through disuse. These general observations form no irrelevant introduction to a more special examination of the branchial organs.

Temporary external Gills. — The larval branchiæ of the frog and toad are less enduring and less complex than those of the salamandridæ. From the earliest almost to the latest moment of their existence they are furnished with a ciliated epidermis. The gills are not specially ciliated. The whole cutaneous surface in the larva of the frog and toad is similarly endowed. The cilia are in active play for some time *before* the larva emerges out of the egg: an admirable instance of foresight in the provisions of nature. The covering of the external gills of the ranidæ is strictly cutaneous. In this situation, as everywhere else, the epidermis betrays its real nature by the presence of pigmental cells. It is little less dense than the ordinary covering of the body. Nor does the vascularity of these temporary branchiæ much exceed that of the rest of the cutaneous surface. These facts proclaim their provisional character. At first they consist of a single minute lobe. This increases into two and then into several. They are cylindrical, not flattened, processes. They bear a *single* vessel returning upon itself. In this particular of ultimate structure they differ from the branchiæ of the salamandridæ. In these a *capillary* net-work is constructed between the artery and vein. This greater

Fig. 228.

a indicates the right auricle, which with *v*, the ventricle, constitutes the heart of the true fish; *a′* shows the left or pulmonary auricle, which, being superadded to the two former parts, raises the cardiac organ to the reptilian standard, marked by the presence of two auricles and one incompletely partitioned ventricle; *b*, *b′*, denote the circuit of the branchial system in conformity with the pisciform type. This system of vessels being obliterated during the metamorphosis of the larva, the pulmonary vessels (*c c′*) enlarge, the rudimentary lungs at the same time expand, the associated auricle grows in muscularity and dimensions, and the fish rises to the grade of an air-breathing reptile. *d*, is an enlarged view of the gill of the larva of the newt soon after its escape from the ovum. Secondary processes (*d*, *d*, *d*, *d*) are extended backwards, which materially multiply the surface. The whole gill is clothed with ciliated epithelium, the cells of which lose their cilia, and become *non-vibratile* for some time before the cessation of the branchial breathing, and the oblong-cilia-bearing cells (*e*) are transmuted into epidermal scales (*f*) entirely destitute of cilia.

elaboration coincides with their longer duration. What is ephemeral in purpose is temporarily formed. This is nature's workmanship. They consist literally of small prolongations of the skin, which is everywhere, as here, ciliated. At the moment of their fullest development, the larval branchiæ of the frog consist of four filamentary lobes. These are sessile upon the body or stem of the branchiæ; they are somewhat granular on the surface, and slightly irregular in form. There is also frequently a short additional branch at the base of the posterior one. In these interesting organs the movement of the blood is readily demonstrated. It is a beautiful spectacle. It advances in a single current along one side and returns along the other. No sooner have these exquisite organs attained their greatest development than they begin to diminish in size. They become obtuse, and are gradually so reduced as to be withdrawn within the branchial cavity, and concealed by a little operculum of the integument. The *nature* of this change of structure, which attends the transition of the branchiæ from the external to the internal condition, has never yet been defined by anatomists. It will be immediately described.

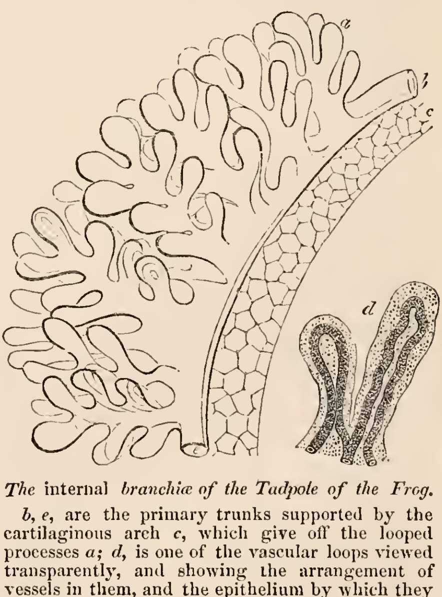
The *external Gills of the Salamandridæ* exceed the former in size, in the number of the appended lobules and in the complexity of their vascular system (*figs.* 227, 228.) Like those of the ranidæ they are clothed in a vibratile epidermis, numerously starred by pigmental cells, in common with the rest of the body. For some time before the decadence of these organs in the larvæ of the triton they cease to exhibit the phenomenon of ciliary vibration. The vibratile epidermis undergoes a change by which the ciliated cell becomes succeeded by the simple. This event foretells the approaching extinction of the parts. In their earliest condition the branchiæ of the newt discover only four minute simple cylindrical filaments. Each grows in length and thickness, and throws out from the inferior surface a *double* row of pectinated processes. These are more complexly constructed than the primitive filaments. They carry not only an afferent and efferent trunk, but an elaborate plexus of capillary vessels. The pigment cells are limited in their distribution to the larger lobes, and to the line of the larger vessels. The epidermis of the secondary processes of the branchiæ is reduced to extreme tenuity. Through it the eye readily tracks the movements of the individual blood corpuscles on the branchial capillaries. These elliptical bodies move like a boat, their long axes coinciding with that of the channel in which they are travelling. Sometimes several proceed abreast. The diameter of the vessels of the temporary branchiæ is greater than those of the lungs. In general terms it can be confidently stated that the quantity of blood circulating in the temporary branchiæ of the amphibia, at the period of their maximum development, is far less in relation to the amount contained in the whole body than that which the lungs, when fully formed, are capable of carrying. This inferior amount of blood is physiologically expressive of an inferior functional power in the case of the temporary organs. Their respiratory function is really only supplemental to that of the whole body. The whole cutaneous surface, as in the Næmatoid annelids, is richly ciliated. It is organised like the branchiæ. On these parts, however, the epidermal layer is not so attenuated as that with which the branchiæ are invested. On these latter there *is*, however, a very perceptible epidermal covering. Its scales exhibit the ordinary hexagonal figure.

This demonstration, which dispels all doubt, establishes the physiological principle, that the *presence* of epithelium is compatible with the *respiratory* office of the part which it clothes. This *law* prevails throughout the class of fishes; it has also been reduced to actual fact by the author throughout the whole sub-kingdom of the invertebrata. But it must not be forgotten that its office on the breathing organs is almost exclusively mechanical. In no known example among vertebrated animals does the epithelial investment of a respiratory surface develop itself into *any* of the forms of a secreting organ. No "follicles" are, at any time or under any circumstances, discovered on these localities, in this class of animals, but in the invertebrata follicular glandules are constant on the surfaces of the respiratory organs. The constituent scales are therefore functionally *passive*. Nuclei and a granular protoplasm would find no purpose to subserve if they were present in a highly developed form. Thus is exemplified the law of "demand" and "supply:" disuse entails attenuation on all living structures. Either the gases by which the epidermis of respiratory localities is traversed *suppress* the glandular office of the scales, or these latter, from the first, receive a special organisation. The scales of the branchial epithelium contain nothing but a pellucid fluid. This fluid *condenses*, fluidifies, the respiratory gases *in transitu*. *This* is the office of the refined covering under study. The "principle" that the epithelium of the breathing organs is required by the physical conditions of its office to be reduced to the state of the utmost thinness receives new proofs from the study of the internal branchiæ.

From all that is known it is probable that in minute structure the branchiæ of the perenni-branchiates conform to the plan of the temporary organs just described. The general arrangement of the primary branchial vessels and the structure of the heart are identical.

The internal temporary Branchiæ of the Amphibia. — The process by which these organs are withdrawn into the interior of the branchial chamber is not simply that of shortening. It is the labour of a *new* organisation. The internal gills of the tadpole differ in type

Fig. 229.



The internal *branchiæ of the Tadpole of the Frog.*

b, e, are the primary trunks supported by the cartilaginous arch *c*, which give off the looped processes *a*; *d*, is one of the vascular loops viewed transparently, and showing the arrangement of vessels in them, and the epithelium by which they are covered.

of structure from the external. The ultimate vessels of the latter are differently looped.

In both they are simple loops, but a distinction is obvious; so evident as to render it impossible that the transition from the exposed to the concealed state of the branchiæ can consist in a bodily retractation. On the *external* organs, preparatorily to their disappearance, the vibratile cilia first cease, the epidermis then increases in density, the meshes between the blood-capillaries enlarge, and the vessels become obliterated. These declining changes are not limited to the extreme distal ends of the branchial lobules. They occur simultaneously on every part of the surface. Temporary arches (*c*) of delicate cartilage now arise within the branchial chamber. It is from the convexities of these arches after the manner of the pisciform type that the *new* vessels (*a*) of the internal temporary gills proceed. They are appended under the character of delicate flocculi. Enlarged, they appear as minute digitations. Each carries a looped vessel, and is *loosely* invested with a delicate membrane (*d*). This membrane belongs to the mucous, not to the epidermal, class; and yet it differs in a striking manner from that which lines the rest of the branchial chamber. *Nowhere is it ciliated.* That covering the branchial vessels is remarkably thinner than the parietal portion. The former, however, *is true epithelium.* Its constituent scales are distinctly traceable by their outlines, though they are as structureless as a basement membrane. It is not often that it happens that the epithelium of a breathing organ overlies, as in this instance, perfectly homogeneous parts. Nothing but the proper coats of the vessel lie underneath. They are literally structureless and hyaline. The cells of the superficial epithelium, therefore, admit of indisputable definition. It is not "basement membrane," but epithelium, though attenuated, that here invests the respiratory vessels. By this demonstration a *principle* is established. Epithelium is *not* supplanted by any other structure on the organs dedicated to respiration. No other instance, however, is known within the limits of the vertebrate kingdom in which this epithelium is ciliated, than that afforded in the case of the temporary external gills of the Amphibia. On those of fishes these motar organisms do not exist. Wherefore this distinction? Why should they exist on the external and not on the internal gills? It is not a *law* of the mucous membrane that they should *not* exist, for they occur in other tracts of this same structure. These are questions of ultimate design which it is not given to science to answer.

Air-bladder of fishes. — This organ represents the prototypal form of "the lung" in the animal kingdom. It is present in nearly all osseous fishes. It is always tensely filled with gas. In that of marine fishes, oxygen predominates; in that of fresh water, nitrogen. Humboldt found the gas in the air-bladder of the electric gymnotus to consist of 96 parts of nitrogen, and 4 of oxygen. Biot found 87 parts of oxygen, nitrogen, and carbonic acid in the deep Mediterranean fishes. No hydrogen has ever been detected in this organ. It occupies the roof of the abdomen, between the kidneys and chylopoætic viscera, and sometimes (*gymnotus ophiocephalus, coius*), beneath the caudal vertebræ to nearly the end of the tail. In some species of *diodon, tetradon, dactylopterus, pemelodus,* and *poianotus*, it is bifurcated. In *arius gagora, polypterus and lepidosiren,* it is divided lengthwise into two bladders. In the *cyprinidæ* and *characinidæ* it is divided transversly into two communicating compartments. Many other varieties of form occur. (*Vide* art. PISCES.) The proper walls of the air-bladder consist of a shining silvery fibrous tunic, the fibres being arranged for the most part transversely and circularly, and in two layers. They are contractile and elastic. This coat yields the finest gelatine. Its fibres belong to the white variety: they "swell" under the action of acetic acid. A stratum of vessels is interposed between the mucous membrane and the fibrous layer. The meshes formed by these vessels are considerably larger and more oblong than those of the pulmonary capillaries. In the latter instance the meshes *exceed* the vessels in diameter. The arteries of this organ are derived sometimes from the abdominal aorta, sometimes from the cæliac artery, sometimes from the last branchial vein; and in the lepidosiren they are continued from the aortic termination of the two non-ramified branchial arteries, and therefore convey *venous* blood to the cellular, lung-like, double air-bladder (Owen). The veins of the air-bladder return, in some fishes, to the portal vein; in some to the hepatic vein; in some to the great cardinal vein; and in the lepidosiren, they penetrate by a common trunk the great portal vein formed by the confluence of the visceral and vertebral veins of the trunk. In the *protopherus* and ganoid fishes the vessels of this organ form no *retia mirabilia* and vaso-ganglions, but rather a diffused capillary network, more close and rich in the anterior than the posterior part. In the osseous fishes, several varieties of the vascular system of this organ occur. That of the carp forms tufts of capillaries throughout the whole interior of the organ, a variety of which tufts occurs in the pike. The perch and cod exhibit a vaso-ganglion, a body peculiar to the air-bladder of fishes. In the cod-fish, a large artery, a branch of the cœliac, and a still larger vein, which empties itself into the mesenteric, perforate together the fibrous tunic of the bladder. Before they reach the inner surface, they divide into some branches which then radiate and subdivide upon the mucous membrane. The arterioles frequently anastomose with each other. Both are inextricably interwoven, and form the basis of the so-called "air-gland," which is essentially a larger "bipolar rete mirabile" (Müller), or vaso-ganglion. In the cod the ultimate vessels of this gland have a loop-like arrangement, their free surface (*a a*), being covered over with another layer of vessels and epithelium This organ, however, is further composed of a number of pecu-

a, *a*, indicate a stratum of fibres, vessels, and epithelium lining the internal surface of the gland in common with the whole interior of the air-bladder.

liarly arranged, elongated corpuscles, which descend in two rows from each vascular branch, and are bound together by a loose cellular tissue: the corpuscles are beset with fine villiform processes. Thus it should be noticed that the *veins* as well as the arteries concur to form the vaso-ganglions. The vaso-ganglions of the eel and conger are placed at the sides of the opening of the air-duct, are "bipolar," and consist of arteries and veins; their efferent trunks do not ramify

Fig. 231.

in the immediate margin of the vaso-ganglion from which they issue, as in the vaso-ganglion of the cod, turbot, acerine, and perch, but run for some distance before they again ramify to form the common capillary system of the lining membrane of the air-bladder. In the parasitic and suctorial dermopteri and pleuronectidæ and ray-tribe the air-bladder does not exist.

The *ductus pneumaticus* exists in the *eel*, *sturgeon*, *amia*, *erythrinus*, *lepidosteus*, *lepidosiren*, *polypterus*. It is remarkable that in these fishes the vaso-ganglion is not developed. "Under all diversities of structure and function the homology of the swim-bladder with the lungs is clearly traceable; and finally, in those orders of fishes which lead more directly to the reptilia — as, for example, the salamandroid *ganoidei* and *protopteri*—those further modifications are superinduced by which it becomes also analogous in function to the lungs of the air-breathing amphibia." *

The Lungs in the Batrachia.—In the ichthioid amphibia there exist two long membranous pulmonary sacs, extending, like the air-bladder of fishes, far backwards into the cavity of the abdomen, above the other viscera, but freely moveable in the cavity of the peritoneum, and invested with this serous membrane. They consist of smooth plane-walled sacs, and communicate with the pharynx by means of their membranous *ducti pneumatici* or tracheæ. This simple condition of the lungs occurs in a permanent form in the salamandridæ. Each sac is provided with a pulmonary artery, which runs in a straight course along the outer side of the organ. From this vessel, branches proceed with great regularity at right angles and at definite distances. From the midpoint of the space between the arterioles, a venule arises to run round the opposite semi-cylinder of the organ into the chief trunk of the pulmonary vein. In consequence of this regularity in the distribution of the arteries and veins, the true capillary interspaces present a regularity of area. It follows from this arrangement that each drop of blood, in its passage from the extreme artery to the extreme vein, undergoes in every part of the lung the same *quantum* of aeration. It is commonly supposed, by comparative anatomists, that the simple lungs of the *salamandridæ* present a perfectly smooth and uniformly plane surface internally, such that every spot participates with equal activity in the office of aerating the blood. This, however, is not the case. The *septa* which, in the case of the frogs and toads, divide the internal superficies into *cells*, exist in a rudimentary state, but *unquestionably* in the lung of the newt. *They are indicated by intersecting lines of vibratile cilia.* They coincide chiefly with the principal branches of blood-vessels. Bundles of elastic fibres also *run parallel* with the vascular trunks, which confer upon these delicate organs an uncommon amount of elasticity. To the next point in the minute structure of the lungs especial

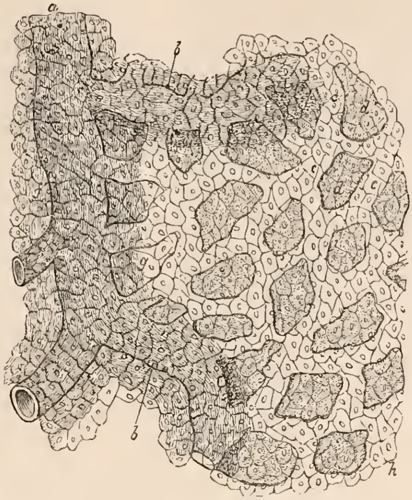
attention is invited. The conclusions hereafter to be drawn will be found opposed to

Fig. 232.



A small portion of the lung of the Newt laid open and examined by transmitted light, under a high power, such that only the surface (internal or mucous) is in focus. (Original.)

a, a leading branch of the pulmonary artery, giving off at very regular intervals which break at once into the true capillaries *c, c, c.*; *d, d, d,* denote the parenchymous islets which fill up the meshes of the capillary plexuses. (They are the true *pulmonary parenchyma.*) *g*, marks the abrupt line which abruptly limits the distribution of the *ciliated* epithelium, which follows the larger vessels in tracts; *d, c, c, c,* coinciding with the true respiratory or capillary areas of the lung, are seen to be destitute of *ciliated* epithelium.

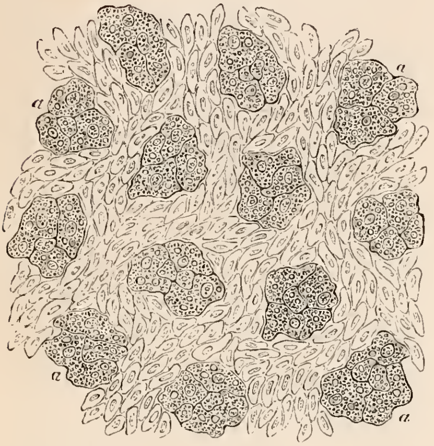
the views of Mr. Rainey. This excellent observer* has affirmed the principle that, on the true breathing portions, or capillary segments of the lungs, there literally exists no epithelial lining of any description whatever, the vessels being as literally naked. To this "principle," deliberately enunciated and supported by elaborate "proof" by an acute and truthful observer, many anatomists have yielded implicit assent. First, it is here objected that such a "principle" violates directly all the lessons of analogy. Analogy! Is not demonstration better than analogy? In the science of organised beings, the connected reasoning founded on analogy cannot be despised. The closest scrutiny in individual instances may miss the truth. The manifold illusions of the microscope may readily mislead. Analogy supposes a mass of *cumulative* evidence. The general law neutralises particular errors. In no instance whatever, either in the vertebrate or invertebrate kingdom, has it been proved, in the course of the present extended inquiry, that the vessels of a real breathing organ can exist under a perfectly "naked form." What is true of invertebrate animals as an organic law cannot be untrue of the vertebrate. The gills of fishes are furnished with a very marked epithelial covering. The temporary branchiæ of the amphibia are clothed with epidermis. The air-bladder is provided with an epithelial lining, the cells of which admit of ready and conclusive demonstration. Why should it not exist in the case of the true pulmonary structures? No *reason* can be imagined; but the *fact* that it does *not* has been affirmed by Mr. Rainey. Mr. Rainey's observations were instituted upon *injected* preparations. This is the source of the error into which he has fallen. If the lung of the newt be carefully, but quickly, laid open, covered, but *not pressed*, with a thin slip of glass, and examined under the microscope, it will be found that the vibratile cilia have a *limited* distribution. Under the favourable opportunities afforded by such a preparation it is perfectly easy to follow with the eye *the continuation of the epithelial cells* (*c, c, fig.* 232.) *beyond the limits of the ciliary areas* into the *true capillary or active breathing segments.* The ciliated portions of the epithelium (over the vessels *b, b*) exhibit a *flocculent* character, precisely as shown in the *preparations* of Mr. Rainey; while the areas immediately adjacent appear *smooth* or *naked.* But under the use of a higher power and a steady gaze the polygonal *outlines* of the epithelial scales can be *distinctly* discerned most readily between the islets of parenchyma (*d, d*). If this covering consist of "basement membrane," then basement membrane is composed of scaliform parts; but it is not. It is a true and real and unbroken continuation of the tracheal and bronchial mucous membrane. It is only the ciliary appendages to the cells that cease at a certain limit; the cells themselves continue to invest the *whole* superficies of the lungs. It is full of interest also to note that the epithelial scales which cover the *capillary areas* of the lung of the newt (parts which coincide with *air-cells* of the mammalian lung) lose not only the *external* appendages (cilia), but also their *internal* parts (nucleus and granules). This successive reduction leaves nothing but a *hyaline involucrum* enclosing a pellucid fluid. *This* is the *real* structure, supported indeed by a hypothetical basement membrane, by which the capillary areas of the pulmonary organs are invested. It finds a parallel in the transparent scales which cover the cornea.

In these ribless amphibia the operation of breathing resolves itself into an act of "swallowing" air. The glottidean chink is embraced by two minute semilunar pieces of cartilages and furnished with muscles for opening and closing the orifice. In the parietes of the lungs no trace of muscular fibres can be discovered; but elastic fibres are present everywhere among the vessels. It is by the agency of this elastic tissue, aided by the abdominal parietes, that the act of expiration is performed. The exterior of the lung is lined by peritoneum, the scales of which are much attenuated compared with those of other parts of the same membrane, as those

* Med. Chir. Trans. 1848.

of the internal lining. It is a curious fact that the *exterior* of the lung should be destitute of cilia, while they should be present on that of the liver in the newt. They are, however, on this last organ, limited to the margin. Nothing is more easy than to exhibit the living circulation in the lung of the newt. The

Fig. 233.



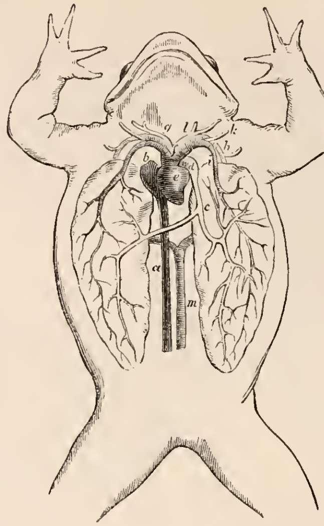
A small piece coinciding with the true capillary or respiratory area from the lung of the Newt, viewed by transmitted light under a high power. The blood-corpuscles in streams are seen in the spaces between the islets a, a, a. *Only these parts are in focus. The hyaline epithelium covering the near face of the picture is out of sight. The eye looks beyond it. In this fresh uninjected state the blood-channels do not appear to be bounded by separate and independent parietes.* (*Original.*)

a, a, a, are parenchymatous islets occupying the meshes of the capillary rete. They are composed of cells carrying nuclei and granules.

internal bore of the vessel viewed by transmitted light is much greater than the long diameter of the red corpuscles. The meshes (*a*, *a*) are mere points. The scene is one thick, rich, surpassingly beautiful network of moving blood.

In the *frogs* and *toads* the lungs consist of two large, short, and broad, slightly cancellated shining bags. They are situated on either side of the spine, at the roof of the abdominal cavity. They are remarkably elastic, like those of the newt. They are capable of slowly expelling their contents even after the removal of the abdominal walls, and of drawing themselves up into little hard balls on either side of the pharynx. They exhibit well the living circulation. The glottidean aperture communicates directly with the interior of the organ. There is, therefore, no trachea. The orifice of the glottis is surrounded by rudimentary cartilages somewhat further developed. The mechanism of breathing is the same in the frog and toad, in which, like the newt, the thoracic ribs are wanting, as in the salamanders. The steps of the process are, however, better studied in the frog. The outer surface of the lung in the frog is closely invested with peritoneum, the epithelium of which forms a thin pavement coating. This surface is destitute of cilia. In the frog, as in

Fig. 234.



Heart, vessels, and lungs of the Frog.

the newt, the edges of the liver are fringed with motile cilia. The pulmonary artery (see art. CIRCULATION), derived from the aorta, proceeds along the outer side of the lung. It lies immediately underneath the peritoneal epithelium. The very reverse course is taken by the large venous trunk on the opposite side. *This* lies in immediate contact with the internal or mucous surface. By this arrangement the contact of the blood with the air is prolonged. The contributory branches of the vein course along the *free* internal edges of the septa bounding the cells. The branches of the artery occupy the opposed *fixed* borders of the same septa. The flat surfaces, or sides of the cells, being the areas dividing the arteries and veins, are the scenes of the capillary segments. To this rule, of course, the eye, by close scrutiny, may detect many exceptions. By this distribution of parts, every spot of the internal superficies is functionally utilised. The *ciliary* epithelium is limited, in its distribution, to the margins of the cells and the lines of the larger vessels. The true capillary areas whereon alone respiration actively proceeds are covered only by a *hyaline* epithelium, the cells of which can only be distinguished by their outlines (*fig.* 232. *c*, *c*). The ciliated tracts, according to the manner already described in the lung of the newt, terminate by abrupt borders. The epithelial cell only is continued over the capillary areas. There prevails an *average* uniformity in the dimensions of these areas. Each particle of blood, therefore, in its transit from the artery to the vein across this area, is exposed, for the same period of time, to the influence of the air. In the lung of the frog and toad the *septa* support *two* layers of reticulate vessels, one on either side of a fibrous partition. A plane of vessels disposed in such a manner can only receive the influence of the aërating element on *one* side. This fact constitutes a real anatomical distinction between the lung of a reptile and that of a mammal. In this latter case the partitions of the cells are composed only of a *single* stratum, *both* sides of which are exposed to the air. By this simple mechanical provision the amount of the respiratory agency is everywhere doubled. In the structure of the reptilian lung the elastic fibre forms a predominant element. It is a substitute for ribs and other accessory apparatus of breathing. The lungs of the frog, relatively to the cubic capacity of their interior, present a much more extensive active surface than those of the Salamandridæ. Thus the purpose of "the cells" is fulfilled, of multiplying the operative surface. The "septa" project from the sides into the interior of the organ. In this respect they may be likened to the gills of fishes; for, like the latter, "they penetrate the surrounding medium." The lungs of ophidian reptiles are generally composed of true unsymmetrical, long cylindrical or fusiform sacs, extending from the pharynx far into the cavity of the abdomen, above the other viscera, and surrounded with the serous lining of that cavity. They are capable of containing a considerable quantity of air, which, when driven out with force, produces the "hiss" peculiar to the serpent. In some genera, as the coluber, typhlops and vipera, the lung of one side only is developed; in others, as the boa and python, the two lungs are symmetrically or equally developed. The lungs, in these families, communicate, by means of a long and narrow trachea, surrounded by incomplete cartilaginous "rings," with the back part of the tongue. In all ophidia, the lungs display internally, but *only* on the anterior and upper parts, an elaborate system of alveoli or cells, more like secondary lungs than air-cells. The posterior two thirds of the internal superficies are almost plane, or devoid of "cells," like the lung of the newt. The alveoli, traced from before backwards, become shallower and shallower, until at length they disappear. It thus appears that the serpent may store up in its lung a considerable volume of air which, slowly passing out over the vascular air-cells, prevents the carbonic acid, the effete product of the process, from contaminating the whole contents of the organ. Each "alveolus," separately examined by vertical section, is found to communicate by a single opening with the general chamber of the lung. Traced inwards, it divides and subdivides into secondary and tertiary tiers of "alveoli," each cell being *isolated* by dissepiments of which the structure is identical with those of the frog's lung already described. Each cell is a separate cavity. It does not communicate with those adjacent by openings in the septa. These septa are utilised in the outspreading of the vascular *rete*. Each septum, as in the frog, carries two layers of capillary blood-vessels, separated from each other and supported by an intermediate stratum of elastic tissue. In the mechanism of breathing, this tissue enacts an important office. Over the interior of the ophidian lung, like the batrachian, the *ciliated* epithelium is limitedly distributed. The true capillary areas which chiefly coincide with the flat sides and bottoms of the cells are clothed only with 'hyaline epithelium.' Everywhere throughout the interior of the lung, along the courses of the larger vessels, the borders of cells, or along lines of thickened tissue, the phenomenon of ciliary vibration may be readily detected. It is thus evident that the office of cilia is mechanical, if not to cause determinate currents in the *air*, at least in the *halitus* and fluid which, by accumulating, may obstruct the respiratory function of the capillary areas.

In the *boa* and *python* the length of the left lung is generally less by a third or half than that of the opposite side; but in *coluber*, *crotalus* and others, it is much smaller and quite rudimentary, appearing as little more than an obliterated appendage. The genera *Cæcilia* and *Amphisbœna* have the left pulmonary organ developed, and the right shortened: this arrangement probably varies according to the species. Vipers and other serpents possess only a single lung, which on that account is very long. The lungs of the *saurian reptiles* conform in character to those of the *ranidæ* and *salamandridæ*. They are elongated sacs, cellulated internally. They extend far back along the roof of the abdominal cavity. Like those of the ophidians, they are divisible into a cellulated and smooth or non-cellulated portion. The former is limited to the *upper* and anterior half of the organ; the latter to the inferior wall and posterior half. There may be a mechanical reason in this peculiar distribution of parts. The cells in the lungs of the saurians exhibit none of the regularity so characteristic of those of the ophidians. They are larger and more irregular. The partitions of the cells are more slender and more delicately-membranous.

The whole interior of the lungs in the higher saurians is multiplied into cells. An axis without definite walls, like a trachea, runs from one end of the organ to the other, as is the case in the lung of the turtle. From either side of this axis, large orifices lead to the more subdivided portions, or secondary and tertiary air-chambers. On the contrary, each lung in *Scincus officinalis* forms a single continuous cavity; but the *entire* surface of the parietes is cellulated by small projecting reticulate septa. The internal dorsal and anterior half of the lung of the chameleon is, as usual in the *sauria*, minutely cellulated. Further back the cells become larger, and the septa smaller, until at the posterior part the walls consist only of plane membrane both less vascular and less cancellated than the anterior. The cœcal extremity of the organ is drawn out into an appendage-like process, which reaches the farthest boundary along the roof of the abdominal cavity. These appendages may be aptly compared to the abdominal air-cells of birds which communicate with open extremities of the bronchial tubes. The "diaphragm" in the mammals precludes this interblending of the thoracic and abdominal organs, or the diffusion of air into any of the cavities of the body.

With reference to the *minute structure* of the lungs in the saurians, it coincides precisely with the account given of those of the *ranidæ*. Each *septum* consists of a central basis or framework of elastic fibrous tissue lined on either side by a reticulate layer of vessels. This plexus is again overspread by a "hyaline pavement epithelium." Rich *tracts* of ciliary epithelium may be discovered along the margins of cells, the course of vessels, and the lines of condensed structures. The double layer of vessels borne by each septum may be noted as a point of structure distinctive of the reptilian lung. The lungs of the *chelonian* reptiles are very voluminous. They extend over the whole dorsal part of the trunk as far as the pelvis. They are fixed by the pleura to the ribs, which also separate them from the cavity containing the digestive and generative organs. They are symmetrically developed on the two sides. Through the centre of each lung longitudinally an *un*walled axis extends from the anterior to the posterior extremities. This is the main road for the air-currents. From this axis, secondary passages, parietally cellulated, radiate towards every point of the circumferences of the organ. The ultimate cells are very capacious. They communicate little with each other. Each group has its common outlet, thus resembling a lobule. In the reptilian lung, however, there exist no lobules; an anatomical particular in which they are distinguished from that of all mammalia. It is a criterion of lower organisation. The vibratile cilia which line the nasal and buccal passages, the pharynx and œsophagus, the larynx and trachea of all reptiles are *most* remarkable for tenacity of life in the lungs of the chelonia. In the trachea of the turtle, along certain tracts of the lungs, the motion of cilia may be detected several months after death. The physiological value of the breathing process in any given animal corresponds, not with the volume of air inspired per any unit of time, but with the measure of the blood-surface exposed to its agency, the rate at which the blood-current moves, the numerical proportion of its red corpuscles,and the frequency of the respiratory movements. The small, but minutely, subdivided lung of the mammal presents a much more extensive surface for the outspreading of the *rete mirabile* than the very voluminous, but spacious-chambered lung, of the chelonian. The total volume of air inhaled by the mammal is less than that which the lung of the turtle is capable of containing; but in the former case it is more minutely distributed and divided; it is more effectually employed; the contact between it and the blood-web is far more extensive and intimate; while it acquires a higher temperature than in the latter. In these several particulars, cold differ from warm-blooded animals.

Respiratory Organs of Fishes.

The aquatic type, distinctive almost universally of the breathing organs of invertebrate animals, obtains also in the lowest order of the vertebrata. Fishes and the lower amphibia respire on the branchial plan. The difference between a gill and a lung rests more on apparent than real and ultimate grounds. In the last anatomical analysis this difference vanishes, and the eye is arrested only by the close structural affinities which reduce the two varieties to an essential unity of type. In *both*, the blood is exposed to the agency of the aerating element by means of reticulated vessels, furnished with distinct parietes, and presenting a diameter little in excess of that of the corpuscles of the blood; so that these latter must travel through the true respiratory capillary in a single series. This fact denotes the extreme measure to which the subdivision of the blood-stream is carried. It is a fundamental requirement of the breathing organ, that all structures interposed between the blood and the surrounding element should be reduced to the utmost degree of attenuation. Accordingly, it is found that the epithelium overlying the *rete mirabile* consists of a *single* layer of attenuated scales, perfectly destitute of those contained parts which give bulk and density. In no instance whatever within the limits of the vertebrata (excepting, as stated already, the branchiæ of the amphibia) are the true respiratory capillaries covered by a *ciliated* epithelium. This rule applies also to the branchiæ even of the higher invertebrata, such as the crustacea and cephalopoda. The gill of the fish differs from that of the crustacean in the extreme minuteness with which the blood current is subdivided, and in the existence of specially parieted vessels; conditions which denote an intensified measure in the function of breathing in the instance of the vertebrate animal. — In the blood of the vertebrata the floating cells are infinitely more numerous, relatively to the bulk of the fluid, than in that of the invertebrata; — a fact more expressive than the former of the greater activity of the respiratory process in the vertebrate than in the invertebrate animal.

It is an axiom in physics, that no gas is capable of passing through an organic septum without first assuming the fluid form. This axiom destroys the apparent difference between a gill and a lung. In contact with the gill the aerating medium is *already* fluid: in the case of the lung, it takes this condition only in *the act* of passing through the partition dividing the blood from the external medium. Between the gill of the fish and the true lung ofthe vertebrate animal there is discernible, however, this differential character, that in the former the epithelium clothing the active capillary segments forms a thicker layer (than in the latter. This is the only true and ultimate anatomical distinction between a gill and a lung.

The preceding general facts will form an appropriate introduction to the study of special details, on which it is proposed now to enter.

The Lancelet (Branchiostoma) occupies the first grade in the vertebrate series. It exhibits the branchial organs under the least complex terms. A capacious branchial sac, the dilated œsophagus, occupies the mid-portion of the body. It communicates with the exterior in front by means of a large œsophageal opening, and behind by a branchial outlet and a short intestinal canal. The parietes of the stomach display special provisions for breathing under the character of membranous duplications of the internal surface. These folds are invested with a vibratile epithelium. In this particular the branchiæ of this fish approach those of the lower molluscs, and depart from those of all other fishes. A convenient arrangement of this subject will consist in first studying the mucous membrane of the branchiæ of fishes; 2nd. the blood-system; and 3rd. the supporting frame-work.

Mucous membrane of the branchiæ. — The gills of fishes are lubricated and defended by a glary viscid secretion: this is the product of the epithelium. This latter, therefore, even on these parts enacts a secernent office. On the plane superficies of the leaflets, the epithelium constitutes a single stratum, resting immediately on the expanse of the *rete mirabile.* In this situation, as in all others, the epithelial layer is supported by a limitary membrane. From its extreme attenuation, however, it does not easily admit of separate definition. Neither cytoblasts, granules, or any other immature particles, mingle with or underlie this layer of *adult* epithelium. It is difficult to conceive the mechanism of their renewal. In the interior of its component cells, however, the eye clearly distinguishes a nucleus and a few pellucid granules. It has already been proved that these latter parts are almost suppressed in the epithelium which lines the active capillary segments of the true lung. Of the branchial epithelium of fishes it may be said that it unites the glandular to the mechanical function of the pulmonary epithelium, that its office is exclusively mechanical. The *halitus* of the air-cells is not a *secreted* product. It is a transpiration.

Viewed with reference to the principles of exosmoses, a layer of amorphous granules, the cytoblasts of future epithelia, interposed between the blood-vessels and the superficial strata of adult cells, would obviously render the partition to be traversed by the gases engaged in respiration very inconveniently dense. The structure presented by the epithelium of the branchiæ implies, that in the organs of aquatic respiration the blood is brought less directly into relation with the external medium than in those of atmospheric breathing. The cells investing the branchial capillaries are not structureless, hyaline, flattened scales, devoid of nucleus and granules, as though the principle aimed at were merely the mechanical one of *thinning* to the extremest practicable limit all structures between the blood and the outer medium. They constitute irregularly oval bodies, carrying a nucleus, and provided with a few pellucid molecules. No cilia exist in the gills of fishes. In their fixed condition, as in the cyprinoid families, in their concealed situation, as in the shark tribe, or their exposed and free position, as exhibited in the higher osseous orders,—forms enough diversified, these organs are characterised alike by the complete and uniform absence of vibratile epithelium.

The Vascular System of the Branchiæ. — In fishes, the whole force of the heart and bulbous aorta is expended upon the branchial circulation. The power of the heart is materially reinforced by the resilient structure which composes the parietes of the aortic bulb. This structure is remarkably contractile. By all standard authorities on comparative anatomy the muscular nature of the walls of the bulbous aorta is admitted without question. The interior of this "bulb" is strengthened by *carniæ columnæ.* It is a fact of no common interest that the colour of the muscular structure of the ventricle is higher or redder in ground-fishes than in those species of which the habitat is superficial in the water, and which are gifted with the power of active locomotion. These facts are indicative respectively of superior and inferior degrees of muscular irritability, and well shown to conspire with other proofs to determine a difference in amount between the respiration of deep and surface-swimming fishes. The valves which guard the proximal and distal portions of the *bulbus arteriosus* vary in situation, number and size, in different families. The movement of contraction which takes place in this vessel is not instantaneous in duration, like that of the ventricle: it is slow and vermicular. The pressure which is thus exerted upon the column of the blood is continuous. The near proximity of the delicate capillary structures of the branchiæ to these powerful centres of force, demands the graduated manner in which the aorta reacts upon the stream of the blood. This mode of action also explains the purposes subserved by the "valves," which in some instances occupy an advanced situation in the vessel. The abdominal aorta, which results from the confluence of the branchial veins, differs considerably in structure from the pre-branchial division of the vessel: the parietes of the former resemble those of a vein. *No pulsations* are detectible in the abdominal aorta of fishes. The pulsatile movement of the blood, derived from the systole of the ventricle, ceases at the branchial capillaries. In fish, therefore, arterial pulsations exist in no other part of the circulating system than in that limited segment which intervenes between the branchial network and the cardiac ventricle. Neither the head nor any other part of the body receives blood *directly* from the cardiac ventricle. The carotids, the homologues of the subclavian, the hyo-opercular and orbito-nasal arteries proceed from the abdominal aorta at the point of confluence of the branchial veins. In these vessels, therefore, the blood is arterialised, while its movement is impulsatile or venous. The propulsive agents, under the form of diminutive lymphatic hearts, which Dr. M. Hall*, M. Fohman†, and J. Müller‡ have shown to guard the several points of communication between the absorbent and venous systems, probably renders as great assistance in circulating the contents of the latter as those of the former orders of vessels. In the whitebait (*Clupea alba* of Yarrell) these microscopic hearts can be most perfectly observed. From a consideration of the preceding traits distinctive of the circulation of fishes, it will be afterwards shown that the laws of aquatic respiration are destined to receive new elucidation.

Minute Circulation of the Branchiæ. — The branchial arteries proceed on either side, symmetrically, from the aorta, and travel through a groove along the convex border of the branchial arches, the veins lying to the outside of the artery, that is, *next* to the pectinated fringes of the gills. The cartilage system of the arches and that of the penknife-shaped processes (bearing the ultimate bronchial leaflets) are quite distinct and unconnected save by fibrous structure. It is in the intervals between these solid parts that the trunks of the vessels are disposed. As the pectinated processes (*a*, *fig.* 235.) arise, when biserial, alternately from the arch, the arterial branches leading to them observe a similar arrangement. The arteries carrying venous blood invariably run along the thick border or outer margin of each process, the vein occupying the innermost edge. A branchial process, attached at right angles to the convex border of the arch, resembles a penknife, the back of which corresponds with the thick and outermost borders, and the *edge* of the blade with the thin or acute side of the process. A string carried from base to point would mark the position of the branchial artery conveying venous blood: brought back along the acute edge, it would denote the line of the branchial vein bearing arterial blood. In the marsupio-branchii (as the myxine, lamprey, &c.), in which the gills are fixed and inoperculate, this is also the virtual arrangement of the secondary trunks. In the lophobranchii (sea-horse, pipe-fish, &c.), in which the branchiæ are tufted, the disposition of the minute vessels is not dissimilar. The *flat* surfaces of the penknife-shaped process are gorgeously festooned by foliaceous multiplications of the membrane (*fig.* 235, *b*). In the annexed illustration, *one* of these leaflets has been shown. In length it does not coincide with the width of the process; the secondary trunks, passing through the substance of the

† Sangader system der Wirbelthiere. 1827.
‡ Elements of Physiology, by Dr. Baly, 2nd ed. Lond. 1839.

are placed, like the leaves of a book, in close apposition with each other, the unattached sides floating freely in the water, the current of which, as it traverses the branchial passages, bearing directly on the flat surfaces or the leaflets, separates them effectually from each other. Viewed edgewise, as represented in the following sketch, the arrangement of these respiratory membranous extensions may be more fully understood. On the branchial processes of the eel these leaflets amount to 700 in number; on those of the turbot, to 900; on those of the cod, to 1000; on those of the salmon, to 1400. Especial attention is invited to *fig.* 237. It shows that *only* the mucous membrane (*i. e.* the layer of epithelium and basement membrane) is *doubled* upon itself, so as to assume the form of folds, *the stratum of capillary blood being single.* From this beautiful arrangement it results that the blood, in its passage through the labyrinth of this plexus, must present *two* sides of an extremely divided stream to the agency of the circumfluent medium. If the network of vessels were duplicated upon a supporting basis, only one side of the sheet of blood could receive the influence of the surrounding medium. Regarded mechanically, such a plan would present little of the delicacy and perfection which really distinguishes this most elaborate specimen of organised structure. This *single*-layer disposition of the respiratory vessels, doubling thus the surface of exposure, obtains as the universally prevailing type of structure in the breathing organs of aquatic animals. It is an arrangement which facilitates in a very remarkable manner the interchange of gases between the blood and the water. The capillary vessels of the branchiæ of fishes, in internal diameter, exceed very little the long axis of the blood-corpuscle. The internal calibre of these channels varies from $\frac{1}{900}$ to $\frac{1}{700}$ of an inch; the blood-corpuscle in the cod measure in the long diameter $\frac{1}{1547}$ inch, and the channels forming the capillary network present in all parts precisely the same calibre.

Cartilage, or Supporting System of the Branchiæ. — The skeletons of fishes are structurally distinguishable into three classes; the osseous, fibro-cartilaginous, and true cartilaginous. In the conventional language of comparative anatomists the last is described as the least completely organised, and the first the most. This distinction, however, which obtains in the adopted nomenclature of science, has no counterpart in that portion of the skeleton which sustains the foliage of the branchiæ. In the *petromyzon fluviatilis* the wicker-work of cartilage which Müller has called the cartilaginous basket of the branchiæ, and which Prof. Owen regards as homologous with the epibranchial system of osseous fishes, detaches processes of almost membranous tenuity stretching inwards to supply a mechanical support to the slender respiratory foliage. In the myxinoid families, cartilage and calcigerous structures are substituted, in various parts of the body, by elastic fibres. In the osseous fishes the

Fig. 237.

a, section of the branchial arch, which, in osseous fishes, consists of well-marked bone, and in the cartilaginous, of soft cartilage; *b*, marks the junction between the system of the arch and that of the lamellæ, proving that the latter is quite distinct from the former; *c*, illustrates that portion of the framework which occupies the obtuse border of the lamella, exhibiting its external thick marginal fluted channel destined to convey the branchial *artery* from the base to the apex of the lamellæ *d*, denotes that part of the skeletal fabric which coincides in situation with the acute margin of the lamella; *e*, marks the situation of the branchial *vein* as it emerges from the innermost aspect of the axis supporting the lateral processes *f*, which, by their elasticity, keep open or stretched the true membranous respiratory leaflets.

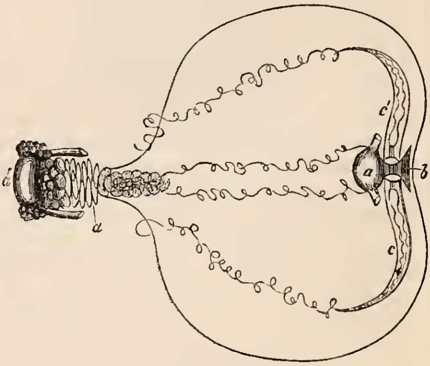
branchial skeleton presents itself under the most readily distinguishable characters. From this class, accordingly, the following illustrative details will be drawn. The respiratory segment of the skeleton comprises the hyoid system and its dependencies, in which are included the branchiostegal rays and the branchial arches, on which, finally, is elaborated an exquisite arrangement of solid points upon which important mechanical functions devolve, in the movements of the apparatus of respiration.* The

* As it is the design of this paper to refer no more to the descriptive departments of comparative anatomy than is found indispensable to elucidate questions of ultimate structure, I must refer the reader, for the solution of the homological and teleological details on this subject, to the work of Prof.

gill-bearing arches are not composed of single undivided curved bones, but of several elements, adjusted with express reference to the elasticity and flexibility of the whole. Six of these arches are primarily developed, and five permanently retained. The first four support gills, the fifth is beset with teeth which guard the opening of the gullet: this latter is termed the pharyngeal arch; the rest the branchial arches. From the convex side of the branchial arches a double series of interlocking penknife-shaped processes radiate. On the flat surfaces of these processes a gorgeous arrangement of membranous leaflets is disposed in a transverse manner, each leaflet standing, as already described, on its edge (*fig.* 237.). This rich foliage, bearing the complex web of the respiratory capillaries, is itself sustained by a machinery of elastic solid parts, hitherto unknown in comparative anatomy.

The series of curvilinear bones denominated the arches of the branchiæ, and exhibited in section at *a*, *fig* 237., are inferiorly attached to the sternal chain of bones, proceeding upwards and backwards, and describing a curve, which in different genera varies in degrees of sharpness, and which finally affix themselves by means of ligaments to the base of the cranial bones. These curved bones are constructed of several separable pieces, adjusted with artful reference to the resilient properties of the curvilinear figure. The act of opening the mouth in the fish determines a consecutive series of movements, which end in the preparation of the gills to be traversed by the branchial current. By an appropriate intervening mechanism the movements of protruding and retracting the mouth occasion irrespectively the approximation and separation of the branchial processes, accompanied by an alternate increase and decrease of the curvature of the sustaining arch. The straight penknife-shaped processes (1, 2. *fig.* 239. *x.*), as stated, diverge from the convexities of the branchial arches. In nearly all the osseous fishes, these processes form a double series, the gills being accordingly distinguished as *biserial*. In those genera in which these processes form a single line the gills are said to be *uniserial*. In the genera *cottus* (bull-heads), *labroidæ* (rock-fish or wrasses), sebastes, (Norway haddock), scorpænidæ (hog-fish), Teidæ (John Dory, &c.), the nilotic-fishes, *polipterus*, gobroidæ (blennies and gobies), *lepadogastidæ*, a genus of small sucker-fishes), and the cyclopteridæ or lump-fishes, may be ranged under one great group, characterised by *three* biserial and one *uniserial* gill. The genera sophiidæ (angler), batrachoidæ, the tetraodons (or globe-fish), the diodons (commonly called the sea porcupines), and that curious genus of monopterus found on the seas of the Mollucas, the gill opening in which is united by transverse partitions of membrane, are characterised by *three* symmetrical *biserial* gills. Other less regular genera present other diversities in the disposition of the branchial processes * The penknife-shaped processes (*fig.* 237.), which radiate from the convexities of the branchial arches are bony in the osseous fishes; but only that part of the solid basis of the process is bony which corresponds with and forms the substance of its blunt or thick margin. In the cartilaginous orders this portion is composed of cartilage, the component cells as well as the outline of which are very dissimilar to those of the former class. As indicated in the above illustration, that piece in the skeleton of the branchial process which forms the obtuse border exhibits a groove seen sectionally at (*b*, *b*, *fig.* 237.), serving for the lodgement of the processal branch (*g*) of the branchial artery. The internal edge of this bony piece is dentated by projecting spines, adapted perfectly to support

Fig. 238.



Plan exhibiting the skeletal framework of the lamellæ of the gills of Fish in transverse section. (*Original.*)

a, shows the osseo-cartilage of the obtuse margin of the lamella, presenting three distinct varieties of component cells, and on the external edge opening into a groove for the lodgment of the branchial artery *a'*, from which, on either side, the ultimate ramusculi, emptying themselves into the *rete mirabile* of the leaflets, may be seen to proceed; *b* and *c*, *c'*, define the beautiful framework which lies parallel with the acute border of the lamella, the lateral processes *c*, *c'* stretching on either side along the circumference of the membranous leaflets, preventing, by their continuously acting elasticity, the injurious folding of the latter, and, therefore, the tangling of the respiratory web of capillaries. The extremities of these processes are produced by means of the curled elastic fibres shown in the plan. The dotted lines define the area of the respiratory membranous leaflets supporting the capillary network.

Owen on Fishes: Rymer Jones's Animal Kingdom; Article Pisces, in this work, by Prof. R. Jones; Art. Skeleton, by Mr. Maclise. I wish only here to observe, that the branchial arches appertain to the apparatus of the visceral skeleton, and in antero-posterior order succeed the hyoid arch, on the keystone of which they are more or less dependant, and the altered configuration of which they more or less follow.

* See Yarrel on British Fishes; Leçons d'Anatomie Comparée, par M. Cuvier; Owen's Lectures on Comparative Anatomy, vol. ii.; Monro, on the Structure and Physiology of Fishes, 1785; Art. Pisces, in this Cyclopædia; Wagner's Anatomy of Vertebrated Animals, by Tulk, 1845.

the soft structures. This part is represented transversely in *fig.* 238, in which also the disposition of the constituent cells may be remarked to bear advantageously upon the mechanical functions of the parts. As regards the arrangement of these cells, this piece in the framework of the gill-process may be divided into two parts, by a longitudinal line, on the outer side of which the long axes of the cells, which are oblong, are directed transversely with respect to the inner: the axes of the cells are parallel with that of the processes of which they are the constituents parts. This arrangement is most distinctly marked in those genera in which the skeleton is little calcified. Functionally considered the piece occupying the blunt edge of the process determines its penknife-like contour, and confers strength and straightness of direction, thus favouring the contact between the respiratory foliage and the surrounding medium. It discharges the passive office of sustaining the soft structures and of extending the plane superficies over which the branchial blood-vessels are distributed.

The internal or acute margin of the branchial process conceals, in the recent structures, under the labyrinth of the superimposed respiratory membrane, a skeletal mechanism of singular novelty and beauty (*f*, *fig.* 238.) From the innermost side (near its root) of the denser piece which lies parallel with the outer margin of the lamella, a less dense, more transparent, and more cartilage-like process (*d*, *fig.* 238.) rises, to advance along the internal margin of the lamella from its base to its extreme apex. From either side of this process, at right angles, processes (*f* and *c c*), still more slender, delicate, and transparent, are detached, to follow for some distance the circumference or free margin of the membranous leaflet on which the vascular network is outspread.

This part of the skeletal fabric of the branchial lamella is *actively* and importantly concerned in the mechanism of the respiratory function. It is to the branchiæ what the ribs are to the mammalian lungs. The fine extremities of these transverse portions, as seen in *c*, *c*, taper off into a species of curly fibre, which *travels accurately along the extreme margin* of the membranous leaflets to the point (*a*) at which the latter rest upon the flat surface of the osseo-cartilage of the obtuse margin. The axis which supports this system of elastic "*ribs*" (in section at *c* and *d*) exhibits under the microscope a median transverse line apparently filled with an oleaginous fluid, which communicates with the moniliform system of cells, occupying the axes of the curved pieces (*c*, *c*), where probably it performs the two-fold office of mechanically distending and nourishing the parts. No vestige of an Haversian order of canals can be discovered in any portion of this branchial framework. The calcareous granules of Tomes are distributed irregularly over the parietes of the cartilage cells. It is not easy to misapprehend the office which devolves upon this apparatus. By means of two needles the recent branchial ray may be separated into two longitudinal halves, to the inner of which, exclusively, the *membranous* leaflets remain adherent, a circumstance which illustrates the anatomical connection between these softer parts and the delicately adjusted framework of the internal border of the leaflet. The elastic transverse processes (*c*, *c*), from their constrained curved position, constantly tend to straighten themselves, and to convert the curved into a direct line of action. This straightening tendency, which is a constantly and unremittently operating force, constitute the immediate agency under which the tangling, folding, or crumpling of the leaflets bearing the capillary network is rendered impossible. Under the ceaseless operation of this resilient property, the true breathing surface is regularly maintained in a state of uniform extension, and that at a degree of lightness, measured with wonderful precision, to suit the exigencies of structures so surpassingly refined. A superficial consideration indeed might have sufficed to render it improbable, that a system of blood-channels of such extreme delicacy as that which constitutes the breathing apparatus of fishes could exist uninjured, unless by aid of a basis of support at once appropriate in its physical qualities and mechanical disposition.

Morbid anatomy of the lungs and air passages. — It is possible in the space here allowed to do little more than to enumerate the pathological conditions to which these parts are liable. The diseases of the lungs and bronchi since the era of Laennec have received a considerable share of the attention of pathologists. The normal anatomy of the lungs is now known with precision. The characteristics of the alterations of structure which in disease they undergo, within recent years have also been defined with corresponding precision. The community between the bronchial and pulmonary circulation established by the recent researches of Dr. Heale, will probably oblige pathologists to modify their views with respect to the supposed distinctness and independence of the diseases of the lungs and the bronchi. The following tabulated arrangement, as given by Rokitansky, in the 4th vol. of his Pathological Anatomy, exhibits the abnormal conditions of these parts in lucid summary.

1. Deficiency and excess of formation.
2. Deviations in size.
    - *a.* Morbid dilatations of the air passages.
    - *b.* Dilatations of the larynx and of the trachea.
    - *c.* Dilatation of the bronchi.
    - *d.* Contraction of the air passages.
    - *e.* Hypertrophy and Atrophy.
3. Deviations in form.
4. Deviations in position.
5. Interruptions of continuity.
6. Diseases of texture.
    - A. Diseases of the mucous membrane and of the subjacent areolar tissue.
        - *a.* Hyperæmia and Anæmia.
        - *b.* Inflammations of the mucous membrane.

1. Catarrhal inflammation.
   a. Acute.
   b. Chronic.
2. Exudative processes (croupous inflammation.)
3. Pustular inflammation.
4. The typhous process on the mucous membrane of the air passages.

c. Inflammation of the submucous areolar tissue.
d. Ulcerous processes.
e. Œdema of the mucous membrane of the air passages.
f. Gangrene of the air passages.
g. Adventitious products.

B. Diseases of the cartilaginous skeleton of the air passages
a. Inflammation of the perichondrium of the laryngeal cartilages.
b. Inflammation and softening of the epiglottis.
c. Ossification.
d. Adventitious products.

7. Anomalies in the contents of the air passages.

Abnormal Conditions of the Lungs.

1. Deficiency and excess of formation.
2. Anomalies of size.—Hypertrophy and Atrophy.
3. Anomalies in form and position.
4. Diseases of texture.
   a. Rarefaction of the pulmonary tissue (Emphysema.)
   b. Condensation of the pulmonary tissue.
   c. Hypæremia (stasis). Apoplexy of the lungs.
   d. Anæmia of the lungs.
   e. Œdema of the lungs.
   f. Inflammation of the lungs (Pneumonia).
      1. Croupous pneumonia, typhous pneumonia.
      2. Catarrhal pneumonia.
      3. Inflammation of the interstitial tissue of the lungs (Interstitial pneumonia).
   g. Deposits in the lungs (Melastatic processes).
   h. Gangrene of the lungs.
   i. Softening.
   k. Adventitious products.

The preceding distribution of the morbid conditions of the air passages may be advantageously methodised under two heads: first, those of the bronchi (as defined in the account of their normal anatomy); secondly, those of the lungs.

The bronchi are liable to several forms of inflammation:

a. Acute bronchitis.
b. Chronic bronchitis.
c. Plastic bronchitis.

Collapse of the lungs should be considered, pathologically, as rightly ranking under the denomination of the diseases of the *bronchi.*

The various forms of *asthma*, and *hooping cough*, belong to this species.*

The bronchi are subject to two forms of *dilatation.* In the *first*, a tube is uniformly dilated at every part of its circumference. In the *second*, the dilatation is *saccular.* The small bronchi and those near the surfaces and borders of the lungs are most liable to suffer this change. The walls of the tubes at the dilatations are hypertrophied and thickened. Sometimes, with the saccular variety, the same parts are relaxed and attenuated.

The *bronchitic collapse* of the lungs occurs under two distinct aspects, the diffused form, and the limited or *lobular* form. Of these the latter variety is the more striking or characteristic, and has been, especially in the lungs of children, the subject of more discussion than the former. But the diffused form is by far the more common, and is of frequent occurrence in its slighter degrees. In both conditions the pulmonary tissue presents a dark violet colour as seen beneath the pleura; internally it is red.

In considering the causes which tend to produce this condition they seem to resolve themselves into the following: 1st. the existence of mucus in the bronchi, which is more liable to produce obstruction according as it is more thick and viscid; and 2ndly, weakness or inefficiency of the respiratory power; 3rdly inability to cough and expectorate. Of these conditions, the first must be considered as the exciting cause, the others as predisposing, co-operating with the first, but incapable, without it, of producing collapse.*

With bronchitic collapse of the lung is almost always associated *emphysema* of the unaffected portions of the same lung (Gairdner).

Inflammation of the mucous membrane of the bronchi produces changes which are denoted by redness and tumidity of the tissue, a secretion of muco-serum, purulent mucus, or pus, according to the stage and intensity of the inflammation.

This latter is the condition of *superficial suppuration.* The swelling of the mucous membrane and sub-mucous tissue, which assumes the form of watery infiltration into the

* For an account of the morbid statis of the larynx, and upper part of the trachea, see Art. Larynx.

* For a full discussion of this interesting subject, see "Pathological Anatomy of Bronchitis, and the Diseases of the Lung connected with Bronchial Obstruction." By W. T. Gairdner, Edin. 1850. On the Diseases of the Organs of Circulation and Respiration, Art. Atelectasis. By Hasse. Sydenham Society. Die Bronchio-pneumonie der Neu-gebornen und Säuglinge. Berlin, 1837. By Seifert. Medico-chirurgical Trans., for 1830. By Dr. Alderson. Der Mechanismus der Respiration und Circulation. By Mendelssohn. Beiträge zur Experimentellen Pathologie und Physiologie. By M. Traube. Die Bronchitis der Kinder. Leipzig, 1849. Dr. Fuchs. Diseases of Infancy and Childhood. West.

areolar tissue, being accumulated at individual spots, is important and worthy of great attention, on account of the facility with which it interferes with the calibre of the tubes.

Chronic inflammation of the bronchial membrane gives rise, especially in parts abounding in glands, to *glandular hypertrophy*, *mucous polypi*, *epithelial growths*, *spongy* and *velvety* thickening, *relaxation* of the muscular and fibrous elements, *follicular ulceration*, &c.

The pathological conditions of the broncho-pulmonary mucous membrane differ in no respect from those of any other membrane of this class.

In *plastic* or *exudative bronchitis* are characterised by a morbid action of a *croupous* nature.

In *bronchial croup* the tubular exudations from the larger bronchi present a calibre inversely proportional to their thickness, and those thrown off from the finer ramifications occur as solid cylinders.

Asthmatic affections may either have their exciting cause in the lungs or in the condition of some remote organ. They partake of a nervous and muscular character, and are frequently caused by a *collapse* of a portion of the lung. The collapsed part operates as an excitor of the muscular spasm.

English pathologists recognise the following forms of disease proper to the parenchyma of the lungs: — *Pneumonia*, or inflammation of the cell-tissue of the organ; *gangrene; hæmorrhage; œdema; emphysema; phthisis; cancer*.

Inflammation of the vesicular tissue of the lungs is marked by the exudation of the coloured elements of the blood. This fact was once supposed to prove the absence of epithelium in the air-cells. This inference is erroneous.

Inflammation of the lung is divided into *three* stages, according to the consistency or physical condition of the exuded product. The first is that of *engorgement*; the second is that of *hepatisation*; the third is that of *grey hepatisation*.

Gangrene of the lungs occurs under *two* anatomical forms, the diffused and the circumscribed.

Cancer of the lung, most commonly of the encephaloid species, occurs in the forms of secondary nodules and primary infiltration, accompanied or not by tuberous formation on either mediastinum about the main right bronchus (Walsh).

The anatomical changes which occur in the lungs in phthisis are referrible to three main stages, corresponding habitually to certain varieties in the symptoms, and always to modifications in the physical signs. The first stage is that of *deposition* and *induration;* the second that of *softening;* the third that of *excavation*.

The exact *seat* of pulmonary tubercle has proved, from the dawn of pathology to the present time, a controverted point. The question is whether the deposit of the morbid product occurs first on the free surface of the air-vessels into the substance of their walls, or *between* them into a supposed intervesicular tissue. From Morton and Bayle to Rokitansky and Lebert, advocates for each of these "seats of election" have contended in turn. The free or aerial surface of the air-cells is now the commonly accepted situation of the tuberculous deposit.

The *nature* of the tuberculous matter is not less disputed; witness the following definitions: —

Tubercle is a *specific* exudation (Ancell).

Tubercle is a degraded condition of the nutritive material (Dr. C. J. B. Williams).

Tubercle is composed of the products of inflammation (Reinhardt).

Tubercle is composed of the dead-tissue elements (Henle).

Tubercles themselves consist of *abnormal* epithelial cells (Dr. W. Addison).

Tubercles are composed of metamorphosed organised elements; a metamorphosis co-ordinate with the fatty and the waxy degenerations (Virchow).

Tubercle is a product *secreted* from the blood by the *epithelium* lining the air-cells (Schroeder Van der Kolk*).

The *mechanism* of emphysema is still *sub judice*. Some authors, with Laennec, explain it on the supposition that the walls of the air-vesicles *yield* under the force of the air when the *expiratory* current is impeded. Another class of writers attribute it to an excess in the inspiratory force. Mr. Rainey contends that the parietes of the air-cells suffer a change of structure by fatty degeneration, and that this change stands to emphysema in the relation of a causal condition. Dr. Gairdner affirms that emphysema of one portion of the lung *cannot* occur unless a *collapse* has happened in another part. Emphysema fills up pneumatically the space lost by the collapse, and no more. The chest can only be *filled;* it cannot be inflated beyond a given inspiratory limit. The air-passages of the emphysematous portions are *free*, not obstructed. If already the cavity of the thorax be *uniformly* filled, it is certain that emphysema is rendered physically impossible. Emphysema is *plenum* counterbalancing collapse — a *vacuum*.

It is yet by no means determined to what extent, if at all, the shedding or desquamation of the *epithelium* of the air-passages takes place in disease.

Germ.; ἔντερον, Gr.; *Intestinum*, Lat.; *Intestino*, Ital. Sp.; *Intestin*, Fr.*)

What are called the organs of the animal body consist of a diversity of tissues, so grouped and united with each other as to form a more or less continuous and aggregate mass;—the functions of these various structures being also associated in a single general purpose, which may be regarded as the sum of their several actions on the system at large.

Among such groups of structures, there is none more remarkable than that which effectuates the series of processes collectively termed Digestion. For other organs are so far exclusively dependent on the blood, as that many influences of the outer world can scarcely reach them, except through the medium of this fluid. Entrenched, as it were, behind this the great river of animal life, they are secured from any but the indirect action of numerous physical agents. But the organ of digestion lies outside this stream: and occupies a kind of neutral territory, between life and matter, where the various forces of both can cooperate for its benefit, in equal and harmonious conjunction. Or rather, let us say, the digestive canal is the threshold of the House of Life, where dead matter is first endowed with those properties which enable it to become a living constituent of the animal body.

The group of organs before us has indeed a special relation to the animal. For although digestion is usually enumerated amongst those general or organic functions which are shared in by everything that has life,—vegetable as well as animal,—still the means by which the process is effected in these two forms of organization, constitute as important a distinction between them, as the mere presence or absence of other functions. So that, the digestive cavity is, on the whole, as characteristic of the animal, as the organs of locomotion and innervation of which it is the exclusive possessor.

How far the so-called vegetative functions are really alike, or even comparable to each other, in the two kingdoms of nature, it is not our object here to inquire. As little do we wish to introduce, what some might perhaps think less out of place, a detailed comparison between the digestive functions of the plant and animal. But as the cavity which it is our express object to describe is all but universally present in the latter, and absent from the former organization, it seems desirable briefly to contrast them in this respect.

In the animal, a highly azotized composition is connected with,—and probably essential to,—an active life; which, in its turn, implies a rapid waste of substance. On the other hand, the plant lives slowly, wastes little, and contains but a small quantity of azotized material.

The food of each appears to correspond with these requirements. That of the plant is, in great part, inorganic; consisting mainly of compounds which pervade the soil that surrounds its roots, or the air which bathes its leaves. While that of the animal is organic:—*i. e.* the substances which compose it are the products of a previous organization.

The elaboration of the food repeats the preceding contrast. The plant builds up inorganic into organic matter;—a process of chemical synthesis, which may well be effected with great difficulty, and by slow stages. While the animal scarcely does more than convert one proximate principle into another;—a metamorphosis which involves no change of composition, and the facility of which is but partially counterbalanced by its requisite rapidity and amount, and the delicacy of its adjustment.

The agents of these processes are also susceptible of comparison. For in the vegetable they appear to be closely connected with various external forces, such as light and heat; while in the animal they seem more inherent to the organism.*

And in both, the site of the elaboration or change in the food corresponds to those situations where the above agents are most readily applicable:—viz. in the plant, to the leaves and other green parts of its surface; in the animal, to a cavity in its interior. The presence of such a cavity not only permits the less frequent application of nutritious substance to be compensated by the ingestion of large quantities at particular times; but, while it thus meets the peculiar requirements of an animal organism, also allows of that locomotion which is so necessary to the mere prehension and selection of its scarcer food. Its subjection to volition renders ingestion a work of rapid and powerful mechanical force, in place of a slow physical imbibition. And finally, the same internal situation which directly subjects its contents to the agents of the digestive metamorphosis, also isolates them from all surrounding objects, besides favouring the temperature often necessary to the operation.†

* In respect to the etymology of these names we may conjecture as follows:—The word γαστὴρ is radical. The *stomach* is so called from its connection with the mouth (στόμα). *Maw* and *magen* are derived from its relation to food (*meat*). *Intestine*, ἔντερον, *entrail*, *ventriculus*, (and *darm?*) connote its internal and hidden position. *Bowel* (*botellus*), and *tripe* (τρέπειν), refer to its convoluted or tortuous form: *gut* (*geotan*, Anglo-Saxon, to pour), to its carrying fluent contents.

* Traces of this contrast between the animal and plant during life may be found in those processes of putrefaction and eremacausis which respectively effect their dissolution after death.

† Hence, instead of a digestion corresponding to that of the animal, the plant presents us with a process in which mere reception is so predominant, that we might almost compare it with the absorption of the chyme and chyle into the blood. As a kind of fanciful corollary to this, we might regard the crust of the earth, and the atmosphere which surrounds it, as forming a common stomach or receptacle of food for the whole vegetable kingdom. For they include, or receive, detain, and give up, the chemical food of the plant;—in quantities which, though

The reader will, however, observe, that the title of the following article does not announce an essay on the process of digestion, or the various organs which effect it; but limits itself to two portions of the alimentary canal, hitherto undescribed in this work. But it is impossible to treat of the functions of the stomach and intestine except in connection with the entire process in which they take so large a share. While the numerous observations and researches which have been made since the appearance of the earlier article DIGESTION require some notice in the *Supplement* of which the present essay forms a part. For these reasons the author has felt it advisable not to confine himself too strictly to the exact limits which the heading "Stomach and Intestine" might seem to imply. Hence, though the following essay will treat chiefly of the above segments of the alimentary canal, it will also comprise a very brief account of whatever is at present known concerning the whole digestive act. Commencing by a rough sketch of the anatomy of these parts in the animal kingdom, we shall successively consider, their structure and functions in the human subject; their relation to digestion and nutrition; and finally, their appearances in disease.

COMPARATIVE ANATOMY.—In the *Infusoria*, whose minuteness places them at the lowest extremity of the animal kingdom, the organ of digestion has already attained such a development as to form the chief basis of their nomenclature.

One or two genera present us with a rare and exceptional condition:—viz. the absence of all traces of digestive cavity. Such are the parasitic *Gregarina* and *Opalina;* in whom, as in some of the *Entozoa*, digestion and absorption appear reduced to a simple physical process of endosmose, which carries the nutritious substances dissolved in the fluid medium they inhabit at once into the mass of their corporeal juices.

The *Polygastria* possess a plurality of stomachs or internal sacs; and the relations of these to the intestine, together with the condition of the latter tube, subdivide this group into numerous families and genera. Thus many are named "anenterous," because they appear to be devoid of intestine. Of these the *Monas termo*—which has four or five globular stomachs, of $\frac{1}{20000}$th of an inch in diameter, appended immediately to its mouth—may be taken as the type. Others possess similar sacs in connection with a simple Intestine; and are chiefly distinguished by the straight, curved, or wavy course of this canal,—or by the single or double character, and lateral or terminal position, of its apertures. Most of them devour a living prey of kindred Infusoria;—prehension being often visibly effected by cilia, the voluntary action of which carries a current of food into the mouth, or removes egesta by a simple reversal of the stream. And sometimes this act of ingestion is aided by a dental apparatus, in the shape of a hollow cylinder enclosing long teeth,—as in the genus *Napula*.

The *Rotifera* are so named from the currents produced by their prehensile cilia; which are here limited to groups surrounding the mouth of the animal.

Many of them have an organ of mastication. This usually consists of three pieces:—each of the two facets of a kind of anvil being worked upon by the rough or toothed terminal surface of a recurved jaw, the longer limb of which receives a muscle at its extremity.

The intestinal canal generally exhibits a pharyngeal enlargement, which is followed by a narrow "œsophagus," of varying length, ending in a wider "intestine." In the *Gasterodela* a dilatation, called a stomach, precedes the intestine. In the *Rotifer vulgaris* and others, an almost globular enlargement of the narrow canal is so immediately followed by the constricted cloaca, as to have been compared to a large intestine. The organ of digestion is also often complicated by the presence of blind tubes; which vary, not only in number and size, but also in position, and possibly in import. Thus they may open, either into an uniform and narrow canal, or into the commencement of the intestine, or into the presumed gastric dilatation;—or, finally, as in the *Diglæna lacustris*, a set of such tubes may occupy both of these latter situations.

The various members of the order *Entozoa* are grouped together in obedience to a classification which is here and there arbitrary and anomalous, but in the main both natural and useful. It offers three chief varieties of the digestive organ, all of which are very interesting.

α. In many—as in the *Echinococci* and their congeners—no trace of a special digestive cavity is present. Without mouth, stomach, or intestine, the creature floats free in the cavity of its enclosing cyst, or buries its barbed head in the tissues of a living habitation;—whose juices, thus brought into relation with its exterior, are applied to its nourishment by what seems to be rather a process of endosmose than of digestion properly so called.

β. In other genera belonging to the *Cestoid* and *Trematoid* divisions, there is, however, a canal, which is apparently related to digestion, and the main features of which—repetition and ramification—may be represented by the *Tænia* and *Distoma* respectively.

For example, in the Tape-worm, a minute mouth opens into a slender tube, the bifurcations of which reach the margins of the body where this begins to assume its regular jointed form. From hence onwards the canal might be compared to a ladder, with rungs at the fore and aft extremity of each joint, at the right angles of which its longitudinal and transverse branches unite. It is probable that these canals possess valves. But whether they have any constant or valid terminal orifices seems doubtful.

ordinarily sufficient, are capable of being locally exhausted by the excessive demands of a particular class or species, and renewed by an artificial supply.

Many species of *Distoma* or Fluke may be regarded as types of an arborescent or ramified digestive tube. From a mouth which is suctorial—and sometimes visibly muscular—a canal passes backwards, to divide into two large branches. These run along the margins of the oval and flattened animal, giving off other branches; from which proceed a final series of anastomosing twigs.

γ. In many creatures closely allied to the preceding by conformation and habits, this ramified canal is reduced to its primary bifurcations, the ends of which are sometimes slightly dilated. Occasionally there is an enlargement, which has the situation of a pharynx; and which, in a few instances, encloses an apparatus perhaps masticatory. In the genus *Diplostomum* and others, a distinct set of vessels, which occupies the immediate neighbourhood of the intestine, has been supposed to represent a chyliferous or vascular system.

As regards these latter forms of digestive apparatus, it may be conjectured, that the ramification witnessed in the *Tænia* is referrible, not so much to that mere vegetative repetition of similar structures which affects the whole animal, as to a merging of the digestive in the circulatory function. In any case, the more simple form of tube last mentioned appears rather akin to an advance, than to a retreat, of development; while it sometimes visibly coincides with the appearance of a new system of canals, connected with the circulation of a proper nutrient fluid.

In the *Nematoid* Entozoa, the alimentary canal is generally a straight tube, which occupies the axis of the vermiform animal, and opens at its extremities. In most genera — as in the *Trichina*, *Tricocephalus*, *Ascaris*, *Strongylus*, and others — it widens posteriorly; where it often experiences a further dilatation, which only ceases near the anus. Rarely, other indications of separation are added: — an œsophageal dilatation, as in the *Ascaris lumbricoides;* or an enlargement corresponding in position to a stomach, as in the *Linguatula* and *Filaria*.

Rudiments of the organs accessory to digestion have also been detected. Blind tubes opening into the canal near its mouth are found in several genera: and the position of these has sometimes led to their being regarded as salivary. While rarely there is a tube which opens into the intestine in the situation of a biliary organ.

In the mode of attachment of their digestive canal, this division of the *Entozoa* offers a marked contrast with the preceding. In the *Sterelmintha* (or *solid* worms) the tube is scarcely distinguishable from the mass of the body. While in these *Cœlelmintha* (or *hollow* Nematoid worms), it is suspended from the wall of the belly by filamentous processes. And though such an acquisition of an abdominal cavity is no doubt partly referrible to the isolation demanded by the organs of locomotion, yet not only does this itself imply a general advance of development, but it is actually accompanied by a curious structure, which is apparently connected with nutrition, and possibly renders the cavity of the abdomen the receptacle of a kind of chyle. Its more perfect form in the *Ascaris lumbricoides* may be briefly described as consisting of a series of pyriform processes, the peduncles of which are seated immediately upon the mesenteric filaments previously alluded to, and which project freely into the abdominal cavity, so as to be surrounded by the serum and grey transparent substance that fills this space. Their shape resembles that of the villi of higher animals; and their size increases towards the median line of the body.

The alimentary canal of the *Polyp* exhibits so wide a range of development, that while by one extreme it approaches that of the simplest anenterous *Infusoria*, by the other it attains a complexity akin to that of the highest Invertebrata.

The *Hydra* is little more than a stomach or sac, fixed by a sucker at its closed extremity, and having at its other end a mouth surrounded by prehensile tentacles. Digestion is, however, energetic. The living prey, which is paralysed by the deadly grasp of the tentacles, undergoes a rapid solution in this stomach, while its colours often visibly mix with those of the parietes common to the organ and the animal; and finally, its excrementitious residue is speedily rejected by the same orifice through which it previously entered.

In other solitary Polyps—for example in the marine *Actiniæ*—the folded bag formed by the stomach is separated from the mouth by an œsophageal constriction. It is at the same time attached to, and isolated from, the general wall of the animal, by radiating muscular bands; which extend vertically down the whole depth of the organ, so as to resemble the septa of a poppy capsule as seen in a transverse section.

The *compound* Polyp appears chiefly to vary from this type by virtue of its individuals possessing a common stem, the proper nutrition of which requires it to be closely connected with the organ of digestion. Thus, in some of the *Anthozoa* which possess a stomach very similar to that of the Sea-anemones just described, an orifice of small size at the bottom of the gastric sac seems to admit the results of digestion into the general cavity of the animal, within which they experience a kind of circulation.

In the *Tubularian* Polyp, the canal is modified by the addition of a structure which may be regarded as a pharyngeal proboscis. It is a globular projection, surrounded by tentacles at its free extremity, and by its other end received immediately within a circle of similar organs;—the place of its attachment being marked by an internal constriction, through which the cavity of this appendix communicates with that of the stomach.

In many of these Polyps, the stomach has been seen to possess a ciliated lining; and there are grounds for presuming the existence of a similar structure in several other species. Some of the circulatory movements observed in their ingesta are perhaps accomplished by the aid of such an apparatus. While their vigorous and almost peristaltic character in other instances is due to structures, the voluntary and powerful contractions of which entitle them to rank as muscles.

The *cilio-brachiate* Polyp possesses an abdominal cavity occupied by fluid, in which the alimentary canal is free to move. The canal itself has a mouth and anus, which are both situated at the free extremity of the animal;—the former orifice being within, the latter without, its whorl of tentacles. The mouth opens into a pharyngeal dilatation, from which a narrow tube leads into an organ analogous to a gizzard. This organ possesses radiating muscular fibres, and rhomboidal teeth, that are capable of crushing its contents. Immediately beneath it is the stomach, in shape like a two-necked flask, and having its blind extremity fixed to the attached base of the animal by a retractory muscle. The pyloric aperture is guarded by cilia, which rotate, and thus delay, the food. The intestine is narrow and simple, and its excrementitious contents are expelled from the anus, to be immediately hurried away by the current arising from the action of the neighbouring cilia.

The body of the *Acalephæ* generally constitutes a disc with a fringed margin. It is convex above, and concave below, with large dependent processes. And it swims by what seems to be an alternate preponderance of contraction in these two surfaces.

The condition of the alimentary canal is here very remarkable. The Entozoa have already offered us a ramified tube, that could scarcely be regarded as strictly digestive. But these Sea-nettles further complicate this branched state by the possession of a central cavity. This is sometimes placed between a convergent and a divergent set of anastomosing canals; and sometimes approaches the stomach of the Distoma in possessing the latter set only. In the latter case, the so-called stomach communicates, by a short and simple tube, with the centre of the lower or concave surface. And in one species it also radiates unbranched tubes which open on the margin of the disc. The movements of the contents of these canals seem to be effected by cilia. The ramifications of the canals chiefly occupy the under surface of the animal.

The large order of *Echinodermata* again presents us with an important advance of development in passing from its lowest to its highest members.

Thus the alimentary canal of the *Asterias* has a single aperture on the under surface of the animal. This leads by a short tube to a central cavity, which divides into two processes for each ray. These processes give off secondary branches at right angles to themselves, and the latter end in tertiary cæca. In *Comatula* the cæca disappear, and the canal acquires a distinct mouth and anus, which open near each other. In all, the canal is muscular, is enclosed in a ciliated peritoneum, and has its primary divisions attached by a kind of mesentery.

In the *Echinus*, the anus generally opens on the upper or opposite surface of the body. Many of this genus have a complex masticatory organ, which is acted upon by powerful muscles. The first part of the canal opens into an intestine of much larger diameter, opposite to a blind dilatation very like the human cæcum. The intestine is coiled twice around the inner surface of the shell; the second coil reversing the direction taken by the first, and both exhibiting a sinuous course. Its width tapers away to the anus. Its structure is delicate and transparent; it possesses a mucous membrane, and longitudinal and transverse fibres; and it exhibits an intestinal vein, which is especially marked towards the termination of the canal.

In the vermiform *Holothuriæ* the canal forms a kind of Z in the abdominal cavity;—passing first backwards, then forwards, and again backwards to its posterior extremity. The first part is wider and stronger than the rest, and its more glandular mucous membrane presents longitudinal folds which terminate in a slight circular one. Such a structure causes this dilatation to be regarded as a stomach. The narrowing intestine often terminates in a large oval cloaca, into which open two branching cæca.*

The *Annelida* form a class of animals so diverse in nature and structure, that it is difficult to include all the varieties of their digestive apparatus within a mere brief sketch. The canal always possesses a distinct mouth and anus, which occupy the opposite ends of the more or less elongated and cylindrical body. Prehension is generally aided by teeth, which, as in the Leech, perforate the skin of their prey; while in others—as in some of the *Errantes*—it is effected solely by a proboscis. In many of the marine *Errantes* the intestinal canal is simple. In the *Lumbrici* the canal soon dilates into a membranous pouch, which is followed by a thicker and more muscular portion, supposed to be a gizzard. In some genera, this part of the tube is complicated by being produced into pouches. These are either numerous, as in the Leech; or few, as in some kindred genera. Finally, in the Earth-worm, they are reduced to mere constrictions of the canal; while in the *Aphrodita*, they are developed into tubes, which expand, divide, and terminate as almost globular pouches. Clusters of glandular follicles, which are supposed to be biliary, open into the posterior half of the complicated canal of the leech just alluded to: and analogous structures are found in other genera. In the Earth-worm, there is a singular apparatus, the *typhlosole*. This is a blind tube, which occupies almost the whole length of the canal, being attached to its dorsal aspect, and

* Such a complex organization is strangely contrasted with the alleged fact, that the animal, when alarmed, can shed the whole canal. This extraordinary act is presumed to be voluntary, and is only paralleled by the growth of another digestive apparatus, which replaces that evacuated.

projecting into its cavity. Its interior surface is folded and villous. The whole structure appears to be connected with a kind of chylous absorption.

The alimentary canal of the *Epizoa* differs from that of the cavitary *Entozoa*, in being generally surrounded by a glandular mass, the function of which is probably hepatic. The *Cirripeda* have prehensile jaws, and a terminal mouth and anus. In some, the canal has a gastric dilatation. Hepatic follicles, similar to those already described, occur here also. And St. Ange and Serres have found a tube analogous to the typhlosole.

The digestive tube of the *Crustacea* may be reduced to two chief forms, which correspond with other differences in the nature and structure of their possessors. Thus in those lower Crustaceans which are suctorial and parasitic, the canal is a very simple one. A proboscis conceals a pair of lancet teeth, and is followed by a straight intestine, around which are clustered a dense mass of follicles, supposed to constitute a liver. The higher Crustaceans possess a complicated apparatus of forceps and jaws. A short œsophagus leads to a large spherical cavity, which occupies the head of the animal, and which, although sometimes called a stomach, contains hard structures that render it analogous to a gizzard. A well-marked constriction separates this organ from the intestine, which is sometimes simple and nearly straight, sometimes divided into two portions distinguished by a projecting valve. The liver is conglomerate, and divided into lobules. Rarely, one or two cæcal tubes are also present.

The alimentary canal of the *Insect* offers what are rather varieties of development than any regular transition, such as we have remarked in some of the preceding orders:— varieties which the metamorphosis of the larva at present seems to complicate instead of explain.

In the *larva*, the canal is comparatively simple, and somewhat approaches the condition seen in the lower *Annelida*: being a straight tube, with a mouth and anus at opposite ends of the body. In many Hymenopterous larvæ, the latter aperture is absent. In others it is only developed towards the end of this stage of life, when an excrement—or *meconium* as we may perhaps call it—is for the first time expelled. But though such an intestine might seem to resemble that of the anenterous Infusory, or the hydriform Polyp, we must recollect that it differs from these in the important fact of its not being used for the double purpose of ingestion and egestion. The complications of the above simple canal relate chiefly to its subdivision, and to the addition of blind tubes. A gastric dilatation is the first to appear; its extremities then become constricted, and its calibre enlarged. An œsophagus, a crop or ingluvies, a small and a large intestine, may also be added. Sometimes the supposed stomach is transversely divided into two cavities, and complicated by short cæca. In other instances, longer tubes open into the same part of the canal. While in others, they open into the intestine below this point; and are hence presumed to be biliary.

In the *perfect Insect* the varieties of form are still more numerous and perplexing. Besides the complicated prehensile and dental apparatus, there is often an œsophagus, a crop, a muscular gizzard, a stomach, a small intestine, a large intestine, and a narrower rectum. But development is manifested, not only by differences in the diameter and structure of different lengths of the tube itself, but also by its complication, through the addition of supplementary organs of a more or less tubular form.

The *ingluvies or crop* is present in many but not all of the suctorial genera. It is sometimes distinctly glandular. And even where, as in the Bee, this character is less prominent, it is still probably a secreting organ. But its uses seem to be mainly those of accumulation.

The *gizzard* is generally added to the former organ. It is characterized by distinct muscularity, and a more or less hard or horny epithelium, which is often developed into plates, protuberances, hairs, or teeth. Sometimes it is only rudimentary:—a toothed œsophagus subserving its functions in some insects; while in others, it is reduced to a mere thickening of the muscular wall of this part of the canal.

The *stomach* is also of various form and size. In some insects it is simple; in others it is more or less plicated or cellulated, or its cells are even prolonged into short cæca.

The peculiarities of the remaining subdivisions of the canal are chiefly those of their length and width, and in the degrees of constriction by which they are separated from each other. As yet, however, it has been found impossible to make out any intimate connection between these differences in the anatomy of the tube and the habits of the animal possessing it. Indeed, the general relations of this kind seen in other orders often seem to be interrupted or even reversed in the insects.

The numerous tubes which open into the intestinal canal present still more diversity. They are often named salivary, biliary, or urinary organs. Thus those tubes which open into the earlier part of the intestinal cavity are called salivary; those which empty themselves into the commencement of the small intestine are regarded as biliary; and, finally, those which open into the canal at or near its termination, are considered urinary. It is only the first of these that, after many gradations, fairly attain the glandular development which a conglomerate condition implies. The second vary chiefly in number, and in the frequency of their anastomosis. The third are rarely vesicular in shape.

The digestive canal of the *Arachnida* offers, on the whole, more uniformity. The chief divisions of this order are the parasitic, the spiders, and the scorpions. All are "carnivorous:"—a term which here, as often elsewhere, is only approximatively correct; since most of them do not devour the flesh, but rather suck the juices, of their casual or more permanent victims.

The simple digestive tube of the *Acari* or Mites is prolonged in a straight line from mouth to anus. It is sometimes complicated by gastric cæca or dilatations.

In the *Aranei*, or spiders proper, a slender œsophagus passes back from the mouth to a "stomach." This is sometimes a mere dilatation; sometimes is indicated by four sacculi, that radiate from a narrow tube; and sometimes presents a cavity, having blind prolongations that extend into the bases of each of the maxillary palpi and thoracic legs. All these parts occupy the anterior or cephalo-thoracic division of the body. The remainder of the canal, entering the abdominal segment, dilates, after a single convolution, into a large and sometimes globular intestine, to reach the anus by a short portion, of narrower diameter, called a rectum. The long tubes met with in the Insects recur in this order. One set, of varying size, open in the neighbourhood of the complicated apparatus of prehension; these, from their position, are supposed to be salivary. And occasionally a special poison gland appears to empty itself in this neighbourhood. A middle set, called hepatic, often forms two pairs of tubes, with orifices much posterior to the gastric sacculi; in other cases they are very numerous, and are concealed by a granular mass, which occupies the same situation. The posterior set are one or two pairs of long cæca, which join the intestinal cavity close to its termination, and are hence compared to urinary organs.

The *Scorpions* have a tolerably straight, narrow, and simple tube, complicated by several pairs of straight sacs, which come off at right angles to its anterior part, and are probably gastric crops. Below these, two bifurcating tubes, of great length and small diameter, open into a constriction of the canal. They are regarded as hepatic.

In the order of *Mollusca*, many of whom inhabit the sea, we may again trace a gradual advance of development in the intestinal canal.

The *Tunicata* is its lowest subdivision. Here a simple canal begins by a wide œsophagus, that leads from the bottom of the branchial sac to a stomach or dilatation. This is surrounded by a number of hepatic follicles, that open into its intestinal end; and it leads to a wide recurved intestine, which ends by an aperture on the upper and outer surface of the animal. Sometimes the liver varies from this description in the fact that its follicles are aggregated.

The *Brachiopoda* possess a digestive apparatus of nearly equal simplicity with the preceding. Dental structures are wanting; and the liver is still follicular.

The *Lamellibranchiata* exhibit a somewhat similar condition. Their gastric cavity is sometimes preceded by a short œsophagus. From hence a comparatively simple intestine continues, with a few convolutions, through a mass of liver, to terminate, by a long straight portion, in the anus. The latter segment, or rectum, lies along the hinge of their shell, and often perforates the heart in its course. Although the liver is large and aggregate, it opens by several ducts into the gastric dilatation.*

The *Gasteropoda* have a head, jaws, and salivary follicles. Their longer œsophagus sometimes dilates into an ingluvies or crop. Their stomach often possesses a thickened lining, and a masticatory apparatus of teeth or plates, which make it a kind of gizzard. Sometimes it is divided into two or more compartments. The large liver opens into the pyloric extremity of the stomach, or the commencement of the intestine, by one or more ducts; or, rarely, it empties itself into the œsophagus. One or two large glandular cæca also open into the beginning of the intestine, and are regarded as a rudimentary pancreas. The remainder of the tube is simple, and ends anteriorly in the body, in accordance with the general structure of the animal. In the numerous herbivorous species, the intestine is longer and more tortuous; while the crop, the gizzard, and the masticatory apparatus all reach a high development.

The intestinal canal of the *Pteropoda* is very similar. It possesses jaws and salivary glands, together with an œsophagus, a crop, a gizzard, a short and simple intestine, and a conglomerate liver that often opens by a single duct.

The *Cephalopoda* exhibit a marked advance of development. Their mandibles form a powerful organ of mastication; and, in many species, salivary glands co-exist. The mouth leads to a long and dilatable œsophagus, which descending, sometimes expands into a crop before it finally reaches the gizzard or muscular stomach. This organ is of tolerably uniform appearance. Its shape is round, or somewhat elongated; it has a thick and whitish epithelial lining, and its muscular layer consists of two sets of fibres, each of which radiates from a central tendon on one side of the organ. The cardiac and pyloric orifices are situated at its upper part. The intestine coming from the latter soon communicates with another cavity, which is sometimes regarded as a stomach. This is, in the lower Cephalopods, nearly spherical. But in many of the higher or Dibranchiate division, it is of less simple form, being triangular, elongated, or folded spirally like a snail shell. Its mucous membrane is rugous and follicular; and the large liver, which is still supplied by arterial blood, opens into it by a single duct. The intestine continues hence as an uniform tube, which, after one or two slight curves, bends upwards to open at the base of the funnel. In some species we also find cæcal appendages, the ducts of which join those of the liver before they enter the

* In some species a curious style or hard conical process occupies a tube of similar shape, that communicates with the gastric dilatation. The use of this implement is unknown; but it has been suggested to effect a triturative process:—a supposition which, if true, would render the cavity containing it the analogue of a gizzard.

intestinal cavity. These have been supposed to constitute a rudimentary pancreas.*

The alimentary canal of *Fishes* is simple, wide, and short, compared with that of other Vertebrata. Its chief subdivisions are an œsophagus, a stomach, and an intestine.

The *œsophagus* is large, dilatable, and muscular. Its mucous membrane is generally simple, sometimes involuted or glandular; and offers a remarkable contrast to the redder and more vascular membrane of the stomach at the point of their junction. As the diameter of the tube rarely undergoes any great and sudden increase in this situation the above contrast of structure is often the only distinction between the two cavities.

The *stomach* varies greatly in size and shape. Usually, however, it forms a curved tube like a siphon. The obliteration of the concave side of this tube converts it, by many gradations in different genera, into the shape of a two-necked flask, or of a blind tube with a double orifice at one end. In other instances it is dilated, or almost globular. Where tubular, it generally tapers away towards the pylorus. And this end of the stomach, which is usually more muscular than the cardiac, sometimes approaches the structure of a gizzard, having constricted extremities, a thick muscular coat, and a scaly epithelium on its mucous membrane. The valve itself is almost always present, as a circular ridge of muscular fibre, covered by a fold of mucous membrane.

The *intestine* of the fish is short and wide: and generally consists of two portions, which are separated from each other by a slight constriction into a small and large intestine. The first receives the bile-duct, and the follicles which form the rudimentary pancreas. The latter also occasionally receives a cæcal tube. The intestine has the usual three coats—serous, muscular, and mucous. The serous membrane is often pigmentary, and its cavity communicates by apertures with the exterior. It rarely forms a continuous mesentery: — the attachment of the intestine being generally ligamentous or filamentous, or even, as in one instance †, by means of a mass of areolar tissue that involves the whole tube. The muscular coat is of unstriped fibres ‡, which form two layers, the circular generally external.§ The mucous membrane is variously folded: it sometimes contains ductless glands: rarely it is ciliated.|| The chief deviations from these the ordinary characters of the intestine are, either an increase of length, which is sometimes accompanied by a diminution in width; or an equally real increase of active surface, which is due to the development of folds, such as the spiral valve of the Shark.

The *appendices pyloricæ*, or pancreatic follicles, are absent in many fishes. They vary in number from one to two hundred. In structure they range from simple, short canals, to elaborate branches, which are united by areolar tissue and vessels, and are enclosed in a muscular tunic.

The alimentary canal of *Reptiles* preserves much of the simplicity, width, and shortness, seen in that of Fishes. But it offers important differences in many respects. The thick, semi-transparent, gelatinous-looking intestinal parietes generally possessed by the Fish, are strongly contrasted with the thinner and more condensed and opaque tube present in the Reptile. Such a comparison seems to indicate a great advance in the development of the Reptilian digestive canal. This advance, though no doubt correlative with that of the tissues generally, probably depends chiefly on the increased efficiency of the respiratory function.

The *œsophagus* varies greatly in size and appearance. It is usually large and dilatable. In the Ophidians this width and laxity are so greatly increased, that it forms a tube which can be distended to almost any extent; and the parietes of which are so thin, that they may be regarded as supplanted by the muscular parietes of the belly itself.

The *stomach* rarely possesses any well-marked cardiac constriction. Hence the characters of its mucous membrane are the chief means by which it can be distinguished from the œsophagus. Its form, in the Chelonian and Batrachian divisions, somewhat resembles that seen in many fishes. Beginning by a dilated cardiac pouch, it tapers away towards the pylorus, taking a curve like a siphon. In the Crocodiles, the stomach may be regarded as consisting of two portions. Of these, the first is a gizzard: which resembles the form and appearance of that of the Cuttle-fish; and consists, like it, of a plane of muscular fibres, that radiate from a central tendon on each side of the organ. The second is a small pyloric pouch or diverticulum, which passes out of the gizzard at its upper part, close to where it receives the dilated œsophagus. In many Serpents the pyloric extremity is so narrow and muscular, that the organ has been distinguished into two parts:—an upper, or cardiac, which is thin and saccular; and a lower, or pyloric, which is narrow, strong, and tubular. The pyloric valve varies in development. But even where best marked, it never approaches the distinctness seen in man and the higher Mammalia. It consists, as usual, of a projection, which is formed by the circular muscular fibres, and is covered by a fold of mucous membrane.

The *intestine* is short, and rather wide. It is usually divided into small and large by a circular constriction or valve.

* Many anatomists, however, consider the office of this gland to be fulfilled by the cavity previously mentioned. But strong arguments against this view might be derived from the development of glands in general, and of the pancreas in particular; both in the phases of individual life, and in the advance of the animal series. In addition to this, the gastric character of this cavity, and the unfitness of a gizzard for solvent or digestive functions, further justify us in preferring the above interpretation.

† The *Tetrodon mola*.

‡ In the Tench (*Cyprinus tinca*), they are striped.

§ Reversing their ordinary arrangement in the Mammalia.

|| As in the *Branchiostoma*.

In the *Batrachian* division, however, the separation into these two segments is sometimes absent. While sometimes, as in the Toad and Frog, there is a distinct large intestine, into which the smaller portion opens laterally, so as to form a cæcum. In the former of these two genera there is no valve.

In the *Ophidian* the two portions are generally distinct and short. But their relative extent varies considerably: the small intestine being sometimes lengthened, and often presenting a very peculiar appearance in the shortness of its mesentery and the closeness of its folds. The indistinct ilio-cæcal valve is chiefly marked by a change in the diameter of the tube. The large intestine is often subdivided into distinct portions by one or two transverse valves.

In the *Chelonia* the intestine is longer and much more muscular. There is generally an ilio-cæcal valve, and often a well-marked cæcum. The valve is also present in most of the *Sauria*. But in the Crocodile the cæcum is absent.

Birds.—In this class, the *stomach* is generally complex; being separated into three distinct cavities, which differ greatly in their form, structure, and office.

The *œsophagus*, which leads to the first of those cavities, has a length corresponding to that of the neck which it occupies. Its width and dilatability mainly depend on the nature and form of the food. Thus, in some of the birds of prey, or those which swallow large fish entire, it is very lax and dilatable. And in this respect, as well as in the direct continuity of its cavity with that of the stomach, it offers a great similarity to the gullet of the Ophidian reptiles and many fishes. Its mucous membrane is follicular, and folded longitudinally.

The *ingluvies*, or *crop*, is a dilatation of the œsophagus, somewhere about the middle of its length. In some of the smaller Raptores it is but small; in the larger and more voracious it is a considerable enlargement, that affects one side of the tube more than the other; in the Gallinaceans it is a distinct sac, appended to the canal by a narrower neck; and, finally, in the Pigeons, it attains its maximum size, and becomes double. Its muscular and mucous membrane are similar to those of the œsophagus. The food which it contains undergoes a kind of insalivation and maceration. And the highly-developed form of crop, which is seen in the Pigeon, pours out a milky fluid during that period of the year in which this bird feeds its young by regurgitation. At this time its mucous membrane also acquires a thicker and more glandular character.

The *proper stomach*, or *proventriculus*, communicates with the inferior part of the œsophagus, and corresponds, both in structure and function, with the true stomach of the *Mammalia*. The glandular tubes which open on its free surface secrete a fluid that possesses all the properties of gastric juice. In the degree of complication these glands differ considerably; varying from simple tubes in the carnivorous birds, to tubes that open between prominences and prolongations, and finally form primary and secondary branches. The shape and size of this organ are subject to great variety in different genera. In those that swallow a large prey, it is wide and straight, like the stomach of the Serpent. In others, it approaches the spherical form, or passes towards the right side to join the gizzard. The comparative size of these two organs also varies considerably.

The *gizzard* is a flattened ovoid of highly muscular texture. It is lined by a dense horny cuticle, and contains sand, gravel, or other hard inorganized matters, which are the passive agents in the trituration of the food. Its size varies greatly. Its apertures both occupy the upper part of the organ, so that its cavity terminates below in a blind extremity. Its walls contain a variable amount of muscle, the arrangement of which is usually that of the radiation of fibres from a central tendon, such as was previously noticed in speaking of the Cephalopoda. Its epithelium is hardest in the granivorous birds. And even in the same individual, it offers an increased density at the precise situations of most pressure. In like manner, Hunter noticed that a thickening, both of cuticle and muscle, was produced by feeding a Sea-gull upon grain.

The pyloric valve is, as a rule, well marked. In some species there is a small supplementary cavity, which immediately precedes it, and receives the orifice of the gizzard.

The *intestine* has a length about midway between that of the Reptilian and Mammalian bowel. But although longer than in either of the preceding classes, it retains considerable simplicity of form. It presents, however, much variety, both in its length and in the number and appearance of its convolutions;—differences which, as usual, are related (though not very closely) to the food and habits of the animal. The duodenum which immediately follows the pylorus has the form of a long loop or fold, the concavity of which includes the pancreas. The small intestine, more or less folded, terminates in a large intestine, the commencement of which receives two cæcal tubes, one on each side. These cæca offer remarkable differences in length:—varying from papilliform offsets, as in the Solan-goose, to processes three feet long, as in the Grouse. Sometimes only one is present. The short and straight large intestine is continued from the termination of the small intestine, without any distinct valve, to end in a cloaca common to the digestive, urinary, and generative organs. Connected with the small intestine is an appendage, supposed to be a relic of the duct of communication between the yolk bag and intestine of the chick. It is devoid of a muscular tunic, and in some birds equals or exceeds the size of the cæca themselves.

Mammalia.—The form, length, and arrangement of the alimentary canal vary so much in the different orders of Mammalia, that it will be necessary briefly to state its peculiarities in each.

In the *Carnivora* the shape of the stomach approaches that of the human organ: it has a cardiac pouch, and a greater and lesser curvature. The intestine is short, its length being to that of the body as* 5 to 1 in cats and dogs, and 8 or 9 to 1 in the hyæna and bear, but reaching 15 to 1 in the *Phoca vitalina*, one of the amphibious seals. The mucous membrane is destitute of folds. The convolutions of the small intestine are few and simple. The cæcum is short, and scarcely wider than the rest of the large intestine.† And the latter segment of the canal is short, wide, and cylindrical.

The *Insectivora* have a very similar intestinal tube. The simple and elongated stomach is transverse to the axis of the body. In some genera, its spherical cardiac pouch is enlarged, while its lesser curvature becomes shortened. The intestine is short—from three to six times the length of the body; it has no cæcum, and a nearly uniform diameter. Its mucous membrane exhibits zig-zag folds, which run longitudinally throughout its whole length.

In the *Cheiroptera* three chief varieties of stomach have been distinguished by Cuvier. The first approaches that seen in the preceding order, and belongs to those members of this group which feed upon insects. Here the nearly spherical organ has a cardia and pylorus, which are situated close to each other. The second form is seen in those which subsist by sucking the blood of animals: it differs from the preceding in being longer, and more conical from cardia to pylorus. The third, which obtains in the frugivorous division, is very different from both the preceding.

Thus, in the *Pteropus* the stomach is a long tube, placed transversely to the axis of the body. One-third of its length is formed by the cardiac pouch, which lies to the left of the œsophageal aperture, and is divided into two by a slight constriction, while its terminal or pyloric third is bent back so as to be parallel and near to the middle portion. The mucous membrane of this stomach is folded longitudinally; the left subdivision of the cardia is smooth, and the lower part of the œsophagus — which is somewhat dilated — differs from the upper.

The pylorus is well marked in all the Cheiroptera, and the intestine, which is much narrower than the stomach, and is devoid of cæcum, is of nearly uniform diameter. It often presents concentric windings or coils. Its length varies greatly;—thus, in the frugivorous Pteropus it is six or seven times, in the insectivorous Bat only twice, the length of the body.

Edentata.—The stomach of this order differs greatly in different genera. Most of them possess a simple organ; the cardiac pouch of which is large and globular, while the pyloric extremity is conical, and is sometimes almost absorbed into the spherical cavity. A single genus, the *Manis*, adds a further distinction to these two parts in the shape of an internal fold of mucous membrane; and one of its species exhibits a long blind sac, springing from the right of the pyloric aperture. In the *Tardigrade* genera the stomach assumes much of the complexity seen in the Ruminantia. For it has two cavities, a cardiac and a pyloric, which, if regarded from the exterior, look like mere exaggerations of the distinction mentioned above, but, when examined internally, are seen to be divided by prominent folds, and by differences in the character of their mucous membrane. Thus the cardiac pouch has a dry epidermoid lining, and is subdivided by a fold into two parts, and prolonged into a short blind tube, while the pyloric sac has a soft and delicate mucous membrane, and more muscular parietes. And its interior is also subdivided, by a fold of membrane, into a terminal part, which is analogous to the fourth stomach of the Ruminants, and an intermediate cavity, which resembles the third stomach of the same order in its possessing dentate processes, and a direct communication with the œsophagus. The latter tube also exhibits a *cul-de-sac*, which is sometimes further divided by folds.

The form and length of the remainder of the canal is subject to great variety. Its mesentery is very long. In many genera there is no distinction of the intestine into large and small. In some there is no trace of a cæcum. In others there are two of these tubes, which occupy the confines of the large and small intestines, and open by what are sometimes extremely minute apertures.*

The *Ruminantia* are remarkable for the complete subdivision of their stomach into four distinct cavities. The first of these, the *rumen*, or *paunch*, is generally of very great size. It is situated to the left of the œsophagus, from which it receives the food when first swallowed: it has a villous texture, but its minute conical processes are covered by a dense white pavement epithelium. The second cavity, the *honeycomb* or *reticulum*, is so called from the appearance of its mucous membrane, which, in all other respects, has the same structure as that of the preceding cavity. The third portion, the *maniplies* or *psalterium*, is named from the many longitudinal plies or folds which occupy its interior. In the Camel, the circumference of the cells or excavations of its reticulum and paunch have been long recognized as containing muscular fasciculi, the contraction of which enables these cavities to retain water free from admixture with the general contents of the stomach. And

* We owe these measurements to Meckel.

† In the dog it is convoluted.

* In such a case they can hardly be supposed to receive fæcal matter. But in the *Dasypus mustelinus*, the ileum ends by a slit between the larger apertures of two such tubes; and hence appears to admit of being closed by the lateral pressure of their contents. (See Prof. Owen's Catalogue of the Hunterian Museum, vol. i. p. 219. 729 A.)

eight or nine years ago, the author discovered that all these projections from the surface of the ordinary Ruminant stomach,—viz. the villi, honeycombs, and plies—are constructed chiefly of unstriped muscular tissue, lined by scaly epithelium. The uses of such a structure are too obvious to need any comment. The fourth cavity or *abomasum*, is the true stomach: it secretes the gastric juice, and possesses the ordinary tubular structure. As regards the uses of these cavities, the bolus is probably moulded for rumination in the honeycomb, and is thence regurgitated into the gullet; while a muscular fold forms a direct pathway for the ruminated food to pass at once from the œsophagus to the maniplies.

Pachydermata.—The Elephant has a stomach which is elongated, and subdivided by very numerous folds. In other respects it is simple. That of the Rhinoceros is similar; but the cardiac pouch is devoid of folds. The shorter stomach of the Pig is divided internally by two folds of mucous membrane into three portions:—a cardiac pouch, a pyloric extremity, and an intermediate portion, which receives the œsophagus. The lesser curvature, and the back of the cardiac pouch, are both occupied by a white and dense epithelium, which is similar to that of the œsophagus, and forms a broad quadrilateral band along this aspect of the interior. In the Pecari there are external indications of the same subdivisions: but the white epithelium extends over a wider surface; so that it is only the pyloric third, and the lower parts of the middle and cardiac pouches, which exhibit the proper gastric or tubular structure. In the Hippopotamus, the stomach is long and tubular, and is complicated by the addition of two pouches, which have a size almost equal to its own, and communicate with its cavity by corresponding orifices on the right of the œsophagus and at the back of the cardia. The internal surface of the organ is so folded as to allow the alimentary bolus to enter either of these two cavities.*

The stomach of the *Solipeda* has a rounded shape, and a cardia and pylorus which are close to each other. The cardiac half of the organ is lined by a white epidermis, which terminates by an abrupt dentated margin.

In all these three orders — Ruminants, Pachyderms, and Solipeds—the *intestine* is characterized by great length, width, and convolution, and by the possession of a capacious cæcum. Thus, in the Ruminant sheep, the intestine is thirty times the length of the body. And although in the Soliped horse this proportion sinks to fifteen or twenty, still the sacculation of the cæcum and colon which obtains in this and the Pachydermatous order perhaps compensates such a diminution in length. The ilio-cæcal valve is represented by a narrow passage, the mucous membrane of which forms six or eight thick longitudinal folds. The cæcum, smallest in the Pachyderm, attains its maximum size in the Soliped; being, in the Horse, two feet long, and thrice as capacious as the stomach. In one Pachyderm—the Cape Hyrax—two additional cæcal tubes open into the large intestine by wide apertures.

In the *Rodentia* the stomach is separated by an external constriction into two portions: —a cardiac, clothed with a thick epidermis, and a pyloric, occupied by a mucous membrane which has the ordinary tubular structure. The size of the former pouch varies in different genera; the latter sometimes presents an imperfect subdivision. The whole organ occasionally approaches a conical or spherical shape. In the Beaver and Muscardin, the stomach is complicated by the addition of glandular crypts and cæca, the import of which is unknown. The intestine of the Rodent is very long and convoluted, and the small and large intestine are of nearly equal diameter; but the latter is deeply sacculated. The cæcum is usually very large, and is sometimes subdivided by spiral or circular folds. But in the omnivorous Rat it is small; and in the Dormouse it is altogether absent.

Marsupialia.—In a large proportion of this order, the stomach has a considerable resemblance to that of the human subject. Such an organ is found in both carnivorous and herbivorous Marsupialia: and indeed, it is difficult to point out any differences in its size or shape which are distinctly referrible to the habits of its possessors. In some, however, a stomach of very similar outside shape exhibits a lesser curvature, which is occupied by a gastric gland like that of the Beaver, composed of numerous irregular crypts. In the Kangaroo (*Macropus*) both the shape and the structure of the organ differ widely from the preceding. The stomach is of a length which equals that of the whole body; the cardiac pouch is subdivided into two cæca; and the middle part of the organ is sacculated by three bands of longitudinal muscular fibres, so as closely to resemble the ordinary arrangement of the colon,—except that the interspace between the upper two, or that third of the surface which occupies the lesser curvature, is not sacculated. The gastric gland is broken up into numerous follicles, which are placed in three rows parallel to the longitudinal muscular bands. The mucous membrane of the œsophagus is continued right and left of the cardiac orifice for a considerable distance; somewhat as in the stomach of the Pig. The remainder of the mucous membrane is of the ordinary soft character.

The intestine of the Marsupial is also subject to great differences. The carnivorous members of the class are devoid of a cæcum,

* The above is a description of the organ in the fœtal Hippopotamus, to which alone our present information refers. Cuvier suggests this to have been an incomplete development of a compound organ, akin to that of a ruminant: the stomach being the abomasum, and the diverticula representing the paunch and honeycomb. But the tough and wrinkled character of the mucous membrane which lined the supposed abomasum in the greater part of its extent seems to negative this view.

The insectivorous Marsupials have a longer intestinal canal, which is separated into large and small intestine, and exhibits a cæcum of moderate size. Those that live upon fruits have bowels which are still longer, and a large cæcum of twice the length of the whole body. Finally, the true vegetivorous genera have a cæcum which is thrice as long as the body. In those which are possessed of a sacculated stomach, the cæcum is, however, much shorter. One genus, the Wombat, has a vermiform appendix. The length of the whole intestine varies from two to ten times the length of the animal.

In the *Monotremata* the alimentary canal is chiefly remarkable from its terminating in a cloaca common to it and the urinary and generative organs. A small cæcum separates the long and narrow bowel into two parts. The diameter of the small intestine gradually diminishes to the cæcum, while that of the large intestine gradually increases to the rectum.

The *Cetacea* offer two chief varieties of stomach, which are connected with differences in their food, though scarcely explained by them. Those which live on vegetable food exhibit a simpler form of organ. Thus, in the Dugong, the stomach is long and transverse; and is divided by a deep constriction into a globular cardiac, and a conical pyloric, portion. Two large cæca open into it near this constriction; and a special glandular apparatus occupies the upper part of the cardiac pouch. In the carnivorous Cetaceans, the stomach is subdivided into three, five, seven, or more cavities. In some genera, however, there are only four. Of these the first has an epidermoid lining, while the three last have a soft mucous membrane. The biliary duct often opens into a dilated cavity, the import of which is unknown. The intestine is longer in the herbivorous division. Here there is also a cæcum; which is sometimes large and glandular, but sometimes small, short, and even bifid. In the zoophagous Cetaceans there is rarely either cæcum or valve:—so that the intestine, which decreases slightly in size from the pylorus to the anus, offers no separation into large and small. But in the genus *Balæna* there is a small cæcum, like that of the Cat.

The *Quadrumana* possess a stomach the form of which approaches that of the human organ. In some cases, however, it is more elongated; while in others it assumes a globular shape, with a cardia and pylorus in close proximity. The latter deviation is generally found in conjunction with carnivorous or insectivorous habits. It is usually separated into two portions, a cardiac and a pyloric; and sometimes the latter, which is more globular than usual, is distinguished by an internal fold from a short tubular part, which terminates in the pyloric valve and the duodenum. Rudimentary pyloric cæca have been remarked by Cuvier * in one instance. The *Semnopithecus* presents a form of stomach which recalls that of the Kangaroo. For the cardiac cavity, smooth and almost bifid at its commencement, is soon sacculated by a superior and inferior band of longitudinal fibres which come from the œsophagus; and from thence the stomach continues to the right side, as a sacculated tube, which is bent upon itself, and closely resembles a large intestine. But before reaching the pylorus, these sacculi diminish and disappear.

The length of the intestinal canal in the different genera of this order varies to an extent which is curiously contrasted with the general similarity of their food. Its proportion to the length of the body is in some as 8 to 1; in others as 3 to 1 only. The division into two portions, and the general arrangement of both small and large intestine, is very similar to that seen in man. In all the genera a cæcum exists, but with great variety as to length:—an increased development of this portion of intestine, as well as of the cardiac extremity of the stomach, being sometimes connected with a diminution in the length of the whole canal. The Apes and Gibbons possess a vermiform appendix; but in the latter it is of very small size. The mucous membrane has villi, but no valvulæ conniventes.

General remarks.—Although physiology at present scarcely pretends to interpret this various and complex development of the alimentary canal, still some attempt at its explanation is indispensable. For without any clue to their import, details like the preceding could hardly be recollected, far less made use of; and would scarcely deserve to be stored up in the archives of science, much more brought forward in an essay like this. Nor, in attempting their explanation, can one be rightly charged with breaking those rules which our great countryman has laid down for the pursuit of natural knowledge. All that is necessary to such a superstructure of theory is, that, however slight and temporary, it should at least be founded on the known facts; that it should indicate something like the degree of probability assignable to its several parts; and, finally, that it should be at once yielded up, as soon as a stricter logic, or larger and more numerous facts, offer us a better explanation.

The absence of all digestive cavity is the first peculiarity which demands our notice. The few genera in whom this rare condition has been found all offer the greatest simplicity of structure; and further agree in the fact that they are parasitic:—*i.e.* that they derive their nutriment from the juices of another animal, to whose body they are attached. Hence we need not scruple to assign this apparent deficiency of the digestive organ, partly to the previous elaboration of a highly nutritious animal food, partly to the simplicity of the various tissues which are destined to be nourished by it. But can we therefore say, that the function of digestion is absent, or — what would be nearly equivalent to such an assertion — that it is reduced to a mere physical absorption? Probably not. For, as regards the general development of the animal series, comparative

* Leçons d'Anat. Comp. vol. iv. p. 28.

anatomy conclusively shows that the fusion of certain structures by no means implies the absence of their several functions; while a history of the development of each individual would equally establish that, though the embryo at a certain stage of life is quite devoid of a digestive cavity, it is nevertheless nourished by materials which have been previously set apart from the substance of the parent. And just as it must doubtless effect some change in these materials, in order to assimilate them to its own various textures, so it is evident that such a change, however slight, probably represents what is as much a digestive as an absorptive act:—a digestion in which the absence of many of the ordinary agents is sufficiently accounted for by the minimum of waste which this food supplies, and the minimum of change which it has to undergo. Now some of these parasitic genera are also connected by the circumstance, that the anenterous condition probably forms but a stage of their development;—so that the process of time, or their transplantation to a more congenial dwelling, would often convert them into animals possessing an alimentary canal. Of such creatures we might therefore vaguely say, that they retain the low digestive development of an early ovum; or, in other words, that they are themselves the partially developed embryos of a very simple organization. That, with such a simple structure, they should effect such a complex function, is surely not one whit more extraordinary than what appears to be the case in the action of every ordinary cell; which is what it is—liver, kidney, or the like—by virtue of powers that its mere structure will not explain—powers that enable it to attract and retain certain materials, to relinquish or dismiss others, or even to effect a definite metamorphosis in its own chemical ingredients.

The simplest form of the digestive organ may be seen in the hydriform Polyp, as a cavity of the body, in which the food undergoes a kind* of solution. The agent of this process is doubtless a fluid which exsudes from the membranous walls of the cavity. But as these are also the parietes of the body, it is to the latter that we must probably refer the origin of the solvent. That harmless inversion of the whole animal, which Trembley was able to effect, strengthens such a conjecture. Nor is it impossible, that the poison of the tentacles is itself but a more concentrated form of the gastric fluid. In any case, one cannot avoid suspecting that, in this animal, the alimentary solvent has some very simple chemical relation to the organism generally. The more so that, although it acts upon the swallowed prey with the greatest energy and rapidity, the tentacles of the animal itself, which are often closely entwined around the hapless victim, are quite unaffected by even a prolonged stay in the stomach. And the same impunity extends to another animal of its own species which may have been swallowed while tenaciously clinging round the prize * that both are disputing.

It is usual to call such a simple digestive cavity a "stomach." But though the etymology of the term quite allows of its being thus applied, still the definite character of this organ in the higher animals seems to suggest that we should either restrict its application, or recollect the doubtful meaning which it acquires by such an extended use. Whenever an organ of this kind appears to effect the solution of substances which pertain to the albuminous group†, it is entitled to rank as a true stomach. But in proportion as this fact is uncertain or improbable, the name becomes a vague designation, which ought never to be made use of without recollecting what it really means—a mere receptacle of food. In the instances before us, such a receptacle probably represents, not only the stomach of the higher animal, but a fusion of this with the succeeding ‡ portions of the tube, and with all the accessory organs of digestion,—such as the liver, pancreas, &c. And just as such simple cavities import more than a mere gastric function, so conversely we might find others bearing the same name, which complicate a fully developed alimentary canal, and thus imply less. These, though called stomachs, are probably mere crops.

A *complex digestive organ* might at first sight seem to be the natural antithesis of the preceding. But though complexity forms a useful subjective contrast, without which we could indeed hardly conceive of simplicity—still, as already hinted, instead of a progressive evolution, corresponding to a gradual and successive advance of development, the alimentary canal rather offers a variety of deviations. And most of these deviations appear to result from causes, the number and intricacy of which is such as to defy all analysis. We shall therefore only enumerate those, the influence of which seems to be most direct and important.

1. It is scarcely necessary for us to dwell upon that advance of development, and gradual increase of complexity, which the reader must have observed in the preceding sketch. He has seen how, in progressing from the lowest Infusory to the highest Mammal, a simple excavation first became a membranous canal; how it then acquired an additional orifice; an organ of mastication; a salivary apparatus; a stomachal dilatation; a subdivi-

* For the sense in which we are to understand the word solution as applied to this process, see the remarks upon the action of the gastric juice at p. 337.

* It is interesting to notice that differences of development, such as are obviously almost tantamount to diversity of species, appear to remove all barrier to this solvent action. Thus the Polypiform Medusa devours and digests its Infusory-like younger brethren.

† See p. 335.

‡ The term "chylific stomach," sometimes made use of by comparative anatomists, seems especially to demand such a caution. For we need scarcely point out that, in the higher animals, at any rate, this organ does not "make chyle."

sion of intestine; a liver; a pancreas; and, finally, a compound character of mucous membrane, by virtue of which the whole tube might be compared to one vast expanse or aggregation of glands. Some of these particulars will again force themselves upon our attention. Hence we may here limit ourselves to the remark, that the main elements of this advance consist in the evolution or separation of accessories, and the increase and subdivision of surface:—and that both of these conditions imply a division of labour which, here as elsewhere, enhances both the quantity and quality of its product.

2. Respecting the homologies of the intestinal canal, scarcely anything can be said. As might be expected, form seems always subordinate to purpose:—in other words, neither general nor individual development offers us any permanent or temporary organs of digestion, from which we can deduce a shape that can be considered as a common pattern or archetype.* In rare instances,—as in the Earth-worm and Arachnidan,—the form of the internal canal approaches that of the body and limbs respectively. But even this peculiarity of form is probably teleological.

3. Sufficient allusion has already† been made to vegetative or irrelative repetition, as a possible explanation of the complex canal seen in many of the lower Invertebrata. Some of these ramified canals — such as those of the Acalephæ, and, with less probability, of the Distomæ — may be conjectured to represent a vascular, rather than intestinal, system. But there are others — such as those of the Leech and Spider— which seem to be true processes of the digestive canal, used as reservoirs of food.

4. Some complications seem mainly dependent upon circumstances which may be termed collateral or subordinate to digestion itself. Thus, the crops of many animals, like the cells of the Camel's stomach, are connected with the more or less necessary habit of gorging large quantities of food at distant intervals. While the gizzard, which is possessed by such very different orders as Polyps, Molluscs, Fishes, and Birds, appears to be closely related, not only to the food, but to the mechanical conditions of the animal. This is especially the case with the Bird, whose long neck, and habits of flight, could scarcely be rendered compatible with a heavy masticatory organ occupying the ordinary position.

5. The import of some of those numerous blind tubes or pouches which we have so often noticed as opening into the intestinal canal, has already been suggested in the preceding remarks. They are generally, and no doubt correctly, regarded as earlier developmental forms of the various conglomerate glands which are appended to the canal in higher animals. But as regards the principles of their diagnosis, and the limits of its application, it seems important to remind the reader, that, in the present state of organic chemistry, the situation of their apertures, and the order of their appearance, often constitute our only guides. Thus, for instance, tubes which open into the commencement of the canal, especially in connection with a higher development of the masticatory organs, are probably salivary. In like manner, those which empty themselves in the neighbourhood of the pylorus are supposed to be biliary. And any which, by communicating with the anus and exterior of the body, appear to aim at an immediate and direct extrusion of their contents, naturally remind the physiologist of the highly poisonous characters of the urinary secretion, and so far entitle him to suspect that they serve to expel this important product of animal life. Here, however, chemistry would often assist his decision. The colour of the bile sometimes affords a less certain aid to the diagnosis of this secretion. The order of appearance only helps our conjectures by showing, that, of the two glands which open into the median portion of the digestive tube, the liver is the more constant and important:—and hence, that it is probable a solitary set of tubes are chiefly hepatic. But it is obvious that, in many instances, all these aids to conjecture may leave us in doubt as to the true nature of a set of secerning tubes.

6. In many of the Vertebrata — such as Birds and Edentata—there are cæca to which, as to the smaller vermiform appendix of man, the above explanation cannot apply; since the ordinary accessory glands are also present. And some of the tubes seen in Insects are probably quite as supplementary. The structure of all these tubes seems to indicate that they are true organs of secretion. But whether this is their main function — or if so, what is the nature of their product — is utterly unknown. The supposition of their possessing a special absorptive function only increases this obscurity, by leaving it doubtful whether the lower parts of such tubes reclaim a portion of the secretion poured out by the upper — just as the intestine absorbs the bile after its entry into the duodenum — or whether they absorb materials derived from the general cavity of the intestine. But that increase of surface which facilitates mere absorption is effected by folds and projections so much better than by tubes, that, even supposing this latter reabsorption to obtain, we ought at least to concede some modifying power to the secreting surface. The ordinary situation of their apertures — near the junction of the small and large intestine — scarcely assists our speculations. It may, however, indicate an exposure of their secretions to the long and energetic absorption effected by the large intestine.

* In this respect the intestinal canal may probably be contrasted with both the vascular and nervous systems. At least the author feels sure that the latter of these will ultimately be found reducible to that serial homology of the skeleton which the researches of Professor Owen have done so much to elucidate.

† See p. 295.

7. Finally, we may close these vague conjectures by attempting to include, in one formula, most of the varieties seen in the whole animal kingdom. The complexity of the digestive apparatus varies with that of the digestive function. And this is again the product of two chief elements:—the kind of food used; the nature of the animal to be nourished.

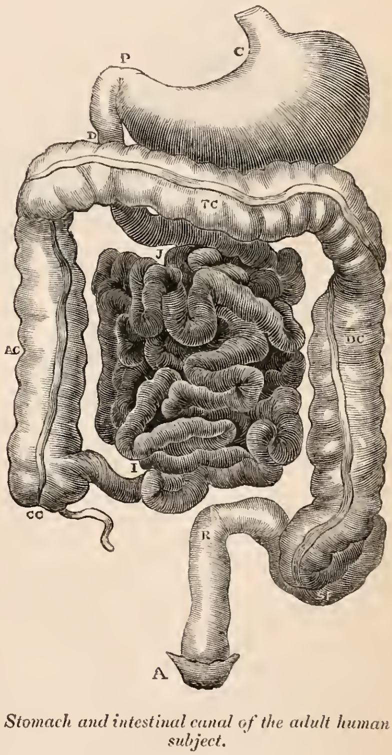
In respect to the food, we might almost form a scale of decreasing simplicity, beginning with the rich chylous fluid that bathes the intestinal parasite, and passing through the various gradations of *liquor sanguinis*, blood, flesh more or less decomposed, vegetable juices, fruits, vegetables, and grains: — gradations which, however increased in number and minuteness, would all find their corresponding representatives in Natural History. And we have already seen that, throughout the Vertebrate series, there is a constant association of a long intestine or a complicated stomach, with a vegetable diet.

As regards the nature of the animal, the Acalephan, Crustacean, Cephalopod, Fish, Bird, Cetacean, all prey upon fish. Yet not only are their organs of digestion most diverse, but they even exhibit a certain correspondence with the general development of each animal. Nor is it difficult to imagine why this is the case. Looking only at the unity of the organism, we might *à priori* expect, that a high development of the whole would imply an equal advance in the complexity of its chief parts. To this we may add, that one organ seems in a certain sense complementary to another,—the necessary, and not merely the formal, result of an increased evolution of its fellow. And, in conclusion, it is not unlikely that the complexity of the digestive organ in the higher animals may be referred to causes even more immediate than either of the preceding: — viz., to the more composite chemistry of their structure, and the more rapid and energetic change of their substance. The structure of every animal is so far self-regulative, as to determine the permanence of its own composition, by a process of which the blood is one main agent, and the tissues generally another. But there is no reason why we should exclude a third — why we may not suppose that the chemical assimilation or likening of the foreign substances taken as food is commenced in the course of the digestive act — why, in short, the absorption of more numerous, abundant, and complex alimentary principles may not necessitate the co-operation of a more highly developed digestive organ.

Human Anatomy.— The alimentary canal of Man is a long membranous tube, which, commencing at the mouth, successively occupies the regions of the neck, chest, belly, and pelvis, to terminate at the lower orifice of the latter cavity in the aperture of the anus.

In this course, the canal first forms at the back of the mouth a dilatation, called the PHARYNX. It next contracts into a straight cylindrical tube, the ŒSOPHAGUS, which is continued through the neck and chest. Immediately after perforating the diaphragm, or septum which divides the thorax from the abdomen, it expands into the STOMACH (C, *fig.* 241.). An external constriction and an internal valve (P, *fig.* 241.) mark the boundary between this organ and the INTESTINE, which forms the remainder of the tube. And, finally, at about five-sixths of its length, the intestine is subdivided into two portions, by an alteration in size and character, which commences at a point corresponding to the presence of a cæcum or blind pouch externally, and of a valve internally. Of these two segments, the upper, longer, and narrower, is called the SMALL INTESTINE (J, I, *fig.* 239.); and the lower or wider, the LARGE INTESTINE (CC, AC, TC, DC, SC, R, *fig.* 239.).

Fig. 239.



Stomach and intestinal canal of the adult human subject.

C P, stomach; C, cardiac; P, pyloric orifice; J I, small intestine; J, jejunum; I, ileum; C C to A, large intestine, viz.:—C C, cæcum; A C, ascending colon; T C, transverse colon; D C, descending colon; S F, sigmoid flexure or sigmoid colon; R, rectum; A, anus.

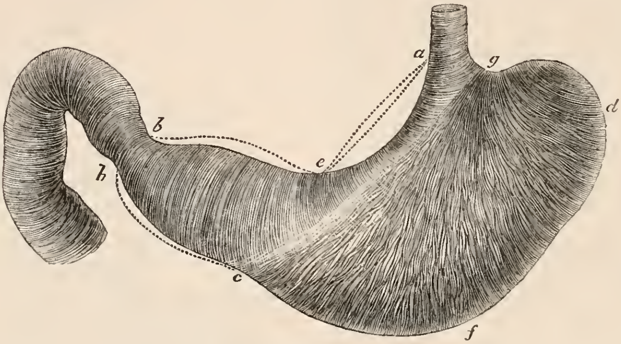
It is the three latter portions of the alimentary canal,—viz., the stomach, small intestine and large intestine,—which form the especial subject of the following article. They all possess the same general structure; being composed of three coats or tunics — an external and serous, a middle and muscular, and an internal and mucous coat. The first of these constitutes their means of attachment to the trunk in which they are enclosed; and it limits, permits, and facilitates those movements, which it is chiefly the office of the second to execute. The third is the most important, since it forms the complex secreting and absorbing surface, upon which the functions of the canal mainly depend. Between these three tunics are interposed two layers of areolar tissue; containing vessels, nerves, and lymphatics for their supply. The various modifications undergone by these constituents of the tube, in the three segments just distinguished as the stomach, small intestine, and large intestine, will form the chief features of the following description.

The STOMACH is the widest and most dilatable part of the alimentary canal.

Its *form* varies greatly in different individuals. Removed from the body, and moderately distended, it generally takes the shape represented in *fig.* 240.*; — a shape which is often compared to that of a bagpipe, and may be best described as a bent cone, the concave aspect of which is joined by a tube at one-fourth of the distance from its base. In it we distinguish an anterior and a posterior surface; a superior and an inferior border; a right and a left extremity; together with the cardiac and pyloric apertures, by which it communicates with the œsophagus and duodenum respectively, and thus becomes continuous with the remaining portions of the digestive canal.

The description of these different parts will vary, according to the full or empty state

Fig. 240.



Stomach and duodenum. The tube has been everted and inflated, and its mucous membrane dissected off, so as to show the subjacent muscular coat.

a g, cardiac orifice; *b h*, pyloric valve; *a e b*, lesser curvature, or upper border; *g d f c h*, greater curvature, or lower border. (The dotted lines joining *a e*, *e b*, and *c h* are intended to illustrate the mode in which extreme distention of the organ affects these curves); *g d*, cardiac pouch; *b h c e*, pyloric pouch. (The surface to the right of the line which would unite *c g* represents the oblique, that to the left of this line the circular, layer of the muscular coat of the stomach.)

of the organ. Thus in the latter condition, the stomach is flattened vertically; so that its anterior and posterior mucous surfaces come into contact, while its upper and lower margins form thin edges, each of which really deserves the title of a "border." But when distended, any transverse section of the organ would be nearly a circle; and hence its borders and its surfaces disappear by merging into each other. Its uppermost part, however, is still distinguished as the *lesser curvature* (*a*, *e*, *b*, *fig.* 242.), and the lower as the *greater curvature* (*g*, *d*, *f*, *c*, *h*). It will be seen that the general concavity of the former curve is especially marked in its first half or two-thirds; at the end of which part (*e*) it usually becomes slightly convex. A very shallow notch (*c*) opposite to this point often divides the greater curvature into two portions; and the two constrictions together define the commencement of the *pyloric pouch* (*b*, *h*, *c*, *e*). The *cardiac pouch*, or *great* or *splenic extremity* (*d*), lies to the left of the *cardia* or the œsophageal opening (*a*), beyond which it projects for about three inches. At this aperture the œsophagus dilates gradually, so as to resemble an inverted funnel. To the right of the œsophagus, the stomach expands slightly, and hence reaches its maximum diameter at about the middle of the organ (*f*). Beyond this point it gradually tapers away to the pylorus (*b*, *h*), where a sudden external constriction marks the site of the valve.

The *dimensions* of the organ are even more variable than its form. The author's measurements are not sufficiently numerous to justify him in offering them as valid averages; but he has generally found that, in a state of moderate distention, its length is about 13 to 15 inches, its diameter at the widest part 5, at the pylorus 2, or through the whole organ 4, inches. Hence its total surface would equal about $1\frac{1}{4}$ square feet; and its capacity about 175 cubic inches, or 5 pints. Its weight may be estimated at about 7 ounces. These estimates are a little larger than those of most other anatomists.

The *attachment* of the stomach is chiefly effected by the continuity of its extremities

* This woodcut is so far inaccurate, that the pyloric constriction is shown more distinctly than it could be actually seen in such a view, in which it would be partially concealed by the backward curve of this part of the stomach.

with the more fixed duodenum and œsophagus. The former tube is connected with the posterior wall of the belly, the latter perforates the crura of the diaphragm a little to the left of the median line, so as to enter the abdomen about one inch in front of the left border of the aorta, by an aperture which is everywhere muscular *, although close to the posterior border of the tendon. The fixation of the stomach is also aided by certain processes of peritoneum. To the left of the œsophagus, the short *phreno-gastric omentum* passes from the diaphragm to the cardiac pouch, which it reaches somewhat posteriorly. Still lower down, the stomach is united to the spleen by the *gastro-splenic omentum*. The lower border of the organ gives off the *great omentum* : this descends for some distance towards the bottom of the belly, and is then reflected upwards to the anterior border of the transverse colon, which it splits to enclose. The upper border of the stomach is attached by means of the *gastro-hepatic* or *small omentum*, which descends from the transverse fissure of the liver. All of these folds are double; though the four layers of the reflected *omentum majus* are often inseparably united to each other. They are more particularly described in the article Peritoneum.

Situation. — The stomach is placed almost transversely in the upper part of the abdominal cavity, in which it passes from the left to the right side, as well as downwards, and slightly forwards. This direction results from its situation relatively to the œsophagus and duodenum : since it is joined by the former at its highest part, and near its left extremity ; while the latter is immediately prolonged from its right or pyloric end. In this course from left to right, the stomach successively occupies the left hypochondriac and the epigastric regions; and, just at its termination, it reaches the right hypochondrium. Its anterior surface is therefore in contact with the diaphragm, where this muscle lines the cartilages of the left false ribs ; and with the anterior wall of the abdomen. Its posterior surface lies upon the pancreas, the aorta, and the crura of the diaphragm, where these parts cover the spine. Its left extremity is in contact, above, with the diaphragm, below, with the spleen ; and, posteriorly, it touches the left suprarenal capsule and kidney. Its upper border is in apposition to the liver : — viz. to its left lobe, to the *lobulus Spigelii*, and to part of the *lobulus quadratus*. Its lower border is parallel, and close to, the transverse colon.

Unusual size or distention chiefly affects the situation of the organ by causing it to extend downwards; so as to overlap or cover the transverse colon, and thus reach the umbilical, the left lumbar, or even the iliac region. Under similar circumstances, its left extremity also passes deeply into the corresponding hypochondrium ; so as to be covered, not only by the cartilages of the ribs, but by these bones themselves. Its extension upwards diminishes the size of the thorax, but is rarely sufficient to be felt as a serious hindrance to the descent of the diaphragm in the ordinary tranquil inspiration of health. Its right extremity may reach the gall-bladder.

It may be useful to trace the effect of its usual progressive distention upon the form, site, and fixation of the stomach. When void of food, and not distended (as it often is) by gases, the flattened stomach hangs almost vertically in the epigastrium. In this state of the organ, the pulpy food that enters it from the œsophagus drops at once into the cardiac pouch, which forms its most depending part. The reception of further quantities effaces its upper and lower borders, and gradually changes them,from almost straight lines, into the curves above mentioned ; at the same time that it separates the previously apposed surfaces, and converts the whole organ into a bent cone, which is convex below and in front. The latter of these two flexures chiefly occupies the pyloric extremity, and is often very sudden. Both result from the increased length of the organ, and the proximity of its comparatively fixed orifices. But both are greatly assisted by the muscular coat : since the distention of the separated stomach tolerably imitates, though it scarcely equals, the curves taken by the organ when moderately expanded *in situ*. The delicate and yielding *omenta* above mentioned allow the stomach to expand between their elastic and extensible laminæ, without undergoing any disturbance of its nervous and vascular connections, or any loss of its serous covering. Finally, although the stomach itself enlarges pretty equally in all directions, still, after filling the hypochondrium, the mobility of its bent middle directs it towards that part of the enclosing cavity where it meets with the least resistance :—namely, towards the yielding anterior wall of the belly. Hence, should the distended intestines not allow it any great descent downwards, it comes forwards; so that what was its vertical anterior surface now looks obliquely upwards ; while its inferior border touches the lower part of the wall of the epigastrium, where its artery has even been felt pulsating in very thin subjects.

The *serous* coat of the stomach is continuous with the double laminæ of peritoneum above mentioned, which split to enclose it where they reach its various borders. Here they are very loosely connected to each other, and to the subjacent coat, by an abundance of highly elastic areolar tissue. But towards the middle of the gastric surfaces, the peritoneum, though still elastic, is closely united to the

* The muscularity of this aperture led Haller and some other anatomists to regard it as a kind of sphincter to the cardiac orifice of the stomach. But we may point out that, though the contraction of its fibres reduces the elliptical opening to a circular one, yet as this apparent constriction coincides with the descent of the diaphragm, the oblique plane of this muscle is at the same instant becoming transverse. Hence this ellipse and circle merely represent an oblique and a transverse section of the same cylinder. The diameter of the œsophagus may therefore remain unchanged.

subjacent muscular tunic. The advantage of such a yielding attachment has already been alluded to. For a description of the structure of this tunic, the reader is referred to the articles PERITONEUM and SEROUS MEMBRANES.

The *muscular* coat of the stomach consists of the unstriped or organic muscular fibre; which the researches of Koelliker have shown to consist of fibre-cells, such as are represented in *fig.* 241. The form and dimensions of these long and spindle-shaped elements vary little in the different parts of the intestine and stomach. Their length is from $\frac{1}{200}$ to $\frac{1}{100}$th of

Fig. 241.

Fibre-cell from the unstriped muscle of the intestine. Magnified about 350 *diameters.* (*After Koelliker.*)

a, nucleus.

an inch: their breadth from $\frac{1}{6000}$ to $\frac{1}{4000}$th at the middle, where they are flattened, and from whence they taper off to conical and pointed extremities. They contain a nucleus; which is from $\frac{1}{2000}$ to $\frac{1}{1000}$th of an inch in length, and about a sixth of this in breadth. Their texture is a pale substance, which generally appears to be homogeneous, but is sometimes seen to consist of a membrane* enclosing granulated or faintly striated contents. In some instances, they are marked by swellings; which, as they are rarely seen in the associated fibres, are probably due to casual local contractions of the sarcous substance itself. The arrangement of these fibre-cells is very simple; they are packed together in parallel rows (*fig.* 242.), their flattened surfaces adhering strongly

a, nuclei of the fibre-cells.

to each other. They thus form small and broadish bundles, between which are interposed the vessels for their supply, enclosed in a sparing quantity of areolar tissue. The union and interlacement of such fascicles of cells, builds up the large flattened strata of the muscular coat of the intestines. The fibre-cells are developed by the longitudinal extension of an oval cell; in which is deposited a special sarcous content, that soon obscures the original cell-membrane.

We shall hereafter see that these fibres surround the intestine in two layers: an external,

* From a comparison of very numerous observations, the author entertains no doubt that this membrane is always present, being only obscured by such circumstances as delicacy, adhesion, or refractility. In the fibre-cells of the adult human pylorus, he has often verified a distinct cell-wall or sarcolemma. And the reappearance of this membrane in the unstriped muscular fibre of the human uterus, as its cells recede or degenerate after parturition, is only one of many significant instances, that we cannot deduce the real absence of such a delicate membrane, from the mere fact of its ceasing to be visible under the microscope.

which is longitudinal: and an internal, which is circular or transverse — a general arrangement to which even the stomach forms no real exception. Before the discovery of the fibre cell by Koelliker, it was a matter of fruitless speculation, how these unstriped fibres terminated;—in other words, what was their individual length. But although this question is of course set at rest, it still remains doubtful, whether the transverse fibres of the alimentary canal return into themselves on completing one circle of the tube, or whether they take a spiral course. The latter view appears to the author much more probable. For some of their bundles often appear to join each other at a very acute angle. And whatever be the precise mechanism of their really co-ordinate contractions, it is clear that, in the longitudinal fibres, the direction and progress of contraction correspond to the axis of the cell: — that is, to the line uniting the greatest number of its sarcous particles. While it is equally obvious that, if the course of these transverse fibres were absolutely circular, the peristalsis of the whole stratum they compose would move at right angles to their axes. Such a difference in their contraction would be so unlikely, as to justify our preferring the supposition of their spiral arrangement. For this would allow of an identity in the contractions of the two strata in this respect. The course of contraction would be axial in both sets of fibres; but, *cæteris paribus*, slower (and hence apparently more local) in the far longer bundles of the transverse coils. The spiral currents hereafter alluded to as seen in the contents of the stomach perhaps strengthen this supposition.

The *longitudinal* layer of the stomach is derived from the similar tunic of the œsophagus. This, on reaching the cardia, radiates on all sides, its bundles becoming thinner as they diverge, and being gradually lost from their decussation and mixture with the various fibres they meet with. But, on the lesser curvature of the organ, they continue much more distinctly, and are often traceable as two or three broadish bundles, to within a short distance of the pylorus. The longitudinal layer which covers the pyloric extremity appears not to have any very direct continuity with the preceding. Its constituent fibres arise by scattered bundles at about the middle of the organ, and — often first uniting into two broad bands which occupy the centres of its anterior and posterior surfaces — they soon form a tubular layer, which proceeds over the pylorus, to join the commencement of the duodenum.

The *transverse* or *circular* fibres lie immediately beneath those of the longitudinal stratum; and form what is, on the whole, a thicker, if not a more uniform, layer. To the left of the cardia its rings are very few and indistinct: their places being taken by those of the third or oblique layer. But from the right of this orifice it continues towards the pylorus with a constantly increasing thickness; until finally, reaching the margin of this valve (*fig.* 243.), it is inflected towards the axis of the stomach by a rather steep and sudden curve, which presents an almost vertical surface

Fig. 243.

s, pyloric sac of the stomach; *d*, commencement of the first portion of the duodenum; *p*, pylorus, formed by a thickening of the transverse layer of the muscular coat of the stomach.

towards the duodenum. Those of the transverse fibres which lie nearest to the left extremity are somewhat less regularly transverse. Hence some of them decussate slightly with each other, while others, which pass downwards from the right margin of the cardia, are directed somewhat obliquely towards the left extremity of the organ.

The third or *oblique* layer lies more deeply than the two preceding, and is therefore best seen by everting and inflating the stomach, and carefully removing its mucous membrane. Where the œsophagus enters the stomach, the transverse fibres of its left margin are so close to a flattened bundle of fibres, which occupies the notch (*g*, *fig.* 240.), limiting the cardiac pouch, that the two are visibly continuous. The right or thickest part of this flattened band passes obliquely downwards towards the right side, soon breaking off from the termination of the œsophagus; and from hence it continues across the transverse layer just described, to reach the greater curvature, where the similar layers from both surfaces of the organ are reflected into each other. Its usually well-defined margin occupies — and indeed forms — the notch (*c*, *fig.* 240.). The posterior or thinner part proceeds, not only from the depression (*g*, *fig.* 240.) on the left of the cardia, but also from the neighbouring upper border of the great extremity; and its more vertical fibres are also continued downwards to the lower border of the stomach, where they meet, so as to complete the circuit of the cardiac pouch.

Movements of the stomach.—That there is an intimate connection between the œsophageal and gastric movements, is only what might be expected from that visible continuity of their muscular coats which has just been alluded to. Thus, at the close of each act of deglutition*, the lower fibres of the œsophagus contract with such force, as not only to obliterate the cardiac aperture, but even to cause the mucous membrane of this part to project into the cavity of the

* For a description of the act of deglutition see the articles "Œsophagus" and "Pharynx."

stomach.* This condition remains for some instants. And when the alimentary bolus has in this manner been impelled into the organ, it excites muscular movements.

The exact condition of the cardia during stomach digestion is scarcely known. It is obvious that the force with which it is shut must be effectively superior to the pressure exerted on the contents of the organ by the gastric contractions. Still we are ignorant how much of this force is due to the contraction of the lower œsophageal fibres, and how much to the shape, position, or structure of the stomach itself. Indeed, one cannot help conjecturing, that the decussation of the transverse and oblique fibres of the organ around the insertion of the œsophagus, might render their contractions a material assistance to the obliteration of the lower part of this tube. From the observations of Magendie†, it would seem that, during digestion, the cardia contracts tightly around a finger introduced from the stomach; and that the distention of the gastric cavity appears to regulate the intensity and duration of this closure,—so much so, that pressure by the hands, or by the diaphragm during inspiration, produces an increase of contraction. ‡ And the disappearance of this efficient closure in the dead, or even in the exhausted§ animal, suffices to show,—what indeed we might gather from its great energy,—that it is not due to mere passive contractility. Hence, on the whole, it appears preferable to regard the cardiac orifice as closed by an active muscular contraction, which is itself excited by the direct stimulus of the food that distends the stomach.

Perhaps there are few more difficult parts of our inquiry than that which relates to the precise nature of those movements which are executed by the stomach, and impressed upon the food, during its sojourn in this cavity. For the vivisection of animals has given few results; and even had they been more marked, they would scarcely have been trustworthy. The human corpse is generally diseased, or, if not, the interval after death which precedes an examination of its abdominal viscera is sufficient to remove all appearances of activity.

* Beaumont (Experiments and Observations on the Gastric Juice. Combe's Edition. 1808), pp. 62, 63., and elsewhere. Valentin, Lehrbuch der Physiologie, Band i. p. 269. Magendie, Précis élémentaire de Physiologie: Quatrième édition, vol. ii. p. 70.

† *Op. cit.* pp. 81, 82.

‡ Magendie (*loc. cit.*) and Mueller (Handbuch der Physiologie, Bd. i. p. 412) state that an alternating and rhythmical movement of the œsophagus accompanies digestion. It is independent of deglutition. The contraction of the tube coincides with the period of inspiration; and, *vice versâ*, its relaxation with expiration. But such results of vivisection cannot be safely regarded as the ordinary phenomena of the healthy body. As to how far the cardia is necessarily closed by the diaphragm in the act of inspiration, I may refer to the note to p. 309.: —to which I will only add, that any one may satisfactorily disprove its real occlusion by swallowing a bolus of food at this period.

§ Magendie, *loc. cit.*

And, finally, the results obtained from newly-killed animals on the one hand, and from Dr. Beaumont's valuable case on the other, are apparently so indefinite, or even so conflicting, that most physiologists seem content to leave the question in abeyance, until more numerous or more comparable facts afford better grounds for a decision.

A careful comparison of such results has, however, led the author to adopt the following views*, which appear to unite in one theory most of the facts hitherto ascertained respecting the muscular action of the healthy digesting stomach.

1. In the fasting state the empty stomach offers no movement whatever. This fact, which is asserted by Dr. Beaumont†, from his observations on the living human subject, may be readily verified by laying open the bellies of the domestic mammalia immediately after death. Some very slight and gradual changes in the shape of the organ, which I have once or twice noticed, form no valid exception to such a rule. This agreement in the above two classes of results is not only interesting in itself, but entitles us to lay somewhat more stress on that which follows. And it is especially useful, in that it frees us from the apprehension that any contractions which we may observe can be caused, or even greatly modified, by the air ‡ to which the dead animal's stomach is exposed.

2. At the *commencement of digestion*, or immediately after the deglutition of food, the movement of the stomach offers three varieties.

a. In some animals, a large quantity of food is often hastily swallowed, after scarcely any subdivision, far less mastication. Under these circumstances, the stomach is found closely contracted around its hard contents, sometimes even adapting its shape to that of these unyielding masses. And, as might be expected, no motion is discernible.§

b. Dr. Beaumont narrates the opposite effect of a very small quantity of liquid food in the human subject. It excites a vermicular action, a gentle contraction or grasping motion of the stomach, so that the wrinkles of the

* These will be found in an Essay which, written in 1847, was published in the "Medical Gazette" for 1849.

† Beaumont, at p. 105. expressly; at pp. 23. 57., by implication.

‡ Though, by the bye, as this would chiefly cause irregular motions, it would rather oppose, than produce, any uniform and constant movement. The effect of air on the intestine is alluded to hereafter.

§ This condition, which is frequent in the domestic Carnivora, appears to be usual in the Rabbit, in whom it is often kept up by the comparatively unyielding nature of the food. In such a case the contents of the stomach are dissolved, as it were, from without inwards, in successive strata; which are slowly and constantly stripped off by the muscular action, and squeezed through the pylorus. In all these instances I have found the movements of the organ much less marked than where the food was present in a smaller quantity and a state of greater subdivision. And in the Rabbit, both the stomach and intestine appear to be unusually sluggish; as shown by the feeble movements of the former during digestion, and of the latter under the magneto-electric stimulus.

mucous membrane gently close upon it, and gradually diffuse it over the whole surface.*

c. The ordinary state of the human stomach during the digestive act lies between these two extremes; and may be defined as one of moderate distention, with food which has been subdivided by mastication, and diluted with saliva and gastric juice, so as to possess a pulpy or semi-fluid consistence.

In attempting to imitate this condition in the Dog, I have found it best to choose an aliment which already possesses a pultaceous or semi-liquid consistence,—such as a thick soup,—and to administer it in large, but not excessive quantity. On pithing the animal a quarter of an hour afterwards, the following movements are seen. The most noticeable is a peristalsis or transverse constriction, which sets out from the cardiac extremity, and travels slowly towards the pylorus. It is comparatively feeble until it reaches the junction of the pyloric two-fifths, and the cardiac three-fifths of the organ. Here it suddenly becomes much more distinct; and from hence continues rapidly forwards, as a well-marked circular depression, until it reaches the pylorus. Having arrived there, an interval of relaxation succeeds, and is followed by the recurrence of a similar contraction. As nearly as can be judged, the average period of relaxation is about one minute, and the contraction itself occupies nearly the same time. Cotemporaneous with this contraction there is a certain amount of longitudinal shortening of the organ. The pyloric orifice is always firmly shut.

In the interior of the human stomach, Dr. Beaumont could only verify an alternate contraction and relaxation; a vermicular action of the transverse fibres, and a shortening produced by the longitudinal coat. The exact details of this occurrence he could not follow. He also noticed a constant agitation of the organ produced by the respiratory muscles.† But Dr. Todd and Mr. Bowman ‡ have mentioned a case, in which the vermicular actions of a distended stomach were distinctly seen through the wall of the belly during life.

So far as this imperfect evidence goes, it is evidently favourable to the view, that the muscular contraction of the human stomach during this stage of digestion is similar to that seen in the newly-killed animal.

It is therefore our next object to inquire — (1) What are the movements which such a peristalsis would necessarily impress upon the food? And (2) how far do they correspond with those which have been actually observed?

(1.) The effect of peristalsis in a closed and distended tube may be represented by an inflexible hollow cylinder, filled with liquid, and accurately fitted with a perforated septum (*b*, *fig*. 244.), which is capable of free movement along its interior. Let such a septum be moved in either direction, and it at once exerts a pressure on the body of liquid (*c*) contained in that end (*a*) towards which its motion sets. The pressure being equal in all directions, a portion of the fluid escapes backwards through its aperture (*d*). This retrograde course is, *pro tanto*, a current; and one which will be continually lengthened by the advance of the septum along the remainder of the tube. And the slow successive movement of a series of such septa would establish two continuous currents in the liquid; a peripheral of advance, and a central of return.*

Fig. 244.

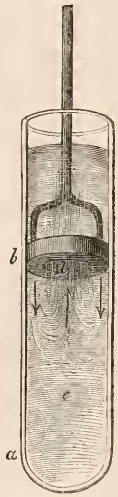

Diagram to illustrate the effects of peristalsis in a closed tube containing liquid.

a, Closed end of the tube; *b*, perforated septum, moved towards *a*, and causing the peripheral currents indicated by the arrows, in the same direction; *c*, quiescent mass of liquid, giving origin to *d*; *d*, central current, prolonged from the corresponding arrow, and passing through the perforated septum.

The existence of two such currents would be little affected by the membranous nature or peculiar shape of the human stomach. Even comparative inactivity of the cardiac pouch would not prevent their occurrence, as a consequence of pyloric peristalsis. While very moderate contractions of this sluggish part would accurately define the axis and its cur-

* Condensed, in Dr. Beaumont's own words, from pp. 62, 63. 96, 97, of his work. This activity of the rugæ themselves may remind us of their inherent muscularity (see p. 325. of this article).

† Probably much exaggerated, if not chiefly produced, by the adhesion of St. Martin's stomach to the wall of his chest.

‡ Todd and Bowman's Physiological Anatomy, vol. ii. p. 196.

* The following description so well supplies the interval between such a model tube and the human stomach, that I cannot refrain from quoting it. "The muscular action of a fish's stomach consists of vermicular contractions, creeping slowly in continuous succession from the cardia to the pylorus, and impressing a twofold gyratory motion on the contents; so that, while some portions are proceeding to the pylorus, others are returning towards the cardia." (Owen's Hunterian Lectures, vol. ii. p. 236.).

rent, as that curved line which unites the cardiac and pyloric apertures (*a, fig.* 245.).

Fig. 245.

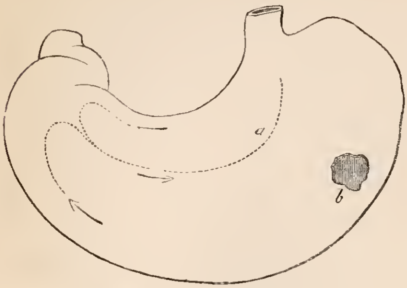

Diagram to show the general direction of movement impressed on the semifluid food in the digesting stomach.

a, real axis of the stomach, uniting its cardiac and pyloric apertures; *b*, situation of the abnormal opening in St. Martin's case. (The arrows correspond to the peripherial current of advance, which is effected by peristalsis; and the central current of return, which is reflected from the preceding at the pylorus.)

(2.) The observations of Dr. Beaumont are as follows* :—" The bolus, as it enters the cardia, turns to the left, passes the aperture, descends into the splenic extremity, and follows the great curvature towards the pyloric end. It then returns in the course of the smaller curvature, makes its appearance again at the aperture in its descent into the great curvature, to perform similar revolutions. These revolutions are completed in from one to three minutes; the bulb of the thermometer invariably indicates the same movements." He is careful to add, that there is an admixture of the ingesta, which implies that the movement is not simply a revolution; for that, if this were the case, "the central portions would retain their situation, until the outer or chymified part had passed into the duodenum."†

Now in order to render the movement thus observed perfectly compatible with that above deduced, we have but to recollect the situation of the aperture from which the inspection of St. Martin's stomach was made. This was at the left extremity of the organ (*b, fig.* 245.). Whence it is obvious, that any backward movement along the real axis (*a*), connecting the two orifices of the stomach, would be so near to the superior curved border, and so far from the point of view, that Dr. Beaumont could scarcely have avoided imputing to it the course which he has done. While, since every part of the stomach would be occupied by one or other of the two currents, the mutual interference of these at their borders must gradually cause an uniform diffusion of the various alimentary matters moving with them. And finally, the reflection of one current into the other at the pylorus, insures an equal contact of all the semifluid food with the surface of the mucous membrane; since those portions of the ingesta which occupy the axis of the stomach during one moment, are destined to move along its periphery during the next.

3. In the *later stage of digestion*, the movement seen in the Dog's stomach soon after death differs from the preceding.

The cardiac extremity appears even less active than before; and the longitudinal shortening of the organ is also less marked. The chief visible commencement of contraction is at the same place where it was formerly increased, and where it now forms a deep constriction or hour-glass contraction. After this constriction has continued a short time, it sends onwards towards the pylorus a rapid peristalsis, which appears nearly to obliterate the tube in its course, and ends by engaging the muscular ring of this valve. A slight relaxation closely follows this peristalsis; and is succeeded by a complete dilatation of the pyloric sac. Lastly, the hourglass contraction itself sometimes disappears; and an interval of about two minutes precedes the repetition of the whole process. Often, however, the constriction remains until the peristalsis recommences.

Dr. Beaumont's observations* again seem to supply the counterpart to this description. He states that, when chymification has advanced, the motion is quicker. And on attempting to pass a thermometer tube towards the pylorus, it is stopped by a stricture†, which is situated about three or four inches from this aperture. A forcible contraction is first perceived; but in a short time, there is a gentle relaxation, when the bulb passes without difficulty, and is then drawn forcibly towards the pyloric end for three or four inches. It is then released, and forced back with a spiral motion for the same distance, when it seems to be again obstructed by the stricture. But if pulled up through this, it moves freely in the cardiac portion, mostly inclining towards the splenic extremity. The repetition of the contraction is preceded by an interval of about three minutes, during which the food revolves as in the previous stage.

It is scarcely necessary to point out, that when the almost obliterated pyloric tube is filled by the tightly grasped thermometer bulb, no axial current can possibly be produced by the peristalsis. The pylorus having contracted, and its pouch relaxed, the contractility of the whole organ would determine a rush of fluid around the bulb; and this would be reflected from the valve into the axis of the

* *Op. cit.* p. 101.

† This admixture he ascribes to a triturating or agitating motion, which is partly gastric, partly respiratory. But the existence of the circulating movement described sufficiently proves that this mixture was inherent to the process, and not (as his supposition would imply) a result of its disturbance.

* *Op. cit.* pp. 102. 104.

† The similar narrowing seen in the digesting stomach of animals has been called the "transverse band"; a term which is objectionable, inasmuch as it implies the presence of a special structure that does not really exist.

tube. We should thus get two currents, which, at least in situation, would be identical with those produced by the peristalsis of the succeeding interval.

Action of the pylorus.—The structure of the pylorus (πυλωρὸς, *portæ custos*) has already been described. As regards its action, it is obviously the sphincter of the stomach. As such, it has been supposed to possess a kind of selective power; by virtue of which it contracts against the food in the earlier stage of digestion, but subsequently relaxes to permit the passage of the chyme. This view, however, appears to me very doubtful.

In the empty stomach, the pylorus is generally open, and readily * allows of the passage of bile from the duodenum. In the early stage of digestion, it is firmly shut; and retains the contents of the organ against gravity, or even against such a manual pressure as readily expels them from the cardia.

But just as in the second stage of gastric digestion, it is plain that the valve does not undergo any sudden or great relaxation,—for such would allow the passage of a large quantity of the moving and semifluid food, much of which would be still crude and undigested — so the very gradual diminution†, noticed by Beaumont in the early stage, renders his inference,—that, even from the first, chyme is constantly passing into the duodenum— very probably correct. ‡ Supposing this to be the case, it is evident that the action of the pylorus must be very similar at both these periods. And after numerous and careful observations on this part of the Dog's stomach towards the close of its digestive act, I have never yet been able to substantiate any definite relaxation of the pylorus; or any but an inconsiderable oozing of chyme at the time of that active peristalsis which has been described above. Hence I prefer to regard the passage of the chyme as produced by that great increase of force which the contractions of the pyloric sac acquire at this period;—a cause which appears so sufficient, that it seems scarcely justifiable to assume any additional one. The supposed relaxation of the pylorus seems also contradicted by a remark of Beaumont's, that, even at the end of the process, when the passage of chyme is greatly accelerated, the above contractions still continue.

In short, instead of a relaxed pylorus, through which a moderate peristalsis urges a selected portion of the food, it appears the state of this aperture during the close of gastric digestion is that of a contracted valve, through which the tolerably uniform chyme is being strained in small quantities, at frequent intervals, by a comparatively violent muscular contraction.* Hence the separation of the chyme from the other contents of the stomach seems to be effected by a process somewhat analogous to a coarse filtration, aided by pressure.

How little the pylorus could reject the "crude" portions of the tolerably homogeneous chyme, to transmit its more fluid or dissolved constituents, is shown by the facility with which indigestible substances of various shapes and sizes pass into the duodenum. Of these we can only say, that it is probable they are generally carried through the constricted pyloric sac and valve by a very forcible peristalsis.† The weight and solidity of many such masses allow them to remain some time in the cardiac pouch, perhaps lodged behind the transverse constriction which separates this from the pyloric sac. Both of these circumstances often defer their passage to the later stage of digestion. Smaller substances, however, sometimes traverse the whole canal in so short ‡ a space of time, that it is difficult to avoid believing that they leave the stomach very shortly after entering it.
