But while we may thus regard the pyloric valve as exerting but one and the same action during the whole period of gastric digestion, we shall find it difficult to substitute any other theory of its action for that local appreciation or selection which we have attempted to refute. Its contraction is accompanied by that of the whole muscular coat of the stomach; of which the pylorus forms, apparently, but a terminal thickening. And of the only two other facts which are cotemporaneous in their occurrence and duration — viz., the presence of food, and of gastric juice — the first affords little explanation; while the second is more likely to be another effect of the cause, whatever it may be, which excites that co-ordinate muscular action in which the pylorus appears to play an important, though simple, part.

It is interesting to observe how little the action of the pylorus is connected with any stimulus other than a gastric one. The flow of bile into the fasting stomach may perhaps be regarded as a passage, such as this janitor might well concede to a fluid which is not only harmless, but recrementitious. But in

* Bile is almost always found in the empty stomach of Dogs and Cats. (Compare Beaumont, pp. 86, 87.)

† The diminution due to absorption would probably be at first compensated by the addition of gastric juice.

‡ According to Magendie (*Op. cit.* p. 91.), the pylorus of the Horse is always found open, and is probably relaxed during life. It is only thus one can explain the well-known fact, that the quantity of food taken by this animal at an ordinary meal has a bulk which amounts to four or five times that of its distended stomach. Indeed, water has been found in its cæcum six minutes after being swallowed. (Coleman in Abernethy's Physiological Lectures, p. 180.)

* It is scarcely necessary to add, that the mechanism of such an act does not require that the cardia should be, however momentarily, the stronger valve of the two. For the force of an obliterating peristalsis would be at first almost spent upon the pylorus towards which it sets. While that of a weaker contraction would be chiefly expended upon the pyloric sac. And the residual force of both would chiefly dilate the yielding and quiescent large extremity.

† A peristalsis, the energy of which it is probable that they themselves increase.

‡ Thus the author has known peas traverse the canal in two hours.

the obstructed canal, fæces pass through it from the duodenum with equal facility, although the stomach soon resents their presence by vomiting;—an act which seems generally to imply a shut pylorus. And Magendie* has observed, that the gases of this upper portion of the intestine can be made to pass the valve with equal facility; while those distending the stomach excite its contraction.

Under ordinary circumstances, whatever be the period during which the contents of the stomach sojourn in its cavity, or the movements they experience at this time, they are finally propelled onwards into the duodenum.

Sometimes, however, they take a backward course; and pass through the œsophagus, to re-enter the mouth, and be expelled from this cavity. Such a reversal of their normal direction occurs in the acts of eructation, regurgitation, and vomiting. These acts, however they may differ in their details, must (*à priori*) agree in the conditions of their occurrence. They require a relaxation of the cardia, a closure† of the pylorus, and a compression of the stomach. The latter of these three requirements may either be the result of the contractions of the organ itself, or may be effected by an external or independent pressure.

In simple *eructation* or belching, part of the gaseous contents of the stomach are ejected from the mouth. This act generally occurs towards the close of digestion, and in dyspeptic individuals; the quantities of gas thus evolved being often very considerable. In what way the cardia is opened, or how far the evolution of large quantities of these aëriform fluids in the stomach may not contribute to render it patulous, is at present very doubtful. But the intermittent character of the occurrence certainly looks unlike a mere leakage of an aëriform fluid. While the frequency with which the human stomach contains gases, and the completeness with which the cardia resists their expulsion in vivisected animals‡, increase the difficulty of such a supposition, and, so far, tend to confirm that of a temporary relaxation of this aperture. The direct agent of the expulsive act seems equally uncertain. The contractions of the stomach seem quite sufficient to account for it. And there is certainly no violent abdominal pressure. But such mobile fluids would scarce require a remarkable effort. While, as far as can be judged, the act appears to coincide with the period of expiration.

An examination of that voluntary eructation which most persons can accomplish, may perhaps strengthen the conjecture, that some slight abdominal pressure is a constituent of the ordinary act. Here, by a kind of twitching* action of the œsophagus, which is accompanied by a sensation that is referred to the upper portion of this tube, air is introduced into its interior; and is then expelled, with a considerable sound, by a well-marked movement of expiration, during which the glottis appears to be at least partially closed. And the expulsion of the air artificially introduced is often accompanied by that of a portion which was previously contained in the stomach itself. So that involuntary and voluntary eructation may be said to merge into each other.†

In the act of *regurgitation*, more or less of the liquid contents of the stomach are returned into the mouth. This act closely resembles the preceding, of which it often appears to be an accidental complication; — a small portion of liquid being carried upwards, along with an eructation of gas. In other instances, however, the liquid is unaccompanied by elastic fluid; and rises so quietly, that it is only perceived on reaching the fauces and back of the tongue, where its acid taste causes it to be at once recognized. It is probable that the process which effects this expulsion is similar to that of eructation. If we could conjecture any difference, it would be, that the abdominal pressure plays a less important part.

The act of *vomiting* differs from both of the preceding: not only in the miscellaneous character of the matters which it can expel from the stomach, and in the greater energy with which it is effected; but also in the fact, that a pressure extrinsic to the organ itself here forms what is, at any rate, the chief agent of the process.

This abdominal pressure, which has been before alluded to, we shall now proceed to describe.

In those ordinary movements of respiration which are executed chiefly by the diaphragm and abdominal muscles, the bulk or capacity of the belly is little affected. For during the act of inspiration, the descent or contraction of the former, exactly coincides with the relaxation of the latter muscular structures; while during that of expiration, the compression which these exercise is neutralized by the recession or ascent of the now relaxed diaphragm. Hence the moveable viscera of the belly themselves evade all pressure; and merely transfer a very slight force from the anterior to the upper wall of the cavity, or *vice versâ*. But if, while the diaphragm remains depressed and contracted, the abdo-

* *Op. cit.* p. 83.

† Of course this closure need only be comparative: that is, the mere resistance of the contents of the stomach to compression would suffice to determine their passage through the more relaxed of its two orifices.

‡ As in Magendie's observations, elsewhere alluded to.

* This is often called a deglutition of air, although the movement is utterly unlike that of swallowing.

† Thus the dyspeptic poor who crowd the out-patient rooms of hospitals, sometimes eructate so voluntarily, and even ostentatiously, that the act really seems to be done, not so much to expel gas from an over-distended stomach—as to attract commiseration. And it is said that, in polite Chinese circles, a chorus of eructations at the end of a banquet formally acquaints the host with the repletion of his grateful guests.

minal muscles be also brought into vigorous action, the whole force of either of these two muscular strata may be regarded as compressing the viscera within the abdominal cavity. And since many of these viscera are hollow organs, which enclose moveable contents, and communicate with the exterior of the body, such a forcible pressure will expel the contents from their interior, so soon as their terminal orifices are thrown open; — whether by their relaxing spontaneously, or yielding to any superior force. In this way, the contraction of the walls of the belly plays an important part in the acts of defæcation, micturition, and parturition, as well as in that of vomiting.

Now in the three former of these acts, the intermittent abdominal pressure does but assist those more continuous expulsive contractions which are effected by the muscular walls of the hollow viscera themselves. And supposing that the cardia were open, and the pylorus shut, it is obvious that either pressure on the stomach, or contraction of its walls, would alike tend to expel its contents.

Careful observation of the act of vomiting in any of the higher animals will show that it is always assisted by the abdominal pressure. And the vivisections which many experimenters have practised, agree in carrying this investigation further; and in stating, that this pressure, which ordinarily results from simultaneous contractions of the diaphragm and abdominal muscles, may be due solely to the latter *, (as is normally the case in Birds †), or to the former, or even to an inconsiderable compression exerted by the lower ribs upon the epigastric region.‡ While the solitary observation of Maingault §, which affirms the occurrence of vomiting in the absence of all such pressure, stands expressly contradicted by the Committee of the French Academy appointed to report upon his Memoir.

But whether the stomach really contracts during the act of vomiting, — and if so, what is the amount of assistance which it thus affords this process,—are questions which, long the object of physiological controversy, can even now scarcely be regarded as decided.

On the one hand, there are not wanting experiments, which show that the act of vomiting may be effected without the aid of any gastric contractions whatever. Among such we may specially adduce the vivisection practised by Magendie ‖, in which a Pig's bladder was substituted for the stomach of a living Dog, and was subsequently emptied, by vomiting, of a large part of its contents. Such a result conclusively proves that gastric contractions are not essential to the physical act of vomiting, however frequently they may take a part in the process. And

† Krimer in Horn and Nasse's Archiv. 1816.

‡ Bulletin de la Faculté de Médecine, 1813, No. 10. p. 481. et seq.

§ Sur le Vomissement. Paris, 1813.

‖ *Op. cit.* p. 18.

that inactivity of the stomach, which has been directly observed by many * physiologists in the artificial vomiting of vivisected animals, has been all but actually seen in the living human † subject.

On the other hand, the observations in which a muscular contraction of the stomach has been seen to concur in this act, are even more numerous than the preceding. The amount of such contraction seen appears to have varied, having sometimes been so slight as to be scarcely visible. In all instances, it has specially engaged the pyloric extremity of the organ: and, in most, it is described as either circular‡, and alternating with relaxation; or peristaltic, like that found in the digesting stomach, independently of all vomiting. And though an anti-peristaltic movement is detailed by Haller and others, yet so far as I can find, this doctrine, which is expressly contradicted by the observations just referred to, rests only on one or two § vague descriptions of Wepfer, Rudbeck, and Schwartz.

From these very brief allusions to both sides of this conflicted question, the author has been careful to eliminate every statement which does not refer to actual facts. And the reader must recollect, that not only does the stomach offer few obstacles to such direct observations ‖, but that some of those summed up in the above statements, are rendered additionally trustworthy by being results quite at variance with the theories of their observers; while others have been confirmed by very frequent and careful repetition.¶

Hence, on the whole, I think we must conclude as follows: — The act of vomiting is essentially, and perhaps sometimes solely, the result of powerful abdominal pressure on the contents of the stomach. It implies a patulous cardia. The abdominal pressure which effects it, often coincides with, and is aided

* Bayle, Wepfer, Chirac, Baciaccus, Senac, Schwartz, and (especially) Magendie.

† Lépine, Bulletin de l'Academie de Médecine, vol. ix. p. 146. In this case, which has been strangely misquoted by many English authors, the stomach was protruded from a wound in the belly. It contained food and air, remained quite motionless, and could not even be excited to contract by manual titillation and pressure. But as soon as it was returned into the cavity of the belly, the abdominal efforts at vomiting, which had been previously ineffectual, discharged its contents.

‡ Haller, Opera Minora, vol. i. p. 389.; Schwartz, in Haller's Disp. Anat. vol. i. p. 327.; Wepfer, Sur la Cigue aquatique, p. 253.; the Author, *Op. cit.* p. 11.; Betz, Wurtemberger Corr. Blatt. Bd. xx. pp. 145. et seq.

§ Rudbeck, quoted by Morgenbesser in Haller's Disputationes Anatomicæ, vol. i. p. 293.; Wepfer, *Op. cit.* 251. and elsewhere; Schwartz, *loc. cit.* Rudbeck describes it as a contraction, which began at the pylorus, and was followed by a systole of the whole organ, from the lower to the upper orifice. While, according to Wepfer, it commenced in the duodenum, and passed hence towards the pylorus and the middle of the stomach.

‖ See remarks on the gastric movements, p. 312.

¶ Although unable to quote exactly, I believe Magendie somewhere alludes to his own results as confirmed by the vivisection of about two hundred animals.

by, a contraction of the muscular coat of the stomach itself. But there is no sufficient reason for supposing that an anti-peristalsis ever obtains, far less for imagining that it constitutes a special element of this expulsive process.

We may, perhaps, find some corroboration of this statement in the circumstances which constitute, so to speak, the *juvantia* and *lædentia* of this complex act. Perhaps the easiest variety of vomiting is that which frequently occurs in the sucking child. Here it is probable that three conditions, each of which might have some influence in facilitating the return of food, are all present at once: — namely, a distended stomach, an active gastric movement, and the peculiar form of deglutition which continuous sucking would imply.* The first of these three circumstances would mainly act by affording a greater resistance to the abdominal pressure; which although probably reduced to a minimum, is no doubt necessary to the process. And the second may perhaps constitute one of the chief occasions of this regurgitation, by impelling the contents of the stomach through the cardiac orifice. While the latter aperture might be thrown open by some slight and accidental † irregularity in the act of deglutition.

These conjectures are strengthened by the observation, that distention of the stomach, from any cause whatever, appears greatly to facilitate the occurrence of vomiting. That experience of this act, which a sea-voyage affords, may suffice to recall to most readers how much more easily the process goes on in a moderately full stomach than in an empty one. It is for the same reason that copious draughts of water are used to assist the action of emetics. And during the vomiting of both Man ‡ and animals §, the stomach is often gradually distended with air by a series of involuntary "retchings," which thus probably afford a similar assistance to the process. ‖ In like manner, it is to that distention of the whole belly which intestinal obstruction produces, that we must ascribe the peculiarly easy character of the vomiting that is then set up. The easy vomiting which occurs in cases of pyrosis may be similarly explained.

In addition to these mechanical elements of the process of vomiting, there are others which, though less constant, must not be overlooked. For not only do they take a frequent share in the phenomena of this act, but they also remarkably indicate its co-ordinate nature and arrangement. Thus the act is generally ushered in by a feeling of indistinct uneasiness, distention, or even pain, in the gastric region; which is often attended by an increased secretion of saliva, and a loathing of food, that is soon heightened into positive nausea. This is shortly followed by giddiness, dimness of sight, and languor: — symptoms which are evidently of cerebral origin. Next occur the retchings, or efforts at vomiting, before alluded to; which are probably irregular movements of the œsophagus, unaccompanied by abdominal pressure. Where the stomach is but little distended with fluid, these movements often seem to favour the subsequent occurrence of vomiting, by filling the organ with air. Finally, an uncontrollable effort so far reverses the ordinary action of the muscles of respiration, as to bring into one period contractions which usually occupy different and alternate times. An energetic closure of the glottis follows the descent of the diaphragm; so that this muscular septum is fixed by the distention of the thorax, as well as by the contraction of its own fibres. And the abdominal muscles now contract violently upon the stomach. During each actual effort of vomiting, the compression which is exercised by the muscles of the trunk causes the head to become greatly congested; so that the features are red and swollen, and the large veins of the face and temples visibly dilated. The pulse is also quickened; and the skin often rises in temperature, and perspires. The expulsion of the contents of the stomach from its cavity is sometimes attended by great pain, which is referred to the lower part of the œsophagus. And in spite of what is apparently a tolerable (though reversed) imitation of the movements of deglutition, a good deal of liquid generally eludes the curtain of the soft palate, and gushes through the respiratory channel formed by the nasal fossæ and nostrils. The subsequent phenomena mainly depend on the origin of the vomiting. Where, as is often the case, its immediate cause is removed by the expulsive act itself, the patient soon recovers his normal condition.

A proper consideration of the various causes of vomiting would belong rather to a medical than to a physiological treatise. We need but point out that they may all be divided into two classes:—(1) those in which there is an irritation of the nervous centre itself; and (2) those in which an irritation, applied to the nervous periphery, is transmitted thence to the centre, from whence it is reflected into the various organs which constitute the agents of the expulsive process. As examples of the first class, we may adduce the frequent instances in which vomiting accompanies a cerebral injury * or disease. As

* Schultz and Salbach (Valentin's Lehrbuch, vol. i. p. 281.) seek to explain the vomiting of infants by the peculiar form of the stomach at this age. But comparative anatomy entitles us to doubt whether the mere absence of a cardiac pouch would imply such a result. And I believe that their description somewhat exaggerates this peculiarity. For the stomach of the mature fœtus often has a cardiac extremity not much less projecting than that of the adult.

† Compare Beaumont, p. 62.

‡ Lépine, *loc. cit.*

§ Magendie, *loc. cit.*

‖ This so-called deglutition of air has a close resemblance to that which precedes voluntary eructation. Its chief conditions seem to be, a spasmodic action of the œsophagus, and a patulous cardia.

* To such centric irritations might also be referred that kind of vomiting which sometimes results from

instances of the second, we might adduce, not only that ordinary form of vomiting which is brought about by a direct irritation of the stomach itself, but those numerous cases in which it follows the application of various stimuli to similar or different parts. Such are mechanical irritations of the soft palate, intestines, or peritoneum; disgusting smells, sights, or sounds; prolonged immersion in cold water; or even wounds of the extremities.

The path by which these several kinds of peripheral irritation reach the nervous centre probably varies in different cases. Where they are mechanical, it is obvious that they are conducted to the central organ by the afferent or sensitive nerves upon which they impinge. Thus, as regards the stomach itself, irritation or section of the pneumogastric or splanchnic nerve often produces vomiting. But some emetic substances, such as antimony*, are equally active when introduced into the blood. And Magendie's experiment † shows that — whether the poisoned current of this fluid generally exerts a local action upon the stomach or not — it is to its influence upon the nervous centres that the act of vomiting must mainly be referred. The various constituent phenomena of the process sufficiently indicate the medulla oblongata as that segment of the cerebro-spinal centre in which the reflection towards the periphery occurs. But the ensuing movement is by no means a simple reflex action. On the contrary, the number of organs linked together to produce it, and the alteration in their ordinary times, modes, and degrees of activity which they exhibit, render the whole process so complex, so truly coordinate, that, far from limiting our attention to the mere reflex course which its exciting cause sometimes takes, we ought rather to regard vomiting as an involuntary or physical nervous action of the highest order. The sensations that have been noticed as accompanying it seem probably due to the cognizance taken by different organs, of changes which are perhaps themselves motor. At any rate, we are hardly justified in classifying them along with the "reflex sensations" sometimes met with in disease.

In some instances, a curious variety of the process of vomiting seems to return different parts of the gastric contents at different intervals of time; — the expulsion of more fluid and digested portions being followed, after the lapse of a considerable period, by that of crude and undigested masses of food. A small number of such cases perhaps depend on a peculiar hour-glass shape of the organ, aided by a casual constriction due to its muscular coat: — conditions which might unite to isolate a part of the contents of the organ for a longer or shorter period. But most of them might probably be explained by the weight, bulk, and situation of the alimentary masses in the organ; and by the other mechanical circumstances which favour or impede the act of vomiting itself.

The last efforts of a prolonged vomiting often bring up a quantity of bile. But from what has already been stated, it is evident, that during the intervals of energetic vomiting, a portion of the duodenal contents may easily find their way into the stomach, and be subsequently expelled thence. Indeed, it may be doubted whether the pylorus is completely occluded at the moment of the expulsive act: — especially in those cases in which the intestines are themselves distended with fluids exposed to the same violent pressure as the contents of the gastric cavity.

Rumination.— There are certain individuals who are capable of returning, at will, a greater or smaller portion of the contents of the digesting stomach into the cavity of the mouth. This act has received the name of *rumination*, from its analogy to the ruminant process which forms a stage in the normal digestion of some animals. Like the latter, it is a voluntary return of the undigested food, which is often followed by a re-mastication of its more solid portions. Apart from its voluntary character, it might be regarded in either of two points of view :—as a more complete form of regurgitation; or as a peculiar variety of vomiting, akin to that seen in infants, and, like it, especially distinguished by the absence of nausea and of constitutional disturbance.

The mechanism of the process appears to be precisely what these analogies would imply. A very deep inspiration is followed by a voluntary contraction of the abdominal muscles; and, after a moment during which the trunk is kept motionless, the food rises into the mouth.* From hence, after more or less mastication, it is again swallowed in the ordinary way. The abdominal contraction sometimes requires to be aided by manual pressure in the gastric region. The date and duration of the act, as well as the frequency with which it is repeated, vary greatly in different cases.

The precise share taken by the stomach itself in this rumination seems just as obscure — and is probably as variable — as that by which it assists in the act of vomiting.

In many instances an examination of the organ after death has shown no peculiarity of

purely mental emotion, and which is typified in the exaggerated phrase of "being *sick*" of any thing or topic.

* With respect to the vomiting produced by tartar-emetic, the author has made an observation which tends to show that, whatever the mechanical share taken by the stomach itself in the act, this organ does, in some instances, effect such a local secretion of the emetic from the blood into the gastric cavity, as may tend to remove the drug from the system. On injecting a solution of tartar-emetic into the superficial femoral vein of a dog, the mineral was found ten minutes afterwards in the fluid contents of the animal's (digesting) stomach, in a state of concentration much exceeding that in which it must have been mixed with the mass of the blood. And there seem to be reasons for conjecturing that a similar local secretion occurs in the case of the salts of some other metals; and, probably, of ipecacuan.

† Quoted at p. 317.

* Magendie's Physiologie, tome ii. p. 152.

its muscular coats *; in others, the œsophagus has been found greatly thickened; and in others †, this thickening has also implicated the stomach itself. In other cases ‡, this organ has been found with a narrowed or hardened pyloric sac, or a dilated and relaxed cardiac extremity or aperture; or even in a state of suppuration. From a comparison of these appearances, it would therefore seem, that the act is often at least assisted by vigorous gastric movements. And the existence of such movements is also implied by the fact, that this rumination occurs at the period of digestion, when the organ is distended, and its pyloric aperture shut.

As regards the main feature of the process—namely, its subjection to the will, — it is important to notice that great variations obtain. Thus, in some of these cases, the expulsion of the food has required a violent effort. In the majority, it has been easily evoked or suppressed. While in others, it has been almost uncontrollable; or its non-occurrence at the habitual time has been followed by a painful feeling of fulness, or by the act of vomiting.

On the whole, the variable condition of the stomach itself, the slow acquisition of the habit in some subjects, its close resemblance to the easy vomiting of young children, as well as its analogy to voluntary eructation — all these circumstances favour the belief, that the unusual effort of volition which forms the main feature of the act has for its object to open or relax the cardiac orifice and the lower part of the œsophagus. Without such a relaxation, any further efforts on the part of the active pyloric sac would be inefficient: while, with it, their place might be more than supplied by the presence of powerful abdominal contractions. Finally, it is much more consistent with all we know of these two segments of the alimentary canal to suppose the œsophagus capable of being slightly affected by a voluntary effort, than to imagine any part of the stomach placed in the anomalous position of a powerful voluntary muscle, its muscular coat sometimes remaining unaffected, sometimes being positively disorganized by structural disease. And the hypertrophy of the gastric coats, in some of the instances before alluded to, may be interpreted as the effect of rumination, quite as much as its cause; in other words, as being possibly produced by that prolonged gastric movement which would result from such an act, in those instances in which the organ was otherwise healthy.

Mucous membrane.— The mucous membrane, on which the functions of the various parts of the intestinal canal essentially depend, is so modified in the stomach, as to offer a complex arrangement, such as remarkably contrasts it with the simpler layer that lines the upper part of the tube.* And it is distinguished from the compound membrane of the intestine by the possession of certain special structures :—namely, the proper gastric cells, or glandular epithelia, as they are sometimes called.

The remaining histological constituents of this mucous membrane are similar to those met with in other parts of the canal. A delicate membrane is variously involuted or moulded upon a quantity of areolar tissue. The latter texture, which is thus immediately subjacent to this "basement" membrane, forms the matrix of the mucous coat, and, as such, contains its vessels, nerves, and lymphatics, and connects it with the middle or muscular coat. While on its opposite side, the delicate limitary membrane sustains a number of minute cells, that bound the cavity of the tube.

Examined by the naked eye *in sitû*, the mucous membrane of the stomach is seen to be a tolerably firm but soft layer, of a pale pink colour, which everywhere loosely lines the interior of the muscular coat, and projects from its surface in numerous wrinkled folds. These *rugæ* chiefly occupy the cardiac half of the organ, forming convolutions which, though somewhat irregular, are mainly longitudinal. They are effaced by distention of the stomach. And on putting the mucous membrane on the stretch, we may often discern that its whole internal surface is occupied by extremely minute pits or depressions †; the confluent and projecting intervals of which become so much longer as they near the pylorus, that they may almost be compared to very short and scattered villi. These depressions are the openings of the stomach-tubes or proper gastric glands.

The *stomach-tubes* (*c*, *a*, *d*, *fig.* 246.) may be described as cylinders of basement membrane: which are packed vertically side by side in a sparing matrix of dense areolar tissue, and are filled by a peculiar cell-growth. Below, they terminate in closed and rounded extremities (*d*). Above, they expand slightly before reaching the free surface of the membrane, where their margins finally become continuous with each other, so as to form a series of low ridges, the height and width of which vary somewhat in different parts of the stomach. The length of these tubes is, on an average, about $\frac{1}{25}$th of an inch. But this estimate, which is tolerably accurate as regards the middle of the organ, may be almost doubled for the pyloric, and halved for the cardiac region, — a difference which forms the main cause of the very different thickness of the mucous membrane in these two parts.

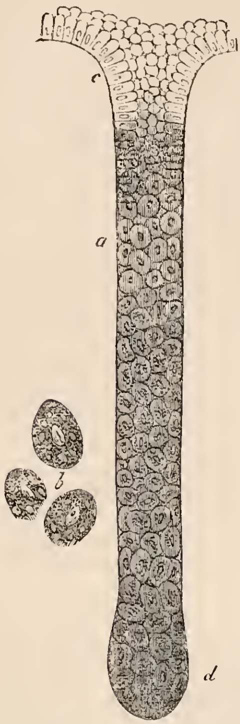
† Such details may be best verified by everting and inflating a perfectly fresh stomach; and removing the adherent mucus by pouring on it a very gentle stream of water, from a gradually increasing elevation.

Their diameter is about $\frac{1}{350}$th of an inch, but is also increased towards the pylorus. Thus their length has to their breadth a pro-

Fig. 246.



Stomach-tube from the middle of the human stomach. Magnified 140 *diameters.*

a, wall of the tube, lined with large oval nucleated cells; *b*, the same oval cells isolated, and magnified 800 diameters; *c*, nucleated cells of columnar epithelium, occupying the upper parts of the tubes, and the intervening ridges; *d*, blind extremity of the tube.

portion of about 10 to 1. Their form frequently so far deviates from that of a simple cylinder as to present slight constrictions or undulations. And occasionally they even exhibit a kind of cæcal pouch or blind offset of greater or less length. These pouches usually spring from the lower extremities of the tubes, which generally have a somewhat increased diameter in their neighbourhood.* But with these exceptions, the gastric tubes form simple, straight cylinders, which only widen where they open on the inner surface or cavity of the stomach.†

* These appearances are generally more marked in the separated fragments of a specimen, or on its exposed edges and surfaces, and are certainly often absent. From this and other reasons I have long entertained the suspicion that they are chiefly due to mechanical violence.

† A widening of diameter which obviously cannot exceed the thickness of the matrix around each tube, and may therefore be easily estimated from the amount of this latter tissue seen in looking at any vertical section of the mucous membrane *in situ*.

The *limitary* or *basement membrane* which forms these tubes precisely resembles this delicate homogeneous layer of the mucous structures generally, except perhaps in the fact of its possessing an even greater tenuity. It is usually seen only as a dark outline, bounding some part of a tube that happens to have been isolated entire. Rarely, however, it may be identified as a delicate, floating, and collapsed fold, which, on the addition of a dilute alkali, first swells up, and then altogether disappears. On the ridges which unite the tops of the tubes it is quite impossible to separate it from the subjacent structures;—an intimate adhesion which forms a striking contrast to the ease with which we can often isolate the tubes themselves.

The *contents* of these tubes appear to be everywhere alike. In the upper fourth or fifth of their length, they contain a single layer of columnar epithelium (*c*, *fig.* 246.). Seen as isolated cells, the particles of this epithelium have a cylindrical shape, and enclose a very distinct nucleus near their attached extremity. But when we look at them in their natural situation, from the free side of the mucous membrane, we see that they are rather hexagonal prisms than cylinders; and contain nuclei, which appear to lie so near to their lower ends, as to be separated from the basement membrane by little more than by the cell-wall at this part. The remainder of the tube is occupied — and under normal* circumstances appears to be filled — by oval or somewhat angular cells (*a d*, and *b*, *fig.* 246.) of considerable size. The largest of these oval cells are about $\frac{1}{1200}$th of an inch in diameter. They have a more or less distinct membranous wall. The nucleus they contain is usually in contact with that side of their parietes which is attached to the basement membrane of the tube; and it sometimes exhibits a nucleolus. Their contents are finely granular, with here and there refractile dots that have a close resemblance to oil globules. And the author has been able to establish the fact, that a large proportion of these cells enclose, beside the above granular material, numerous (5—15) pale, flat, and extremely delicate cytoblasts. Whether the centre of the layer formed by these cells constitutes a distinct calibre or cavity of the tube, — or whether it is merely an interval occupied by granules or cytoblasts — he is unable at present to decide.

As has already been hinted, the gastric mucous membrane is distinguished from most other parts of the body, not only by the great delicacy of its structure, but by the complexity of its arrangement; and above all, by the remarkable facility and rapidity with which it undergoes disorganization and de-

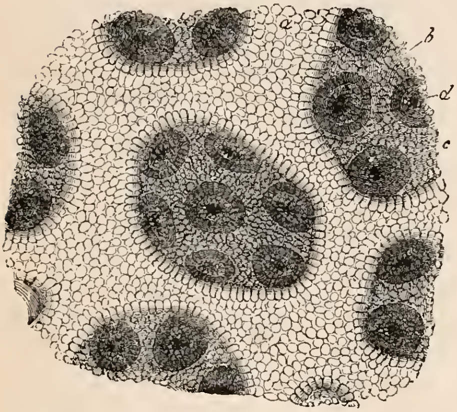
* It is very common to find portions of the tubes quite devoid of these cells, and occupied by a granular substance, with nuclei and cytoblasts in varying proportion. But I believe that this appearance, which is especially frequent in the blind ends of the tubes, is generally the result of mechanical injury of the original cells. (Compare p. 324.)

composition. These changes seem to be the result, partly of putrefaction, partly of a self-digestive process. And since we scarcely ever have any opportunities of examining the perfectly healthy stomach of Man immediately after death, we are compelled to lay unusual stress upon the structure seen in those of the higher Vertebrate animals which approach most nearly to the human conformation of this organ.

Among the various domestic Mammalia most accessible for such purposes, the structure and habits of the Dog render its stomach, in many respects, one of the best we can select for examination.

In this animal, the tubes of the *cardiac* extremity (B, *fig.* 248.) begin on the free or

Fig. 247.



Mucous membrane from the middle of the Dog's stomach, as seen from the free surface. Magnified 150 diameters.

a, ridges which intervene between the primary tubes, covered by columnar epithelium; *b*, primary tubes, lined by similar columnar cells; *c*, secondary tubes, given off from the preceding, and lined, at their commencement, by similar cells; *d*, central calibre, or cavity, of a secondary tube.

cavitary surface of the organ, by apertures which form the intervals of a kind of network of ridges. These apertures are polygonal, or irregularly six-sided, and the tube into which each soon merges has a diameter that is very little less than the distance between the ridges; — on an average about $\frac{1}{200}$th of an inch. The tube now proceeds downwards for a short distance, before bifurcating into two smaller tubes. And each of these again divides at a further stage of its descent. In this manner, what was at first a single large cylinder, ends as a bundle of about four or five small tubes, which are collectively enclosed in a portion of matrix thicker than that occupying their interstices.

At the *pyloric* extremity of the organ, the tubes (A, *fig.* 248.) commence by apertures, which have a diameter twice as great as those seen in the cardiac region, and from hence they pass vertically downwards for some distance, with a simple cylindrical form. All the terminal branches of these long pyloric tubes are for the most part given off at nearly the same height, so that they constitute only one-sixth, or thereabouts, of the whole thickness of the mucous membrane, instead of about five-sixths, as in the cardiac extremity. In both the above regions, however, the number of these terminal tubes is rarely less than three, or more than six. Their diameter is generally about one-third that of the larger and simple tube from which they originate. And the total bulk of the bundle which they form, as seen on transverse section, is as nearly as possible equal to that of the primary tube.

But these differences in the width and ramification of the cardiac and pyloric tubes are accompanied by a much more remarkable and important contrast in the form, size, and arrangement of their respective contents.

The whole of the *pyloric* tube (A, *fig.* 248.) is occupied by a single layer of columnar epithelium, the cylindrical or slightly prismatic cells of which are placed vertically to the basement membrane, and contain a very distinct nucleus near their attached extremity. The only difference offered by these cells in the terminal branches of the tube is, that they are shorter in proportion to their width, and enclose darker and more granular contents.

Fig. 248.

Tubes from the cardiac and pyloric regions of the Dog's stomach, to show the contrast of their structures. Magnified 60 *diameters. Altered from Koelliker.*

A. pyloric tube; *a*, primary tube; *b*, three secondary tubes. B. cardiac tube; *a*, primary tube lined by columnar epithelium; *b*, two secondary tubes; *c*, four terminal branches containing large oval cells.

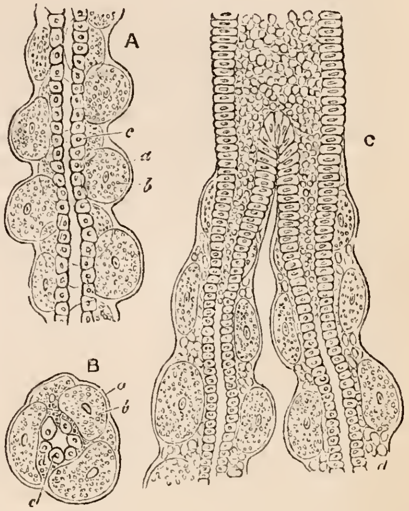
They everywhere bound a tube with a distinct calibre.

In the *cardiac* region, it is only the ridges, and the upper part of the tubes, which are covered by columnar epithelium. At the first (B *b*, *fig.* 248.) or second bifurcation of the primary tube, the character of its lining altogether changes: and from hence onwards to their rounded blind extremities, the secondary tubules are immediately lined by peculiar oval cells (B *c*, *fig.* 248.). These cells are analogous to those seen in the human stomach. They differ however from them, not only in their great size, and more distinct walls, but also in the fact, that they generally bulge the basement membrane of the tube, so as to give it a somewhat moniliform outline. A closer examination shows this appearance to be caused by the prominent cells occupying irregular heights around the wall of the tube.

On getting the middle of such an isolated tube into the focus of the microscope, we find that in the higher part of the tubule, near where it opens into the primary tube, the oval cells, which are always in immediate contact with the basement membrane, form a double row with a somewhat sinuous interval. This interval is a distinct though narrow calibre. Below this visible calibre, I had long been aware that the similar interval between the larger cells was occupied by an immense number of small nucleated cells or cytoblasts,—many of which are firm, with distinct and somewhat angular outlines; while others are excessively delicate, pale, flattened, oval, transparent, and of equal or much smaller size. And the more skilful manipulation of Koelliker has recently enabled him to state, that the centre of the tube presents a continuous narrow calibre or cavity (A, *fig.* 249.), which is immediately bounded by these small, roundish, or angular cells (*c*, A and B). Between these small cells and the limitary membrane, the large oval cells are interposed (*b*, A and B). Below, the latter often seem to form the sole contents of the tube.

The truth of Koelliker's description I can fully substantiate; so far as regards the upper part of these secondary tubes, in the cardiac five-sixths of the organ. Even the blind extremities of the tubes seem to have their axes occupied by the delicate cytoblasts previously alluded to; but they are here, so far as I can see, disposed irregularly. Higher up, the cells are more angular, and possess more distinct outlines; and are often arranged in two rows, which are in contact at the centre of the tube. It is only towards the apertures of the secondary tubes, where the oval cells are beginning to be more thinly scattered prior to their disappearance, that these small cytoblasts appear to form a distinct calibre or tubular cavity of appreciable width. Here they merge into the columnar form;—a change which begins by their becoming elongated towards the axis of the tube, and allowing water to develope a distinct cell-membrane at this part (C, *fig.* 249.). But there are many appearances which render it by no means impossible that the whole length of the tube possesses a narrow calibre, formed by a regular arrange-

Fig. 249.



Portions of tubes from the cardiac extremity of the dog's stomach. Magnified 350 diameters. (Partly after Koelliker.)

A. portion from the middle of such a cardiac tube; *a*, limitary membrane of tube; *b*, large oval gastric cell; *c*, smaller axial cells. B. Same seen in transverse section; *a*, *b*, *c*, as above. External to c are seen indistinctly some delicate cytoblasts; *c*, junction of the primary and secondary tubes, showing the mode in which the small axial cells of the latter are continuous with the columnar cells which form the epithelium of the former.

ment of these small cells. While I have no doubt that the interstices left between the large cells and this central tube of epithelium are also filled up by numbers of cytoblasts, of excessive delicacy, and various degrees of minuteness (*d*, B and C).

Besides these free cytoblasts within the tube, we may find others of endogenous origin. Very careful observation of the large oval cells will show that they enclose cytoblasts in addition to their minutely granular contents (compare *b*, *fig.* 246.). The number of these cytoblasts appears to vary from two to twenty in different cells. They are excessively delicate, of about $\frac{1}{3000}$th inch diameter: their shape is a flattened oval; and they contain a bright spot or nucleus. They seem to be chiefly in contact with the inner surface of the mother-cell; so that in many animals, specimens of their outline can often be distinctly seen through the nearly transparent wall of this cell under the higher powers of the microscope. They may, however, be easily overlooked. And their distinctness never equals that of the proper nucleus of the cell; closely as they resemble this structure in size and shape. They may sometimes be seen projecting from the broken half of a mother-cell; or set free from it, owing to its having been ruptured by the rapid endosmose of water. But they are very quickly dissolved or burst, by contact with most of the fluids which are generally used in preparing such specimens for microscopic examination.

During the five years that I have made the stomach an object of frequent (though interrupted) research, I have examined numerous specimens from the perfectly fresh stomachs of about thirty species of Vertebrata. The following is an outline of the few results I have obtained. As regards the *pyloric* tubes, those of the Cat, Rabbit, Hog, Ox, and Guinea-pig, resemble those of the Dog, in containing a columnar epithelium, and having a distinct calibre to their termination. Those of the Horse resemble the tubes of the human stomach in possessing the oval or gastric cells. In most, if not all of these animals, the tubes ramify. As respects the *cardiac* tubes, the minute central calibre observed by Koelliker in those of the Dog appears to be also present in the Cat and Guinea-pig; and, from analogy, is not unlikely to exist in most Vertebrata. The large oval cells are the rule throughout the Vertebrate kingdom. And in many Reptiles, as well as in the very young animals of most orders, the numerous cytoblasts enclosed by these cells are much more distinct. In only two instances have I found no large cells present in the cardiac tubes, and in both of these, the stomach was evidently disorganized by commencing putrefaction. In some Fishes, however — such as the Mackerel — it is only the middle or apex of the *V*-shaped stomach which is occupied by tubes. And in the Minnow, Carp, and Tench of the Cyprinoid genus, as well as in the river Lamprey (*Petromyzon fluviatile*) no tubes are present. Finally, while there are many species in which the gastric structures appear to be softer and more delicate during the time of digestion than in the fasting state, in none have I been able to verify the least difference in the morphology of the organ at these two periods.

Those who are familiar with the difficulties that oppose the successful examination of the softer tissues of the animal body will probably bear with me if I end this description by what may seem a superfluous caution to the observer. There are many appearances seen in these delicate tubes, which are produced by the mechanical violence necessary to their isolation, aided by the softening of incipient putrefaction or self-digestion, or by the endosmose of the dilute fluids which are sometimes added to such specimens in preparing them for the microscope. Thus the tubes often deviate from the above account in the absence of gastric cells, in the presence of short branches that are given off near their blind extremities, and in the spiral or bulbous shape which these ends sometimes assume. Indeed, when we reflect upon the extreme tenuity of their basement membrane, the nature of their contents, and the firmness with which they are imbedded in a dense areolar and muscular tissue, we shall scarcely be surprised to find, that the violent disruption of these attachments can distort the tubes, or break up their soft contents. But the careful manipulation of perfectly fresh specimens, in a proper fluid medium (such as the serum of the blood, or a strong solution of common salt) renders these appearances so rare, as to render it highly probable that they are accidental. While conversely, the application of a slight pressure, the use of water and dilute acids, and the commencement of digestive or putrefactive softening, will often produce them in a specimen from which they were formerly absent.

In addition to the cylindrical tubes, some * anatomists have found in the stomach ramified glands, which end in *acini* or dilated extremities. These are stated to occupy the neighbourhood of the pylorus, where they form a kind of transitional structure between the gastric and the duodenal glands. I have once or twice seen appearances in the tubes of this part which corresponded pretty closely with the above description. In two other instances, a single flask-shaped dilatation was appended to some of the ordinary tubes, which it thus doubled in diameter. But the arrangement of these latter dilatations, as well as the condition of the remainder of the specimens, left me little doubt that they were due to accidental violence, which had distended the terminal branches of a tube with a large portion of its displaced contents. While their shape and situation (in the mucous membrane itself, instead of its submucous tissue) sufficed to show that they were not lenticular glands; — an argument which will equally militate against the notion of their being a transition to the duodenal glands, since these occupy a similar position.

Lenticular glands are also found in the stomach. As regards their shape, size, situation, and contents, they correspond so completely with the solitary glands of the intestine, that we may refer the reader to these for their special description. Their number varies extremely. Sometimes it is impossible to find any. In other specimens, they are scattered more or less thickly throughout the whole organ. They are said chiefly to affect the lesser curvature; but I have seen them sown very plentifully over the pyloric region only. In children, they are rarely absent. And among the brute Mammalia, they are found occasionally in the Dog †, and constantly in the Pig. ‡ Structures more or less analogous to these glands probably also exist in the Beaver, Kangaroo, Dugong, and many other animals.

Matrix. The cylindrical tubes of the stomach are united to each other, in their whole length, by a sparing quantity of a fibrous

* Bruch (in Henle and Pfeufer's Zeitschrift. f. Rat. Path. Bd. viii. p. 272. *et seq.*); Ecker (*id. op.* 1852. p. 244.). Compare Bischoff (in Mueller's Archiv. 1838. p. 503.)

† Bischoff, *Op. cit.* p. 510.

‡ *Id. op.*; also Wasmann (De Digestione Nonnulla. Berlin. 1839. p. 8.), and Koelliker, *Op. cit.* p. 150.

network or *matrix;* — their blind extremities being also imbedded in a considerable stratum of this texture, which is continuous with that surrounding their sides. The arrangement of the latter part of it is best seen by making horizontal sections of the mucous membrane, so as to cut transversely across the gastric tubes at different heights. Its quantity is small in proportion to the diameter of the tubes. And in it we may recognize, besides cut extremities of vessels, indistinct concentric fibres, which appear to surround the tubes, and decussate with each other. In the ramified tubes of many animals, each original tube, and its set of secondary branches, is enclosed in a tolerably thick sheath of this kind, which gives off slenderer partitions of the same nature between the smallest individual tubes. On the surface of the stomach, this matrix is nearly homogeneous; but its fibrous character is more distinct at the deeper parts of the membrane, and in those tubes which occupy the neighbourhood of the pylorus. Here its quantity is also increased. Many years ago, the author was struck with the remarkable difference between that layer of this fibrous tissue which lies beneath the tubes, and the submucous areolar tissue upon which it is placed; — the former being characterized, not only by its darker colour, and its dense and closely interwoven texture, but also by its being much less acted on by acetic acid. But Middeldorpf* has since made the important discovery, that this peculiar layer, which extends from the cardia to the anus, is in reality composed of a mixture of areolar tissue, and organic or unstriped muscle: — the fibres of the latter structure being arranged in two series of bundles that decussate with each other at an acute angle. Externally, these fibres are conjectured by Koelliker to be more or less continuous with the ends of the oblique fibres of the muscular coat. Internally, Bruecke states them to pass upwards, in small bundles, between the several tubes. This statement is to some extent confirmed by Koelliker, who has seen numerous cells very like the fibre-cells of organic muscle occupying this situation in Man, some Ruminants, and the Pig. In the latter animal, bundles of these fibres penetrate the rudimentary villi of the pylorus, and occupy their axes. Of the function of these muscular-fibre cells we know nothing. But, from their arrangement, it would seem not impossible that they are destined to maintain the tubes in their normal situation, against the disturbances which the contractions of the proper muscular coat might otherwise produce.

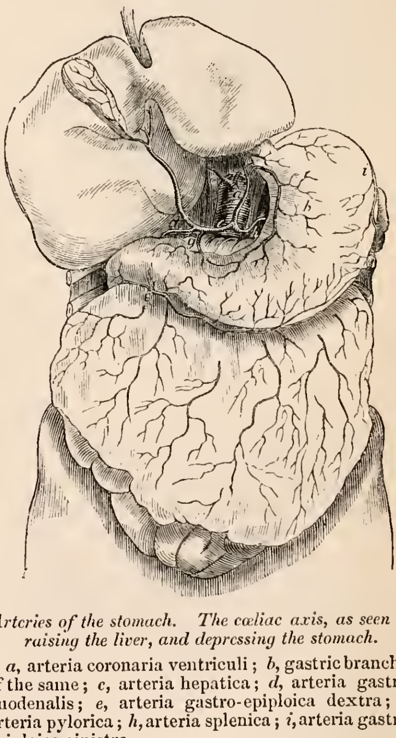
Areolar tissue. A layer of loose *submucous areolar tissue* (the *tunica nervea* of some authors) connects the mucous membrane of the stomach with the proper muscular coat previously described. Seen in vertical section, its thickness is a little greater than that of the denser muscular stratum which receives the extremities of the tubes. Its constituents are the ordinary white and yellow fibrous elements; the elastic filaments of the latter being chiefly of small size. Externally, it is pretty firmly connected with the muscular coat, and appears to receive many of its fibres. But internally, where it approaches the fibrous matrix, its meshes are very large and loose, so as to allow of the mucous membrane being thrown into folds by the contraction of the muscular tunic. It contains the vessels, nerves, and lymphatics destined for the supply of the mucous membrane.

* De glandulis Brunnianis. Vratisl: 1846.

The *vessels* of the stomach are very large and numerous. The arteries are derived from the abdominal aorta. The veins empty themselves into the *vena portæ*, which ramifies in the liver.

The *arteries* of the stomach all come off from the cœliac axis. This vessel, which leaves the aorta opposite the first lumbar vertebra, continues obliquely forwards as a short thick trunk for a distance of about half an inch; when the "axis" ceases, by giving off, at right angles to itself, three large branches: — namely, the *gastric*, *hepatic*, and *splenic*.

Fig. 250.



Arteries of the stomach. The cœliac axis, as seen by raising the liver, and depressing the stomach.

a, arteria coronaria ventriculi; *b*, gastric branches of the same; *c*, arteria hepatica; *d*, arteria gastro-duodenalis; *e*, arteria gastro-epiploica dextra; *g*, arteria pylorica; *h*, arteria splenica; *i*, arteria gastro-epiploica sinistra.

The *arteria coronaria ventriculi* (*a*, *figs*. 250, 251.), or proper *gastric* artery, is the smallest of these three. It passes upwards and towards the left side, beneath the peritoneum which forms the dorsal and outer surface of the sac of the omentum; until, arriving nearly at the upper extremity of this cavity, it turns forwards in a slight projection or fold of the serous membrane. In this fold, it has a very brief and somewhat arched course, which brings it to the left end of the smaller curvature of the stomach. Here it passes between the two layers of the gastro-hepatic omentum. From hence it continues, in a very tortuous course, along this curvature; lying close to the stomach, and diminishing in size by giving off frequent branches; until, towards the right or pyloric extremity of the organ, it is lost by anastomosing with the branches of the hepatic artery.

Its larger or named branches are the *œsophageal* and the *gastric.* The first are given off from the highest point of the vessel, or where it enters the gastro-splenic omentum. They run upwards to the œsophagus, and take a longitudinal course; so as to pass, with this tube, through the opening in the diaphragm. And they anastomose with the thoracic vessels distributed to this tube from the aorta. The *gastric* ramifications (*b, fig.* 250.) run downwards from the coronary artery on both surfaces of the stomach. They inosculate, on the left, with small branches from the splenic artery; towards the middle of the organ, with the gastro-epiploic branches; and at the pylorus, with the superior pyloric artery.

The *arteria hepatica* (*c, figs.* 250, 251.), which is the next largest branch of the cœliac axis, passes for a short distance outwards, and slightly forwards, from the axis or common trunk, to reach the commencement of the duodenum. It now runs almost vertically upwards between the two layers of peritoneum that form the gastro-hepatic omentum, and in front of the foramen of Winslow (though still with a slight inclination towards the right side), to end by being distributed in the liver. In this course, it gives off two branches, — the gastro-duodenal and the pyloric — both of which take an important share in supplying the stomach with arterial blood.

Fig. 251.

Arteries of the stomach. The cœliac axis, as seen by raising the stomach, so as to expose the arterial branches behind it.

a, arteria coronaria ventriculi; *c*, arteria hepatica; *d*, arteria gastro-duodenalis; *e*, arteria gastro-epiploica dextra; *f*, arteria pancreatico-duodenalis; *g*, arteria pylorica; *h*, arteria splenica; *i*, arteria gastro-epiploica sinistra.

The *gastro-duodenalis* (*d, figs.* 250, 251.) is the first and largest artery of these two. It leaves the hepatic vessel behind the duodenum, passing vertically downwards across the intestine to the lower border of its first portion. In this course, it gives off a few small branches to the neighbouring parts of the stomach and intestine; some of which twigs have been distinguished as the *inferior pyloric* arteries. And at the inferior margin of the bowel, the gastro-duodenal artery bifurcates into two: — a large *gastro-epiploic*, and a small *pancreatico-duodenal* branch.

The *gastro-epiploica dextra* (*e, figs.* 250, 251.), the large vessel which continues the *gastro-duodenalis,* is so named from its situation between those layers of the great omentum which descend from the stomach to form the "epiploon" or apron-like fold that covers the greater part of the intestinal canal. Beginning at the lower border of the duodenum, the artery runs from right to left, along the lower margin or great curvature of the stomach, and at a little distance from it, with what is usually a wavy or tortuous direction. In this course, it gives off branches which pass upwards on both surfaces of the organ; as well as others of less importance, both upwards and downwards, to the fatty and serous tissues of the omentum itself. And rather beyond the middle of the stomach, or towards its cardiac pouch, it ends by uniting with a corresponding branch, of smaller size, from the splenic artery.

The *pancreatico-duodenalis* branch (*f, fig.* 251.) has precisely the situation and distribution which its name would imply. It runs between the duodenum and the head of the pancreas, lying in the concavity formed by the horse-shoe curve of the canal, or around the convexity by which the gland fits into this hollow. It gives off ramifications to both these structures, and ends by anastomosing with a branch, which comes upwards from the superior mesenteric artery and also occupies the same interval between the pancreas and the lower portion of the duodenum.

The *arteria pylorica* (*g, figs.* 250, 251.), which is sometimes distinguished by the title of the *pylorica superior* from the smaller branches of the gastro-duodenal above alluded to, is generally given off from the trunk of the hepatic artery opposite to the upper border of the duodenum. More rarely it is derived from the commencement of its gastro-duodenal branch. In either case, it enters between the layers of the gastro-hepatic omentum, and runs in this fold, from right to left, along the upper margin or lesser curvature of the stomach, to join the coronary artery from the cardiac extremity of the organ. It gives off numerous branches to both surfaces of the organ.

The *arteria splenica* (*h, figs.* 250, 251.), or second branch of the cœliac axis, has no direct connection with the alimentary canal, until near its division into the terminal trunks by which it enters the spleen. Here it gives off a left *gastro-epiploic* artery; and numerous small and short vessels, the *vasa brevia.*

The *gastro-epiploica sinistra* (*i, figs.* 250,251.) leaves the trunk of the splenic artery close to where this divides at the inner surface of the spleen. It passes downwards, forwards, and towards the right side, first lying for a short distance in the gastro-splenic omentum, and then entering between the layers of the great omentum which is continuous with this fold. It then runs along the lower border or great curvature of the stomach, to anastomose with the corresponding vessel on the right side. Like it, it supplies branches to both surfaces of the stomach.

The *vasa brevia* are numerous small branches which come from the primary and secondary divisions of the splenic artery, and run in the gastro-splenic omentum to the cardiac pouch. Here they break up and anastomose with each other, as well as with the coronary and left gastro-epiploic arteries.

The *veins* of the stomach are the *superior pyloric*, and the *right* and *left gastro-epiploic.*

The *vena pylorica superior* receives and continues a large vein, which corresponds to the coronary artery, and takes a similar (but reversed) course along the lesser curvature of the stomach to the pylorus. It now passes upwards for a little distance, before opening into the *vena portæ* (*a, fig.* 281.) near its termination in the liver. In other instances, it bends down to join the splenic vein.

The *vena gastro-epiploica dextra* corresponds to its artery in the greater part of its distribution. It usually ends by emptying itself into the superior mesenteric vein, just before this forms the *vena portæ* by joining with the splenic vein (*e, fig.* 281.).

The *vena gastro-epiploica sinistra* also runs with its artery, and joins either the splenic vein, or one of its primary branches.

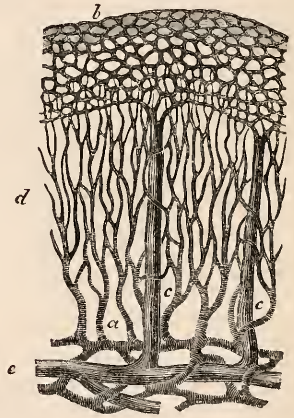
All of the foregoing vessels are characterized by the great freedom and frequency of their inosculations in every stage of their course from the aortic to the portal trunks. This condition is especially well marked in the arteries. And, as ordinarily injected, the latter appear to be both larger and more numerous than the arteries distributed to an equal bulk of most of the other structures of the body.*

Their tortuous course, and their loose connection with the stomach, chiefly refer to the distention of this organ. For as the stomach expands between the laminæ of peritoneum, it gradually straightens these vessels, and alters their position with respect to itself and to each other.

The distal branches of the arterial and venous trunks perforate the muscular coat at different intervals, by twigs which unite with each other in the loose submucous areolar tissue, so as to form two broad and somewhat flattened networks: — one, which is composed of small arteries, and another, of veins. The vessels of the latter plexus are, as usual, both larger and more numerous than the corresponding arteries.

Capillaries. — The arterial branches which leave the above sub-mucous network, to enter the dense muscular layer of the matrix of the stomach, divide here once or twice. And their ultimate ramifications, which have a diameter of about $\frac{1}{1500}$th to $\frac{1}{1800}$th of an inch, pass vertically upwards, along the sides of the tubes to their upper apertures, where they form a superficial network of capillaries. In passing

Fig. 252.



Plan of the vessels of the mucous membrane of the stomach, as they would be seen in a vertical section.

a, arteries from the plexus occupying the submucous areolar tissue; *b*, superficial plexus of capillaries occupying the ridges of the mucous membrane; *c*, veins passing downwards between the gastric tubes; *d*, capillaries between and around the tubes; *e*, plexus of arteries and veins occupying the submucous areolar tissue.

upwards, they also give off other capillaries; which surround the tubes, at all parts of their height, with a second and deeper network. The meshes of this latter plexus are somewhat oblong, but less decidedly so than those of the capillary network of striped muscle; and are about $\frac{1}{100}$th to $\frac{1}{250}$th of an inch in size. The capillaries which compose them are, on an average, little more than $\frac{1}{5000}$th of an inch in diameter. The more superficial network is contrasted with this deeper one, not only in the fact that its capillaries are about double the above diameter (or

* Assuming this fact to be as true as it seems to be, it becomes interesting to inquire what peculiarities of the circulation may be presumed to be connected with it. Other things being equal, the passage of a larger quantity of blood to and from an organ may be fairly supposed to be associated with a greater amount of that change which absorption or secretion there impress upon this fluid. Again, Volkmann's researches have shown that the anastomosis of channels diminishes the resistance in their interior; — a diminution which, if not met by any counteracting circumstance, would increase the velocity of their contents. But the most plausible conjecture that can at present be offered is, that this increase in the number of these small arteries, — which have a distinctly muscular structure, and are plentifully supplied with nerves, — has reference to that efficient and sudden control of their calibre which the varying exigencies of their capillary circulation would seem to imply.

$\frac{1}{2500}$th of an inch), but also in its meshes being nearly twice as close (or about $\frac{1}{300}$th to $\frac{1}{600}$th of an inch). But the two plexuses inosculate so freely, as to be quite continuous with each other at the upper apertures of the tubes. As

Fig. 253.

Superficial capillaries of the mucous membrane of the human stomach, from an injected specimen. Magnified 70 *diameters.*

a, ridges intervening between the stomach-tubes; *b*, capillaries occupying the ridges; *c*, orifice of a stomach-tube.

regards the form of the superficial network, it may be stated to correspond exactly with the intervals of the primary tubes. For the ridges which occupy the surface of the organ are all, as it were, moulded upon capillaries, the union of which forms what we may distinguish as a primary network, that surrounds the aperture of each tube with a capillary loop. In Man,* however, this comparatively simple network is complicated by the addition of other meshes, which lie on either side of it, and just within the orifices of the tubes. In their shape and size, these closely resemble the loops beneath the ridges, and are, indeed, no way distinguishable from them except in their situation. Below, their diameter diminishes, their loops elongate, and they finally merge into the general network which surrounds the tubes.

It is from the large capillaries which compose the superficial network that the radicles of the veins almost exclusively arise. They begin as small vessels of about $\frac{1}{1500}$th of an inch in diameter; and by one or two successive unions of these and their resulting larger branches, they soon attain a width of about $\frac{1}{400}$th of an inch. They now pass vertically down the intervals between the tubes, to open into the flattened venous plexus which occupies the submucous areolar tissue.

The general result of this arrangement on the circulation in the stomach seems to be, that the blood which has already traversed the capillaries of its tubes is passed on to its surface. Hence in respect to their situation and size, these superficial capillaries of the gastric mucous membrane offer a distant resemblance to veins. This fact, as well as their connection, both with small arteries on the one hand, and with confluent capillaries on the other, renders it probable that the velocity of their contents exceeds that of the blood which circulates in the capillaries of many other tissues. Such a peculiarity would admirably adapt them to that absorptive office which their mere situation on the cavitary surface of the organ indicates as one of their chief functions.

Changes in the stomach during digestion.—The introduction of food into the healthy fasting stomach gives rise to two chief alterations in the organ. Its muscular coat is excited* to movement. And, at the same time, its mucous membrane deepens from a pale to a bright pink colour†; and begins to pour forth a liquid secretion—the *gastric juice.*

Gastric juice.—An inquiry into the characters of the gastric juice is opposed by many difficulties. For it is obvious that the properties of this or any other secretion can only be established from its examination in a state of perfect purity. While the situation and functions of the stomach are such that, under natural circumstances, its secretion is necessarily mixed with many other substances. It is true that the bile often found ‡ in the stomach during fasting is shut out from its cavity, during digestion, by the closure of the pylorus. But, on the other hand, the saliva, which generally covers the mucous surface of the empty organ, as a thin viscid layer with a superficial alkaline reaction, is swallowed at this period in much larger quantities; while the food itself forms an equally constant impurity. To such less avoidable sources of error are often added the alterations produced by disease in the unhealthy individual, or by putrefaction or digestion in the healthy subject after death. And though even the most careful study of all these circumstances will scarcely explain the discrepancies and contradictions of numerous (and apparently faithful) observers in their accounts of the gastric juice,—still they evidently constitute conditions which, according as they are obviated, or noticed, or neglected, will respectively render any particular observations valid, or comparable, or utterly useless. §

* In many animals the superficial network appears limited to this simpler form; especially in the cardiac region, where the intervals of the tubes are smaller.

* See *ante*, p. 312.

† Beaumont, *Op. cit.* pp. 94. *et seq.*

‡ See *ante*, p. 315.

§ The above remarks form a key to the following historical summary of the more important observations which have been made on this fluid; as well as a reason why the author has reduced it to a mere enumeration,—such as will not, however, preclude a fuller subsequent reference, where this is required.

Reaumur, in the year 1752, obtained an artificial digestive fluid from the stomachs of animals by means of sponges attached to strings (Mém. de l'Académie, 1752. pp. 705. *et seq.*). About 1780, Spallanzani (Ueber das Verdauungsgeschaeft. Leipzig, 1785) adopted the same method; and also examined matters which had been vomited. He thus determined the gastric juice to be a neutral, antiseptic solvent. He quotes Scopoli and Gosse to the same effect. Carminati (Untersuchungen ueber die Natur des Magensaftes, 1785) also deduced his results from substances vomited; and found that it was only the acid fluid secreted after eating which possessed antiseptic and digestive powers. Several observers, however, — among whom were Viridet

Physical Properties.—Pure gastric juice is a structureless, limpid, and transparent fluid, of a pale straw colour. Its taste is slightly saline, and distinctly acid. And it has a peculiar faint odour, which is probably characteristic for each of the different* species of animals, like the smell of the blood from whence it is no doubt derived.

Where, as is often the case, the gastric juice is mixed with saliva, mucus, or relics of the food, its appearances will of course differ from those above described. The froth of the saliva sometimes distinguishes this admixture. The mucus thus added is ropy or viscid, and generally presents scaly epithelium, which, together with its neutral or alkaline character, betray its origin from the mouth or œsophagus. Both it and the fragments of food are frequently deposited from the gastric juice, as a dirty flocculent sediment. And they may always be removed from it by careful filtration ; when the fluid loses its greyish, brownish, or turbid character.

The *specific gravity* of the gastric juice was observed by Silliman to be about 1005·0. But from the condition of the specimen he examined, and the mode of weighing† he adopted, very little reliance can be placed on this statement. Lassaigne ‡ also made direct observations with the same view, and found that the irritated empty stomach poured forth a fluid of sp. gr. 1001·0 ; while that secreted on the contact of flesh was 1005·0, and with bread 1010·0. But it must obviously be very difficult directly to determine the specific gravity of such a fluid, in the small quantities in which it is generally obtained. The per-centage of solid contents is more easily estimated.—Tiedemann and Gmelin rated it at 1·95 in the gastric juice of a dog who had been made to swallow small pieces of limestone ; and at 1·6 in that of a horse. Berzelius gives it at 1·27 in the specimen sent him by Beaumont ; Lassaigne at 1·32, and Blondlot at 1·0, from the gastric fistulæ of dogs ; Frerichs (appa-

(De Primâ Coctione, Geneva, 1692), Brugnatelli (Crell's Annalen, 1787), and John Hunter (Animal Œconomy, 2nd ed. p. 205. 1792)—had found that the stomach contained an acid. Macquart (Mémoires de la Soc. Roy. de Médecine, 1786) stated this acid to be phosphoric in the paunch of Ruminants. Treviranus extracted the proventriculus of Birds with water : he thus, amongst other results, was able to confirm Hunter's conjecture, and regard it as lactic acid (Biologie, vol. iv. p. 358. 1814). Chevreul (Magendie's Physiologie, 1st & 2nd ed. 1825, vol. ii. pp. 11, 12.) analyzed a fluid obtained by voluntary vomiting. He not only confirmed the presence of lactic acid, but announced the presence of the muriates of ammonia, potash, and soda; together with an animal substance soluble in water, but not in alcohol.

In 1824, Prout led the way to a better knowledge of this fluid by an analysis of the contents of the stomach in Rabbits during digestion, in which he found hydrochloric acid and chlorides (Philosophical Transactions, 1824, pt. i. p. 45.). Dr. Children confirmed this statement from the gastric fluid of a dyspeptic patient (Annals of Philosophy, 1824, vol. viii. p. 68.). Leuret and Lassaigne, however, using this latter method, confirmed Chevreul as to the presence of lactic acid (Récherches physiologiques et chemiques pour servir à l'Histoire de la Digestion. Paris, 1825.) Tiedemann and Gmelin excited the secretion of gastric juice by introducing stones into the stomachs of animals, and found hydrochloric acid on examining the contents of the stomach after death (Die Verdauung nach Versuchen. Leipzig, 1831). In 1833-4, Beaumont's unique case afforded specimens for three analyses ; by Dunglison, Silliman (Beaumont, *Op. cit.* pp. 69. et seq.), and Berzelius (Annuaire des Sciences chemiques, p. 282.). They all essentially corroborated Prout (Annales de Chemie, t. lix. p. 348.) ; as did Braconnot in 1835, with gastric juice from the sponged stomach of animals. Wasmann, in 1839, made some excellent experiments on artificial digestion with an infusion of pig's stomach ; but added little or nothing to our knowledge of the gastric acid (Nonnulla de Digestione. Berolini, 1839). Huenefeld, adopting Prout's method, obtained lactic acid (Chemismus in der Thierischen Organization. Leipzig, 1840) ; a result in which, as well as in the cause of Prout's and Dunglison's view, Lehmann either preceded or confirmed him (Physiologische Chemie, 1840. Bd. i. p. 284.). Enderlin, however, who examined the digesting stomach of a beheaded criminal, and repeated Dunglison's process, reasserted its results (Liebig's Annalen der Chemie und Pharmacie, 1843. Bd. xlvi., p. 122.) In this year, Blondlot imitated Beaumont's case, by instituting fistulæ in the stomachs of dogs ; and announced biphosphate of lime as the acid principle (Traité Analytique de la Digestion. Paris, 1843). Lassaigne (Journal de Chemie, 1844, pp. 73. 183.) ; and Bernard and Barreswil (Comptes Rendus, 1844, t. xix. p.1285.) made use of the same method ; but denied the accuracy of Blondlot's chemical results in detail, and affirmed the presence of lactic acid. Pelouze corroborated some of their statements (Comptes Rendus, t. xix. p. 1227.) ; as subsequently did Thomson also (Philosophical Magazine, 1845, p. 419.). Schmidt next asserted that the active principle of the gastric juice was hydrochloric acid, modified by combination with the digestive principle ; but did not detail the analyses on which this view was based (Annalen der Chemie u. Pharmacie, 1847, Bd. lxi. p. 311.). Lehmann, in 1849, corroborated the lactic acid view, by examinations of gastric juice from fistulæ (Berichte der Gesell. der Wiss. zu Leipzig. Bd. i. pp. 100. et seq. ; and *Op. cit.* Bd. i. s. 97.). And Frerichs about this time came to the same conclusion (Wagner's Handwoerterbuch der Physiologie, vol. iii. p. 815.) from similar experiments.

But this comparative unanimity in favour of lactic acid was not destined to last long. In 1851, Huebbenet for the first time found a simple method of preventing that admixture of saliva which had hitherto rendered the gastric juice obtained in such experiments with fistulæ an impure secretion. This he did by obliterating the ducts of the larger salivary glands. And the researches which Bidder and Schmidt instituted upon the gastric juice thus procured seem at length to have established, that it is the hydrochloric which constitutes the proper acid of the gastric juice.

[In preparing the greater part of this essay for the press, the author found it impossible to procure a copy of Bidder and Schmidt's valuable Essay ; and was hence only acquainted with such portions of it as are mentioned in Lehmann's (Physiologische Chemie, vol. iii.) recent work ; in the reports given of Huebbenet's Dissertation by Scherer and Valentin, in Canstatt's Jahresbericht (1852, Bd. i.) ; and by Funke in Schmidt's Jahrbuecher (1851, p. 275.).]

* At any rate the author's observations tend to show that this is the case in Man and many animals. Human gastric juice is stated by Dunglison (Physiology, vol. i. p. 503.) to smell of hydrochloric acid. And Beaumont (p. 76.) asserts, that it tastes like this acid in a state of dilution.

† Beaumont, *Op. cit.* p. 72.

‡ *Loc. cit.* pp. 183. et seq.

rently from dead animals) at 1·72, 1·80, 1·15, after feeding with hay, bones, and peppercorns respectively; Lehmann at an average of 1·4; Bidder and Schmidt at 2·694 in the gastric juice of a dog with deligated salivary ducts, 2·883 in another dog in whom they were free, and 1·385 from a sheep. These latter high numbers indicate that, whatever may be the influence of an admixture of food or saliva in increasing the residuum of the gastric juice, it is more than counterbalanced by the loss which attends the analysis of small quantities. The first of these three quantitative analyses by Bidder and Schmidt I have made the basis of a calculation *, according to which the specific gravity of the gastric juice would be 1003·3,—an estimate that tolerably agrees with the observations of Lassaigne and Silliman.

The *quantity* of the gastric juice is even less accurately established. From Beaumont's experiments, it would appear that at least eight ounces may be secreted in an hour. It is, however, not impossible that ten times this amount may be poured out during the digestive process. For Bidder and Schmidt's observations on animals give an average of about $\frac{1}{200}$th of the weight of the whole body per hour, with a maximum of $\frac{1}{20}$th in the same period. But it is probable that the latter proportion exceeds that which could be secreted by a human being † in the same space of time.

Chemical composition.—In inquiring into the chemical composition of the gastric juice, it will be convenient successively to consider its acid, its saline, and its animal constituents.

The gastric acid.—Although this obvious and unmistakeable character of the gastric juice has been recognised for more than 150 years, yet the nature of the acid on which it depends is probably still regarded as uncertain. An impartial and searching criticism of all the numerous and conflicting analyses that have been made would far exceed the limits of this essay:—even had the author (what he has not) the abilities and leisure necessary to such a task. The reader will therefore only expect such a sketch, as may include some of the chief facts which justify us in preferring, if not in adopting, one particular view.

Not to mention those exceptional instances in which acetic, butyric, or other acids, have been found in inefficient quantity in the contents of the stomach, there are at least three views of sufficient importance to demand some notice. The first of these regards the gastric acid as the hydrochloric: the second as the lactic. While the third attributes the acidulous character of the secretion to the presence of a salt, the acid phosphate—or, as it is sometimes incorrectly termed, the superphosphate*—of lime.

The latter view, which denies the presence of a free acid, is the more recent of the three. It rests solely upon the statements of Blondlot †; from whose writings we select some important details, which are directly contradicted by the concurrent testimony of other chemists, and even by his own later researches. According to him, the gastric juice is precipitated by lime, does not act upon chalk, and contains no chloride of calcium. He also states (or rather implies) that biphosphate of lime is decomposed by incineration, so as to leave a neutral residue. Each of these statements is met by Lassaigne, Huenefeld, Melsens, Dumas, Bernard, and various other authorities, with a direct denial. And in a more recent Memoir, Blondlot himself lays especial stress upon the presence of a large quantity of chloride of calcium, the absence of which salt he had previously insisted on.‡ After these remarks, it is unnecessary to detain the reader by any further consideration of the various other errors—qualitative as well as quantitative—which invalidate the chemistry of this observer. But it is impossible to make these necessary allusions to Blondlot's analyses without passing a tribute to his talent, in devising an operation to which we owe all the brilliant experiments that have lately done so much for the physiology of digestion.

Of the two remaining views, the partisans of each were, until lately, so equal in number, in repute, and in the validity of their arguments, that few physiologists could decide in favour of either: and those who could not suspend their judgment; were probably beginning to believe in both.

On the side of lactic acid was the united testimony of Chevreul, Lassaigne, Thomson, Lehmann, Payen, Bernard, and Frerichs; who had all verified its presence in gastric juice, sometimes when unmixed with food. While against the analyses of Prout §, Dunglison, Braconnot, Tiedemann, and others—in which hydrochloric acid was either lost from the

* This calculation is founded on a method suggested by Schmidt, and quoted by Lehmann (*Op. cit.* Bd. iii. pp. 4, 5, 6.). I have assumed that the condensation of the ferment on solution equals that of albumen; that the chlorides of calcium and ammonium stand about midway between those of potassium and sodium in this respect; and that the hydrochloric acid occupies no bulk at all. On these suppositions, the 26·938 grains of residuum would take the space of 23·617 grains of water; whence 1000 — 23·617 + 26·938 = 1003·3.

† In a person of average weight, the above proportion of $\frac{1}{20}$th of the whole body would correspond to a secretion of about seven pints (nearly one gallon) of gastric juice in an hour.

* The formula of which is $CaO, 2\,HO, P^2\,O^5$.

† *Loc. cit.*

‡ Compare *Op. cit.* pp. 246. 250., and Comptes Rendus, t. xxxiii. p. 118.

§ This allusion to Dr. Prout's analyses may seem to require some explanation; the more so, that they have sometimes been misquoted. He analyzed the gastric juice of rabbits who had been fed shortly before death. The contents of the stomach were filtered, and divided into four parts. The first was evaporated to dryness, and ignited. The second was supersaturated with potash, and similarly treated. The third was exactly saturated with the same alkali of known strength. In the case of the first two portions, the saline ash remaining after ignition was dissolved in water, and tested with nitrate of silver for hydrochloric acid. It was presumed that the first method would give the amount of fixed chlorides present; the second, the total amount of residuum, or found in the distilment, of the gastric juice — they* brought forward the fact, that towards the close of the process of distillation, the fixed lactic acid was capable of displacing the volatile hydrochloric from the salts in which it had been formerly combined; leaving lactates and lactic acid, in a thick acidulous residue of a syrupy consistence. They added, that this late appearance in distillation (as shown by nitrate of silver and peroxide of manganese) proves the absence of the free acid; as does also the precipitate effected in gastric juice by oxalic acid, — a precipitate which would not occur in water containing but $\frac{1}{500}$th of hydrochloric acid.

To this one might have answered, that such a displacement of hydrochloric acid could scarcely have occurred in any of these analyses. Dr. Prout examined in vain for organic acids. And just as he expressly affirms, so others imply, their absence. While Dunglison † and Berzelius found that the residuum contained a large quantity of chlorides. And if it be difficult to suppose the chlorides of the gastric juice sufficient, both for a large distilment of acid, and a still larger residuum of salts, — it is even more difficult to imagine (with Lehmann ‡), that the chloride of calcium alone can yield the former, and yet also appear in the latter.

The absence of the ordinary reactions of hydrochloric acid is, indeed, explained by a theory of Schmidt's, which will be noticed again hereafter, and according to which the acid is in some degree fixed and retained by its chemical combination with the organic principle of the gastric juice. He shows that, if a solution of nitrate of silver be added to this secretion, it throws down a precipitate, which consists of chloride and organic matters; while conversely, it leaves some silver in the clear supernatant fluid. But such a fact scarcely requires the aid of the above theory. The way in which the affinity of even small quantities of organic substances can disturb various chemical processes, offers a well-known analogy to this retarded precipitation. And without some such an action really obtained, the non-precipitation of dissolved albumen by gastric juice would (as Blondlot indeed assumes) disprove the presence of both lactic and hydrochloric acids in this fluid.

The analysis of Enderlin, however, carried the investigation a step further, by distinctly asserting the presence of hydrochloric acid in the residuum of the distillation.* And Bidder and Schmidt's recent experiments seem quite conclusive, both as to the presence of this, and the absence of lactic, acid.† These observers avoid distillation, and treat the fresh gastric juice, previously acidulated by nitric acid, with nitrate of silver; so that the precipitate is free from all organic matters. To the supernatant liquid, they add hydrochloric acid, so as to remove all excess of silver; and then determine its bases by evaporation and ignition. These they find insufficient to neutralize the chlorine of the precipitated chloride. And on saturating a quantity of the same juice with potash, baryta, or lime, they find that the amount required for its neutralization is exactly equivalent to the deficiency observed in the previous analysis.

But this leaves us with two gastric acids, the hydrochloric and the lactic. Hence three questions suggest themselves. — (1.) Are they present together? (2.) Do they substitute or replace each other? Or (3.) is the lactic acid a mere secondary and accidental product?

Even since Bidder and Schmidt's analyses, Lehmann has again answered the first of these questions in the affirmative; having found both acids together in a quantity of gastric juice collected from 14 dogs. The second and third questions cannot at present be replied to. As regards the second, we have no valid proof that the species of the animals examined, their health, or even the nature of their food, ever effects any such qualitative alteration in this secretion. In respect to the third, we may point out, that the variable (and often large) quantity of lactic ‡ acid is precisely what might be expected, supposing it to be a secondary production. And, according to Lehmann, the particular variety of lactic acid seen in the stomach is that produced by the fermentation of sugar, and not that obtained from the fluid of muscle. This fact has induced me to conjecture, that the lactic acid thus observed can scarcely be directly secreted from the blood. But it must remain for future experiments to decide, whether its absence in the later (and apparently exact) analyses of Bidder and Schmidt, was due to the exclusion of saliva, to the fresh state in which the gastric juice was examined, to its careful separation from all food and peptone, or, finally, to the avoidance of the process of distillation. Still, waiting

hydrochloric acid, as well free as combined. The third method would allow of the estimate of the free acid. And this, together, with the fixed hydrochlorates of the first method, subtracted from the total of the second, would leave the quantity combined with the volatile alkali ammonia. He thus found, that rather more than half the chlorine present was combined with hydrogen, in the form of free hydrochloric acid, while, of the remainder, nearly half was united with ammonia, the rest with potassium and sodium. A fourth portion was examined in vain for an organic acid. And other salts, such as sulphates and phosphates, were only found in very small quantity.

* Aided and confirmed by the observations of Blondlot (*Loc. cit.*), Huenefeld (Chemismus in der Thierischen Organization, Leipzig, 1840, p. 207. *et seq.*), and others.

† With the "astonishing quantity" of chloride of silver obtained from the distilled liquid by Dunglison, there ought to have been at least half as much lactic acid in the (apparently uninjured) residuum.

‡ Compare *Op. cit.* vol. i. p. 98. and vol. ii. p. 43.

* Lehmann (vol. i. p. 97.) urges against this observer, that, in a previous analysis, he had failed to find carbonate of soda in the ash of the blood: — an argument which seems somewhat invidious as well as inconclusive.

† Lehmann, *Op. cit.* vol. iii. p. 331.

‡ Compare Lehmann, vol. ii. p. 42.; vol. iii. p. 33.

the results of such a laborious inquiry, there seems little doubt that we ought to regard the balance of evidence as inclining decisively towards a single gastric acid, and that acid the hydrochloric. *

Whatever the number or nature of the substances to which this acid reaction of the gastric juice is due, there can be no doubt as to their source: — namely, the blood. And it is to a derivation of acid from some of the constituents of the latter fluid that we must refer the important fact established by Dr. Bence Jones:— namely, that, during digestion, the healthy urinary secretion loses that acidity which is proper to it at other periods.

Salts. — As regards the salts of the gastric juice, we can only refer to the accurate analyses alluded to above; — which, while they confirm the large quantity of chlorides mentioned by most observers, exhibit rather less of the chloride of ammonium than the united (but rather vague) statements of many observers would have led us to expect.

The details of an analysis of the gastric juice may be best comprehended (if not explained) by placing them side by side, with a similar quantitative examination of the *liquor sanguinis.* The following table† exhibits such a comparison, for a thousand parts of both fluids.

	Liquor Sanguinis.	Gastric Juice.
Water - - -	903·	973·2
Animal matters -	88·5	17·0
Mineral substances -	8·6	9·8
Chlorine - - -	3·6	5·6
Sodium - - -	3·3	1·2
Potassium (in dog, ·2?)	·3	·6
Phosphoric acid -	·2	·6
Phosphate of lime -	·3	1·2
Phosphate of magnesia	·2	·2
(Lime corresponding to ·624 Ca. Cl.) -		·3
	1000·0	1000·0

Hence, while most of the blood-salts are present in increased quantity in the gastric juice, the chloride of sodium is so greatly diminished, as to lower the total saline contents of this secretion below those of the liquor sanguinis. While the amount of its hydrochloric acid is so great, as not only to compensate this loss, but even to raise the total of its mineral constituents above that of the liquor sanguinis than before. The origin of this acid is obvious. Its mere quantity is sufficient to refer it to the chloride of sodium, which is the most plentiful chloride of the parent fluid. And the remarkable diminution in the sodium of the secreted fluid further confirms this view. Indeed, it is difficult to avoid noticing, that many of the differences between the salts of the two fluids might be included in some such hypothesis as the following: — (1.) a rapid transudation of the blood-salts generally, followed by their concentration through absorption of part of their water of solution; (2.) a decomposition of about half of the chlorides, probably of the chloride of sodium*; (3.) a return of the base of this salt into the blood.

Organic substance, or Pepsine. — The addition of alcohol to pure gastric juice, or to a watery infusion of stomach, causes a white flocculent precipitate; which, when dried at a low temperature, forms a much less voluminous mass, of a yellowish grey colour, and a somewhat gummy appearance. This substance reddens litmus, and is soluble in cold water; but may be again precipitated from its aqueous solution by alcohol. Its ultimate analysis yields sulphur and nitrogen, together with carbon, hydrogen, and oxygen. But we neither know the exact proportions in which all these elements are present, nor the manner in which they are combined: — and may even doubt, whether its composition is really quite definite and constant in different specimens.

Two analyses of this precipitate have however been made:—one by A. Vogel †, of the extract of Pig's stomach; and one by Bidder and Schmidt‡ of the pepsine obtained from pure gastric juice. They are as follows: —

	Pepsine.	
	Vogel.	Schmidt.
Carbon - - -	57·72	53·0
Hydrogen - -	5·57	6·7
Nitrogen - -	21·09	17·8
Oxygen (+ other elements, and loss)	16·06	22·5

Of these two analyses, the latter is probably the more correct one. It offers us a composition closely resembling that of the various protein compounds, from which it

* It is only many months after writing the above lines that Bidder and Schmidt's admirable treatise (Die Verdauungssaefte und der Stoffwechsel) has come into my hands. From it I may translate the following paragraph (p. 44): "The result of eighteen corresponding analyses was, that pure gastric juice of carnivora, after eighteen to twenty hours' fasting, contained *free hydrochloric acid only*, without a trace of lactic or any other organic acid: while the gastric juice of herbivora contains, with free hydrochloric acid, small quantities of lactic acid; which may, however, be referred to their more amylaceous food."

† Here I have calculated the composition of the gastric juice from the purer fluid of Schmidt's first dog. That of the liquor sanguinis, which is quoted from Lehmann (vol. ii. p. 153.), may be safely (*Id.* p. 179.) extended to this animal. To facilitate comparison, both are simplified to one place of decimals. And for the same reason, the phosphate of lime in Schmidt's analysis has been assumed to be the biphosphate, and divided into phosphoric acid, and neutral phosphate.

* Such a decomposition would obviously present many analogies to an electrolysis. But, at present, we should hardly be justified in naming it after this process. That the acid and base are unloosed and separated is certain. But I think no one who has carefully studied the phenomena of current affinity would like definitely to refer the above decomposition to this cause in the existing state of our knowledge. We may, however, notice, that both the quantity and quality of the chloride of sodium would render it more susceptible to electrolytic action than any other of the salts present in the liquor sanguinis.

† Simon's Beitraege, Berlin, 1843, p. 168.; Ann. der Pharmacie, 1839, Apr. p. 36.

‡ *Op. cit.* p. 46.

differs chiefly in containing about 2 per cent. more nitrogen.

The addition of a few drops of dilute muriatic acid to a solution of this precipitate in cold water, constitutes a liquid which possesses energetic solvent powers over ordinary animal food. Hence the organic substance itself has been termed *pepsine* (πέψσις, *concoctio*) :—a name to which there can be no objection, so long as its meaning is confined within proper limits; and is not extended to imply a single and definite organic compound, capable of digesting all the alimentary principles.*

The chemical properties of pepsine offer a striking resemblance to those of many albuminous compounds. Its chief differences from these substances seem to consist in the fact, that it is little or not at all precipitated from its watery solution, by some of the salts which would throw down dissolved albumen. But the precise degree of this resemblance has been found to vary greatly in different observations. Nor is this want of uniformity surpizing. For, as Frerichs has pointed out †, the various watery extracts of stomach made use of in such experiments have all been mixtures of gastric juice with a variable quantity of albuminous matters, from which substances the pepsine is but partially set free by the subsequent process of purification. To this fact we may add, that it is not impossible the quantity and quality of the mineral constituents contained in these impurities have also affected the results. Frerichs therefore examined a quantity of the gastric secretion, which had been obtained from fistulæ; and from dogs who had been made to swallow indigestible substances, such as pebbles and peppercorns. In such cases saliva would probably form the only impurity.

The reactions of gastric juice, and probably of pure pepsine, are as follows: it is not precipitated by boiling, by ferro-cyanide of potassium, sulphate of copper, alum, chloride of iron, or mineral acids. It is precipitated, though not completely, by bi-chloride of mercury. Carbonates of the alkalies give a precipitate of its lime salts. And the soluble salts of silver and lead throw down the chlorides of these metals. In all of these instances a portion of the pepsine is carried down with the precipitate. In the case of the lead, the greater part of the pepsine is thus deposited; but almost all of it may be recovered by washing.

Action of the gastric juice. — It is to the repeated and careful experiments on artificial digestion, which were begun by Eberle, and continued by the various observers before alluded to*, that our knowledge of the details of stomach-digestion is chiefly due. This method of inquiry has not only allowed a continuous and close inspection of changes which must have escaped observation in the living body, but has so varied the several conditions of the solvent process, as almost to acquaint us with the share which each takes in the final and united result. In short, these "questionings of nature" have so far been answered, that we may be said to know, not only what substances the stomach digests, but by what means it digests them. Of the nature of this process, however, we are still ignorant; or at most, can only find in its circumstances some analogies, such as may justify and support a few vague conjectures respecting it.

Temperature exercises an important influence on the gastric solvent. At the ordinary temperature of the atmosphere, the action of the gastric juice is scarcely perceptible, even when continued during many hours.† Lower degrees of cold suspend its action still more completely. Heated to the temperature of the body—namely, to about 100° Fahrenheit — it acts very energetically. A further accession of temperature at first increases, but soon injures, and finally for ever destroys, all its digestive powers. The precise point at which this change of effect occurs is not clearly known; but it is probably at or near 120°. The dried pepsine of the artificial digest-

* Here, again, the author thinks it better to subjoin in a foot-note the successive additions to our knowledge that have gradually built up the brief statement of the text,—to which many readers will probably prefer limiting their attention.

As before mentioned, Reaumur, Spallanzani, and Carminati, may be regarded as having collectively determined that the gastric juice is an acid, antiseptic liquid, secreted on the introduction of food, and capable of dissolving certain alimentary substances, even when removed from the body.

The first attempt to analyze the organic matters of the gastric juice was made by Tiedemann and Gmelin (*Loc. cit.*). They announced the presence of mucus; an alcoholic extract or osmazome; and a substance, soluble in water and precipitated by various metallic salts, which they stated to be *Ptyaline.*

Eberle (Physiologie der Verdauung, Wuerzburg, 1834) adopted a more synthetical method of inquiry. He found that the addition of dilute acids to an infusion of the gastric mucous membrane formed an artificial digestive fluid. Schwann (Mueller's Archiv. 1836. pp. 70. *et seq.*, 90. *et seq.*: and Poggendorff's Annalen, Bd. xxxviii. p. 358.) went still further. He found that it was only the glandular part of the stomach which possessed this power. And by previously removing the albumen of a gastric infusion, and neutralizing its acid, he was enabled to precipitate with bichloride of mercury a substance, which, when mixed with very dilute hydrochloric acid, and freed from this metal, formed a powerful digestive agent. He therefore named it *Pepsine.* Wasmann (*Loc. cit.*) adopted a different method. He precipitated a very carefully prepared watery extract of stomach with acetate of lead or bichloride of mercury. After removing the metal and acid, he threw down the pepsine by alcohol, and thus purified it from osmazome, which is soluble in this liquid.

The various observers who have since corroborated Wasmann's statements do not seem to have effected any important improvement in this process. Amongst these we may enumerate Pappenheim (Zur Kenntniss der Verdauung, Breslau, 1839), Valentin (Repertorium, B. i., s. 64.), Elsaesser (Magenerweichung der Saeuglinge, Stuttgart, 1846), Buchheim (De Albumine, Pepsino, et Muco. Lipsiæ, 1845), Vogel (*Op. cit.*), Lehmann (*Loc. cit.*), Scherer, Stannius, and many others.

† *Op. cit.* p. 785.

* In the foot-note to this page.

† Beaumont, *Op. cit.* p. 146.

ive fluid will, however, sustain a temperature of 160° without damage. But at a heat above this, it becomes wholly inactive, and partially insoluble. And Dunglison* found the organic principle of the gastric juice to be insoluble in hot water.

Alcohol, acids, and alkalies, when applied in excess, have also a destructive influence on the digestive power of pepsine.

In the case of acids, this injurious effect is much less marked. As might have been expected from the constant reaction of the gastric juice, an acid is essential to its digestive efficacy;—indeed, we might almost say, to its very existence. Even that incomplete loss of acid, which we have seen to be involved in the precipitation of its pepsine, must be compensated by an artificial acidulation, before the aqueous solution of this substance regains its former digestive powers.

Here, however, as in the case of heat, it is necessary that certain limits should be observed. Wasmann found that an addition of about 3 parts of hydrochloric acid per 1000 formed a tolerably effective fluid:—a quantity which corresponds with about half of that present in the gastric juice according to Bidder and Schmidt's analyses.† But much larger proportions of this acid may be added, not only with impunity, but even with advantage. Thus Schwann used from 6 to 12 parts per 1000. And Elsaesser thinks that the most favourable proportion for digestive purposes is about 3 or 4 per cent. of muriatic acid:—a quantity which would be about five times as great as that present in the gastric juice.

But the nature of the acid seems a matter of indifference.‡ Nitric, phosphoric, sulphuric, acetic, and lactic acid, have all been successfully made use of. And the range of amount already specified for hydrochloric acid might, *à priori*, prepare us for the fact, that the requisite quantities of each of these acids seem solely related to their more or less dilute state; and do not allow us to recognize any trace of an equivalent chemical proportion.

Applied in still larger quantities, all of these acids first weaken, and then destroy, the digestive power of the solution of pepsine. The comparative amount of injury inflicted by equal quantities of the different acids appears to depend, like their solvent efficacy, chiefly on the degree of their concentration, and that of the digestive fluid itself.

How essential its acid is to the solvent powers of a natural or artificial gastric juice, is well shown by the effect of neutralizing it with an alkali. Under these circumstances, not only does it lose all action upon albuminous substances, but if mixed with them, soon shares in the putrefaction which they are liable to undergo. An equally rapid putrefaction occurs in the simple aqueous infusion of stomach. Left to itself, however, the powers of the neutralized gastric juice are only suspended; and can be restored by the addition of a proper quantity of acid. But in the course of time, the neutral fluid gradually becomes mouldy:—a process which appears to differ in its rapidity only from the similar decomposition that occurs in pure gastric juice, apparently after the slow evaporation of its acid.* A still larger quantity of alkali permanently destroys all its solvent powers, and is followed by its rapid putrefaction.

That incomplete loss of acid which was noticed as occurring in the ordinary processes for obtaining pepsine, does not entirely suspend its specific action. On the contrary, its watery solution still retains the power of precipitating large quantities of casein, and even of exerting a feeble digestive or solvent influence.

But while all such observations on the artificial digestive fluid agree in representing an acid as one of its most essential elements, some physiologists have gone further, and have asserted it to be so far the true and only principle of the gastric secretion, as to be capable of imitating its action. And others, who allow that the dilute acid is only rendered efficacious by the presence of the organic matters with which it is combined, have doubted the specific nature of the gastric principle; and have asserted that acidulated saliva or mucus, or an acidulated infusion of bladder, diaphragm, trachea, or intestine, is capable of effecting a solution of the protein compounds like that seen in artificial digestion. Each of these remarkable statements demands a passing notice.

Many dilute acids—such as sulphuric, nitric, acetic, hydrochloric, and phosphoric—can certainly produce appearances resembling imperfect solution, in meat and many of the protein compounds. But such a solvent action, even when most marked—as in the steeping of small pieces of coagulated albumen in dilute hydrochloric or phosphoric acid—differs greatly, both in nature and amount, from the true stomach digestion. It requires the aid of a much higher temperature; it is excessively slow, superficial, and imperfect; and the resulting weak and turbid solution often parts with its dissolved constituents on the addition of the ordinary reagents.

The same statement will apply to various experiments that have been made with an acidulated infusion of large or small intestine; in which the process of solution, though somewhat † more energetic, is still so feeble, slow, and imperfect‡, as to be scarcely comparable with that effected by the gastric juice. While we ought not to forget, that the superior

‡ In any future observations of this kind it would be very desirable to institute a strict comparison between the reactions of the resulting solution, and those of true peptone or albuminose.

efficacy of such infusions, and especially that of the duodenal membrane, is at least partially explained by the way in which the gastric juice is necessarily diffused, with the food, over the surface of the intestinal canal.

The effect of the neutral salts on artificial digestion has scarcely been investigated with all the attention it merits. But it appears not improbable that many of these inorganic substances assist solution, when present in small quantities, but oppose it when added in excess. This is especially the case with chloride of sodium, the ordinary condiment of mankind and of many animals. The effect of this salt in facilitating the digestion of albumen, fibrine, and casein, has been verified by Lehmann for the proportion of $1\frac{1}{2}$ per cent.

The effect of alcohol is also regulated by its amount and concentration. Diluted, it seems to have no chemical action whatever. In larger quantities, as before remarked, it precipitates pepsine. And in still greater excess, it permanently destroys all its digestive energy.

The way in which the process of gastric solution, whatever be its nature, is assisted by the minute division of the substances submitted to it, as well as by the movements of the stomach, is too obvious to require any special mention. It only remains to add that, according to Purkinje and Pappenheim, an increase in the amount of the atmospheric pressure furthers the artificial solution of albuminous substances. These observers therefore regard natural digestion as somewhat aided by the pressure of the gastric and abdominal parietes.

The quantitative relations between this organic principle and the proteinous substances which it dissolves, form a very important subject for inquiry. An exact determination of the quantity of pepsine which these substances require for their solution, would greatly assist us in solving many problems with respect to the chemistry of digestion. Or conversely, a knowledge of the exact numerical details of nutrition, and of the daily gastric secretion, would enable us to calculate the proportionate quantity of pepsine periodically required and used. But it is obvious that such calculations can only confirm direct observations; that they multiply all the known errors of their elements, and neglect their unknown ones. And the estimates derived from actual experiment are very conflicting: — if, indeed, they can be considered really comparable. Thus that precipitation of casein, which is effected by the watery extract of stomach, is producible, according to Mitscherlich*, by a quantity of pepsine amounting to $\frac{1}{500000}$th of the milk made use of: while Schwann states $\frac{1}{2000}$th to be required. Wasmann found that dilution of the pepsine to $\frac{1}{60000}$th did not destroy its power of dissolving coagulated albumen. Frerichs† and Schwann give estimates, which (allowing for the impurity of the extract of stomach) may probably be regarded as an assertion,—that one part of pepsine will dissolve 500 of meat, or moist and finely divided albumen. With these statements may be contrasted those made by Beaumont, Blondlot, Lehmann, and Schmidt. In describing his observations conducted with gastric juice, Beaumont* implies that this secretion cannot take up more than 50 per cent. of roast meat. From what he says, however, as well as from some observations by Blondlot†, it seems very doubtful whether even this can be regarded as a perfect solution. And Lehmann would fix its solvent properties at about 25 per cent. for moist albumen. While the average and maximum power of Bidder and Schmidt's pure gastric juice is stated by them at what would be about 10 and 20 per cent. respectively for the same substance. Reducing gastric juice to pepsine in accordance with their analysis, it would seem that one part of the organic principle cannot dissolve more than 12 of albumen. And even Beaumont's highest estimate would but raise these 12 parts of albumen to 30 of the more digestible meat:— a quantity which is still small enough to form a striking contrast with the larger proportion deducible from the statements of Frerichs. But it is scarcely necessary to observe, that the state of the substances used, the dilution of the fluid, and the amount of acid, will always exercise a great influence on the results; and may at least partially account for these great discrepancies.

As already implied, the gastric juice is capable of dissolving, not only albumen, but the protein-compounds generally, including in this term the various substances known by the names of fibrin, casein, globulin, vitellin, hœmatin, &c. To these we may add gelatin, chondrin, and gluten. In the case of all these, however, their physical condition seems greatly to regulate the rate of the process: density and bulk rendering it very slow; while, conversely, it is accelerated by minute division. Nor is it impossible that the quantities of the solvent required vary with the nature and aggregation of the particular substance. But in any case the ultimate effect is the same—the production of a complete solution.

The application of the term "chyme," by the older authors, to the food which had undergone stomach-digestion, sufficiently indicates that the mass possesses a comparatively uniform physical appearance. And even when further observation pointed out, that the chyme was liable to considerable variations in colour and consistence, the above opinions as to its uniformity required but a partial modification. For physiologists then began to be aware, that the gastric change was not so much a stage in the digestion of the whole of the food, as the solution of a certain class of its

* Bericht, &c. der Akademie der Wissenschaften zu Berlin, 1842, p. 147. *et seq.*

† *Op. cit.* p. 794.

* *Op. cit.* p. 133.

† *Op. cit.* p. 264.

constituents. It was reserved for Mialhe* to show, that the homogeneous physical constitution, which the whole contents of the stomach were erroneously supposed to assume at the end of its digestive act, is true in a much more important chemical sense, if limited to certain portions of the food. He found that the gastric digestion of the various protein compounds affords a solution which, whatever the nature of the substance originally dissolved, possesses the same physical and chemical properties:—these properties being due to its containing a substance which, from its relations to albumen, he called *albuminose*. Lehmann †, who has confirmed and extended Mialhe's researches, proposes for this substance the better name of *peptone*. ‡

Peptone.—According to these observers, the following properties are common to all kinds of peptone, from whatever substances they may have been derived. Reduced to the solid form by careful evaporation, peptone is a white or yellowish-white substance; almost tasteless and inodorous; very soluble in water; but insoluble in alcohol of 83 per cent. Its watery solution reddens litmus; and is precipitated by chlorine, tannic acid, and metallic salts; but is unaffected by boiling, by acids, or by alkalies. With alkalies and bases it forms very soluble neutral compounds or salts. An aqueous solution of these is still less precipitable by reagents than one of peptone itself. Thus it is thrown down only by tannic acid, bichloride of mercury, and a mixture of the acetates of ammonia and lead:—the acetate of lead, and the ferrocyanide of potassium causing but a faint cloudiness; and even concentrated acids, nitrate of silver, and alum, having no effect.

The ultimate chemical composition of any particular peptone so closely resembles that of the substance from which it is formed as scarcely to require any further remark.

In speaking of these chemical phenomena of stomach-digestion, there remains but to notice, that the addition of water, or a small quantity of fresh acid, is capable of restoring some of its original digestive powers to saturated gastric juice, or a solution of peptone. The degree in which this renovation can be effected is obviously a question of great importance. But at present there are no exact observations on which to found any conjectures respecting it. It seems, however, sufficient to explain the discrepancy previously alluded to § between the quantity of hydrochloric acid which is present in the normal gastric juice, and that which is required to be added in preparing an artificial digestive fluid of maximum solvent power.

The foregoing brief summary of the chief physical and chemical properties of the gastric juice, naturally leads us to the important question—What is the nature of its action?

1. It is obvious that the phenomena of gastric digestion do not constitute a simple process of solution by a dilute acid. For the organic principle is essential. The substances are not merely dissolved, but exhibit altered reactions. And, finally, they are not restored to their original form by the neutralization of the acid.

2. Some have supposed that the organic principle exercises a contactive influence, like that of spongy platinum in the acetification of alcohol.

3. Others have imagined that it produces a fermentation, like that excited by yeast in a solution of sugar.

But we have seen that gastric juice will not dissolve more than a certain quantity of protein-compounds. While, in both of the above processes, a small quantity of the contactive or fermenting substance excites an action, which continues until the whole mass has been oxidized or fermented, as the case may be. This objection appears fatal to both these theories. And as regards the latter of them, we may further point out, that, unlike the particles of yeast, which are themselves undergoing metamorphosis, those of the digestive fluid are singularly stable, and enjoy a singular immunity from the putrefactive process.

4. Schmidt * has propounded a fourth theory, according to which the organic principle, and the acid, of the gastric juice are united to each other in the form of a complex acid, which he calls the *hydrochloro-pepsic*. This is decomposed by heat into pepsine and hydrochloric acid. In the stomach it unites with protein-compounds as bases, to form soluble combinations. When treated with an alkali its pepsine is precipitated. And even when saturated with a protein-compound the power of the gastric juice is restored by fresh acid; because the latter, by uniting with the base, sets free the hydrochloro-pepsic acid, and thus enables it to combine with another portion of proteinous substance.

But in respect to the two latter statements, it would appear that an alkali precipitates from the gastric juice but a very small part of its pepsine; and that even this portion is in combination with calcareous salts. While the reactions of peptone show that the original pepsine is neither present as such, nor is capable of being set free from its state of combination by the addition of an acid.

And other facts, which seem to speak strongly in favour of this view, will as little bear a close investigation. Such are the close union of the acid to the organic principle; the definite amount of acid required for artificial digestion; and the similarly definite amount of proteinous

* Journal de Pharmacie, t. x., pp. 161. *et seq.*

† *Op. cit.* vol. ii. p. 50.

‡ Both names being comparatively recent, there can be little objection to the adoption of the preferable one. And "*peptone*" not only connotes its relation to digestion, but avoids the disadvantage of "*albuminose*":—viz., that of giving an undue prominence to the connection of albumen with the gastric function.

§ See p. 334.

* *Loc. cit.*

substances which the gastric juice will dissolve. For the more abundant of the salts contained in the gastric juice appear to be almost as closely united to its pepsine as is the acid itself. The supposed complex acid has never been isolated; still less has its combination with the supposed base. The latter, again, does not saturate the acid, and has never yet been replaced by other bases. In like manner, the tolerably fixed proportions of acid and of protein cannot be reduced to definite equivalents. And, finally, while the restorative action of fresh acid cannot be fully explained, the equally marked effect produced by pure water is still more mysterious.

We are thus gradually led to the conclusion, that neither of these four theories — solution, combination, contactive excitement, or transferred metamorphosis — will afford an adequate explanation of that process of stomach-digestion, from the observed phenomena of which they all so widely differ. It is indeed scarcely to be wondered at that we are unable to form a satisfactory theory. For it is probable we are still ignorant of many processes of organic chemistry. While it is possible that the action of the gastric juice is quite *sui generis*. And hence any view which unites most of the circumstances of the case, will be certainly as useful, and probably as true, as one which, like each of the preceding, assumes an undue parallel for the sake of a full explanation.

If we must connect the above details by some theory, we may first remark, that the gastric juice dissolves protein-compounds; that it renders them highly soluble; and that it assimilates their form and reactions to its own, without changing their composition. For any parallel to such a process we can only look to those lower degrees of chemical action, where solution and combination, adhesion and affinity, may be supposed to meet and merge into each other; where proportions are tolerably definite, but true equivalents indistinct; and where, though form is changed and reactions modified, elementary composition remains little affected. Actions of such a kind may be found in the union of many substances with water, or its elements, to form the compounds called hydrates. And the conversion of protein into peptone, by the gastric juice, presents so many analogies to the formation of a hydrate*, that it seems not impossible the chief office of this secretion may be, that of enabling water to combine with the various members of the albuminous groups of alimentary substances, in order to their acquiring that solubility, and uniformity of constitution, which must probably precede their admission into the current of the blood. To this vague indication of a theory, I will only add, that the mode in which a definite quantity of the organic principle takes part in such a process cannot even be conjectured. Its action certainly appears no way comparable to the effect of diastase on starch, or of emulsine on amygdaline. It seems to be an assimilation, in the strictest chemical sense. It is not impossible that the acid commences the process by a slight, though genuine, solution of the more resisting substances. And at any rate, this constituent seems to have the power of checking putrefaction, if not of arresting all metamorphosis, in the other ingredients of the secretion:—like the small quantity of oil of vitriol which is added by the chemist to hydrocyanic acid with the same object.

Process of secretion.—The process by which the gastric juice is secreted from the mucous membrane of the stomach, forms one of the most interesting problems in physiological science; and one which, if satisfactorily explained, would probably throw much light on the morphology of secretion generally.

Ever since the discovery of the stomach-tubes by Dr. Sprott Boyd, it has been generally assumed that the secretion of the gastric juice is mainly effected by a discharge of their glandular contents. The precise mode of this expulsion seems usually to have been left undecided: though it has been implied that the pressure of the muscular contractions of the organ upon the more or less solid food would almost compel an evacuation of the tubes. And more recently, Frerichs has asserted that the act of secretion is really aided by such an expulsion; and that the food becomes enveloped in a layer of the large gastric cells, the discharge of which from the stomach-tubes leaves them collapsed and empty.

To all of these statements the author ventures to offer a deliberate contradiction. In researches upon this organ which have extended over some years, he has never seen these gastric cells free from the tubes except when there was good reason to attribute their expulsion to mechanical violence. They are never present in large quantities. In the majority of examinations they are almost absent. With the proper use of the precautions previously alluded to, they will rarely or never be found. In addition to this, it may be added, that the arrangement seen in the Dog—where the stomach-tubes are lined by a continuous tube of epithelium, which is prolonged into the layer of columnar cells that occupies their intervening ridges—renders it almost impossible that these cells should be shed in their original form.

Another part of this statement has already been contradicted. During every stage of gastric digestion, the tubes may be seen with precisely the same form, size, arrangement, and contents, which they exhibit during the fasting state. This remark even applies to that narrow calibre of epithelium, which is seen within the axis of the proper gastric tube in the Dog. And hence, ignorant as we are of the exact mechanical arrangement of the fibre-cells at the bottoms of the tubes, still the excessive delicacy of these secreting organs, taken in conjunction with this uniformity of appearance, renders it highly improbable that they are evacuated by any extraneous pressure.

* Compare Dr. Prout's treatise "On Stomach and Renal Diseases," 5th edition, p. 470. *et passim.*

The anatomy of the fresh stomach also suggests other conjectures, which confirm the conclusion which we have deduced from the above sources. We have already noticed that, in the Dog, the columnar epithelium forms but a single row, and that it covers all the ridges during the digestive act. Hence the columnar cells can scarcely be stripped off in successive layers at this time. While the close attachment of each of these cells to those around it, together with their uniform appearance *in situ*, renders it alike improbable, either that a cell is extruded singly and then bursts, or that each, as it fills, ruptures and collapses. All those within a tolerably wide circuit of membrane seem absolutely similar and coeval.

In some cases, however, the gastric juice does contain columnar epithelia mingled with the food. In the Dog, this appearance is unusual, and the number of such shed cells is small. In the Rabbit, their separation is more frequent and extensive. While in the Pig, it often forms a more or less continuous layer, which is almost moulded to the ridges of the stomach and the mouths of its tubes*, and leaves the mucous membrane below denuded of this its proper covering. But it remains for future researches to show, whether this appearance is due to mechanical violence; to commencing putrefaction; or to the disturbances implied in the muscular contraction, the exsudation, and the other incidents of the act of death.

And whatever the interest attaching to such a dehiscence of these columnar cells, it can scarcely have any but a very indirect relation to the healthy secretory process that obtains in the living man or dog, in whom the pure gastric juice is completely structureless. This fact, announced by Beaumont, at a period when microscopy was much less understood than at present, has since been repeatedly confirmed in observations on gastric fistulæ which have been instituted by Blondlot, Bidder, Schmidt, Huebennet, and myself. And if great care be taken not to disturb the surface of the mucous membrane, we may often verify it in the fresh stomachs of dogs which have been killed immediately after feeding.

Here again we may refer to Dr. Beaumont's numerous observations.† He made use of magnifying glasses, by the aid of which he could distinguish the spheroidal glandular follicles, and the papillæ situated in their interstices. These papillæ, or *villi*, he found to be scarcely visible until food was applied to the mucous membrane; when they underwent a kind of erection, and protruded from its surface in the shape of small sharp processes. From these, according to this faithful observer, the gastric juice appears to exsude. Its secretion begins by the gradual appearance of innumerable lucid specks, which are smaller than the mucous follicles. These specks or points rise through the transparent mucous coat: and seeming to burst, discharge themselves upon the very points of these vascular papillæ, as a thin, transparent, colourless, limpid, acid fluid; which collects in small drops, and spreads over the whole gastric surface.

So thoroughly persuaded was Dr. Beaumont that the fluid exsuded from the papillæ alone, that he had not the least doubt the excretory ducts of the follicles were enclosed in these villi, and terminated in the lucid specks just alluded to; although he admits that he could not see any apertures here.

Comparing this description with what we now know respecting the anatomy of the mucous membrane, it is difficult to avoid coming to the conclusion, that the large and numerous capillaries beneath its ridges are in some way intimately connected with the secretion of the gastric juice. And whether this conjecture be right or wrong, the characters of this secretion corroborate the conclusion already deduced from the anatomy of the dead stomach: — viz. that the gastric juice is not composed of a shed epithelium. In like manner, the rapidity with which it exsudes seems to contradict any theory of even the most rapid solution of columnar* cells. And since anatomy shows that, until the end of gastric digestion, these cells, if dissolved, are immediately replaced by others, it follows, that to assume such a process of dehiscence would imply a rapidity of growth and organization, such as has never yet been verified in the higher Vertebrate animals.

The latter quantitative objection may be better carried out in detail. In Schmidt's experiments, a dog secreted $\frac{1}{20}$th of its weight of comparatively pure gastric juice in one hour. Transferring such an estimate to an average man of 140lbs. weight, it would follow that the human stomach, the whole mucous membrane of which scarcely weighs 4oz., can completely reconstruct its entire cell growth, — which is, at most, only half of this weight, — about sixty times in a single hour!

As regards the source of the acid, the above statement by Dr. Beaumont is supported by an interesting obervation of Bernard†; who finds that it is only the surface of the mucous membrane which exhibits an acid reaction, either in the digesting or fasting state. This statement I can confirm: al-

* Compare Koelliker, p. 150.

† *Op. cit.* pp. 95, 96, 128. *et passim.*

* When freed from their attachment, these columnar cells often undergo what seems to be a rapid solution in the surrounding fluid under the microscope. The first stage of this exhibits them as very delicate husks, which appear to have emptied themselves after losing the lid of cell-wall at their larger extremities. Their sides now often collapse: and increasing transparency soon renders them invisible. This process occurs so quickly as to resemble a digestive solution. But it is difficult to determine how far it is effected by the contents of the cell itself, apart from the surrounding fluid. A layer of mucus generally occupies the neighbourhood of any cut surface of gastric mucous membrane, and appears also to consist of the dissolved contents of cells.

† Gazette Médicale, Mars 16. 1844.

though I have sometimes found below the surface a faint acidity, such as might have been due to a mere admixture or imbibition of the fluids above.

But supposing Dr. Beaumont's conclusion true — that the gastric juice exsudes chiefly from the papillary ridges that intervene between the tubes — what office shall we assign to these latter structures themselves?

The occurrence of these tubes is the rule throughout the Vertebrate classes. And not only are the large cells which form their contents equally constant, but Goll and Koelliker's* researches have shown that it is in these cells,—or at least in that part of the stomach which contains them,—that the digestive power chiefly, if not essentially, resides. Any indirect or collateral action seems insufficient to explain such a close mutual association of structure and function :—an association which not only ranges a great part of organized nature, but repeats itself in the organ of the individual. Hence, whatever the office of these cells, it is probably concerned with the elaboration of at least one important constituent of the gastric juice. It would seem that this constituent is not the acid. Shall we therefore conjecture it to be the organic principle?

This conjecture, which rests on foundations so slight that the author feels he has no right to propound it, except in the interrogative form in which it presents itself to his own mind, is perhaps more compatible with the facts at present known than any other that he can indicate.

It is, however, possible, that the observation of Dr. Beaumont just cited was based on some optical illusion : — that, for instance, the lucid specks which he saw on the villi only, had in reality extended up these processes from dark and depressed openings of the tubes. But even supposing this to have been the case, the superficial acidity of the stomach may be regarded as showing, that the preparation of its secretion is only completed by the cell-growth which lines the lower part of the tubes.

At any rate, it seems certain that the gastric juice is not composed of the dehiscent nucleated cells of the mucous membrane of the stomach. This fact appears so well established, that we ought not to shrink from receiving it, however it may impugn what is ordinarily understood as the cell-theory. In respect to the latter doctrine, the author can only mention another view, which, though novel and plausible, he has long felt obliged to give up.

After verifying the obscure cytoblasts which fill the large oval gastric cells, and the more distinct ones which line the axis of the stomach tube†, as well as the gradual transition of these into the ordinary columnar epithelia covering the ridges,—it occurred to him that this structure, together with Bernard's and Beaumont's observations, were all susceptible of a single explanation. According to such a view, it might be supposed that the mother-cell gradually enlarged, ruptured, and discharged its contained cytoblasts. These arranged themselves in the axis of the tube; and urged by a gradual pressure, or by the growth of new cytoblasts below them, passed up the follicle to where the mother-cells ceased. There they became attached to the wall of the tube itself, and acquired a columnar form by a gradual distention of their interior;—a distention, which increased as they approached the summit of the ridge, where they were finally extruded, or burst. Thus the cell which was constructed below, was filled above :—a subdivision of the secretory process, which might be supposed to depend upon the solvent powers of the secretion being injurious, either to the production of blastema, or to the multiplication of cells. Such a view seemed more or less to account for the structure of the mother-cell; for the gradual transition of the cytoblast into a columnar cell; for the superficial acidity, and for the vascular arrangements, of the mucous membrane. It also appeared to be confirmed by the tendency of the columnar epithelia to cohere strongly with each other, and adhere slightly to the subjacent basement membrane. But the uniform anatomy of the ridges, and the completely structureless character of the gastric juice, were insurmountable objections, which ultimately led to the complete abandonment of this theory.

And as regards the whole theory of secretion by cells, surely it is high time to modify it so that it might involve, not a less immediate action, but a somewhat less extravagant expenditure, of these minute organs. For the improbability which we have shown to be implied in the application of this theory to the stomach, holds good in a far higher, not to say a very different sense, of many other secreting structures. Indeed in some of these, it is obvious, that their situation would involve an enormous waste of life and matter, supposing the bulk of their organic products to be really enclosed in deciduous or dehiscent cells. Amongst such we may specify the kidney, the most important duties of which are supposed to be executed by secretion into a cell-growth, from a venous surface — a cell-growth of which we may doubt whether it even undergoes a rapid solution, while we can definitely predicate that it is not discharged entire, in any quantity at all commensurate with the large amount of solid constituents which is removed from the body in the urine.

Small intestine.— The next portion of the alimentary canal is that which is included between the pyloric and ilio-cæcal valves, and is named, from its diameter, the *small intestine*

* *Op. cit.* Bd. ii. p. 146.

† It is interesting to notice the close structural analogy offered by these small axial cells to those which line the buccal and duodenal glands. The more so that the latter appear to secrete a fluid which possesses the capacity of effecting a rapid and important metamorphosis in another class of organic substances. (See p. 362.)

(Lat. *Intestinum tenue*, Fr *Intestin grêle*, Germ. *Duenndarm*).

The shape of all this portion is cylindrical. Its average length is about 20 feet; its diameter about 1¼ inches.* But apart from those varieties in its dimensions which it presents in different individuals, the yielding nature of the tube allows it to be narrowed by artificial extension. While, *vice versâ*, it is just as easily shortened by dilatation. And it is very difficult accurately to estimate those minor degrees of distention to which it is liable. Hence little stress can be laid upon the statement of Cruveilhier, that the small intestine tapers away from the duodenum to near its extremity, where it suddenly dilates to enter the large intestine.

The small intestine occupies the cavity of the belly. Its commencement, at the pyloric extremity of the stomach, is placed in the right hypochondrium; its termination, in the cæcum that begins the large intestine, occupies the right iliac fossa, to which this part of the intestinal canal is fixed. The few inches of bowel immediately above this extremity frequently occupy the pelvic cavity. But almost all the intervening portion is so free to move, that each particular point of its length may be found in any part of the abdomen or pelvis.

* Trustworthy observations on this point are still to be desired. Meckel states that the length of the whole intestine is from three to ten times the stature. And most authors have been content to follow him in estimating its average proportion as six times the height of the body. As I presume such a comparison of the two measurements was never intended to be more than an aid to the memory of the Anthropotomist, I need scarcely point out its inherent improbability, as well as the difficulty of establishing a close ratio between a multiple assumed to be so high, and a multiplicand known to be so variable. Besides, differences in the dimensions of the canal are not easily established, unless their amount is very considerable. For the facility with which, in such a tube, length is convertible into width, forms one palpable source of error, which can only be obviated by a very careful comparison of both the above measurements. The effect of a more or less complete removal of the mesentery is almost as obvious; and perhaps entitles us to suspect that all such estimates of the length of the separated bowel represent it as somewhat greater than it would be *in situ*. And we are still more unable to determine that alteration of both dimensions which the simultaneous dilatation or contraction of its two muscular strata would necessarily effect. While it is only after we have either obviated, or allowed for, all the preceding causes of inaccuracy, that we can come to any valid conclusion respecting those differences which doubtless obtain in different individuals.

The statement I have ventured upon in the text is based upon a number of measurements made by myself. In making these, the healthy intestine was laid upon a board, and spread out to what seemed a proper width, before taking its length. Their number (less than forty) is too small to justify us in regarding their average as a very valid one. They afford no information as to the effect of age or obesity. But they give what is probably a more accurate estimate than that ordinarily adopted by authors. And they agree with an average given by Cruveilhier, as well as with four cases, in which it seems not unlikely that he adopted precautions similar to those just alluded to.

The duodenum.—That upper part of the small intestine which is directly continuous with the stomach, is distinguished, both from this organ, and from the lower part, by certain peculiarities. And though these chiefly affect its external anatomy, still we shall hereafter find that they are not unaccompanied by differences in the structure of its mucous membrane. Starting from the constriction before alluded to, as marking the site of the pyloric valve, the intestinal tube forms a curve in the shape of a horse-shoe around the head of the pancreas;

Fig. 254.

Shape and arrangement of the duodenum. (The stomach and liver are raised to show the pancreas.)

st, stomach; *p*, its pyloric valve; *l*, liver; *g*, gall-bladder; *d*, duodenum; 1, 2, 3, its first, second, and third portions; *pa*, pancreas; *h*, head of the pancreas, which is received into the concavity of the duodenum; *sp*, spleen; *a*, aorta, behind the inferior transverse portion of the duodenum; *sm*, the superior mesenteric artery, in front of it.

receives the duct of this gland, as well as that of the liver; and is closely fixed by peritoneum to the posterior wall of the belly. This fixed commencement of the small intestine has been named the *duodenum*, in consequence of its length being estimated at twelve finger-breadths (δωδεκαδάκτυλον, *zwoelffingerdarm*). It has also been called the *ventriculus succenturiatus*, or supplementary stomach;—a vague term, which was probably based upon an inaccurate notion of its office.

Beginning at the pyloric constriction, the duodenum proceeds outwards, backwards, and a little upwards, to the under surface of the right lobe of the liver. It then turns downwards, and a little inwards, in front of the right kidney; so as often to impress a shallow fossa on the hepatic surface in front of that depression which corresponds to this organ. After a short perpendicular course, it finally makes a second bend, by which it regains a horizontal direction, and passes from right to left, and a little upward, in front of the vena cava, the aorta, the right crus of the diaphragm, and the vertebral column. It terminates opposite the left side of the body of the second lumbar vertebra, at a point which corresponds to the commencement of the mesentery. Here the intestine becomes free, and is named the *jejunum*.

The length of all this curve, when unfolded, is about ten inches. But for the sake of greater exactness, the three chief portions of the duodenum may be described separately.

The *first portion* is called the *superior transverse* or *hepatic*. It is much the shorter of the three, being scarcely two inches in length. It lies solely in the right hypochondrium; and, near the neck of the gall-bladder, terminates by bending downwards to merge into the second portion. Like the stomach, it is invested by peritoneum on both surfaces. This membrane is derived from the gastric omenta previously described; the extreme right of the gastro-hepatic omentum being sometimes called the *ligamentum hepatico-duodenale.* The latter fold of serous membrane also forms the anterior boundary of the foramen of Winslow, or opening by which the general sac of the serous membrane communicates with the bag of the omentum; and it contains the hepatic duct and vessels.

The above relations of this first portion of the duodenum to the peritoneum confer upon it a mobility which approaches that of the stomach; while its close proximity to the gall-bladder explains that discoloration by bile which is generally seen in the dead intestine,—as well as the adhesion and ulceration of its parietes, which so frequently occur in the course of disease of the liver or gall-bladder.

The *second*, the *descending* or *vertical portion*, which is rather less than three inches long, passes downwards, and slightly inwards, to the right side of the third lumbar vertebra. Above it is the right lobe of the liver. In front it is crossed by the right extremity of the transverse colon. Behind it is the inner border of the right kidney, together with a variable extent of its anterior surface, and its emulgent vein. On its right side is the termination of the ascending colon. On its left it is intimately connected with the head of the pancreas. Every one of these anatomical relations has more or less pathological importance.

The partial covering of peritoneum received by this portion of the duodenum may be traced, from the front of the great omentum, to the anterior surface of the intestine; and around its external or right side, to the wall of the abdomen. Here it is fixed to the right kidney, by an attachment that is sometimes termed the *ligamentum duodeni renale.* The posterior and left surfaces of the intestine, which are devoid of this serous membrane, are connected with the neighbouring organs by a loose areolar tissue, that concedes to the tube a considerable degree of distention and movement.

The *third or inferior transverse portion* is about five inches in length. In its course across the spine it lies upon the structures already named. Above it is the lower border of the pancreas. In front of it is the posterior or attached border of the transverse meso-colon,—the superior lamina of which covers it above, the inferior below, so as to leave an uncovered space along the line of their bifurcation. Anteriorly to this double process of peritoneum, is the large and moveable transverse colon which it serves to attach. And close to the commencement of the mesentery the end of the duodenum is crossed by the superior mesenteric artery and nerves.

Owing to this very partial covering of serous membrane, the inferior transverse portion of the duodenum is even less mobile and dilatable than either of the preceding. And, from the position of the pancreas above the intestine, distention of the latter chiefly affects its inferior surface, which may thus be rendered so convex and bulging as to cover the aorta to within a very short distance of its bifurcation.

Hence the duodenum becomes most fixed in the second and third divisions of its course. Its fixation and curvature may together assist in delaying the passage of its contents, and in facilitating that admixture of the biliary and pancreatic secretions to which its attachment perhaps chiefly refers. Its use as a means of fixing the stomach has already been sufficiently alluded to. Its comparative immunity from hernia is explained by its site.

The *jejunum* and *ileum.*—Below the duodenum, the small intestine is loosely attached to the posterior wall of the belly by means of a double lamina of peritoneum which is called the mesentery (*μέσος middle, ἔντερον intestine.*) Behind, this fold is fixed to the cellular tissue that covers the aorta and vena cava, by a line of attachment which is not quite vertical, but descends from the end of the duodenum to the commencement of the cæcum, passing very obliquely across the spine from the left to the right side of the lumbar vertebræ. In front, its two laminæ split to enclose the bowel, around which they become continuous with each other. Its antero-posterior depth between these spinal and intestinal borders is about three or four inches; but tapers away suddenly at its commencement and termination. We may, perhaps, gain a better idea of the peculiar shape of this process of peritoneum by imagining it as a very obtuse triangle of some flexible material. Such a triangle we may suppose fixed to the spine by a truncated apex of three inches in length. While its broad base, which is about twenty feet long, is attached to the intestine, where it is plaited so as to occupy the least possible space.

It is the extreme freedom of movement which such a mode of attachment concedes to the small intestine, that gives rise to the convoluted appearance so characteristic of this part of the tube. The exact figure of these convolutions is probably never quite alike at any two different times in the same individual,—being the conjoined result of the muscular movements of the canal, the nature and amount of its contents, the size of the neighbouring viscera, and the state of the abdominal parietes. The effect of dilatation resembles that seen in some other parts of the alimentary canal:—namely, distention of the tube always causes it to split up the loosely connected laminæ of peritoneum, and extend backwards between them, so as to shorten the length of its tether of mesentery.

The terms *jejunum* and *ileum* refer to a division of the small intestine which, though to some extent an arbitrary one, is not only too convenient to be altogether dispensed with, but is also connected with certain peculiarities in the structure of the mucous membrane, that will be hereafter alluded to. The jejunum includes the upper two-fifths, and the ileum the lower three-fifths, of the small intestine.*

Muscular coat.—The muscular coat of the small intestine consists of the fibre-cells previously described, the bundles of which are arranged in two layers,—an outer or longitudinal, and an inner or circular. The first constitutes a very delicate lamina, which is often scarcely visible at the mesenteric border of the tube, but is thickened at the opposite margin, where it is firmly united to the peritoneum. The circular fibres form a much stronger and more perfect stratum; and many of their bundles, like those of the same layer in the stomach, seem to take a slightly oblique direction; so as to join with others above and below them. Both layers (and especially the transverse) are somewhat stronger at their commencement in the duodenum. But from the middle of the jejunum their thickness remains unaltered throughout the rest of the small intestine.

Movements of the intestine.—The muscular actions of the intestine have long been reduced to two:—a normal *peristalsis*, which urges the contents forwards towards the anus; and an abnormal *antiperistalsis*, by which they are propelled backwards towards the stomach. But each of these movements has rather been maintained as a doctrine, than verified as a fact.

From the mere tenuity of the muscular coat of the small intestine, we might infer that its movements are much less vigorous than those of the stomach and œsophagus, in which this tunic has a thickness from two to six times as great. Indeed, an active and continuous peristalsis, like that which may be seen in these segments of the canal, would scarce allow the time necessary for the digestive act. Even a slow progressive contraction of two inches per minute would traverse the whole length of the intestine in from two to three hours:—a speed which we have every reason to believe very unusual in the healthy subject.

To obtain direct evidence respecting these movements, various methods have been resorted to.

In the healthy living intestine, it is but very rarely that any definite muscular action can be seen or felt through the wall of the belly. In some of the Polyps, however, the alimentary canal appears to exhibit a peristaltic, but intermittent, movement. And in Man, the *borborygmi* which sometimes occur in conditions but little removed from those of health, constitute sufficient evidence of a valid intestinal movement. While in cases in which abnormal obstruction of the intestine has been followed by an accumulation of fluid in the segment above the occluded part, the wall of the belly often becomes so extremely distended and thinned, as to allow us to recognise a progressive rolling contraction of the dilated bowel. Such observations at least prove that its muscular coat is capable of very vigorous contraction, while in this state of undue distention.

When the intestines of a healthy living animal are exposed by vivisections, surgical operations, or accidental injuries, they are found at rest. Hence, could we implicitly trust these appearances, we should assign but a very slight mechanical value to the intestinal contractions. But such an estimate would obviously be at variance with that propulsion of their contents which we know them* to effect. And, apart from this implied contradiction, it is evident that such observations can never be regarded as affording us trustworthy evidence of what really obtains in the healthy uninjured animal. For not only is it possible that the slow and feeble contractions of the intestine are much interfered with by the pain and disturbance which such operations or accidents presuppose, but I would add, that there are considerable grounds for suspecting that irritation of the peritoneal tunic of the bowel can produce relaxation of its subjacent muscular coat.†

Until lately, it has been usual to augur the movements which occur during life, from an inspection of the intestines of healthy animals immediately after their death. On laying open the abdomen of a newly-killed animal, its intestines are seen lying perfectly still. But in a short time, those parts of them which are exposed to the air begin to experience vigorous contractile movements. In many instances, these contractions are irregular and undefinable, and are hence rather "vermicular" than "peristaltic." But in other cases, they take on appearances of a forward or backward course, or sometimes of each of these directions alternately. Where transverse constriction is marked, it almost always takes a direction downwards, or towards the anus; and is preceded by a dilatation which stretches the intestine to the full length of its mesentery. After a few minutes, the contraction of

* The former derives its name from the *jejune* or empty state in which it is usually found after death: and the latter either from its convoluted form (εἰλέω, *circumvolvo*), its being the most frequent seat of the disease called *ileus*, or its relation to the iliac bone (*os ilii*).

* It can scarcely be necessary to argue the question which has sometimes been raised:—namely, whether it is the muscular wall of the belly, or the muscular coat of the intestine, that propels the contents of this tube. For this is obviously an inquiry, which might be decided by a reference to its human and comparative anatomy, even in the absence of all direct observations as to the nature of its contractions, and their necessary mechanical effects.

† The effect of scratching the peritoneal coat (see opposite page) is perhaps partly due to an action of this kind.

the intestines generally gives them a nodulated or almost moniliform shape, and the movement gradually ceases. On uncovering portions of the canal hitherto concealed, all these appearances are repeated. The contracted state remains for some hours, and finally again disappears.

Now the tranquillity of these portions of intestine previously to the admission of air, the irregular and diffuse nature of the contractions themselves, the final result on the intestine, and the effect of uncovering fresh portions—all these circumstances together offer the strongest probability, that the movements witnessed are due to the contact of the air. And hence, although it is interesting to notice that these contractions often assume the form of a peristalsis (that is, of a circular constriction which travels slowly in a direction towards the rectum), still they do not warrant any conclusions as to the nature or force of those definite movements which are doubtless executed by the intestines during life.

Nor are the movements which result from applying a local irritation to the bowel, under the same circumstances, much more uniform or conclusive. Unless excited before the commencement of the vermicular movements, or towards their close, they are obviously liable to be confused with these;—which, indeed, they closely resemble. Thus, when the surface of the bowel is irritated mechanically, a mere local contraction is sometimes produced. In other instances, and especially when the duodenum is the part attacked, the contraction extends downwards, or even upwards, from the irritated point. Sometimes this diffused contraction occurs almost immediately after the application of the stimulus; sometimes only after the lapse of a considerable interval of time. Sometimes, without any repetition of the stimulus, such waves are repeated; with short intermissions, and of gradually diminishing strength. Sometimes, instead of one continuous wave, a broken or interrupted one is produced;—a condition which is chiefly seen in the small intestine. Similar contractions may also be excited by the mechanical or chemical irritation of the nerves which immediately supply the intestines. But irritation of the mucous membrane has little or no effect. Direct galvanic stimulation, by means of the rotary electro-magnetic apparatus, repeats many of these appearances. On applying the approximated electrodes to a given point, a short interval precedes the occurrence of a local contraction: and this contraction endures after their removal. In some animals, this local contraction is slowly propagated onwards, for a variable distance, towards the rectum. This continuous movement may even be repeated without any fresh application of the stimulus. But that more diffuse irritation which may be produced by stroking the intestine with the wires gives rise to none but local contractions. While galvanizing the nerves reproduces the lively, but general, movements above alluded to. And finally, whatever be the form of irritation, it ceases to have any effect, soon after the lapse of that period at which the vermicular movements usually cease. This departure of irritability may, however, be retarded by warmth, or by preventing the access of air. And the capacity for such movements may sometimes be restored by returning the divided and dead intestine to the belly of the living animal. Finally, though the repeated irritation of any one part soon exhausts its contractility, still, after a short interval of repose, it is at least partially restored.

On mechanically irritating the exposed intestines of the living animal, very different results are obtained. Compressing them between the fingers produces a local contraction, which lasts some few minutes, and then disappears. Scratching their peritoneal surface usually gives rise to elevations, which are just as local as the preceding depressions. These elevations,—which seem to be due to relaxation of the outer or longitudinal muscular layer,—are accompanied by contractions of the deeper transverse fibres. And the latter can still be excited, after all possibility of producing the former has been destroyed by cold. Mechanical or chemical irritation of the mucous membrane, or pinching or section of the nerves, produces no movements whatever:—even where the degree of nervous stimulation is such as to cause convulsive movements of the hind feet of the animal. And distention of the bowel with water seems to be equally inefficacious; indeed, it appears to leave the ordinary irritability by local stimuli very little affected.

The observations of Schwarzenberg and Ludwig *, upon dogs in whom intestinal fistulæ had been carefully instituted, afford much more direct and trustworthy evidence respecting the normal intestinal movements. They introduced into the canal balls of wax, attached to slender lead wires; and thus verified the following details. The contents of the canal are propelled by a slow continuous peristalsis, which has a definite direction towards the rectum. And although irritation always excites a local contraction, it only gives rise to peristalsis at definite times, during the intervals of which the intestine remains at rest. These times have a general connection with the digestive act: the period of minimum activity being before a meal; while the maximum of movement is usually from four to six hours after it. But the act of peristalsis is essentially independent of the presence of food; since it may be produced in a starving animal, or in an empty segment of tube. And not only does this intermittent character affect the general occurrence of the propulsive act, but even, to all appearance, its specific phenomena. For when applied at the proper period, a single continuous irritation produces a repeated and intermittent peristalsis. Hence it is obvious that, during

* Zeitschrift fuer die Rationellen Pathologie, Bd. vii. p. 315.

the short intervals of this peristaltic act, the irritation is incapable of exciting contraction.

We may perhaps sum up all these results as follows. Direct irritation of this mass of organic muscle excites loca contractions; which are of slower access, feebler power, and longer duration, than those of the striped fibre. Shortly after death, these contractions of the intestinal coat evince a general disposition to extend beyond the site of their origin. But during life, this tendency is so modified by some governing force, that, in obedience to the requirements of the digestive organ, it is either exalted into a definite and effective peristalsis, or altogether suppressed. This definite peristalsis forms the ordinary muscular action of the bowel; and is the chief agent in the proper propulsion of its contents. As regards its intensity, we can only conjecture that it is scarcely more than sufficient to propel the normal contents. As respects its character, it is essentially intermittent. As to its extent, it seems to traverse long segments of the tube. But it remains very doubtful whether every — or indeed any — contraction proceeds continuously throughout the whole length of the intestine. Finally, we have a right to suppose, that at least the more active forms of peristalsis have in them so much of rhythm, as to be not only repeated, but self-repeating, at definite intermissions of time.

But the exact mechanism of this peristalsis remains in obscurity. Nay, more, the information at present at our disposal will not even enable us to take the first step in that process of induction by which alone it will probably be arrived at.

In his admirable Essay on Muscular Movement, E. Weber* has well illustrated the peculiar characters of the contractions which are excited by the irritation of organic muscle. He has shown that in the Tench (*Cyprinus tinca*), in whom the muscular coat of the intestine is composed of striped or animal fibre, galvanizing the chief nerves of the tube produces an immediate, powerful, and cotemporaneous contraction, in place of the slow, feeble, intermittent, and enduring action seen in the unstriped or organic intestinal muscle of the other Cyprinoid species. He has also found that the Iris of various animals repeats the same contrast of structure and irritability. Hence he argues, that the organic muscle is less directly influenced by the nerves; and that these are only connected with this contractile tissue in some such mediate way, as that by which irritation of the sensitive or afferent nerves gives rise to the reflex movements which are producible in voluntary or striped muscle.

But do these facts warrant such a conclusion? On the contrary, do they not render it more probable, that the above varieties of contraction are in some way inherent to the very structure in which these kindred animals differ, rather than that they are brought about by supposed differences of the nervous centres or trunks:—differences (by the way) such as the existing state of our knowledge would rather contradict than establish? In the intestine of a single Cyprinoid species, the fibre-cell gives place to the striped fibre. Hence, failing all proof of other differences, is it not precisely to this remarkable contrast of structure, that we must refer the parallel contrast which is observed in its contraction, when a stimulus is applied to its nerves?

This direct reference to the structure of the organic muscle seems to be most justifiable in the case of the local contractions above alluded to; many of the peculiarities of which are almost what might have been expected from the rudimentary structure, the little vascularity, and (especially) the mode of aggregation, of the fibre-cells. But as regards the less local contractions of the unstriped fibre, their tendency to peristalsis and intermission soon after death, appears to demand some wider and less continuous connection of different points and times, than the tissue itself would directly afford. Such a means of association suggests itself in the nervous system. And, since the removal of the mesentery does not deprive the contractions of this peristaltic character, any supposition of this kind would appear to refer it to the nerves within the walls of the intestine. But it is difficult to believe that these nerves have ganglia; nor have any of these essential elements of a nervous centre ever been seen in this situation. While it has been pointed out by Wild, that the excision of a portion of the œsophagus prevents all propagation of its peristalsis beyond the interrupted point: — a fact which tends to show that the contraction of each segment is in some way conditionated by that of its immediate predecessor. The latter experiment, however, supposes such a serious interference with the tube, that any negative result can hardly be regarded as conclusive. And hence, until future researches bring additional information respecting the ultimate distribution of the nerves of this unstriped muscular tunic, and the exact arrangement of its constituent fibre-cells, the relative share of the muscular and nervous tissues in these peculiar contractions can hardly be conjectured. The stimuli by which we excite them in our experiments are in reality far too rude, diffuse, and uncertain in their application, to afford much ground for a decided preference of either muscle or nerve, as forming the chief modulator of that contractility which is, no doubt, essentially inherent to the sarcous substance itself.

From the appearances noticed in the healthy intestine soon after death, it may be doubted, indeed, whether even this last phrase is quite specific enough; — whether we ought not to regard* contraction itself (rather than an abstract "contractility") as the inherent property of the living organic muscle. In the observations just mentioned, we have seen that the death of the animal was soon followed by an irregular, but distinct, contrac-

* Wagner's Handwoerterbuch der Physiologie.

* A contraction answering to what has been philosophically distinguished by Professor Bowman as "*passive*" in the case of the striped muscle.

tion of the unstriped muscular coat of its intestine:—a contraction which was apparently excited by the air, but was certainly independent of the nervous centres. This remained for a time, and then disappeared, never to return. Hence it seemed, in short, "a kind of precipitate *rigor mortis*, hastened by exposure to the air."*

The truth of this analogy between the unstriped and the striped muscle is confirmed by observations made on corpses in which all exposure of the intestine has been avoided until an hour or two after death. A comparison of such examinations would show that the death of the intestine, like that of the arteries, is accompanied by the access of a definite *rigor mortis*, which is closely analogous to the stiffening seen in the voluntary muscles. Both the access and disappearance of this contraction are, however, more rapid than in the striped fibres of the proper organs of locomotion. And its appearances are much less distinct. In the intestinal canal, it is chiefly recognized as a narrowing of the tube; which is attended by an increased thickness of its walls. But it is sometimes better evidenced by intus-susception of the canal; or by irregular contractions of its calibre.

But whatever the exact relation which the various contractions producible in the intestine bear to the specific structure that forms its muscular wall, it seems certain that the true propulsive peristalsis of the healthy living animal is a complex and co-ordinate act, which is at least indirectly dependent upon the cerebro-spinal centre. And Weber's experiments on the highly excitable intestine of the Tench point definitely to the medulla oblongata, as that segment of the nervous centre by which this connection is chiefly brought about. While, as might have been expected, numerous observations concur to represent the pneumogastric and splanchnic nerves as the channels by which this central organ influences the alimentary canal. But the exact degree in which the various vertebral and prevertebral centres of the sympathetic can transmit, modify, or originate the nervous changes which pass to and from the bowel, is at present utterly unknown. There are however various reasons for suspecting, that neither of the two main ganglia which intervene between any part of the intestinal surface and the cerebro-spinal centre, really limit the transmission of an afferent, or give origin to an efferent, change.

Anti-peristalsis.—The ordinary theory of intestinal anti-peristalsis may be thus stated. At a certain stage of an intestinal obstruction, the immoderate irritation which it implies reverses the natural peristalsis of the bowel; so that, instead of proceeding towards the anus, it passes in the contrary direction. In this way it impels the contents of the tube towards the stomach; whence they are vomited by the aid of an extension or reproduction of the same action.

About eight years ago, the author † was led to investigate this doctrine, until then universally accepted. He was thus led to the conviction, that it ought to be unconditionally rejected; that it was probably false; and certainly had never been proved to be true. The following were his chief reasons for coming to such a conclusion:—

1. It is difficult even to conjecture anything in the degree or kind of irritation present in intestinal obstruction, which should limit the occurrence of anti-peristalsis to this state. 2. Since the physical state of occlusion is the necessary condition of fæcal vomiting, it is probable that the causative process by which this occurrence is brought about must be physical also. 3. No anti-peristalsis has ever been observed;—the movements which occur in the obstructed bowel after death being similar in their nature to those witnessed in the healthy intestine under similar circumstances. 4. The whole of the appearances seen after death in the obstructed bowel, show that its contents have been propelled forwards towards the occlusion, and not backwards from it. 5. Distention of almost all the interval between the pylorus and the occluded part appears to be a condition of fæcal vomiting;—so much so, that the date of access of this symptom roughly indicates the locality of the obstruction.

Hence, instead of an imaginary anti-peristalsis, the author ventured to propose a theory which seemed to deduce the process of fæcal vomiting from the ascertained conditions of its occurrence.

The complete obstruction of the intestinal tube at any point, gives rise to an accumulation of its contents above the seat of the structure. This gradual distention of the bowel is accompanied by an active propulsion, which may often be seen and felt through the wall of the belly, as a violent writhing peristalsis. After a variable period, vomiting either occurs for the first time, or if already present from other causes, it becomes fæcal. But peristalsis in an obstructed tube distended with fluid, not only implies a forward movement in the particles that occupy its periphery, but also necessitates more or less of a backward current in those which are situated in the axis or centre of the canal. And the uniform consistence of the distending fluid, or the return of solid fæces, through many feet of tortuous bowel, into the upper part of the canal, constitute frequent phenomena, which are best explained by the mixture and circulation that these two currents must tend to establish. On the fæcal fluid reaching the stomach, vomiting is excited. And it is scarcely necessary to add, that this latter process, as usual, involves the more or less complete evacuation not only of the stomach, but also of the upper part of the distended small intestine.

Mucous membrane.—Having thus briefly described the peritoneal and muscular coats of the small intestine, we may next proceed to consider its mucous membrane:—the structure on which its various functions essentially depend.

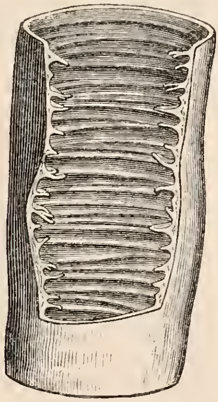
* Author, *op. cit.*

† *Op. cit.*

This tunic everywhere consists of the ordinary elements of a mucous membrane: — namely, a basement membrane, an epithelium, and a layer of areolar tissue that contains an admixture of the muscular fibre-cells. But, instead of forming a simple, flat expanse, it undergoes numerous modifications; which, under the names of *valvulæ conniventes*, *intestinal tubes*, *villi*, *agminate follicles*, *solitary follicles*, and *racemose glands*, will especially claim our notice.

Valvulæ conniventes. — Almost all the small intestine is complicated by the presence of transverse folds of mucous membrane; which project from its inner surface into its cavity. These projections, which were known to many of the earlier anatomists, were named by Kerkring the *valvulæ conniventes*;—apparently from his thinking that they delayed the intestinal contents, but still as it were, connived at their passage. They begin in the second portion of the duodenum, and only cease in the lower fifth or sixth of the small intestine. They are best shown by moderate distention of the tube with alcohol; which slowly hardens them, so that they retain their shape, even after a portion of the wall of the bowel has been removed to display its interior.—

Fig. 255.



Small intestine distended and hardened by alcohol, and laid open to show the valvulæ conniventes occupying its interior. (From a preparation in the Museum of King's College.)

Extreme distention greatly diminishes their size, but never effaces them altogether. And such a permanent character sufficiently distinguishes these folds from those temporary creasings which are seen generally throughout the stomach and intestine, and which are sometimes spoken of as preceding them in the first part of the duodenum. At first they are very small and scattered, rise little above the general mucous surface, extend but a short distance across the tube, and break up at their extremities into still more minute creases, which often pass obliquely to join those next them, above and below. In the lower part of the duodenum, they gradually acquire a number and size, which are retained throughout the whole of the jejunum. But from the beginning of the ileum, they again diminish; first in frequency, and latterly in length and depth. And in the lower third of this segment, they generally disappear altogether.

Each of these folds consists of a duplicature of mucous membrane, enclosing a process of the loose areolar tissue which everywhere separates the mucous from the muscular coat. Opposite the attached border of the *valvula*, this layer is somewhat thicker; but does not appear to contain more than its ordinary small quantity of fibre-cells. The process which it gives off to each of the folds contains vessels, nerves, and lacteals. The relation of this tissue to the *valvula* is well shown by the result of its inflation; which produces a kind of artificial emphysema, that completely obliterates the whole projection. When the cavity of the intestine is forcibly distended, the *valvulæ* are placed vertically to the general surface. But in the ordinary state of the bowel, they are easily moved by any external force; so that their free margin is generally directed obliquely upwards or downwards. Their direction is nearly transverse to the axis of the tube. Their variable extent around the wall of the bowel forms one-half, two-thirds, or even three-fourths of a circle. Their greatest projection occupies the middle of their length, where they are often from one-fourth to half an inch deep. But towards either extremity, they gradually sink into the general mucous surface. In doing this, the valves usually swerve a little from their hitherto transverse and parallel course; so that each joins by one or both ends with the fold immediately before or behind it. And sometimes a bifurcation of the tapering fold unites its extremity to two of its neighbours.

The office of these permanent folds has been a matter of considerable speculation. It is evident that they increase the extent of the mucous surface to at least twice or thrice what it would be in a simple hollow cylinder of equal size. It is equally obvious, that their transverse position is peculiarly calculated to render this enlarged surface an effective one. For they are at right angles to the direction of peristalsis, and therefore to the general course of the intestinal contents. Such an arrangement of the mucous membrane, taken in connection with the great mobility of these folds, must not only insure a thorough admixture of the various constituents of the chyme, but, by delaying its direct passage onwards, bring every portion of it into contact with the greatest possible extent of the active intestinal surface.

Intestinal tubes. — The structure of the remaining constituents of the intestinal mucous membrane can only be seen distinctly by the aid of the microscope. Amongst these minute organs, the *intestinal tubes* — or, as they are commonly called, the *follicles of Lieberkuehn* — are the first to demand our notice. For, with slight modifications, they occupy the whole of the small and large intestine. An allusion has already been made to the fact that, in many animals, they appear to usurp a portion of the gastric cavity. While the importance which this wide distribution would imply, is confirmed by their immense number; which is such that we may estimate their aggregate surface as from ten to fifteen times that of the cylinder of intestine into which they open.

Each tube may be described as a hollow cylinder, having a length which is about five times its width, and ending below in a rounded

Fig. 256.

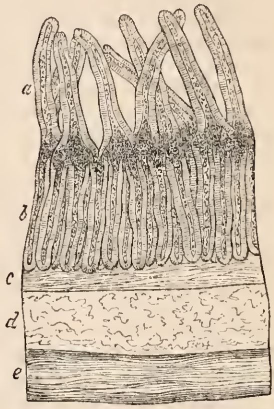
a, Limitary or basement membrane; *b*, nuclei of the columnar cells which line its interior; *c*, calibre or cavity of the tube; *d*, mouths of the tubes opening into the general cavity of the intestine; *e*, blind extremities of the tubes, corresponding to the submucous areolar tissue.

blind extremity. Its average diameter is about $\frac{1}{360}$th of an inch, except at its orifice, where it is somewhat wider. The lower part of the tube is often slightly enlarged: and rarely it appears to bifurcate. But while it is doubtful whether these appearances can be depended upon*, it is certain that they are not sufficiently marked or frequent to alter the above general description.†

This cylindrical tube is composed of basement membrane and epithelium. The former constituent needs no special description. The latter is a single layer of short columnar cells. It clothes the whole interior surface of the tubes; and becomes continuous, at their upper extremities, with the epithelium covering the villi, the constituent cells of which generally appear to be somewhat longer in shape. The cylindrical cavity bounded by these cells has a diameter which amounts to about one-fourth the width of the entire tube.

The arrangement of these tubes so precisely recalls that of the gastric glands into which their structure appears sometimes to merge, as scarcely to require any separate description. Like these, they are placed vertically side by side, in a sparing quantity of dense fibrous matrix; and are imbedded by their lower extremities in a layer of a similar appearance. The latter contain much unstriped muscle, the characters of which can be seen

Fig. 257.



Vertical and longitudinal section of the small intestine in the lower part of the jejunum, showing the general arrangement of its coats. (*Magnified* 50 *diameters.*)

a, villi; *b*, intestinal tubes; *c*, submucous areolar tissue; *d*, circular fibres of the muscular coat; *e*, longitudinal fibres, external to these, covered by peritoneum.

even more distinctly than in the analogous gastric structure. The aggregate mass of these vertical tubes forms the great bulk of the mucous membrane. So that a vertical section of this tunic exposes a dense pallisade of tubes, the depth of which corresponds to the thickness of the membrane: while a transverse one shows that the interstices of the cylinders are only occupied by a scanty matrix enclosing numerous vessels.

The chief interruption to their presence is caused by the racemose glands, villi, and follicles, which will shortly be described. The ducts of the first of these three structures merely occupy a certain portion of space which would otherwise be taken up by follicles. But the two latter encroach upon the surface of the mucous membrane much more considerably. And since it is only between the villi that we find the intestinal tubes, so the number of such tubes which occupy the intervals of these processes must necessarily correspond to the thickness with which the latter are strewed over the surface. Over the more projecting parts of the follicles, the tubes are also absent; in a circular space which is surrounded by a ring of apertures. The latter belong to the inflected upper extremities of

* See foot-note to p. 321.

† A more valid exception to the above statement may be found in the upper part of the duodenum of some of the domestic Mammalia; in whom many of these tubes divide, a little below the surface, into three or four smaller ones. This condition may be regarded as a transition from the structure of either the pyloric tubes, or the clustered glands of Brunn, to that of the ordinary intestinal tube. From the appearances offered by the cylindrical epithelium that lines their interior, the first of these conjectures may be regarded as the more probable of the two.

those tubes which immediately encircle each follicle.

When fresh, these tubes always exhibit the structure just described; their only contents being a clear, structureless, homogeneous fluid. But from their minute size, it is obvious that this fluid can never be obtained from their interior in sufficient quantity for any trustworthy analysis. While unless the secerning process were extremely rapid, even the secretion poured forth into the tube would often be mixed with those coarsely filtered contents of the intestine which can enter its upper orifice from the general cavity of the alimentary canal.

And as regards all fluids found in the general cavity of the intestine, we ought never to forget that to procure them in a state of absolute purity is impossible. Under normal circumstances, the fluid present in any part of the bowel can only be regarded as a complex mixture of several ingredients, all of which are probably themselves undergoing a continual metamorphosis. Could we deduct from the contents of the intestine all chyme, bile, and pancreatic secretion, the residue would be strictly an *intestinal juice*. And by far the larger quantity of such a juice would be composed of the secretion of the intestinal tubes. Now we shall hereafter find that analogy supplies us with some plausible conjectures respecting the fluid secreted by the duodenal glands. While the closed follicles which abut on the cavity of the bowel can scarcely furnish sufficient fluid seriously to affect the composition of any mixture which it may contain. Hence whatever the share taken by the villi, the secretory office of these tubes might apparently be to some extent determined from an examination into the chemical and physiological properties of even such an impure or mixed intestinal juice.

The reader will, however, hardly be surprised when he is informed, that these conditions have never yet been fulfilled; and hence, that a satisfactory account of this interesting fluid remains at present impossible. But he must not therefore think the above allusions superfluous. For it is only by a reference to these conditions of experiment, that we can judge how far we ought to accept the statements made by various recent observers respecting this fluid.

Thus Frerichs * obtained intestinal juice from fasting cats and dogs, in whom a few inches of intestine had been emptied, and tied at both ends, about five hours before they were killed. Lehmann † procured it from a fistula of the small intestine, which had followed an operation for hernia in the human subject; and in which another fistula, higher up, gave passage to the ordinary mixed contents of this part of the alimentary canal. Zander ‡ instituted fistulæ in animals. And, finally, Bidder § and Schmidt, who adopted Frerichs' method without obtaining one drop of intestinal juice, carefully compared the mixture withdrawn from simple fistulæ, with a very small quantity of a purer fluid which was yielded by dogs in whom the pancreatic and biliary ducts had been tied, and the gall bladder made to discharge its contents externally.

According to all these observers, the intestinal juice is a transparent, viscid, and strongly alkaline fluid. It contains nuclei, and round or columnar nucleated cells;—an abortive cell-growth, the admixture of which does not substantially affect the structureless character of the secretion. Of its composition and reactions we can only say, that it appears to contain mucus and the ordinary salts; which together form a solid residuum, that amounts to about 2 per cent. of the whole quantity of fluid.*

As regards the physiological properties of the intestinal juice, it has the power of converting starch into grape sugar. But however obvious the usefulness of this capacity, it is possessed in an equal degree by so many other animal substances, that it can hardly be regarded as the specific purpose or function of this secretion.†

But the recent observations of Zander, together with those of Bidder and Schmidt, claim for this secretion a much more important office:—an office which would entitle the whole of the small intestine to that appellation of a "*ventriculus succenturiatus*," which was formerly bestowed on the duodenum. These observers agree in the statement, that the intestinal juice dissolves protein-compounds, both in and out of the body. And from the careful quantitative researches of Bidder and Schmidt, it would follow, not only that its solvent powers upon these substances are from three to four times greater than those of the gastric juice itself, but that in the Dog, about half the daily albumen of a flesh diet is habitually left untouched by the stomach, to undergo solution in the intestine by the secretion.

Against such a conclusion I would suggest the following arguments, which together induce me to think that this doctrine ought not at present to be accepted. That a large organ like the stomach, with a definite and complicated structure, should so incompletely discharge its single chemical function, is a paradox which alone involves a great improbability. This suspicion becomes still stronger when we consider that, under normal circumstances, gastric juice is always conveyed from the stomach into the intestine during the process of gastric digestion; while it is evident that none of the experiments by these observers quite exclude the possibility of such a transit. Nay more, if we suppose—what is surely not

* *Op. cit.* p. 850.
† *Op. cit.* vol. ii. p. 112.
‡ Koelliker, *Op. cit.*
§ Lehmann, *Loc. cit.* and Bd. iii. s. 335.

* Bidder and Schmidt observed a much larger quantity in the mixed fluid; but point out that the fixed contents would be raised by the addition of the more concentrated secretions of the liver and pancreas. Hence I prefer quoting the estimate deduced by Lehmann from what was probably a purer fluid.

† Compare the remarks on the pancreatic fluid, in a subsequent part of this article.

impossible — that the juice carried onwards into the intestine is there concentrated by the partial absorption of its watery part, some of the strange quantitative results obtained by Bidder and Schmidt cease to be altogether inexplicable. It may indeed be urged, that the alkaline character observed in the intestinal juice sufficiently proves that its digestive properties are not derived from the stomach. But although the addition of a caustic alkali destroys the efficiency of gastric juice, still such a process seems very different from that absorption of acid, or that gradual admixture of a dilute alkaline solution, by which a similar reaction would probably be communicated in the living intestine. And, finally, is it like the ordinary economy of Nature, that an elaborate secretion should pass the pylorus, to be at once annihilated, and then replaced by a second and equally complex antagonist juice ? On such a supposition, indeed, there are many animals in whom almost all the gastric juice would be wasted. For example, there is great reason to suppose that the sojourn of food in the Horse's stomach is so brief, that anything like the stomach digestion of Carnivora is impossible. But are we therefore entitled to assert that this organ is utterly useless?

Such considerations appear to render it more probable, that the gastric juice may retain its digestive efficacy after passing through the pylorus ; and that the presence of this secretion in the small intestine sufficiently explains the solvent powers of the juice which is found in this situation.

But we are not left to such arguments alone to disprove the solvent powers ascribed to the intestinal juice by the above observers. They receive a still more direct contradiction from the experiments made by Frerichs* and by Lehmann.† These authorities concur to state, that neither in nor out of the body can it dissolve the protein compounds. And Lehmann's case may be regarded as affording much more than an ordinary negative result ; since in it, all communication between the stomach and the fistulous aperture made use of, seems to have been excluded.

Finally, we may recall to the reader that close parallel which was observed in the action of the gastric juice and the infusion of stomach ;—how, allowing for dilution and impurity, we found the latter behaving just like the former. Now, in striking contrast to this significant fact, numerous observers ‡ agree in representing the infusion of intestine as utterly incapable of that solvent action attributed by Bidder and Zander to its secretion. Indeed, Koelliker and Goll have found the capacity of digesting protein-compounds so intimately connected with the structure of the proper gastric tubes, as to be almost lost in the pyloric extremity of the Dog's stomach ; where these begin to assume the characters of intestinal tubes by losing their oval gastric cells.

Hence all these circumstances throw great doubt on the alleged solvent powers of the intestinal juice ; and render it impossible for us at present to decide what is the exact digestive office which it fulfils. And we are almost as ignorant of its quantity as of its quality. But it is probably secreted by the small intestine in much greater amount than by the large. According to Bidder and Schmidt, it is poured out most freely about five or six hours after a meal. And drinking soon increases its amount, without causing any converse diminution of its concentration. Its strongly alkaline reaction may be conjectured to have some relation to that large quantity of acid, which is apparently withdrawn from the chloride of sodium contained in the blood of the stomach, in order to furnish the gastric juice. Indeed, a liberation of soda or some other alkaline base, appears almost implied in that of the hydrochloric acid. But hitherto no exact analysis has informed us to what particular substance the alkaline character of the intestinal juice is immediately due. And it is only after a careful comparison of the composition and quantity of this secretion with those of the less alkaline bile and pancreatic fluid that we should be entitled to conjecture, how far the neutralization* of the acid peptone constitutes a special function of the intestinal juice. Still, from the great extent of secreting surface which yields this juice, we can hardly doubt, that it takes a large share in this neutralizing process, which was formerly attributed chiefly to the bile. It probably thus forms part of that cycle of alternate decomposition and recomposition, which appears to be undergone by the chloride of sodium.

The vascular arrangements by which these intestinal tubes are supplied with blood, so closely resemble those of the stomach-tubes, as to render any special description of them superfluous. Like the tubes themselves, the vessels are chiefly concerned with secretion. But while we are left in doubt as to the precise degree or kind of that absorptive function which the vessels of these tubes possess, in common with those of all such mucous surfaces, we are perhaps justified in attributing a special capacity of absorption to the plexus of large capillaries, which here, as in the former organ, lies immediately beneath the epithelium, around their open extremities. The loops of this superficial plexus are generally more simple than in the stomach. They encircle the mouth of each tube with what is often only a single ring of capillary (*b fig.* 258.) ; except in the neighbourhood of the solitary or agminate follicles, where they resemble the analogous gastric vessels in forming more complex meshes (*a fig.* 20.) They communicate very freely with the capil-

* *Loc. cit.*

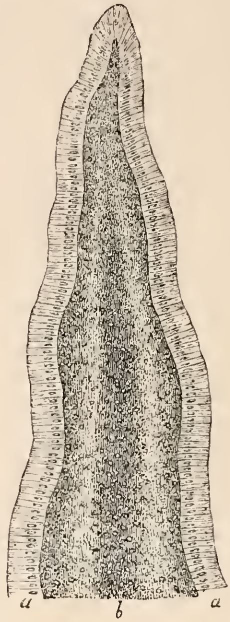
flux in a small vein; that sinks vertically through the mucous membrane, to join the sub-mucous plexus which gives origin to the portal vein.

Villi.— The interior of almost all the small intestine presents to the naked eye a texture very like that of velvet. For it is soft and shaggy: yields readily to pressure: and, on close examination, is evidently composed of innumerable short filaments, which are placed more or less vertically to the general inner surface of the tube. These filaments, — the dense arrangement of which on a common surface causes this general velvety appearance,— are thence usually named *villi.* Their form, and their situation, or office, might also be denoted by the name of *intestinal* or *chyliferous papillæ.*

We have seen that, in the stomach, the confluent ridges intervening between the tubes are here and there raised into slight projections. These are rendered more prominent by artificial injection of the subjacent vessels, or even by that afflux of blood which ordinarily attends the digestive act. In the pyloric extremity of the organ, these projections become more distinct. And just at its termination, some of them often assume the form of bluntly triangular and flattened folds.

In the upper part of the duodenum, the villi begin; by processes which somewhat resemble the gastric elevations just alluded to, and occupy an analogous situation with respect to the intestinal tubes. At first, they may be described as flattened folds, the outline of which is a very obtuse triangle, that has a broad base about four or five times its height ($\frac{1}{100}$th of an inch). In the lower part of the duodenum, this rudimentary form for the most part disappears; and the villi, which are still more or less flattened, have about twice the length, and half the width, of those present in the upper part. But it is in the upper part of the jejunum that they attain their greatest number; being placed so closely together that their interstices scarcely

Fig. 259.



Villus from the upper part of the jejunum, as seen in the fasting state. Magnified 140 *diameters.*

a, epithelium of the villus; *b,* parenchyma or substance of the same.

equal their own bulk. Here they also acquire their maximum length, which ranges from about $\frac{1}{30}$th to $\frac{1}{20}$th, or even $\frac{1}{15}$th or $\frac{1}{12}$th of an inch. Their form, however, is still that of a flattened cone (compare *fig.* 259. and *fig.* 257. p. 347.); —the breadth of the base of which is about $\frac{1}{8}$th, and the depth about $\frac{1}{10}$th, its height. In the remainder of the intestine, the length of the villi gradually recedes to that which they possess in the lower part of the duodenum; while their number also diminishes to a somewhat smaller extent. Throughout all this extent, the shapes and sizes of contiguous villi often present great varieties. But as a rule, the lower we descend in the examination of the intestine, the greater is the number of cylindrical forms we meet with. While towards the extremity of the ileum, the gradual diminution of their size renders many of them scarcely more than $\frac{1}{250}$th of an inch in diameter.

The villi cover the whole surface of the mucous membrane of the small intestine, including its valvulæ conniventes; and they extend to the free margin of the valve which marks the commencement of the cæcum and colon. The only exception to their presence occurs in the agminate follicles, or "Peyer's patches." Here they are absent over the several follicles which together form each patch; and become short, (*a*, *fig*. 272, p. 358.) blunt, irregular, or even confluent, where they occupy their interstices.

We have seen that each of the valvulæ conniventes is a doubled fold of membrane, separated by a layer of areolar tissue. While the minute intestinal tube may almost be regarded as a mere membranous lamina, which is involuted so as to surround a cylindrical cavity, and is packed in a sparing fibrous investment. But the villus constitutes, as it were, a solid process of the mucous membrane. In accordance with this structure, it consists of an epithelium, a basement membrane, a stroma or basis of fibrous tissue, unstriped muscle, and numerous blood-vessels. And in addition to these constituents, which may be found under various modifications throughout the whole intestinal mucous membrane, the interior of each villus encloses one or more branches of the lacteal vessels which contain the chyle.

The *epithelium* of the villi (*a*, *fig*. 259. and *a*, *figs*. 264, 265, 266.) consists of a single layer of cylindrical cells, which, — as regards size, shape, and general appearance, — closely resemble those seen on the ridges between the tubes of the stomach. They are, however, even more delicate in their structure, as well as more conical in their shape. And their contents are, even during fasting, somewhat darker and more granular. The nucleus, which occupies the same situation in both these varieties of cylindrical epithelium, contains a single bright spot, or nucleolus: in rare instances, this appears to be double.

The *basement-membrane* (at *b*, *fig*. 260.) does not require any special mention. As in the gastric ridges, it is very closely attached to the subjacent structures, especially to the vessels. But its continuity with the similar structure forming the intestinal tubes sufficiently indicates that it is really a distinct membrane. And it is often demonstrated to be such by the action of water; which, after transuding it from the outer surface, raises the membrane, in the shape of a delicate transparent bulla, from the general mass of the villus beneath.

The *blood-vessels* of the villi are extremely numerous.

Small arteries, (*a a*, *fig*. 260.) of about $\frac{1}{1000}$th of an inch in diameter, pass between the intestinal tubes. The base of each villus receives one, two, or more of these, according to its size. They now pass upwards in the substance of the process, at some distance from its surface; and rapidly diminish by giving off numerous capillaries, into which their own trunks entirely merge at about the middle of the height of the villus.

The ultimate capillaries themselves (*c c*, *fig*. 260.) are, on an average, about $\frac{1}{3}$rd of the above diameter. They constitute a net-work, which lies directly under the basement membrane; and covers the whole villus so thickly, as to give it a vivid red colour in injected specimens. The shape and complexity of this network is liable to great variety; but is usually such, that the length of its meshes is five or six times their width. The capillaries are distinguished by their being apt to exhibit a wavy and tortuous course (*d*, *fig*. 260.) which often causes their real length greatly to exceed that of the villus itself. This character is especially marked at the

Fig. 260.

Vessels of two villi, injected. Magnified 100 *diameters.*

a a, arteries entering the basis of each villus near its centre; *v v*, veins seen in the same situation; *c*, capillaries lying immediately beneath the limitary membrane; *d*, tortuous capillaries occupying the free extremity of one villus; *b*, limitary or basement membrane of the villus, denuded of its epithelium.

free extremity of the villus:—to the contraction of the muscular layer of which it would appear to be chiefly, though not wholly, due.

The veins (*v v*, *fig.* 260.) come off from this network by the gradual union of capillaries in the upper half of the villus, so as to form two or more venous trunks. These are usually about double the width of the corresponding arteries: they run at a distance from them; and often lie rather nearer to the surface of the villus. Below, these trunks become confluent in the single vein of the process; which, passing vertically downwards, terminates by joining one of the numerous veins belonging to the venous plexus around the orifices of the intestinal tubes. And this latter network also joins that of the villus by such numerous communications, that the two might almost be regarded as merging into each other.

The substance which forms the groundwork or *basis* of the villus resembles, to some extent, that of the gastric mucous membrane; — the morphological constituents of which we have already seen to be indistinct, except at the bottoms of the tubes. It rarely presents any definite structure. Sometimes, however, it is faintly striated. And occasionally this appearance is so marked, as to approach a fibrous character. In this respect, it resembles the papillæ of the skin and tongue; — and, especially, those secondary projections which stud the fungiform papillæ of the latter organ, the basis of which contains no yellow elastic fibres, but is almost homogeneous, and often indistinctly granular.

Mixed with this indistinctly fibrous tissue are numerous delicate cytoblasts or nuclei (*b*, *figs.* 259, 261, 262, 263.). The larger of these attain the size of coloured blood-corpuscles; while the small merge into granules by increasing minuteness. The exact relation of these to the basis of the villus is unknown. Their general effect is to communicate to the whole villus a more or less mottled and granular aspect. This appearance (which we shall find is increased during the period of intestinal digestion) often obscures, not only the vague fibrillation just alluded to, but the whole of the structures which lie beneath the basement membrane.

As regards the *lacteals* of the villi, few anatomical details have been more disputed than those which relate to the commencement of the chyliferous absorbents within the substance of these processes. The progress of microscopical research has, however, reduced the controversy within very narrow limits; and promises at no distant date, to end it by a final decision. At present, almost all trustworthy observers agree in the statement, that each villus receives by its base a single (perhaps sometimes a double) branch of the lacteal system. It is only as to the further course of this vessel that opinions differ. Many affirm it to be continued up the villus as a single tube, which ends near its apex by a blind and often somewhat dilated extremity. Some authorities modify this view for the broader villi, by stating the canal to be double—either as a single loop, or as a bifid and somewhat tortuous tube. While others find that the central and simple lacteal canal ends by branching into a network of more or less complex character, like that of the capillaries.

The first of these statements will at any rate apply to many of the villi. Numerous observers have verified its accuracy for the human subject. And it is not difficult to obtain distinct evidence of its truth in some other Mammalia. Amongst these the sucking Rabbit and Calf are especially suitable for examination. If proper care be taken to examine the chyliferous villi of these animals instantly after death, with the aid of suitable fluids, we may easily convince ourselves of the presence of a single large lacteal tube, with distinct walls, like that represented in the annexed figure (*fig.* 261.). Such

Fig. 261.

Two villi, denuded of epithelium, with the lacteal vessel in their interior. From the Calf. Magnified 350 *diameters.* (*After Koelliker.*)

a, limitary membrane of the villus; *b*, matrix or basis of the same; *c*, dilated blind extremity of the central lacteal; *d*, trunk of the same.

single lacteals are generally very large, having a diameter which often amounts to about one-third or one-fourth that of the villus itself; and exhibit a dilated blind extremity, (*c*, *fig.* 261.) which nearly doubles their width. In man, according to Frerichs *, they are scarcely more than one-half or two-thirds of this size.

But it remains to be considered whether this

* *Op. cit.* p. 751.

statement excludes the possibility of a network, such as has been affirmed to exist by Krause and others. Koelliker, in whose admirable work * the reader will find a copious analysis of the latest observations on this subject, sums them all up very impartially by acknowledging, that, although he has never been able to see a trace of such ramifications, still he cannot venture altogether to deny their existence. On the contrary, he thinks it possible that the above simple mode of commencement,—which certainly holds good for the cylindrical villi,—may be exchanged, in the larger of these processes, for one involving the presence of a greater number of lacteal canals, or the absence of such blind extremities.

But in conceding this much, Koelliker points out—what Valentin † seems previously to have suspected,—the facility with which a striated arrangement of the dark fatty molecules within the chyliferous villus may be mistaken for lacteal vessels. Nay more, even the chyle of the central canal sometimes separates by coagulation into striæ, which closely imitate a branched network. We may add, that, in the various observations which have been made on executed criminals, the possibility of error has probably been increased by the distended state of the vascular and lacteal canals contained within the delicate structure of the villus.

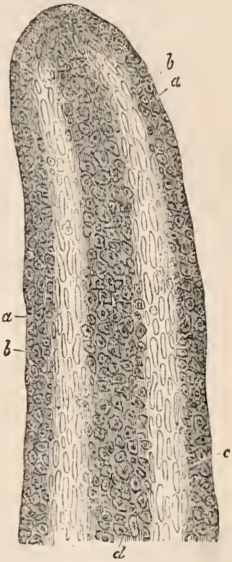
Whatever be the case as regards these conjectures, it seems to me that the large simple tube, and the minute network, are far too unlike to be regarded as mere degrees of development of the same structure in different villi. In like manner, the simple loop of lacteal seen by Henle just beneath the basement membrane is suspicious, not only from its situation, but also from a fact noticed by Valentin and Remak,—that the central canal sometimes coexists with it. And when we add to the foregoing remarks, that the majority of observers have been unable to see any such ramifications, it will seem difficult to avoid concluding, that each villus probably contains a single large lacteal, which occupies its centre, and ends by a blind extremity.

The *muscular* constituent of the villus was first discovered by Bruecke, and has since been verified by Koelliker in many Birds and Mammals. Its shape is that of a thin hollow cone, which closely imitates the form of the villus enclosing it. Hence, from whatever side it is examined, it may be seen as a double longitudinal layer; which is placed immediately around both sides of the central lacteal; and lies so deeply within the villus, as to be beneath its vessels, as well as much of its granular basis. It is more distinct in the lower part of the villus, and in the larger flat specimens; but is easily obscured by oil globules, nuclei, or pigment. The nuclei of its fibre cells are best seen on the addition of dilute acetic or nitric acid, when they assume their ordinary characteristic appearance.

* *Op. cit.* p. 160. et seq.
† *Op. cit.* p. 684.

The action of this contractile apparatus during life is at present unknown. Derived, as it no doubt is, from that general expanse of

Fig. 262.



Villus denuded of epithelium, treated with acetic acid. From a young kitten. Magnified 350 *diameters.* (*After Koelliker.*)

a, outline of the villus; *b*, nuclei beneath this; *c*, nuclei of the unstriped muscle; *d*, roundish nuclei in the centre of the villus.

unstriped muscular fibre which pervades the whole mucous membrane of the alimentary canal, one can hardly avoid ascribing to it a function which is more or less similar,—if not indeed co-ordinate,—with that of the general stratum. That this function is in some respects related to the static or passive mechanical circumstances of the mucous membrane, has already been conjectured (p. 325.) in speaking of the stomach. And the little we know of the ordinary action of the analogous unstriped element in the skin, rather confirms than contradicts such a supposition. But its peculiar position with respect to the end of the lacteal trunk in the centre of the vi lus,—to which it forms a kind of muscular and contractile envelope—has given rise to the suspicion, that it effects the propulsion of the chyle contained in this canal.

How far such a process really obtains must be determined by future research, which ought especially to notice the precise connection of this muscular stratum with that of the mucous membrane generally. In the meantime, we may notice that, as Koelliker justly remarks, an active propulsion by these longitudinal fibres would imply their alternate contraction and relaxation.* But, assuming

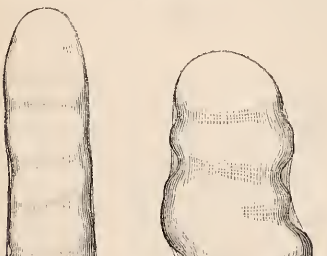
* He also adverts to their apparent want of nerves, and to the essential independence of organic muscle of all but mechanical irritations. However

this to occur, it is evident that such a remittent contraction would not destroy the claims of the absorptive act itself to be considered the chief force which propels the chyle. For in any case, the muscular apparatus would but limit and remove that distention of the lacteal which absorption had previously effected. It would thus, as it were, merely regulate and transfer the mechanical force of the latter act; so as to modify it, either constantly, or at definite intervals of time.

Some observers have attempted to verify the action of this delicate muscular apparatus during life. Gruby and Delafond first instituted such observations on a variety of domestic animals; and they have since been repeated by Bruecke and Koelliker. All of these authorities agree in remarking an alternate shortening and elongation of the villus: — a change of form which is so rapid and marked, that there need be little hesitation in attributing it to a corresponding contraction and relaxation of these unstriped fibres. But the phenomena seen in the course of such vivisections cannot be safely accepted as those of the healthy animal in its natural state.*

Such a caution is still more applicable to those contractions by which the villi share in that irregular movement of the intestine already described as a kind of *rigor mortis*. On exposing the villi of an animal soon after death, they gradually become shorter and

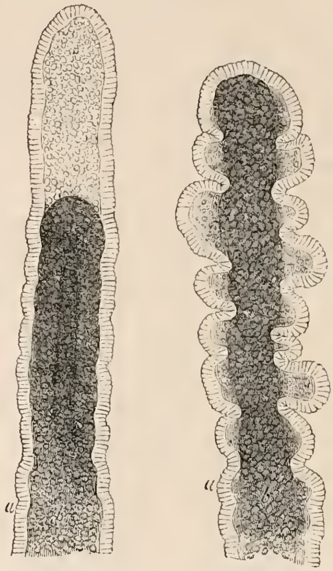
Fig. 263.



Villi contracted and shortened so as to offer circular or transverse wrinkles. From the small intestine of the dog shortly after death. Magnified 100 diameters; and examined by reflected light.

wider; at the same time that their surface is generally thrown into circular transverse wrinkles or folds. A more minute examination shows that these folds consist of epithelium, which has separated from the basement membrane at the points that correspond to the greatest projection between the contiguous wrinkles (*fig.* 264, 2.) A closer adhesion of

Fig. 264.



1. 2.

Similar villi as seen by transmitted light. The villus marked 1, *has been partially withdrawn by contraction from its investing epithelium, which is thus left entire like the finger of a glove.*

a, epithelium of the villus; *b*, granular matrix or substance of the same.

those columnar cells which occupy the free extremity of the villus, frequently causes this part to be defined, as a shallow funnel, by the neighbouring separated cells. While in other instances, a variable length of the whole villus withdraws from its cellular investment with such uniformity, as to leave the extremity of the latter empty, smooth, and uninjured (*fig.* 264, 1.), like the finger of a glove. Frequently, however, some of the epithelial cells are detached.

It is obvious that all these appearances are referrible to a contraction of the unstriped fibres within the villus, withdrawing the substance of the latter from its epithelial investment. The movements which often accompany these changes resemble those above mentioned as beheld during life; and consist of shortening or elongation, to which are sometimes added lateral displacements. The date of their occurrence is limited to the period

general this view of the action of unstriped fibre, I must confess myself very reluctant to accept it on its present evidence.

* For,—to say nothing of the pain, the irritation, and the exposure, which are involved in such an opening into the intestine as is necessary to allow a proper inspection of the villi,—Gruby and Delafond remark, that their surface becomes wrinkled and pale at the time of their contraction. Such circumstances imply so much disturbance of these soft structures, as to throw great suspicion upon any view which would interpret them as part of a normal process.

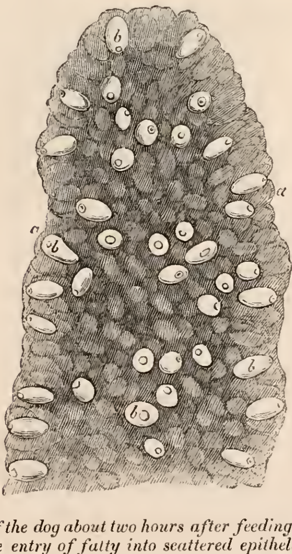
which immediately succeeds death. And their duration is rarely protracted beyond a few minutes.

Changes in the villi during digestion. — During the act of digestion, the villi undergo certain noticeable alterations. At this period, they receive an increased afflux of blood; and become both larger and softer. They acquire a greater opacity; so as to appear whiter by reflected, and darker by transmitted, light. The nuclei and cells which occupy their interior are greatly increased in number and distinctness. And, finally, after the ingestion of food containing the usual fatty ingredients, a portion of these may be found occupying the interior of the villi themselves.

The process by which fatty matter penetrates the villus to enter the lacteal in its centre, deserves our special attention, from the fact that it constitutes the origin of the chyle. At present we shall limit ourselves to a description of the appearances actually observed, in connection with the mucous membrane of the alimentary canal.

The first step towards the absorption of the fatty matter, consists in its entry into the epithelium which invests the exterior of the villus. Each columnar cell of this covering is gradually filled by a large oil globule; which occupies the whole of its cavity, with the exception of that small portion devoted to its nucleus. This change first implicates a few scattered epithelia; and, by rendering them

Fig. 265.



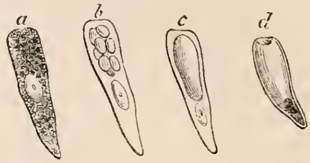
Villus of the dog about two hours after feeding: showing the entry of fatty into scattered epithelia on its surface. Magnified about 400 *diameters.*

a, a, outline of the villus formed by epithelia with their ordinary contents; *b, b,* epithelia rendered bright and refractile by their fatty contents.

more refractile, often causes various parts of the surface of the villus to offer a curious contrast of bright spots (*b*, *fig.* 265.) and darker intervals.* Gradually, however, all the cells become similarly affected; so that the entire villus assumes the altered appearance just alluded to.

The next step towards the absorption of the fatty matter consists in the minute subdivision of the single oil globule (*c*, *fig.* 266.) which occupies the epithelial cell. The way in which this process occurs is unknown:

Fig. 266.



Isolated epithelial cells from a villus, as seen during the absorption of fat into the lacteals. (*Altered from Koelliker.*) *Magnified* 350 *diameters.*

a, columnar epithelial cell, occupied by fatty molecules; *b,* similar cell, containing several small oil-drops; *c,* similar cell, enclosing a single oil-drop; *d,* similar cell completely filled by a larger oil-drop. The upper or free end of the cell (at *d*) is concave.

but the result of the change is to give the columnar cell a darkly granular appearance (*a*, *fig* 266.), in which we may often distinguish separate, though minute, fatty molecules. These molecules are next found in the substance of the villus itself, though chiefly towards its surface and free extremity; — to the apex of which latter part they are often limited.† From the substance or matrix of the villus, the molecules of fat are then transferred to the lacteal trunk occupying its centre; which, in the most favourable instances, they define as a slender column of dark fatty granules.

How far the above process constitutes a mere act of physical imbibition, it is difficult at present to determine. But that it is so, at least in part, can scarcely be doubted. For the experiments of Matteucci ‡ (which are confirmed in all their essential particulars by Valentin §) prove that, when a dilute alkaline solution and a faintly alkaline fatty emulsion are separated from each other by an animal membrane, diffusion occurs between them. And the circumstances actually present in the intestine are even more favourable to such a transit than those which obtained in the experiments of these observers. The lymph and blood are sometimes more alkaline than the solution which they made use of. The degree in which the tenuity of the delicate cell-wall of the villus exceeds that of the

* These appearances, alluded to by Frerichs (*Op. cit.* p. 854.) and detailed by Koelliker (*Op. cit.* p. 167.), were noticed by me eight years ago in the human subject.

† The larger drops sometimes seen in this situation are, I believe, the result of accidental violence to the specimen.

‡ Leçons sur les Phénomènes, &c., pp. 104, 5.

§ *Op. cit.* vol. i. p. 379.

compound membrane forming the diffusive septum in their experiments, would proportionately favour the resulting transit of the separated fluids. And since the continuous movement of the chyle is probably aided by forces independent of any mere act of diffusion, the force of suction thus added must itself conditionate a more active transit than that which they witnessed in the inert endosmometer.

On the other hand, there are good reasons for regarding the reception of fatty matters as a much more complex phenomenon, and the result of what we may venture to call more vital processes. For the way in which ether and other solvents act upon the chyle appears to prove, that the fatty contents of its molecules are still oily; and not saponified, like such diffused fluids. And while the position of the capillary plexus, and the rapidity and quantity of its stream, render it probable that any merely diffusive action would disproportionately affect the blood—which by the way is often more alkaline than the chyle —a chemical and physical comparison of these two fluids would seem to show that the reverse is actually the case: that a larger quantity of fat is taken up by the lacteals than by the blood-vessels. This view is also confirmed by the results of violent inflammation *, or of great interference with the blood-vessels †: — changes, neither of which would probably have much direct effect on the physical action of an independent system of tubes, but which are nevertheless alleged entirely to prevent the formation of chyle. In any case, it would seem that there are strict limits to the quantity of fatty matter which can be absorbed. Hence when the amount of fat present in any particular region at all exceeds what its villi can take up, it is passed on to other portions of intestine; failing absorption by which, it is ultimately discharged unchanged in the fæces.

Intestinal Follicles.‡ — We pass on to the description of a class of structures which are essentially closed sacs; and which, represented in the stomach by the lenticular glands, pervade all the remainder of the intestinal canal under the two forms of *solitary* and *agminate follicles:* the latter being, as their name implies, essentially clusters of the former.

Agminate follicles. — Of the very numerous § names which have been bestowed upon these follicles, that above made use of seems preferable; since it best connotes both their structure and arrangement. There are generally about twenty clusters of these agminate follicles scattered throughout the small intestine. Their shape is commonly that of an oval, having a length about twice its width. They are situated on the free border of the bowel, or opposite to the attachment of its mesentery; and usually correspond to about the lower three-fifths of the small intestine, or to that part of it which is regarded as the ileum. Hence they have been looked upon as, in a certain sense, characteristic of this region. But they sometimes extend into the jejunum, being scattered sparingly throughout its lowest segments. And they may rarely be found even in the duodenum. In such cases, their entire number is usually about twice or thrice that of the average given above.

But amid all their variations of number, size, and extent, the agminate follicles seem to retain a certain predominant relation to the end of the ileum. For it is here that they are both largest and most numerous. And while in the remainder of the small intestine, their length is usually rather under than over an inch, nothing is more common than to find the immediate neighbourhood of the ilio-cæcal valve occupied by a single irregular cluster;— which has a length of two, three, or even four inches, and a width which carries it round $\frac{2}{3}$ds or $\frac{3}{4}$ths of the inner circumference of the intestinal tube.

Fig. 267.

* Frerichs, *Loc. cit.*

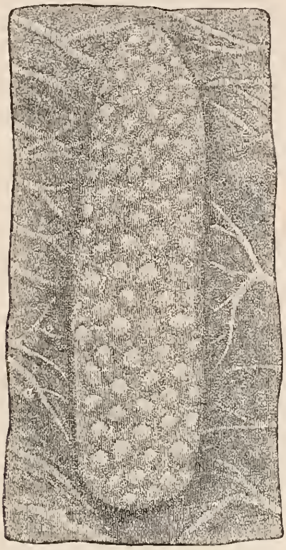
† Fenwick in "Lancet" for 1845, p. 64.

‡ The etymology of the word "*follicle*" quite permits its application to these closed sacs: to which indeed it seems desirable that we should restrict it, in speaking of the various constituents of the intestinal mucous membrane.

§ Until a more uniform nomenclature is adopted, it seems advisable to enumerate a few of these names. Such are the titles of *glandulæ Peyerianæ; agmina Peyeri; glandulæ aggregatæ; glandulæ agminatæ; vesicularum agmina; plexus intestinales; plaques gaufrées;* and finally, *Peyer's patches.* The latter uncouth designation is, perhaps, that most commonly made use of in this country. But as Peyer appears to have been anticipated by our countryman Grew in the discovery of these structures, there is the less need of clinging to one of those unmeaning surnames, which every practical teacher of anatomy will probably agree with the author in thinking very objectionable.

bowel by reflected light, at a place corresponding to a cluster of agminate follicles, we see that its surface (which is raised above the rest of the intestine, but has no very sharp line of demarcation from it) is occupied by a number of irregular shallow depressions (*b*, *fig.* 267.), at tolerably uniform distances from each other. But when inspected by transmitted light, these fossæ are replaced

Fig. 268.



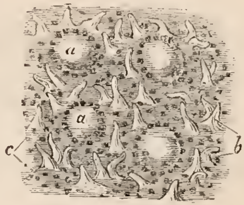
Agminate follicles as seen by transmitted light. Magnified about 5 diameters. (After Boehm.)

a, general mucous surface of the ileum; *b*, *b*, opaque grains corresponding to the several follicles.

by comparatively opaque grains (*b*, *b*, *fig.* 268.), of about the size of a millet seed; the aggregation of which renders the whole cluster very distinctly visible by this mode of examination. Finally, the cluster may often be recognised externally, from the bulging of the peritoneal coat which it causes in this situation. Indeed, its constituent follicles may sometimes be seen glimmering through the delicate muscular tunic.

Each such cluster is composed of a number of follicles, varying from twenty or thirty in the smaller, to at least one or two hundred in the larger, specimens. A careful examination of the mucous surface shows that the depressions just mentioned do not lead to any apertures, but are terminated by a smooth surface, the convexity of which somewhat diminishes their own depth. It is only at the margins, and in the intervals, of these fossæ, that we find the tubes and villi proper to the small intestine. And both of these latter structures are somewhat modified. Those tubes which immediately surround each depression have a circular or elliptical arrangement; so that their orifices generally form a ring of ten to twenty tubes in the fossa (around *a*, *fig.* 269.), and thus give rise to a very characteristic appearance.* In like manner, the villi in their immediate neighbourhood often appear to radiate outwards

Fig. 269.



Portion of a cluster of agminate follicles.

a, *a*, follicles encircled by apertures of the intestinal tubes in the form of a ring; *b*, short and obtuse villi, occupying the intervals of the follicles; *c*, apertures of intestinal tubes, opening irregularly in these intervals.

from a point corresponding to the centre of the fossa. And both they, and those more equidistant to the several follicles, are very different from the villi seen elsewhere:— being fewer (*b*, *fig.* 269; *a*, *fig.* 270.), shorter, of more irregular form, and often confluent at their bases.

To demonstrate the structure and arrangement of the several constituent follicles of the agminate clusters, requires great care, and very delicate manipulation. At the free surface of the mucous membrane, they are extremely difficult to isolate; both from their great tenuity, and their intimate union to the neighbouring tubes. Hence the best way of gaining access to them is from the outside of the intestine, where they may often be seen through the peritoneal and muscular coats.† The removal of these tunics brings them directly into view. To this method of examination must be added careful section in the vertical and horizontal planes.

A proper combination of all these methods of investigation reveals the following facts.— Each follicle is a shut sac: having a roundish form, but a somewhat conical apex, which is directed towards the surface of the mucous membrane. Their diameter varies from 1 to 2 or 3·50ths of an inch. The base of each is in contact with the muscular coat (which is somewhat thinned in this situation); and is united to it by an areolar tissue that resembles the ordinary loose sub-mucous texture, in which the follicle is imbedded by the greater part of its bulk. The short apex of the follicle extends upwards between the lower extremities of the intestinal tubes: and, below their middle, it terminates in the immediate neighbourhood of the general mucous surface, which has already been

* This appearance is somewhat incompatible with that seen in a vertical section. Hence it is perhaps partially due to pressure or over-distention of the follicle.

† Especially after having been rendered opaque by soaking in dilute acids, which coagulate their contents.

described as depressed into a fossa in this situation. The thin stratum of tissue which

a, short and conical villi surrounding the follicle; *b*, intestinal tubes in the same situation; *c*, muscular stratum of the mucous membrane; *d*, submucous areolar tissue, in which the follicle is chiefly situated; *e*, circular layer of the muscular coat; *f*, longitudinal layer of the same; *g*, peritoneal coat; *h*, follicle enclosing nuclear contents; *i*, apex of the follicle projecting into the cavity of the bowel.

intervenes between the follicle and the interior of the bowel (at *i*, *fig.* 270.) is so delicate, that its exact anatomy is not easily verified by vertical sections. It appears, however, to consist of a very small quantity of indistinctly fibrous tissue; which encloses some capillaries, and is covered by the ordinary layer of columnar epithelium.

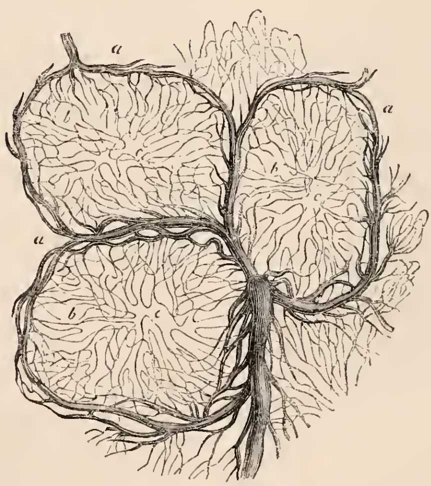
The frequent rupture of the follicle in this situation has led many to regard it as either possessing a permanent orifice here, or acquiring one by a kind of natural dehiscence. But later researches seem to show that this open state is quite exceptional and accidental; being due to disease, putrefaction, or mechanical violence. The author can at least express his own conviction that—as Boehm long ago stated,—the agminate follicles are closed sacs. This conclusion is much confirmed by the fact, that the follicles of some animals are altogether beneath the mucous membrane and the tubes, and quite distinct from both of them; so as to lie wholly in the sub-mucous areolar tissue.* While the vascular arrangements which we are about to describe seem equally incompatible with any theory of their normal dehiscence.

Each of these follicles essentially consists of a capsule, enclosing a number of delicate capillaries, the interstices of which are occupied by a cell-growth consisting of various forms.

The *capsule* is a structure which, though analogous to a basement membrane, differs from such a delicate homogeneous lamina, both in being much thicker, and in offering an indistinctly fibrous texture. Its smooth outer surface contains elastic fibres, and is attached by loose areolar tissue to the surrounding sub-mucous structures.

The *vessels* of the follicle offer a very peculiar arrangement. The small arteries in the sub-mucous areolar tissue give off branches that ramify amongst the several follicles of each "patch;" and thus form a network of

Fig. 271.



Vessels of the three agminate follicles of the Rabbit; as seen by a horizontal section, at about the middle of their height. (*After Koelliker; from an injection by Frei.*)

a, a, minute vessels surrounding the capsule of the agminate follicles; *b, b, b,* delicate capillary loops *a,* penetrating their interior, and bending back from *c, c, c,* the centres of the follicles.

capillary arteries, chiefly occupying the horizontal plane. These vessels, which are in contact with the capsule of the follicle, break

* Compare Koelliker, *Op. cit.* pp. 153. 188.

up into numerous capillaries of about $\frac{1}{3000}$th of an inch in diameter. The latter surround the membranous wall of the follicle with an irregular plexus. But where they reach the middle of that part of it which projects into the interior of the intestine, they are curved back upon themselves ; so as to form long loops, that radiate from a central space quite uncovered by vessels. And this appearance, which was depicted long ago by Boehm, does but represent, at the surface of the follicle, what the more recent researches of Frei prove to be the vascular arrangement that pervades the whole of its interior. The injections of this anatomist show, that the capsule is not only surrounded by the network just mentioned, but is also penetrated by a number of minute capillaries. These, which are of a still smaller diameter than the former vessels, leave them at right angles, and reach nearly to the centre of the follicle, before looping back again to its exterior. And finally, some of the uppermost of them have been traced by Koelliker uniting to form the radicle of one or two veins of about $\frac{1}{1000}$th of an inch in diameter; which descend vertically through the follicle, without receiving any further branches from the neighbouring capillaries.

The remaining *contents* of the follicle form a soft pulpy mass. This is remarkably contrasted with the contents of the neighbouring lacteals, in the fact that it is always of a pale, semi-transparent, greyish colour ; while the latter are, during digestion, of a brilliant white. The application of reagents under the microscope shows this greyish pulp to be composed of a proteinous substance closely akin to albumen. The addition of water causes it to swell up, and effects its partial solution. And as regards its structure, the mass consists of a moderate quantity of fluid, mingled with a variety of cells. These, however different in their characters, may probably be all reduced to various forms of cell-growth, on the one hand; and various stages of the retrograde solution of blood-corpuscles, on the other. The latter process, though by no means uncommon, appears always due to an extravasation of a more or less accidental character. It is the cell-growth which constitutes the specific histological character of these albuminous contents of the follicle.

The cell-growth ranges from distinctly nucleated cells, of $\frac{1}{2000}$th of an inch in diameter, to cells of about one-half, and through these to nuclei of barely one-third, the above size. The latter, however, are of nearly the same bulk as those contained in the largest cells. Hence it would seem that the process of growth which these differences indicate, consists chiefly in the isolation and removal of the cell-wall, from its previously close apposition around the nucleus. In the Sheep, however, Koelliker has sometimes observed an endogenous multiplication of large cells, by a subdivision of their nuclei. And in other specimens from the same animal, he has noticed what is very possibly the opposite extreme of the cell-life : — the cavity of a large cell filled with large angular corpuscles. These corpuscles are sometimes nucleated; they have albuminous reactions; and they appear to be produced from the ordinary cells of the pulp. They ultimately disappear.

The *function* of the agminate follicles it is impossible to specify. Few organs in the body have been the subject of more numerous speculations: — speculations, the absurdity of most of which renders them unworthy of any serious mention. And hence, although what we know respecting the structure of these organs justifies (or rather requires) some attempt to indicate their physiological import, the mistakes of others may well teach us how much caution is requisite in making such conjectures. They are, at most, mere guesses at truth.

The contents of the follicle have just been stated to be composed of a cell-growth that lies in contact with a large vascular surface. Hence it is in the reaction of these innumerable minute agents on a copious and rich nutritional fluid exsuded from the blood, that we must look for the chief office of the follicle. The fact of various stages of cell-life being present simultaneously, appears to indicate, that the cells do not merely select certain materials, but more or less produce them; by a process which, directly or indirectly — by absolutely consuming their tissue, or otherwise — involves their own decay and death. So far, then, the agminate follicle, which closely resembles the vascular gland in its structure, might be conjectured akin to it in its function ; — that function being a choice from the nutritional fluid of certain of its constituents, which, after undergoing a metamorphosis, are subsequently returned into the general current of the blood.

But such a view omits to recognize some of the circumstances it ought to explain. And it especially neglects one which must be supposed of great importance : namely, the situation of the follicle ; or, in other words, its peculiar relation to the cavity of the intestine.

It is obvious that the position of the agminate follicle with respect to the intestinal canal will admit of a double interpretation. On the one hand, the materials on which its enclosed cells have to act, will probably be derived from the contents of the alimentary canal, as well as from the blood. And on the other hand, they may be ultimately excreted from the body through the intestine, as well as returned into that system of closed canals which the blood vessels compose.

The degree in which the intestine forms the channel of such an ingress and egress, must of course depend upon the directness and efficiency of the communication between its cavity and that of the follicle. Hence, where the two are in such close contiguity to each other as in the case of the agminate glands of the human subject, we may presume that an efficient transudation of this twofold nature really does obtain. But where, as in some of the follicles of the Calf, the cavity of the intestine is separated from that of these minute sacs by the intervention of a thick compound mucous membrane, it is difficult to avoid the conclusion; that a transit of their fluid contents, in either, direction can only obtain to a comparatively small amount.

In addition to these important relations between the agminate follicle on the one hand, and the vascular and intestinal cavities on the other, recent observations have shown that there is a third, which is perhaps quite as intimately connected with its function: — namely, the connection of the follicle with the commencement of the lacteal system. For the general analogy of the intestinal follicle to the vascular gland is far surpassed by that close structural resemblance which Koelliker has shown that it possesses to the follicles of the lymphatic glands. The latter, indeed, exhibit a remarkable similarity to the structure of the agminate follicles. Like them, they enclose vessels as well as cells, within the cavity formed by their limitary wall. Hitherto it has certainly been found impossible to verify the presence of lacteals within the agminate follicles; or to establish the existence of any direct communication between their cavities and that of the lacteal vessels themselves. But in spite of this, it seems certain, both that the lacteals occupy the patches in numbers quite disproportionate to the small and few villi here present; and that they possess the closest proximity with the contents of the follicles. Such a * conclusion must, I think, be drawn from Bruecke's researches; in which the cavity of the follicle soon became slightly coloured with reddened turpentine, which had been injected into the lacteals by compressing the distended intestine.

It remains, however, for future researches to determine how far this view is correct, and whether the agminate follicles do really partake of the nature and office of lymphatic glands. In any case, their very variable number, and their occasional absence, would seem to indicate, that (like the similar structures always present in the tonsils, and sometimes found in large numbers within the mucous membrane of the stomach) their function is either not very important; or — what is far more likely — can be more or less replaced by that of other kindred organs. And from the number and size of these follicles, we may perhaps conjecture, that their merely quantitative effect on the chemistry of the organism is not very great.

The little that is known of their changes in health and disease confirms what has just been stated respecting their relations to the vascular and lymphatic systems. Thus, during digestion, they become so swollen, as to project from the inner surface of the intestine: — a condition that may, perhaps, be due to increased absorption from the intestine, but is better ascribed to that energetic determination of blood to the whole of the intestinal structures which then takes place. During the violent drain of cholera the same tumid condition obtains: probably from a similar cause. And finally, the remarkable parallel between the disease of these follicles and that of the neighbouring mesenteric glands, which is seen both in phthisis and typhoid fever, is a strong additional argument for the reality of that analogy which physiology indicates to exist between the two structures.

Solitary follicles. — The *solitary follicles* are so completely what their name implies — isolated structures of the same kind as those which are aggregated to form the "patch" — that any further description of their minute anatomy would be quite superfluous. Indeed, those smaller patches which are formed by two or three follicles, may be almost regarded as a transition between the "solitary" and "agminate" arrangement. But these scattered solitary follicles are seldom or never surrounded by a definite circle of the apertures of intestinal tubes. And they often sustain villi of the usual size and shape. Their number is extremely variable. Sometimes they seem to be altogether absent. But a very careful examination will now and then show, that such a deficiency is one in appearance only; and is due to the very slight degree of distention which obtains in the follicles really present. Whether this explanation would always hold good is more doubtful: though the remarkable constancy with which these structures are found in most animals and in the human fœtus is, to say the least, a strong confirmation of its general truth. In other instances they are strewn thickly over the whole intestinal canal, from the œsophagus to the anus. Such an excessive development is perhaps strictly a morbid phenomenon. But it is also capable of explanation as a mere collective hypertrophy; — an overgrowth which results in an increased number of these minute organs, instead of an increased size of each individual follicle. Which of these two views is the more correct, will only be decided when we know more respecting their office.

They usually occupy the whole of the small and large intestine in considerable numbers. They are, however, more numerous in the latter of these two segments of the digestive tube. And here they also present a larger size, as well as what is generally a deeper situation in the sub-mucous areolar tissue. Hence the depression that indicates the follicle in the small intestine is exaggerated, in the large intestine, into a deep fossa; which, commencing by an aperture over each follicle, widens as it passes downwards between the opposed sides of a few contiguous intestinal tubes, to terminate, near their

* That direct communication between the agminate follicles and the lacteals, which Bruecke deduced from his observations, is, however, contradicted by the time at which the colour above mentioned appeared, and by its diminished intensity of hue: — as well as by the fact, that the agminate follicle never contains white chyle.

extremities, on the bulging surface of the follicle.

Racemose, or *Brunn's glands.* — The remaining constituent of the compound intestinal membrane is one which, unlike all the preceding minute organs, is limited to a very small segment of the canal. It consists of a number of highly ramified tubes, which are usually termed the *glands of Brunn*, but might preferably be named the *racemose* or *duodenal glands.* These glands occupy that upper part of the small intestine already distinguished as the duodenum ; of which segment they are thus, as it were, the natural index, or the characteristic structure.

The racemose glands are small "conglobate" masses ; which in their size, structure, and position, closely resemble those accessory salivary organs that stud various parts of the mucous membrane lining the cavity of the mouth. Like these "labial" and "buccal" glands, they occupy the sub-mucous areolar tissue : and are therefore best examined by pinning out a piece of the duodenum on some flat surface, with its mucous side downwards, and then carefully removing the serous and muscula. coats. Such a dissection easily exposes them, as small roundish white granules of about the size of a millet seed.

They vary considerably in size and arrangement. Immediately beyond the pylorus, they are of one-tenth to one-eighth of an inch in diameter ; and are present in such numbers, as to form what is almost a glandular layer around this part of the intestine. But lower down in the duodenum, their size dwindles to one-half or one-third of the above : and their scattered grains gradually become more sparing in number ; until, shortly before the termination of its inferior transverse portion, they cease altogether.

On tracing out the structure of an isolated duodenal gland under the microscope, it is seen to consist of numerous lobules; which are aggregated into a single mass (*c c*, *fig.* 272.), by an enveloping layer of fibrous tissue. And on applying a still higher magnifying power, each of these lobules may be again resolved into smaller ones, which resemble a bunch of grapes, and constitute the true or ultimate *acini* of the gland. As seen *in sitû*, these vesicles have a globular or slightly polyhedral form; and a diameter which is about $\frac{1}{500}$th to $\frac{1}{200}$th (on an average, $\frac{1}{300}$th) of an inch. But when separated from each other, they often exhibit more irregular shapes (*d*, *fig.* 273.). They are the terminal dilatations of tubes, which are themselves about two-thirds of this size. On tracing these minute tubes towards the general mucous surface, they will be found uniting with other similar ones, to form larger ducts. The successive union of these with other ducts formed in the same way, and of these larger ducts with their neighbours, gradually causes all their cavities to converge into a single canal of outlet, which is the proper efferent duct of the gland. This duct now passes between the intestinal tubes before described, to open on the free surface of the intestine, in the depressions which intervene between the rudimentary villi present here. The valvulæ conniventes are not permeated by any such ducts. But in all other parts of its surface, the general mucous membrane is pretty evenly studded by their apertures, two or more sometimes passing through it in company with each other.

Fig. 272.

Diagram of the arangement of the lobules of a duodenal gland.

a, duct of the lobule ; *b*, collateral branch of this duct ; *c*, the acini around such a duct *in situ ; d*, the same separated, and the duct unfolded.

Hence each of these glands may be briefly described as a tube, which branches repeatedly, and ends in very minute canals, with somewhat vesicular extremities.

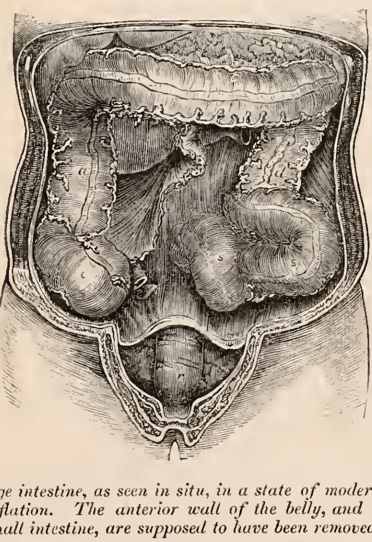
The whole of this involution of mucous membrane is composed of the usual elements ; namely, limitary membrane and epithelium. The former constituent offers no peculiarity worthy of note. The latter consists of a single tesselated layer of cells. These have a polygonal and slightly flattened shape, which somewhat resembles that of the cells lining the smaller branches of the straight urinary tubules. Where the smaller tubes converge to form the efferent duct that perforates the mucous membrane, these cells are exchanged for short cylinders, the structure of which rapidly merges into that of the ordinary columnar epithelium of the general intestinal surface.

As regards the *secretion* of these racemose glands, we can only state that their ducts contain a structureless mucus, which has an alkaline reaction.

With such an imperfect knowledge of its nature, we can scarcely wonder that the office of this fluid remains unknown to us. Like many other animal matters, it converts starch into sugar. But until the precise rapidity and energy of this change have been established, it is impossible to determine how far this action is really comparable to that of the saliva. From the close resemblance between the sub-mucous glands of the mouth and these of the duodenum, many have assumed them to prepare a salivary fluid. But, besides that we are not warranted in regarding the secretion of the buccal glands as identical with the saliva (of which it forms but a very small ingredient), a very moderate knowledge of histology might suffice to indicate the danger of inferring the nature of any secretion from the mere arrangement of the structures by which it is furnished. Hence it must remain for the present undecided, whether this mucus is a salivary or pancreatic fluid; or merely a more concentrated form of intestinal juice, secreted by glands which here reach a higher degree of development than that attained by the short cylindrical tubes of the rest of the bowel.

Large intestine. — The remaining portion of the alimentary canal forms the *large intestine*

Fig. 274.



Large intestine, as seen in situ, in a state of moderate inflation. The anterior wall of the belly, and the small intestine, are supposed to have been removed.

c, cæcum; *a*, ascending portion of the colon; *t*, transverse portion; *d*, descending portion; *s*, sigmoid flexure; *r*, rectum.

(*c a t d s r*, *fig.* 276.) (*intestinum crassum*, Lat.; *gros intestin*, Fr.; *dickes Gedarm*, Germ.): — a name which alludes to the size that is one of its chief characteristics. Beginning at the termination of the ileum, in the right iliac fossa, it passes upwards to the under surface of the liver. Here it turns at a right angle, and runs horizontally below the stomach, to the left extremity of this organ. By a second bend, it here resumes the vertical direction, and then passes downwards towards the left iliac fossa. In this region it undergoes a remarkable curvature, which has the shape of the italic letter *S*. From the lower end of this "*sigmoid*" flexure, it passes obliquely towards the median line; where it terminates in a straight, short tube, that runs vertically through the pelvis to the outlet of the anus. Hence the entire segment of large intestine has the shape of a horse-shoe; and forms a large bend, which is concave downwards, and passes almost round the confines of the abdomen before ending at the inferior extremity of this cavity. While its general arrangement is such, that the intestinal canal, which diverges from the median line at the lower end of the œsophagus, returns to it shortly before terminating in the posterior or lower segment of the trunk.

An accurate measurement of the length and width of this tube is opposed by the difficulties already alluded to in the case of the small intestine. My own observations would indicate an average length of from four to six feet, and a mean diameter of about $1\frac{2}{3}$ to $2\frac{2}{3}$ inches: — the two measurements usually varying inversely to each other, except in the cases of extreme distention or contraction, when both respectively increase or decrease simultaneously. Hence the large intestine has about a quarter the length, and twice the width, of the small. From such an estimate we may conclude that, while its capacity is almost equal to that of the narrower tube, its active surface is scarcely half as large. And even this great difference is much increased by the absence of villi and valvulæ conniventes from the interior of the large intestine.

Like the rest of the canal, the wall of the large intestine is composed of the serous, muscular, and mucous coats; and of vessels, nerves, and lymphatics, which are distributed to them.

The nature and arrangement of these tunics vary, however, in the several parts of the tube. And these differences, aided by others which affect its size, shape, and situation, subdivide the large intestine into the following segments: — the *cæcum*; the *vermiform appendix*; the *colon*, in which we distinguish an *ascending*, *transverse*, and *descending* portion, and a *sigmoid flexure*; and, finally, the *rectum*. The anatomy of each of these will demand a brief notice.

The *cæcum* (*c*, *figs.* 276, 277.) (formerly *blind gut*, Eng.; *blind Darm*, Germ.) is the first and largest of these segments. Its arrangement may be described as due to the fact, that the small intestine, instead of being simply continuous with the large (like the stomach with the duodenum), opens into it at right angles to its axis, and at some distance from its commencement; so as to leave a blind extremity of the larger tube at the site of their mutual junction. The *size* of this *cul-de-sac* generally exceeds that of the remainder of the bowel; it being larger than any other part of the alimentary canal, with the single exception of the stomach. When moderately distended, its diameter ranges from $2\frac{1}{2}$ to $3\frac{1}{2}$ inches; and its length is about as much. Its vertical extent is, however, somewhat arbitrary; since, though defined in part of its circumference by the aperture of the ileum and by the ilio-cæcal valve, it is elsewhere only limited by an imaginary line drawn around the tube at the level of the latter orifice.

The *situation* of the cæcum, in the left iliac fossa, allows it to vary considerably in size, without undergoing any marked change of its relations. Bound down as it is to the fascia over the iliacus muscle by peritoneum and loose areolar tissue, its enlargement merely causes it to displace such portions of the small intestine as may hitherto have shared the occupation of the iliac fossa. After its distention has removed these from its anterior surface, it reaches the anterior wall of the belly in the iliac region; where its size, shape, and contents can be more or less recognized during life, by the ordinary means of physical investigation.

The above dimensions render it obvious that the *shape* of the cæcum is somewhat globular. This shape is, however, modified by the arrangement of its muscular layers; which here begin to offer a peculiarity that is maintained throughout the whole of the colon. The uniform external or longitudinal layer present in the small intestine is here contrasted by one which is separated into three flattened bands, that occupy the side of the tube at nearly equal distances from each other. In the cæcum one of these (and the larger of the three) is anterior; one posterior; and one external. And all three of them become continuous above with the corresponding bands around the ascending colon. Between these slips of muscle, the bowel presents a more or less dilated and projecting external surface; which is again subdivided by transverse constrictions into subordinate pouches or sacculi. On laying open the bowel, and removing the mucous membrane from its inner surface, it may be seen that these transverse constrictions are in reality formed by the circular muscular coat; which gives off projections or incomplete septa, that complicate the general cavity of the tube, by adding a number of supplementary cells. These cells are arranged in three vertical rows; which are separated by ridges, that correspond to the external depressions formed by the longitudinal bands above mentioned. Between these bands, the "*haustra*," or pouches of the bowel possess a muscular tunic of very inconsiderable thickness: the transverse or circular layer being reduced to a thin membranous lamina; and the longitudinal being, as before stated, altogether absent. The close relation of these longitudinal and transverse septa to the length and width of the bowel is well shown by the effect of cutting across or removing its three bands, and then distending the tube by artificial inflation. This obliterates the "falciform folds" or transverse septa; and thus converts the sacculated intestine into a canal, the length and diameter of which are nearly double of what it formerly possessed when retained in its proper shape by its longitudinal bands or "tæniæ."

The *serous* covering of the cœcum is chiefly remarkable from the closeness with which it generally attaches the bowel to the fascia over the iliacus muscle. When the tube is but moderately distended, it covers only its anterior surface. Extreme contraction can, however, render it a more complete covering; and may even produce it into a kind of meso-cæcum behind the bowel. While conversely, great distention of the tube reduces the peritoneum to a partial investment; which occupies but a third, or even less, of the intestinal surface.

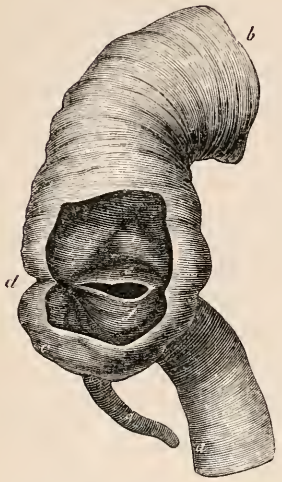
The *mucous membrane* of the cœcum differs in no essential respect from that of the remainder of the large intestine, the structure of which is continued up to the very edge of the valve which severs it from the ileum.

The cæcum has three *apertures*: — one, a large opening by which its cavity is directly continuous with the colon; a second, which communicates with the small intestine, and is guarded by a double valve; and a third, which opens into the slender vermiform appendix.

Ileo-cæcal valve. — The opening into the ileum is situated at the upper border of the cœcum; on its left side, and a little posteriorly. The structures which bound and define this opening are collectively termed the *ileo-cæcal* or the *ileo-colic valve*: — although these names ought in strictness to be limited to those separate portions of the entire intestinal valve which their etymology would indicate.

The arrangement of the intestinal tunics in this valve is best seen by inflating and drying that part of the intestine, which includes, together with the last inch or two of ileum, the cæcum, and the commencement of the colon. On cutting out a piece of such a dried preparation, so as to gain a view of its interior, we see the valve as represented in the accompanying figure (*fig.* 275.) The small intestine, generally inclining slightly upwards as well as backwards, passes towards the cæcum, at what is thus a rather acute angle. Instead, however, of opening into the bottom of one of the sacculi of the cæcum, it selects for its entry the exact site of the deepest and most projecting of those transverse constrictions which project into the cavity of the large intestine. This constriction occupies the inner side of the bowel; and is, as it were, split up by the entering ileum into two laminæ; — an upper and a lower, an ileo-colic and an ileo-cæcal (*e*, *f*, *fig.* 275.) While, at the same time, the hitherto cylindrical calibre of the small intestine is gradually reduced to a horizontal slit or fissure, as it enters this fold.

Fig. 275.



Cæcum inflated, dried, and opened, to exhibit the arrangement of its valve.

a, termination of the ileum; *b*, ascending colon; *c*, cæcum; *d*, transverse constriction projecting into the cæcum from its inner surface; *e f*, valve separating the small from the large intestine; *e*, its horizontal ileo-colic lamina; *f*, its more oblique ileo-cæcal lamina; *g*, the vermiform appendix of the cæcum.

Such a description at once explains the form of the valve: — how each of its segments, for example, constitutes a crescentic membrane, the plane of which meets that of its fellow at an acute angle, and the free edge of which is directed outwards; — and how both end anteriorly and posteriorly in a commissure or fold, that gradually decreases in depth as it passes either forwards or backwards round the intestine.

As regards the details of its construction, each segment of the valve is chiefly formed by the prolongation of a corresponding portion of the circular muscular fibres of the ileum, together with a few proper to the large intestine. The assistance afforded to these by the attachment of the peritoneum and the longitudinal fibres of the ileum, to the fixed margin of each segment, is well shown by the effect of dividing the latter structures. For after such an injury, moderate traction draws out the valve into a surface, which is directly continuous with the lower end of the small intestine; and at the same time converts its horizontal slit into a large elliptical aperture. The difference between the ileo-cæcal and ileo-colic portions consists chiefly in the fact, that the plane of the former is more oblique, and its margin more concave, than that of the latter.

The *mechanism* of this valve may be easily deduced from its structure. In all states short of actual distention, the passive contraction of its muscular walls no doubt insures their contact, and shuts off the cavity of the ileum from that of the cæcum. While any approach towards a more active dilatation of the large intestine — whether of the cæcum, or colon — at once brings about a close apposition of the two portions of the valve. And whatever aid may be given to this mutual apposition of the surfaces of the valve by its own active muscular contraction during life, nothing is more certain than that its closure is essentially independent of any such vital process. For the gradual and equable distention of the cæcum with liquid in the dead subject can also produce this result.

Nor is it difficult to understand how such a closure is effected. The passage of the contents of the large intestine, over either plane of the valve, presses it against the opposite one, so as at once to close its orifice. Besides this, the free margins of the valve form segments of a larger circle than its attached ones. Hence they are disproportionately tightened by the same distending force. In this way, the double curve of each lamina is soon reduced to a straight line, that brings it into exact apposition with its antagonist. So that, within all ordinary limits, the greater the dilating force, the more closely are the two lips of the valve applied to each other.

The only valid exceptions to this rule may be found in those cases in which the ileum and cæcum are filled simultaneously. Such a process of distention necessarily occurs in all cases of mechanical obstruction of the digestive canal below this valve; as a result of the downward flow of the contents of the small intestines. And since it obviously distends the aperture by the application of a counter-force from the side of the ileum, its mechanical action is so simple as to require no further explanation. Its effect may indeed be seen in the cæcum, as usually inflated and dried.*

The function of this valve therefore offers a complete contrast to that by which the stomach opens into the small intestine. For while it affords little or no obstacle to an onward transit of the contents of the canal, it resolutely bars the way to all regurgitation: — an action which we have already seen is exactly reversed by the pylorus. And even in the absence of information respecting the details of its active contraction, its structure entitles us to conjecture, that the greater part of its efficiency depends upon a passive, and therefore permanent mechanism; and not, as is the case with the pylorus, on an intermittent (and vital) shortening of its muscular fibres.

The use of the cæcum is evidently that of forming a receptacle, in which the contents of the small intestine may sojourn for a certain time, before passing onwards into the colon.

* Hence it is scarcely a superfluous caution to add, that in examining such a preparation we ought always to recollect, that the patulous orifice thus seen is in reality an abnormal one, which does not illustrate the mechanism of the valve in the healthy living body.

For not only are its shape, size, and direction such as admirably adapt it to this purpose, but its development in different species and individuals closely corresponds to the degree in which such a delay is advantageous to digestion. Thus the large cæcum of the Herbivora is contrasted, in the Carnivora, by one of but inconsiderable size and development. While there are grounds for conjecturing, that the habitual use of a vegetable diet is capable of increasing its size in the human subject. In all of these respects, however, its development does but parallel that of the remainder of the large intestine. We may therefore defer considering the nature of its secretion, and the changes undergone by its contents, until these segments of the bowel have also been noticed.

The *vermiform appendix* (*g*, *fig.* 275.) which is so named from its resemblance in shape and size to a worm, is a small, smooth, cylindrical tube; that opens into the cæcum below (and rather posterior to) the aperture of the small intestine. Its length varies from one to four or five inches: its diameter from about a fourth to a third of an inch. Its attached end of course shares the situation of the contiguous part of the cæcum. Its distal extremity is usually free; and may hence be found in almost any situation which its length, and that of the short mesentery that binds it down, together allow it to take. Its opening into the cæcum is often partially occluded by a kind of transverse fold or valve.

As regards its structure, the vermiform appendix exhibits all three of the ordinary coats. Its peritoneum is derived from that of the cæcum, and often forms a short fold or mesentery which is prolonged up a part of its length. Its muscular stratum is of uniform and considerable thickness, and is continuous with the three longitudinal bands which give the cæcum its sacculated shape. Its mucous membrane is occupied by tubes and follicles, like those of the colon. And the latter structures are often present in such extraordinary numbers, as to constitute almost a continuous layer of these minute closed sacs. The calibre of the tube, which is in general disproportionately small, is occupied by a sparing quantity of glairy mucus; and occasionally, by small fragments of the ordinary intestinal contents.

The use of the vermiform appendix is unknown. It has been suggested to be a mere relic of the umbilical duct of the fœtus: — an erroneous view, to which allusion will hereafter be made in speaking of the development of the intestinal canal. It is almost peculiar to Man; in whom its situation often causes it to receive small solids in their transit through the cæcum, with the result of their becoming impacted in its narrow cavity. This accident is sometimes followed by inflammation and perforation of the tube, causing fatal peritonitis.

The *colon** (formerly *Great gut*, Eng.; *Grimmdarm*, Germ.), which forms by far the greater part of the large intestine, extends from the ilio-cæcal valve to the rectum. Starting from the right iliac fossa, it passes vertically (*a*, *fig.* 274.) up the posterior wall of the belly, and on the right side of the spine, until it reaches the under surface of the liver. A sudden turn at a right angle marks the end of this *ascending* portion, and the beginning of its *transverse* part. The latter segment, though tolerably horizontal, forms an arch (*t*, *fig.* 274.) with the convexity forwards, so as to pass around the projecting spine and aorta. Below the spleen it merges, by another rectangular bend, into the *descending* colon (*d*, *fig.* 274.) This takes much the same course on the left side of the abdomen as the ascending colon does on the right; and opposite to the crest of the ileum, it ends by becoming continuous with the sigmoid flexure (*s*, *fig.* 274.). The latter portion is attached by a short mesentery to the left iliac fossa; and it terminates in the rectum, at a point corresponding to the left sacro-iliac symphysis.

The relations of each of these segments to the adjacent textures and organs may be easily deduced from their course as described above.

Thus the *ascending* colon lies on the right kidney and quadratus lumborum muscle, from which it is only separated by loose areolar tissue. On its left side, is the psoas muscle; and above it, the vertical portion of the duodenum. In front, it is covered by coils of intestine; or, if sufficiently distended to thrust these away, by the anterior wall of the belly.

The *transverse* colon is almost always in contact with the omentum and abdominal parietes, which it touches in the horizontal line that marks the mutual limit of the umbilical and epigastric regions. Above it, is the first portion of the duodenum; with the stomach, liver, gall bladder, and spleen. Below it, are the coils of the small intestine. Behind it, lie the second and third portions of the duodenum,— the latter covering the aorta. To its posterior surface is attached the *transverse meso-colon;* which connects this part of the intestine with the wall of the belly, by a double fold of peritoneum, that splits to enclose the tube. The double lamina formed by the reunion of these two layers of serous membrane in front of the bowel, is continuous, at the lower border of the great omentum, with the similar process that descends from the great curvature of the stomach.*

The *descending colon*, like the ascending, lies on the left kidney and the left quadratus lumborum muscle, and is covered by a variable quantity of the small intestine.

The *sigmoid flexure* is much more frequently in contact with the abdominal wall than the preceding portion of the colon. And its freedom of movement, to which this contact is partly due, also allows the bowel to deviate considerably from its ordinary curvature and

* This Greek word, which has been adopted into most of the modern languages, is derived indifferently from κῶλον, *membrum*, and κόλον, *alvus* (παρὰ τὴν κοιλότητα).

* See Art. Peritoneum.

position. The shape of this bend corresponds so exactly to its name, that it is scarcely necessary to bestow any further description upon it. Its curve is chiefly in the vertical plane; though a slight lateral curvature is almost always present, and is easily exaggerated into a much more distinct bend by the mobility of this segment of the canal.

The use of the sigmoid flexure seems to be that of forming a receptacle for the fæces:— a receptacle of which the shape and arrangement are such as to spare the rectum and its sphincter from much of the pressure and weight against which they would otherwise constantly have to contend. When full, the convexity of its lower bend often projects below the iliac fossa, so as to descend into the pelvis. Indeed, the whole of the colon is very liable to displacement from the various positions just assigned to it:—prolonged distention by its accumulated contents, or the mechanical force exerted by the pressure of stays externally, or of tumours internally—being all capable of altering its relations, and even confusing its different parts* with each other.

The colon retains the sacculated shape assumed by the cæcum. Its size undergoes a progressive though slight decrease, from its commencement in the cæcum to its termination in the rectum. Its peritoneal coverings reach their minimum in the ascending and descending portions; where they only cover about two-thirds of the moderately distended bowel, and leave its posterior or attached third quite unoccupied by this membrane, and connected by loose areolar tissue to the subjacent parts. Hence it is these portions of the bowel which are selected in the operation for artificial anus.† But, just as great distention can always increase this uncovered portion, so, *vice versâ*, excessive contraction may reduce it to a mere line, or may even develope a kind of short meso-colon in connection with either of these parts. The muscular strata which cause its sacculated shape, also retain the arrangement existing in the cœcum. But on the transverse colon, the internal longitudinal band becomes inferior. And on the sigmoid flexure, this and the posterior band generally merge into a single one. The latter change is accompanied by an indistinctness of the transverse sacculi themselves.

Throughout the whole of the large intestine, the peritoneum is here and there developed into peculiar, processes, called the *appendices epiploicæ* (ἐπίπλοον, *omentum*). These are short pouches of the serous membrane, which generally form flattened duplicatures or folds. They are prolonged from the peritoneum covering the surface of the intestine itself; and are therefore absent from that portion of the rectum, or terminal segment of the large intestine, which does not receive any covering of this membrane. Their number, size, and arrangement, are liable to great variety. Sometimes they are so numerous, as to form a single or double row along the free surface of the bowel. In other instances they are very few and imperfect. Their size is so far related to the state of the bowel, that, like most other processes of peritoneum, they are enlarged by its contraction, and diminished by its distention. From their contents, which consist of areolar and adipose tissue, they would seem to be small reservoirs of fatty matter. Hence in cases of remarkable obesity, their size is much increased. Indeed they sometimes acquire a length of one or two inches; and have even been known to encircle and strangulate the bowel.

Movement of the large intestine.—The exact nature of the movement which is executed by the muscular coat of the large intestine can at most only be conjectured from some of its attendant circumstances. Like that of the preceding segment of the canal, though its general mechanism is obvious, its details remain unknown.

As regards the investigation of the contents of this intestine in its ordinary situation during life, all that can be stated is, that, even in health, they include a quantity of gaseous matter; which usually maps out the cœcum, and more or less of the colon, with tolerable distinctness, from the less resonant convolutions of the small intestine.

After death, the quality and quantity of these contents are so much affected by the nature of the previous food, the mode of dying, and a variety of kindred causes, that scarcely any general proposition can be laid down with respect to them. But on the whole, we usually find, that in addition to much gaseous fluid, the cæcum of the healthy subject is partially distended by pultaceous or semi-fluid contents. While the colon is occupied at various points of its length by matter, the fæcal character of which is still more distinct, and the consistence of which gradually increases as it approaches the rectum.

Where these rudimentary fæces are very imperfect, scanty, and interrupted, they only occupy some of the sacculi or cells of the bowel, leaving its central or general calibre in an empty state. But when better developed, they form what is termed a "figured" mass. This consists of a kind of central rod, that corresponds to the general axis of the tube; and of processes that come off from the sides of this axial portion, and are contained in the rows of pouches formed by the wall of the bowel. In short, the solid and continuous fæcal substance forms a tolerably perfect cast of the bowel;—a cast in which the sacculi of the colon are "figured" as projections, themselves isolated by depressions corresponding to the intersections of its longitudinal and transverse bands.

The characteristic shape thus possessed by the solid contents of the colon, is often retained by the fæces which have been forced through the rectum in the natural process of defæcation. And although it is often absent,—the con-

* See *Abnormal Anatomy.*

† Other things being equal, the left or descending portion is preferred: on account of a larger extent of the canal being thus left to be traversed by the intestinal contents.

sistence of the fæces being such* as to mould them to the cylindrical form of the last-named portion of tube through which they have to pass—still it occurs so frequently in Man, and so universally in many of those Herbivora in whom we can best study the phenomena of a highly developed large intestine, as to afford a valuable testimony to the natural action of this part. It is therefore difficult to avoid believing, that the individual sacculi of the colon, or at least of its later segments, retain the fæces for a considerable period of time; during which they so far complete the action of the large intestine upon these its contents, as to leave nothing for its remaining segments to effect, save their mechanical propulsion towards the outlet of the canal. To this intermittent action of the muscular coat in respect of time, we may probably add a similar interruption as regards space. In other words, the interrupted and irregular manner in which the sacculi are often occupied by solid fæces, entitles us to suspect, that different lengths of the intestine can act independently of each other. But it is difficult to hazard a conjecture as to whether the contraction of the falciform transverse folds ever really shuts off portions of the tube into distinct cavities. The central axis of the figured evacuation is, however, often so slender, or even interrupted, as remarkably to corroborate such a view. And some authors have assumed that the cæcum, during its digestive act, is isolated from the ascending colon by a vigorous contraction of that large fold which is prolonged from the frœna (or anterior and posterior extremities) of the ilio-cæcal valve.†

The little information afforded us by direct observation on the movements of the intestine, confirms what is thus vaguely suggested by the appearances of its expelled contents. The highly developed large intestine of the living or newly-killed rabbit, rarely exhibits any noticeable movement whatever, when first exposed to the air. By and bye, however, a kind of irregular peristalsis comes on. But this is nowhere quite so energetic as that seen under similar circumstances in the small intestine; and is generally very feeble in the cæcum.* And in this movement, as in that produced by mere local irritation, we may notice the peculiar character before attributed to the contraction of unstriped muscle generally;—viz., that of diffusing itself over a time and space greater than those occupied by the irritation which has excited it. As regards the details of this vermicular action, certain sacculi contract and dilate alternately; the transverse constrictions between them sharing in the same movement. This alternate movement is often accompanied by an irregular contraction of the longitudinal bands; which is sometimes carried to such an extent, as to shorten the tube, by approximating and dilating certain of its cells. And even where the effect of the local irritation survives its cause, so as to excite a continuous movement which proceeds along a considerable length of intestine, still it rarely affects all the cells of the bowel exactly alike; but often passes lightly over one or two, to bear with increased intensity on those which immediately succeed them. Very similar movements are produced by galvanizing the solar plexus which gives off the nerves to the large intestine.

On the whole, therefore, the greater solidity of the contents of the large intestine implies a greater resistance to the contraction of its muscular coat. And the structure of this coat shows no proportionate increase, but rather a decrease of strength. Hence we might almost conjecture, that the general movement of the small intestine is here exchanged for one which is slower, feebler, and hence less effective: and which, besides being much weaker, is possibly interrupted by longer periods of rest.†

But it is probable that this comparatively feeble character of the general movement of the large intestine is capable of being more than compensated by that heightened efficacy which the peculiar arrangement of its muscular coat can concede. The thin muscular stratum that forms the wall of its numerous pouches, is evidently capable of assuming a much smaller surface, in obedience to the thick and powerful bands of its transverse and longitudinal coats. Indeed, the simultaneous contraction of these two sets of fibres would convert them into what would form, for the time, a very thick and powerful expanse of unstriped muscle, capable of obliterating the entire calibre of the intestine.

In this way the same muscular apparatus

* The consistence of even a figured evacuation is sometimes so slight, as to render it highly probable, that a general relaxation of that segment of intestine which originally contained the fæcal mass has accompanied the propulsive contraction of the part immediately behind it. Such an apparently co-ordinate relaxation of the muscular coat may be frequently noticed in that vermicular movement of the small intestine which is seen shortly after death. An occurrence of this kind seems almost the only way in which one can account for the fact, that soft and semifluid fæces frequently retain the form of the colon, after passing through its falciform folds. Whether such an action is ever effected by a contraction of the longitudinal bands simultaneously with a relaxation of the circular or falciform folds, it is impossible to determine. But from their mechanism, and from the above appearances of the fæces, it would seem more probable that both these classes of fibres relax simultaneously.

† Energetic contraction of the transverse fibres of this valve would obviously aid in its occlusion; though we have already shown it to be probably independent of all active muscular force.

* The contractions by which this part responds to a local stimulus are far more feeble, slow, and uncertain, than those obtained in any other part of the canal,—the stomach not excepted. This character seems to be a direct result of the tenuity of the muscular coat, which also attains its maximum here. An incident which I have remarked in one or two cases of intestinal obstruction appears to be partly explained by the same structural peculiarity. In these instances, though the stricture was seated in the descending colon, the dilatation and rupture that formed the immediate cause of death occupied the cæcum.

† Compare pp. 343, 344.

which generally concedes to the contents of the large intestine a long delay, and a slight movement over a large absorptive surface, would still be quite capable of effecting their rapid and vigorous expulsion, when required to do so. Nay, more, since much of this expulsive act seems, as it were, removed from the sacculi themselves, and concentrated in the bands around them, we may conjecture that the mechanism of these latter contractile masses is also specially concerned in the nervous part of the process. At least, it is not impossible, that the irritation or stretching of these two sets of muscles (which can be effected only by the general distention of the calibre of the tube, and not by the local distention of its cells) may constitute the immediate stimulus of the evacuation of the whole large intestine, or of any particular segment.

The *mucous membrane* of the colon may be described as only differing from that of the small intestine in the fact that it is somewhat thicker, and quite devoid of villi. Its more numerous *tubes* are about one-third longer than those of the small intestine; and their diameter seems to be, in general, still more increased. Its *solitary follicles* are also more numerous, and of larger size. And the depressions which mark the site of each on the internal surface of the bowel are here represented by a distinct pit; which leads by vertical, or even somewhat divergent sides, to the follicle that occupies its base. But the secretions of these structures, and the cell-growth which lines them, do not present any noticeable difference from their analogues in the small intestine.

The *rectum* (*r*, *fig*. 274.; *r* 1, *r* 2, *r* 3, *fig*. 276.) (formerly *straight gut*, Eng.; *Mastdarm*, Germ.), which intervenes between the sigmoid flexure of the colon (*s*) and the anus (*n*), forms the terminal segment of the large intestine. It has received the above name from the comparatively direct course which it takes. Its length is about seven to eight inches. Its width is at first only equal to that of the small extremity of the colon, with which it is continuous: but gradually increases, so as to form a kind of dilatation or pouch in the immediate neighbourhood of its lower aperture. Here it suddenly contracts to the narrow orifice of the *anus;* which is situated in the perineal space, that closes the pelvis, and forms the lower extremity of the trunk.

Strictly speaking, however, the rectum is by no means straight. Beginning at the left sacro-iliac symphysis (*e*, *fig*. 276.), it first passes obliquely downwards and to the right side, towards the median line of the trunk; which it reaches at a point that nearly corresponds to the body of the third sacral vertebra (at *r* 1, *fig*. 276.). And though, from hence to its termination, it continues to occupy the middle line, still as it rests upon the concave anterior surface of the remainder of the spinal column, it assumes a curve similar to that of the sacrum. It thus acquires a second and more remarkable bend (at *r* 2, *fig*. 276.), which is convex backwards. Finally, at the tip of the coccyx, it quits the antero-posterior direction given it by this bone; and, bending suddenly

a, fourth lumbar vertebra; *b*, bladder; *c*, symphysis of the pubis; *d*, inner surface of the left os ilii; *e*, sacro-iliac articulation; *f*, vas deferens; *g*, ureter; *h*, spine of the ischium sawn through, and left attached by the coccygeus muscle; *i*, left vesicula seminalis; *k*, prostate gland; *l*, bulb of the urethra; *m*, left corpus cavernosum divided at its root; *n*, anus; *o*, levator ani cut across near its attachment to the coccyx; *p*, sciatic nerves and vessels; *q*, fibres of levator ani passing round the lower end of the rectum; *r*, rectum, 1, 2, 3, its first, second, and third portions; *s*, sigmoid flexure of the colon; *r v*, peritoneum forming the left side of the recto-vesical pouch.

downwards at a right angle, becomes vertical for a very short distance (at *r* 3, *fig*. 276.) prior to ending in the anus.

The above successive changes in its direction are associated with others, which affect its relations to the peritoneum and to the surrounding structures. In accordance with these, it is usual to describe the rectum as subdivided into three portions.

The *first or oblique segment* (between *s* and *r* 1, *fig*. 276.) is about 3½ inches long. It is covered on every side by peritoneum; which, at its commencement, attaches it to the pelvis by a short meso-rectum, very similar to the meso-colon of the sigmoid flexure.* It lies on the sacrum, the upper border of the pyriformis muscle, and the sacral plexus. In front of it is the bladder, from which it is generally separated by some convolutions of the small intestine. On either side

* This meso-rectum is sometimes so long, as to give this segment of the bowel a mobility (and often a shape) very similar to that of the neighbouring sigmoid flexure itself.

it is related to the ureter, and to the branches of the internal iliac vessels.

The *middle or arcuate segment* (*r* 2, *fig.* 276.) scarcely exceeds 2½ inches in length. It lies on the sacrum and coccyx; to which it is attached by a loose areolar tissue, that usually encloses much fat. The peritoneum, which invests a small part of its lateral surfaces above, soon becomes limited to its anterior surface as it descends; and ceases altogether at a distance of about an inch from the termination of this part of the bowel. This incomplete serous covering is, in fact, the lower extremity of a process of peritoneum, which is called *the recto-vesical pouch* (*r v*, *fig.* 276.). The apex of this, below, corresponds to the point where the membrane is reflected from the anterior surface of the rectum, to the neighbouring posterior surface of the bladder. Hence the front of the bowel, which, above, comes into contact with the distended bladder, or with any convolution of small intestine that may chance to occupy the recto-vesical pouch, touches, below, the anterior part of the base of the bladder. This it does in a triangular space, that is bounded on each side by the vesicula seminalis (*i*, *fig.* 276.), and behind by the pouch aforesaid:—a space which therefore corresponds to the "*trigone vesicale*" on the inner surface of the bladder; and marks a region, where this viscus may be punctured through the rectum, without any injury to the serous membrane. On each side of this part of the rectum, is a lamina of pelvic fascia which supports it; and externally to this is the coccygeus muscle, which descends from the spine of the ischium (*h*, *fig.* 276.) to the border of the coccyx.

The *third or terminal portion* of the bowel (*r* 3, *fig.* 276.) is about 1½ inches long. It is surrounded, above, by areolar tissue loaded with fat: below, by the sphincter ani externus (at *n*); and by the levator ani (*o* and *q*) which descends from the pelvis to mingle its fibres of insertion with those of the former muscle. In front of it are the prostate (*k*, *fig.* 276.) and the membranous portion of the urethra in the male, the vagina in the female: behind it, the tip of the coccyx in both sexes. The degree in which the prostate projects into the rectum will of course vary, both with the size of this gland, and with the amount of distention to which the tube itself is habitually subjected. Where its distention is very great, the flaccid intestine sometimes appears almost folded around the prostate gland, so as to offer a kind of pouch on either side of it.

As regards the *structure* of the rectum, its peritoneal coat has already received a sufficient description. Its muscular tunic differs remarkably from that of the colon. In place of being divided into three bands, the fibres of the longitudinal coat are again collected into a single uniform expanse, that surrounds the whole of the tube. And both it and the transverse layer are very much increased in thickness. Thus even in the upper part of the rectum, the muscular coat offers a total thickness which at least doubles that of the colon; while near its termination, it is scarcely less than four times as thick. The fibres themselves are of a redder colour, especially the transverse; and near the anus, they are mingled with the striated elements of the adjoining voluntary muscles. And that distant analogy which the rectum seems to offer the œsophagus in all these respects, is rendered somewhat closer by the presence of numerous folds of mucous membrane, which the mere passive contraction of its muscular tunic appears generally to produce. In short, it would hardly be an exaggeration to say that this, the last segment of the digestive canal, resumes not only the median position, but even the structure and action, of the first.

Muscles of the anus.—The muscular apparatus that guards the lower outlet of the rectum, consists chiefly of two sphincter muscles, which close the orifice of the anus by their contraction. Of these, one, the *sphincter ani internus*, which is situated within the bowel, is little more than a thickening of the proper transverse or circular layer of its muscular coat. It lies immediately beneath the mucous membrane, and consists of the ordinary unstriped fibres, which retain their usual pale colour. The other, the proper sphincter, or the *sphincter ani externus*, is a deep-red mass of striated muscular fibre, which surrounds the lower extremity of the rectum (at *n*, *fig* 276.), including the preceding structure. Its form is elliptical and concave; so that its outer border occupies a higher level than its inner one. Hence it receives the end of the bowel as it were into a shallow funnel; and, on contracting, occludes its cavity by the pressure of what is a surface, and not merely an edge, of its plane of fibres. Its outermost bundles arise from a tendinous structure which is prolonged from the tip of the coccyx; and they pass forwards, on both sides of the bowel, to reunite in the central tendinous point of the perinæum. Its innermost or lowest fibres are attached to a dense subcutaneous areolar tissue that lies before and behind the anus. In the female, they interlace anteriorly with those of the constrictor vaginæ, by what is often a distinct decussation.

It is chiefly through the intervention of this sphincter that the *levator ani* muscle is connected with the lower extremity of the rectum. The fibres of this large expanse of striped muscular substance descend from their pelvic origin*, with an inclination backwards, to reach the lower orifice of the cavity of the pelvis, which they assist to close. In front of the rectum, a certain number of them are inserted into the tendinous and areolar tissues which here occupy the middle line of the perineum; and these join more or less directly with the attachment of the external sphincter in the same situation. Behind the rectum, a considerable plane of the more posterior fibres

* For a fuller description of the origin and relations of the above muscle, the reader is referred to the Article Pelvis.

of the levator passes around the tube, returning upon itself in the similar portion from the opposite side, so as to sling and sustain the canal. Between these anterior and posterior slips, is a median portion; which descends to be inseparably united with the upper and outer rings of the external sphincter itself. And besides interlacing with the striped fibres of this muscle, it may generally be traced sending off a certain number of its scattered bundles, to decussate and disappear amongst the unstriped fibres of the longitudinal and transverse layers of the rectum just at their termination.

Movements of the rectum.—The contraction of the muscular coat of the rectum, like that of the other segments of the digestive tube, has for its object the onward propulsion of its contents. But since the rectum ends the intestinal canal, it forms the portal by which these contents are altogether dismissed from the body. Health and comfort alike require that this act of dismissal should be both intermittent and infrequent. While the mere consistence of the fæces is generally such as to demand the application of a comparatively powerful force in order to effect their rapid removal. Hence the entire mechanical action of the rectum is naturally divisible into two stages:—one which propels, and one which expels, the various substances occupying its interior. The latter of these two processes is called *defæcation;* and, as we shall see, involves the aid of various agents which are strictly extraneous to the bowel itself.

Those movements of the rectum which are seen in living or newly-killed animals, can only be regarded as confirming the conclusions that might fairly be inferred from the much greater thickness of the muscular coat in this particular segment of the large intestine.

When empty, the bowel remains in a state of rest, from which it can scarcely be aroused to peristalsis by the application of any local irritation. But when occupied by a moderate quantity of fæces, it will often respond to a direct mechanical stimulus; and still more energetically to the electrical irritation of its nerves. On applying the rapid and powerful shocks of the electro-magnetic machine to those large branches of the sympathetic which are distributed in the muscular coat of the rectum, a violent contraction of this tube frequently occurs. In this intense but irregular movement, we may generally observe a shortening and a constriction:—acts which no doubt represent the specific contractions that form the functions of the longitudinal and transverse fibres respectively. Thus the bowel suddenly becomes straighter and shorter; and hence appears as though it were jerked downwards towards its most fixed point at the lower opening of the pelvis. This shortening is generally accompanied by a less violent and more uniform movement:—in short, by a peristalsis; which offers the ordinary progressive constriction, and is evidently the principal agent in the propulsion of the fæcal pellets. But both of these movements are very irregular. The former commonly alternates with a relaxation, which appears to pull the rectum upwards, and exaggerate its curves. While the latter occupies various parts of the bowel with very unequal intensity and duration; and, occasionally, even seems to take a retrograde course. In most of these details, we may observe the same close analogy between the rectum and the œsophagus, which has already been remarked in their median and terminal situation, and (to a lesser degree) in the nature and thickness of their muscular coat.

The normal movement of the bowel differs from the above in the fact of its being a more exact and co-ordinate action; and, therefore, a much more effective one. But while observation and experiment both agree in representing it as a peristalsis, which is quite capable of slowly expelling fæces of moderate consistence, nothing is more certain than that it is rarely called upon to exert such an independent and unaided force.

Under all ordinary circumstances, its influence is assisted by the action of various voluntary muscles. These may be divided into two classes, which differ in their situation and action.

The first are those large planes of muscle which form the anterior, lateral, and superior, walls of the belly; and thus, by their contraction, exert a forcible pressure on the intestines contained in this cavity.

The second are the similar structures that close the outlet of the pelvis. These have for their office to support the end of the canal. And their muscular nature enables them to effect this support by a texture, the passive or active contraction of which can always increase the reaction or resistance to the abdominal pressure in exact correspondence with the varying demands made upon it. They thus fix the end of the intestinal canal, while it is being emptied of its contents by the pressure of the muscles of the belly.

The mechanism of the abdominal pressure having already been described in treating of the act of vomiting*, but little need here be added with reference to the special conditions under which it is called upon to aid that of defæcation. Of course the chief of these conditions consists in the application of a stimulus to the large intestine itself. And though any irritation of the mucous membrane of the rectum seems capable of producing that violent straining which marks the exertion of the abdominal pressure, still its strictly co-ordinate character is well illustrated by the preference apparently shown to a stimulus which acts directly on the muscular fibres of the bowel themselves. Thus a mechanical distention of the rectum appears to be a more efficient stimulus to the total expulsive act than the application of any ordinary irritant. While, *vice versâ*, there are good reasons for conjecturing, that mere distention of the belly is capable of arousing a sluggish large intestine to expel its contents.† And a

* See p. 316.

† Such a "reflex action," from the animal to the organic muscle, may perhaps explain the operation of one of the ordinary remedies against constipation;

still more frequent association of movement is probably exemplified in the tenesmus produced by dysentery and other disorders, which involve great irritation of the rectum. For the sensations of the patient, and the uncontrollable impulse which follows them, seem to indicate that the irritation of the mucous membrane is often accompanied by violent contraction of the muscular coat of the intestine, both of which unite to excite the subsequent abdominal pressure.

The nature of the contents of the rectum greatly affects the degree in which the muscles of the abdomen are made to assist in their expulsion. When these contents consist only of gases and liquids, they require so little of this aid, as to be sometimes expelled without it. But the extrusion of hard scybalous evacuations often demands the help of abdominal pressure, to an extent such as involves all the viscera of the trunk, and seriously obstructs the flow of blood in the larger veins of the head and thorax.

As regards the levator ani muscle, its origin and insertion, together with the course taken by its fibres, leave no doubt as to what must be the direct effect of its contraction. It raises the end of the rectum, together with the ligamentous structures of the perinæum anteriorly, and the coccyx posteriorly. But as the time of this action seems exactly to coincide with the exertion of the abdominal pressure just alluded to, the degree in which it really raises these structures can only equal the surplus of its force over that of the muscles of the belly. Hence it may be doubted whether the muscle generally does more than fix the bowel: an effect which is, however, of the highest importance to the mechanism of defæcation. The influence of the neighbouring perinæal muscles is still more obscure.

Such being the known agents of the process of defæcation, we may next attempt to sketch the course of its phenomena.

The ordinary peristalsis of the large intestine propels into the rectum a variable quantity of fæces. These, after a longer or shorter sojourn in its first or second portions, excite an active peristaltic contraction of its muscular coat. In general it is only when they reach the lower extremity of the bowel, that the abdominal pressure adds to this peristalsis its far more powerful expulsive force. The combined effect of both these actions urges the fæcal mass against the external sphincter, which relaxes at this instant, by a voluntary effort, so as to permit the extrusion of the descending mass: a small portion of the loose mucous membrane being at the same time generally everted around it.

A variable length of fæcal substance thus passes through the orifice of the anus. The continuity of the descending mass being finally interrupted, the act of respiration* is resumed; the abdominal pressure ceases; and at the same time, the contraction of the levator ani, aided by that of the rectum itself, returns the projecting extremity of the bowel into the pelvis, by a kind of sudden and forcible retraction. The latter act, in which both of the sphincters may be presumed to play an important part, often subdivides a continuous fæcal mass; returning the upper segment thus cut off into the cavity of the rectum which it was just leaving. The total duration of the expulsive act appears to be chiefly determined by the consistence of the fæces, the velocity of their transit, and the exigencies of the suspended process of respiration itself.

The *mucous membrane* of the rectum is connected with its muscular coat much more loosely than that of the colon. Owing to this circumstance, it generally exhibits numerous folds. Most of these are mere temporary results of the passive contraction of the muscular coat. And in correspondence with such an origin, they are very irregular in size, number, and position. They are, however, more frequently found occupying the dilated lower end of the bowel, where they take what is usually a longitudinal direction.

But in addition to such casual and temporary folds, Mr. Houston* has described others, which he states to have a definite direction and situation, as well as a more permanent character. According to this anatomist, three is the number of these folds or valves usually present. The largest and most constant of the three projects from the anterior wall of the rectum, opposite to the base of the bladder, and about three inches above the anus. The valve next above this springs from the left wall of the bowel, about midway between the last and the third or uppermost fold. This latter projects from the right wall of the upper end of the rectum. The shape of all three is nearly semilunar: their depth about half an inch; and they are fixed by a convex border to about half the circumference of the intestine. And Kohlrausch† has described a fold which tolerably answers to the fourth and least constant of those mentioned by Mr. Houston. He states it to be always present, as a transverse projection from the posterior wall of the rectum opposite the middle of the coccyx. In general it contains no muscular fibres: but rarely these may even encircle the bowel, as a continuous ring or third sphincter, which forms the lower boundary of a dilated and sacciform segment of the rectum.

As regards these folds, we may point out, that their usual situation corresponds to the most prominent parts of those three curves of the rectum which we have already alluded to. Thus the third answers to that convex mucous surface which marks the

namely, the application of a wet bandage tightly around the belly.

* The way in which this act is affected during the exercise of abdominal pressure has already been explained at p. 316.

* Dublin Hospital Reports, vol. v. p. 163.

† "Zur Anatomie und Physiologie der Beckenorgane," Leipzig, 1854; also Valentin's "Bericht ueber die Leistungen in der Physiologie" in Canstatt's Jahresbericht, 1854.

transition of the sigmoid flexure of the colon into the rectum; the second indicates the spot where the bowel reaches the median line of the sacrum; and the first is nearly opposite to its bend in the hollow of the latter bone and the coccyx. And frequent as their presence undoubtedly is — and important as they therefore are with respect to the surgery of the rectum, — it may still be doubted whether they possess those characteristic anatomical features that would alone entitle them to rank as true permanent folds, like the transverse or falciform septa which isolate the several pouches of the large intestine. For, unlike these, they are not only somewhat irregular in number and position, but are effaced by complete distention of the tube. And, finally, they appear to contain not a trace of the proper transverse stratum of unstriped fibres. Hence they probably express a mere passive arrangement of the loose mucous membrane; — a relaxation which is perhaps chiefly due to contraction of the powerful longitudinal layer of the muscular coat of the bowel.

In the rectum, the muscular lamina of the mucous membrane resumes its usual thickness. At the lower part of the bowel, the skin and mucous membrane become continuous with each other. But, as might be expected from the great dissimilarity of these structures, there is a distinct line of demarcation between the two. Their junction is situate, not exactly at the anus, but at a point from two to four or five lines above this aperture. Here the skin terminates by a wavy margin, having a distant resemblance with that dentate edge, by which the thick white epithelium of the œsophagus adjoins the delicate pink mucous membrane of the stomach. And the apex of each of these waves usually corresponds to the starting point of a longitudinal fold of mucous membrane; which, after proceeding a short distance up the bowel, either becomes indistinct and disappears, or is crossed and effaced by others that take a different direction. It is nearly in this situation that Kohlrausch * describes a thin layer of unstriped muscular fibres, lying between the sphincter ani internus and the mucous membrane. Traced upwards from their intimate union with the latter structure, these fibres are seen to take a longitudinal course; and to end, about one and a half inches above the aperture of the anus, by joining the layer of circular fibres immediately external to them. Regarding these latter as their origin, it is evident that their action would raise the mucous membrane, and oppose its prolapse. Hence they are described as forming a "*sustentator tunicæ mucosæ.*" Below its junction with the mucous membrane, the moist skin possesses its ordinary structure. And around the anus, it is occupied by numerous hair bulbs; as well as by sebaceous follicles, which pour forth a large quantity of a peculiar odorous secretion.

The *contents* of the large intestine are of two kinds. The first is a mass which, usually of a semifluid consistence, ranges from the state of a thin liquid to that of a hard friable solid. This mass, when evacuated from the rectum, constitutes the fæces, ordure, or excrement. The second is an elastic or gaseous fluid, which occupies the intestine in very variable amount, and unless its quantity be excessive, is not necessarily or regularly expelled at all.

Fæces. It will be some clue to the composition of the fæces if we recollect, that the large intestine so far resembles the small, as to justify our inferring that it continues the various metamorphoses which the contents of the canal begin to undergo in its upper segments. These metamorphoses are due, partly to a spontaneous decomposition of the alimentary substances themselves, partly to changes set up by the various secretions mixed with them. And they are accompanied by processes of absorption and secretion, which may probably be regarded as in some degree peculiar to this segment of the tube. Of these two processes, that of absorption seems chiefly destined to deprive the intestinal contents of their more watery and soluble parts. While the act of secretion pours forth fluids which, from their proximity to the end of the bowel, may be assumed to be, in great extent, excrementitious. The matters thus excreted may be divided, histologically, into two chief constituents: — a structureless alkaline fluid which is furnished by the tubes; and a scaly epithelium, which is a desquamation from the mucous membrane of the rectum.

But it would be wrong to suppose that the whole of the processes which engage the contents of the large intestine can be comprehended in three such acts of metamorphosis, absorption, and secretion as those just alluded to. On the contrary, each of these three exerts its usual complex reaction upon the other two. Thus the soluble results of metamorphosis undergo absorption, as do also some of the substances secreted. The fluids secreted into the bowel no doubt modify the spontaneous changes which engage its contents. And, finally, the slow transit of these contents along the intestine is accompanied by the precipitation of insoluble matters from the various secretions of the upper segments of the canal, prior to their expulsion from its lower orifice.

It has indeed been alleged, that the cœcum is the seat of a special metamorphosis, which repeats, as it were, the process of gastric digestion: — that its mucous membrane pours out an acid secretion, which is capable of dissolving certain constituents of the food preparatory to their absorption. But a closer examination dispels this view, and assigns to this segment an humbler office, which is closely analogous to that of the neighbouring portions of the canal. Its tubes, which have precisely the structure of those found elsewhere, pour out an equally alkaline secretion. Its infusion, whether acidulated or otherwise,

* *Loc. cit.*

has no higher solvent power over albuminous substances than that possessed by the similar fluid prepared from pieces of ileum or colon. While the strongly acid reaction of its contents in many herbivorous animals is sufficiently explained as due to that lactic fermentation, which the various starchy substances are so apt to undergo when exposed to spontaneous decomposition at the temperature (about* 103°) of the intestinal canal. Consistently with such an explanation, this acid reaction is found chiefly or exclusively in those parts of the fæcal mass which are not in contact with the alkaline mucous membrane, and is by no means limited to the contents of the cœcal pouch.

We may therefore regard the fæces as composed chiefly of two constituents: — which are derived, the one from the food taken by the animal, and the other, from the secretions of its digestive organs. And in like manner, we may premise what follows by stating, that the composition of any particular excrement will always depend on the nature of the food, the state of the secretions, and the nature and amount of the metamorphoses which both these constituents have together undergone.

Physical properties of the fæces — Subject to circumstances so numerous and fluctuating, it is obvious that the physical properties of the fæces must vary extremely in different subjects. Their ordinary colour, odour, form, size, and consistence are so well known, as scarcely to require any special description in this essay.

As regards the two first of these characters, the contents of the small intestine are distinctly fæcal. But it is only in the cœcum, where both their colour and odour become much more marked, that the fæces usually begin to acquire a solid consistence. Their form and size is dictated, partly by the shape and diameter of the bowel (as already alluded † to), and partly by the degree in which their consistence has been augmented by the absorption of their watery parts. Where their solidity is much increased from this latter cause, the act of expulsion has little influence in modifying their form. The way in which it usually does this has been previously pointed out.

The odour and colour peculiar to the fæces have been ascribed, by some authors, to the bile which enters into their composition; by others, to the fluids which are poured out into the intestinal canal from the blood-vessels occupying its mucous membrane. It is, however, probable that they are not due to either of these causes exclusively, but depend rather on a combination of both; and are further modified by that admixture of altered (not to say decomposing) food, which forms so large a constituent of the excrement.

Thus, that they depend to some extent on the bile, is well shown by those cases of jaundice, in which a deficient secretion of this fluid, or an obstruction of its normal channel, has arrested its flow into the intestine. For in such instances, the ordinary brownish yellow tint, and fæcal smell, proper to the excrement, are exchanged for a greyish white colour, and an intensely putrefactive odour.

But it is certain that, unless the bile be poured out in excessive amount (as after the exhibition of mercury *), or conveyed through the bowels with unusual rapidity (as in diarrhœa and purging), it is but a small fraction of its total quantity that escapes re-absorption, so as to be found in the fæces. This statement especially applies to the meconium which occupies the intestine of the fœtus. At any rate, this substance contains but little of the acid or the colouring matter of ordinary bile.

Now, the preparation of excrement by the fœtus, and by hybernating or starving animals, is a satisfactory proof that its specific fæcal characters are not essentially due to any modification of the alimentary matters contained in the intestinal canal. And since the bile forms but a small portion of its mass, it is evident that much of it must be derived from the secretions of the digestive tube itself, and that its properties must be partially due to the same source. Indeed, this intestinal constituent, which is probably always a large ingredient of the fæces, becomes, in the hybernant and the fœtus by far the largest: — so much so, that the dried meconium contains about 85 to 95 per cent. of epithelium and mucus, almost all of which must be referred to this source. While, as regards its physiological import, it is impossible to doubt that it is (κατ' ἐξοχήν) the *excrement*:— that it is, in fact, the chief excretory ingredient of the fæces; and hence that ingredient, the dismissal of which from the intestinal canal is most essential to the welfare of the organism generally.

The above view, as to the share which both the biliary and the intestinal constituents take in producing the colour and odour of the fæces, appears so irrefragable, that we may content ourselves with a passing allusion to those experiments by which it has been attempted to establish the predominant or exclusive influence of either. Thus, while it has been pointed out by Valentin † that putrefying bile diffuses the strongest smell of ordure, Liebig ‡ states that he has succeeded in the artificial production of the fæcal odour by a process which essentially consists in imperfectly oxidizing some of the more azotized tissues of the body. The latter experiment has been regarded as leading to the inference, that

* Brown Séquard, "Experimental Researches in Physiology and Pathology," New York, 1853.

† See p. 366.

* The green colour of the stools after calomel has been taken seems to be due, partly to the chemical reaction of the contents of the intestine, partly to an increase in the quantity of bile poured out. The latter fact has been confirmed by experiments, in which this drug has been administered to dogs provided with biliary fistulæ opening externally. The chemical change undergone by the mercury in the intestinal tube consists (like that of the salts of iron under similar circumstances) in the formation of a sulphuret of the metal.

† Lehrbuch der Physiologie, vol. i., p. 370.

‡ Animal Chemistry, 3rd ed., p. 148. *et seq.*

certain effete constituents of the blood are secreted into the intestine, in a like state of partial oxidation. But, even could we assume the chemical identity of two substances merely from their having the same overpowering smell, we should still be left in uncertainty, as to whether these odorous matters were excreted directly from the blood into the bowel, or were introduced into it indirectly, by means of the secretion and subsequent metamorphosis of the bile. The very large intestinal constituent of the meconium, associated as it is with an almost inodorous character of this excrement, would indicate that, on the whole, Valentin's view of the biliary origin of the fæcal odour is the more correct one. At present, however, a satisfactory decision of the question seems impossible.

But whether the peculiar odour of the fæces be biliary or intestinal, there can be no doubt that it is derived, in the first instance, from the blood. For the smell of the excrement of any particular species always has a close relation to that odour, which is specific to the body of the animal, and which appears, in various degrees of intensity, in all its different excretions. And it is even stated by Wehsarg* to present differences specific to the individual.

Finally, we need have little scruple in asserting, that all the physical properties of the fæces are also in a great measure dependent on that alimentary residuum which usually enters so largely into their composition. The quantity of fatty matter and of casein usually present in the excrement of the sucking-child, the deepening (and finally black) colour of the fæces in persons who feed chiefly on vegetables, the lactic acid found in the evacuations of carnivora, or the oil which may often be detected in the stools of persons by whom even small doses of cod-liver oil are being taken medicinally — form instances of this kind, which might obviously be multiplied to almost any extent. Nor is the process always limited to a mere admixture or decomposition of the food itself. On the contrary, the metamorphoses which most of its ingredients have to undergo, often react on the secretory contents of the canal, so as to modify their appearances by the addition of properties more or less foreign to them. And nothing but that comparatively uniform admixture of the chief alimentary principles of the food, which we shall hereafter find is absolutely necessary to the life of the individual, will account for even the imperfect uniformity traceable in examining the excrements of large numbers of individuals.

The reaction of the human fæces is generally acid; sometimes neutral or alkaline. The quantity daily evacuated by a healthy male adult may be estimated as amounting, on an average to about five ounces avoirdupois.

The specific gravity of the fæces is generally greater than that of water, owing to the solids which they contain. But it is far too variable to allow of any average estimate being made. For it varies, not merely with the bulk and weight of the alimentary residue that forms so large a portion of the ordinary excrement, but also with the degree in which the fæcal mass has been condensed by the absorption of its watery constituents. And it would further seem, that the fæces are capable of being partially dried, and rendered much lighter, by a mechanical admixture of intestinal gases with their substance while still within the body. At least it is very common for different portions of the same evacuation to exhibit very different specific gravities: — the first portions of the excrement, which previously occupied the lower extremity of the rectum, being much lighter than water; while those subsequently extruded, though less solid, are so much heavier, as to sink rapidly in this liquid.

The mechanical composition of the excrement might almost be deduced from what has already been said of its origin. A large quantity of its mass no doubt consists of undigested food.* This must, however, be subdivided into two parts, which have a very different import with respect to the digestive function. One of these, which is usually much the larger, includes all those substances that are incapable of being dissolved by the various secretions poured into the intestinal canal. Such are the harder parts of various animal and vegetable tissues: — the sarcolemma of muscular substance, the cells of cartilage, fragments of bone, the elastic fibres of areolar tissue; together with the husks, shells, pods, chlorophyll, epidermis, and various dense membranes, cells, vessels, and fibres of the various fruits and seeds used as food. Some of these tissues quite defend the soluble contents they enclose. The other portion consists of substances which, though really capable of solution in the alimentary canal, have escaped this process: — whether from having been taken in too large a quantity, from not having sojourned in the tube during a sufficient interval of time, or from having been exposed to secretions which are partially devoid of their proper solvent force. Of these three causes of such an admixture, the first is the more common, and probably constitutes an invaluable safeguard against the dangerous results which might otherwise follow every act of over-eating. Hence in the state of repletion, whether relative or absolute, large quantities of fat, muscular fibre, albumen, casein, starch cells, fibrous tissue, and other strictly alimentary substances, escape digestion, and are found in the fæces. And conversely, it is highly probable that individuals (as well as animals) may have their digestive powers so raised by

* Microscopische und Chemische Untersuchungen der Fæces gesunder Menschen. Giessen, 1853.

* The analyses of Wehsarg assign to the dried substance of this constituent an amount which would probably be equivalent to a proportion of about 13 per cent. of the whole excrement. But we may suspect this to be rather too low an estimate; and are at any rate justified in doubting whether the alimentary ingredient could be completely isolated, for the purpose of being thus determined.

hunger and need, as to be enabled to extract nutriment from substances that would otherwise defy the action of their gastric and intestinal juices. In short, these undissolved and insoluble—undigested and indigestible—constituents of the alimentary residuum may almost be said to merge into each other, according to the habits of the individual with respect to the ingestion of food.

That element of the fæces which is derived from the digestive organs of the animal itself, consists chiefly of mucus and precipitated bile. This mucus is, for the most part, structureless; but is mixed with variable quantities of scaly epithelium from the rectum in the neighbourhood of the anus. In violent diarrhœa, columnar cells from the intestine may also be found in the evacuations :—sometimes in the younger cell-form of abortive cytoblasts or nuclei, sometimes in the more advanced state of simple ovoid cells. The latter are sometimes met with in small numbers, even in healthy fæces; and constitute what are often termed mucus-corpuscles. The biliary constituent is found chiefly in the form of minute amorphous masses or molecules of a resinous character; crystals or plates of cholestearine; and soluble colouring matter, that often stains the cells just mentioned, as well as the other mechanical constituents of the excrement.

The crystals of ammoniaco-phosphate of magnesia, which are so often found in the fæces, can hardly be definitely allotted to either of the two foregoing sources. They are easily recognised by their characteristic shape. They were formerly supposed to be peculiar to the stools of diarrhœa and typhus. But they are found in the healthiest fæces. Their occurrence appears to be favoured by all circumstances which further decomposition. They are therefore probably due to the action of ammonia (developed in the fæces before or after their expulsion) upon that neutral phosphate of magnesia, which we shall see forms so large a proportion of the entire saline constituent of the excrement.

The chemical composition of the fæces will of course exactly correspond with the nature and amount of those substances of which it forms the mechanical admixture. Hence, not only is it impossible to lay down any average that can apply to fæces generally, but it is even probable, that no two specimens of excrement are composed of the same proximate constituents mingled in the same proportions.

Berzelius* analyzed the fæces of a labourer who had fed on coarse, hard-baked bread, with moderate quantities of meat and vegetables. He obtained the following results:—

Water			75·3
Substances soluble in water	Bile	·9	5·7
	Albumen	·9	
	Extractive	2·7	
	Salts	1·2	
Insoluble residuum of the food			7·0
Insoluble substances added in the intestinal canal: mucus, biliary resin, fat, and sundry animal matters			14·0
			102·0

* Lehrbuch der Chemie. Bd. ix. p. 341.

Without, however, impugning the accuracy of an analysis conducted by such an eminent chemist as Berzelius, it seems important to point out that, for physiological purposes, it is all but useless. For not only does it afford no inference as to the quantitative composition of the fæces generally, but it even suggests grave doubts as to the correctness with which its own chief results have been grouped together. Recalling, for example, our subdivision of the constituents of the fæces into alimentary and secretory, we inquire in vain how much of the soluble albumen and extractive of this analysis was derived from the food, and how much may be ascribed to the secretions poured into the canal. In like manner we are ignorant whether its fatty constituent was not partly the undigested residue of fat which had been introduced with the food. But from a comparison of this analysis with some observations on the meconium by Hoefle* and Lehmann †, we may conjecture, that while the protein compounds found in healthy excrement belong almost exclusively to the food, a small quantity of its elain and margain, and a larger amount of its muco-gelatinous extractive, are derived from the secretions of the animal itself.

The inorganic constituents of the excrement must also vary greatly with the nature and amount of its alimentary residuum. Porter‡ states that healthy fæces, when dried, contain on an average about 6·7 parts per cent. of mineral substances. Wehsarg reckons these salts at 4·1 per cent., from an average of seven analyses. But an analysis by Dr. Percy§ estimates them at 16·4 per cent. This proportion somewhat approaches that given in the analysis by Berzelius quoted above. It also corresponds with some analyses by Macaire and Marcet ‖ of the fæces of the Dog and Horse, which they found to contain 20 and 25 per cent. of ash respectively.¶ The soluble salts form between one-fourth and one-third of the whole ash. The phosphates of the earths and alkalies constitute about one-third of all the salts present. While the chlorides of the alkalies are reduced to the very small proportion of about one-thirtieth; a proportion which is about equalled by the whole of the sulphates. The chief remaining peculiarities worthy of notice are, that the quantity of potash is from 10 to 40 times greater than that of the soda; and that the magnesia reaches half the amount of the lime. Of these two quantitative disproportions, the first seems due to the food; while the latter has been referred by Berzelius to the more active

§ Day's Simon's Chemistry, vol. ii. p. 375.

‖ Société d'Histoire Naturelle de Genève, vol. v. p. 230.

¶ This difference, like that of the nitrogen of the excrement in these animals (4·2 per cent. in the Dog to ·8 in the Horse), probably depended on the contrast between the animal and vegetable nature of their food.

absorption of lime than magnesia in the intestinal canal. Carbonates of the alkalies are found in the ash of human excrement; but they are apparently almost absent from that of the Sheep, Cow, and Horse. They are probably produced by a combustion of some organic salts of these bases.

The elementary analyses of the fæces hitherto made possess little physiological significance, or general validity. But from what has already been stated, it is obvious that the entire excretory part of the ordure removes from the body very little water or nitrogen;—probably not more than $\frac{1}{30}$th or $\frac{1}{40}$th of that quantity of each of these elements which is daily excreted in the urine.

The time during which the contents of the intestinal tube sojourn in its different segments is probably a very uncertain as well as variable one. In diarrhœa, the whole canal is sometimes traversed by these contents in two hours; while in obstruction, weeks or months may elapse without their complete transit. The mean rate which lies between these two morbid states can only be conjectured. But there are reasons for supposing, that the food of a healthy adult occupies about twelve hours in passing through the small intestine. While from thirty-six to sixty hours may be assumed as its average sojourn in the large intestine, prior to its ultimate expulsion from the rectum.

Intestinal gases.— In speaking of the elastic fluids which are generally contained in the large intestine, and are occasionally expelled from its lower orifice, it will be advantageous to contrast them with the gases found in other parts of the alimentary canal: — viz., in the stomach and the small intestine. Many years ago the composition of these gaseous contents of the canal was correctly given by Jurine, from an examination of the corpse of an idiot soon after death by cold. But it is to Magendie* and Chevreul that we owe the only trustworthy quantitative analyses on the subject. Their observations were made upon the gases found in the bodies of criminals immediately after their execution. Some authors have therefore thought it worth while to allude to their results, as being probably affected by the dyspepsia which the dread of such an impending doom might be supposed to have produced in these unhappy persons. Without, however, assigning any definite value to this contingency, it is enough to say that they still remain far preferable to any other such analyses:—to those, for instance, of Chevillot†, whose rather different results are quite explained by the time after death to which his examinations were deferred, and the decomposition which had therefore begun, both in the tissues of these corpses, and in the alimentary and secretory contents of their intestines.

We may best arrange these analyses in the following tabulated form: —

Whence obtained.	Composition by Volume.					
	Oxygen.	Nitrogen.	Carbonic Acid.	Hydrogen.	Carburetted Hydrogen.	Sulphuretted Hydrogen.
Stomach - - - - -	11·00	71·45	14·00	3·55	- -	- -
Small intestine: average of three analyses - - - -	- -	31·84	29·80	38·36	- -	- -
Cœcum - - - - -	- -	67·50	12·50	7·50	12·50	traces.
Large intestine 1. - - -	- -	51·03	43·50	- -	5·47	traces.
Large intestine 2. - - -	- -	18·04	70·00	11·06	11·06	- -
Rectum - - - - -	- -	45·96	42·86	- -	11·18	traces.
Flatus expelled *per anum* (mean of two analyses by Marchand) -	- -	21·5	40·5	18·75	18·75	·5

It is only from such analyses that we can form any reasonable inference as to the origin of the gases to which they refer.

In making such an inquiry, four sources of aëriform matter at once suggest themselves; either of which seems at first sight capable of at least partially explaining the presence of gaseous substances in the digestive canal. And the claims of each of these must be separately examined before we can conjecture the probable amount of its product, or its share in those reactions which the physical properties of gaseous fluids so easily allow them to excite.

1. Air may be introduced into the intestinal canal from without the body. Just as some of the lower animals can distend the abdomen by a voluntary deglutition of air, while even the higher Mammalia have been noticed to fill the stomach with air by the movements which precede the act of vomiting, so persons have been observed to swallow air, and afterwards expel it by eructation. And apart from such exceptional cases, there is good reason for believing that the ingestion of food always introduces into the stomach an appreciable quantity of atmospheric air; part of which is perhaps mechanically carried down with the alimentary bolus, while another part enters the organ in a state of more minute division, with the frothy saliva.

The air which is thus introduced into the stomach will doubtless here undergo a certain amount of diffusion or interchange with the elastic fluids dissolved in the liquid blood that

* Précis Elémentaire de Physiologie, vol. ii., p. 113.

† Chevillot's figures (Berzelius' Jahresbericht der physischen Wissenschaften, 1831, p. 247) indicate that, in the diseased and decomposing bodies he examined, oxygen was always present; and carbonic acid rather increased; while the nitrogen sometimes reached the large proportion of 99 per cent.

circulates in the capillaries of the organ. And this diffusion probably imitates that which takes place between the air and the blood at the surface of the lungs and skin. It will therefore convert the gaseous mixture of the atmosphere into one containing less oxygen, and more carbonic acid; the extent of the change in both these respects varying chiefly with the duration of its sojourn in the stomach.

But a number of circumstances unite to prove that the gases of the stomach are in great part derived from some other source. Thus the quantity of air taken with the food can be but small. While percussion and auscultation show, that the cavity of the healthy organ is often largely distended with gas. And the above analysis further points out, that not only is the increase of carbonic acid disproportionate to the decrease of oxygen, and therefore (unlike the interchange in the skin and lungs) not due to a mere physical process of diffusion, but that a new element, hydrogen, has been added to it.

The same arguments apply still more forcibly to those gases, which almost invariably distend the intestines. For during digestion, they could hardly pass the pylorus; and at any other time, would be very unlikely to enter the stomach, through which alone they could reach the duodenum. Hence in the case of the intestinal segments of the canal, we are referred almost exclusively to those sources which, we have already seen, will be necessary to explain the greater part of the gas present in the stomach.

2. Gases may be developed in the alimentary canal from the decomposition of the food which it contains.

Difficult as it is to decide on the evidence at present before us, there seem to be valid reasons for regarding this as the process by which the intestinal gases are chiefly, if not exclusively, set free in the alimentary cavity. The food introduced into this cavity is speedily converted into a decomposing mass, which is useful to the organism solely by virtue of the metamorphoses it is undergoing. And though these metamorphoses generally seem to be limited to processes, by which elements are merely re-arranged in the solid or liquid form, and not given off as gases, still they are easily susceptible of being carried further, so as to involve a more or less copious evolution of gaseous fluids.

Now, the putrefaction of the protein compounds of the food, together with the fermentation of its hydrates of carbon, would amply account for these gases; as well as for the ammonia which has been alluded to as probably throwing down part of the soluble phosphates of the intestinal contents, in the form of crystals of the triple phosphate of ammonia and magnesia. For not only are all the gases in the above analyses producible by the various processes of putrefaction external to the body, but their proportions to each other are precisely those which might be expected from the known composition of the food.

The conditions which favour the presence of these gases remarkably confirm this view. Too large a quantity of food—and especially of food that consists of substances which are either putrefying or fermenting, or are peculiarly liable to undergo these changes—notoriously increases the amount of gases thus generated in the bowels. The liability of cattle to a dangerous distention of this kind, when surfeited with green food, is well known to agriculturists. And in like manner, an increased quantity of sulphuretted hydrogen is generally expelled in the flatus of animals which have been fed upon* beans, or made to take sulphur with their food. While the practice of medicine acquaints us with the fact, that all circumstances which lower the tone of the alimentary canal, or lessen the energy of its secretions, further these spontaneous (though abnormal), metamorphoses of its contents; and thus give rise to a corresponding increase in the quantity of the gases which form their direct result. We may perhaps find an additional confirmation of this view in a comparison of the various instances analyzed above. At least, the great deviations which they exhibit, seem better explicable by the variable composition of the food, than by any theory which would refer their development to the organism or the blood itself.

Finally, it is well known that the complete exclusion of food from the digestive cavity often gives rise to a peculiar white and contracted state of the tube, which implies an entire absence of all such gaseous contents from the greater part of its length. This appearance is so generally seen in the bodies of animals after long fasting, as to constitute an important feature in the medico-legal evidence of death by starvation.

3. It has been supposed that gases are set free in the intestinal canal by a kind of secretion or transpiration from the blood.

But in alluding such a process, it is necessary to premise that, strictly speaking, it would hardly deserve the name of a secretory act. Even assuming that it really discharged the gases of the blood into the intestinal canal, we should scarcely be warranted in terming their passage a true process of secretion. On the contrary, all analogy indicates that it would rather constitute an act of diffusion:—a diffusion which would probably obey the same laws, and exhibit somewhat of the same course, as that which chemistry has successfully investigated in the case of the lungs and skin.

In any case, unless we suppose the capillaries of the intestine to be the actual site of an unexampled generation of gas from the constituents of the blood, an inquiry into these latter will probably afford us some grounds on which to accept or reject the above theory.

It is therefore important to point out, that some of the gases found in these analyses—viz. hydrogen, carburetted hydrogen, and sul-

* The legumen of which contains much of this element.

phuretted hydrogen — have never yet been detected in any appreciable quantity in the blood. And hence without assuming their complete absence from this liquid, we may at least infer that they are not present in that amount which would be necessary to explain their secretion from it, to the extent mentioned in these observations.

To this we may add, that no parallel to such a process of gaseous excretion can be observed in the case of any other vascular surface. This statement not only holds good of the serous membranes, but (what is much more conclusive) even of those structures which are specially organized with reference to the giving out from the blood of certain of its gases, and the taking up of others from the surrounding air. It is to the skin and lungs that we should naturally look for evidence of the true secretion of excrementitious or noxious gases from the circulating fluid. And yet, on turning to the results afforded by the eudiometric researches of a number of observers, we find that the gases which we have just stated to be absent from the blood, are equally deficient in the air exhaled from the vessels of these special organs of gaseous excretion. While even the carbonic acid and nitrogen of the intestinal flatus are at once distinguished, by their quantitative relations, from the same gases, as found in the air of expiration. Thus the minute amount of nitrogen in the air exhaled from the lungs is contrasted with an average of 40 per cent. in the gases contained in the intestines; and its proportion to the carbonic acid present, is increased from $\frac{1}{100}$th in the former, to $\frac{1}{3}$d, or even $\frac{2}{5}$ths, in the latter gaseous mixture.

In conclusion, we may point out, that while the carburetted and sulphuretted hydrogen, as well as the pure hydrogen, of these analyses, can only be explained as the result of a process which directly or indirectly involves the deoxidation of water, — the chemistry of the organism seems always to reverse this process. Far from deoxidating this liquid, there are good grounds for supposing that a quantity of water amounting to nearly $\frac{1}{5}$th of the whole aqueous contents of the food is daily formed in the body by a combustion (or in other words, by an oxidation) of the hydrogen of its tissues.

But some will perhaps think that these considerations are sufficiently answered by facts, which deserve more reliance than any such arguments.

They would possibly instance experiments like those made by Magendie * and Girardin, and confirmed by Frerichs †: in which the deligation of an empty portion of intestine had nevertheless been followed by its distention with flatus. Or they might call attention to the tympanites of typhus fever, and other kindred disorders, in which little food has been taken for a long period of time. But a little reflection might teach us that none of these instances have absolutely excluded the presence of all alimentary substances; and that a very small quantity of liquid or solid matter would probably be quite sufficient to yield the gases observed.

4. Lastly, as regards the intestinal gases present in diseased subjects, we may conjecture a fourth source of such elastic fluids:— namely, the decomposition of the various secretions of the canal. For it is not too much to assume, that the decomposition to which the alimentary contents of the intestine appear to be often exposed, is sometimes shared by the secretions poured into its* cavity; especially when we recollect that, in many diseases, the state of all the fluids of the organism is frequently such as notoriously favours the access of putrefaction in the tissues after death.

The gases expelled from the large intestine carry with them the odorous principles of the excrement. It is, indeed, probable that they become impregnated with these volatile substances mechanically, as a necessary result of their contact with them in the bowels. But reasons are not wanting for the conjecture, that the introduction of certain fœtid substances into the blood, is subsequently followed by their specific determination to the mucous membrane of the intestinal canal; which thus forms a channel for their elimination from the system. For after the inhalation of any particularly offensive odour, the fæces and flatus often exhibit what is unmistakeably the same smell, in a very concentrated form. And the active diarrhœa which frequently attends this reproduction of the odour, seems a part of the same effort of nature, towards the removal of what other evidence, beside that of our senses, thus testifies to be an active poison.

Respecting the laws which regulate the forcible expulsion of these gases from the stomach or intestines, little need here be said. Though greatly influenced by habit, still the act is essentially voluntary. Its mechanism is so closely akin to that of defæcation as not to require any separate notice. Whether the immediate stimulus to this expulsive act is always mere intestinal distention, or whether it is sometimes determined by the quality (as well as quantity) of the elastic fluids, cannot at present be decided.

We are equally ignorant as to how far, failing such an expulsion, these gases are capable of being absorbed into the blood; and if so, where they emerge from the vascular system, or what form they assume in doing so. The small quantity of sulphuretted hydrogen really present in the most offensive flatus, and the comparative harmlessness of carburetted hydrogen in the proportions in which it would be dissolved by the blood, prohibit us from coming to any conclusion based on the ordinary physiological action of these two gases. We can but conjecture, that whatever absorption they may undergo is slow enough

* Recherches physiologiques sur les gaz intestinaux. 1824.

† *Op. cit.*, p. 866.

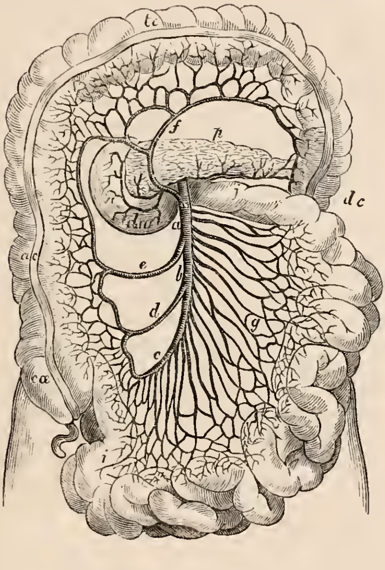
* The cases of physometra adduced by obstetric authors seem to be examples of a similar decomposition occurring in the blood and secretions contained in the cavity of the uterus.

to allow of the much quicker destruction of their poisonous properties by a more or less perfect oxidation.

Arteries of the intestines.—We have seen that the stomach and duodenum are supplied with arterial blood by means of various twigs derived from the three branches of the cœliac axis, which springs from the upper part of the abdominal aorta. The remainder of the intestinal canal is furnished with arteries which are given off by two large branches of the abdominal aorta. These branches are named, from their position and distribution, the superior and the inferior mesenteric.

The *superior mesenteric* artery (*a, fig.* 277.), the longer of these two branches, is distributed over that large segment of the intestine which is formed by the lower part of the duodenum, the whole of the jejunum, ileum, and cœcum, and the first two-thirds of the colon. The

Fig. 277.



Distribution of the superior mesenteric artery to the small and large intestine.

trunk of the vessel comes off from the aorta, at a point which about corresponds to the upper border of the second lumbar vertebra. It is separated from the cœliac axis by the pancreas; and hence is distant about a third of an inch from the origin of the latter vessel. From this commencement, it passes downwards and forwards, crossing over the termination of the duodenum, so as to reach the upper part of the mesentery. It now continues downwards between the two layers of this fold of peritoneum, which it occupies near its attachment to the posterior wall of the abdomen. Hence its length and direction correspond to those of the attached border of the mesentery itself; and are such, as to conduct it downwards and obliquely towards the left side, to a termination that corresponds to the end of the ileum, or the commencement of the cœcum. But the branches given off to these latter segments of the intestine by the trunk of the vessel are so large, and so directly continuous with its previous course, that it is only in a very arbitrary and limited sense that we can speak of it as ending in this situation.

The arrangement of the larger or primary branches of the superior mesenteric artery is liable to great variation, but is generally as follows.

The trunk of the superior mesenteric artery is directly continuous with a large vessel (*b*, *fig.* 277.), which, when it has reached a distance of about two inches from the cœcum, divides into two others; of these the upper (*d*, *fig.* 277.) passes towards the cœcum, and the lower (*c*, *fig.* 277.) towards the ileum. The *ileo-colic* artery (*b*, *fig.* 277.), as the common trunk is named prior to its bifurcation, usually gives off from its right side one of rather smaller size, about three inches from the border of the bowel. The latter, which is called the *arteria colica dextra*, or right colic artery (*e*, *fig.* 277.), often arises by a separate trunk from the superior mesenteric. It takes a course almost horizontally outwards, or towards the right side, lying underneath the single layer of peritoneum which covers in the ascending colon, so as to reach this part of the large intestine at or near the middle of its height. Finally, at a distance of little more than an inch from its entering the mesentery, the trunk of the superior mesenteric artery gives off a large branch, the *arteria colica media* (*f*, *fig.* 277.), which passes upwards and backwards, enters between the two layers of the transverse meso-colon, and is distributed to the transverse colon, which it reaches at the middle of its posterior border. Besides these named branches, the superior mesenteric gives off numerous arteries (at *g*, *fig.* 277.), of almost equal size, which have not received any special designation. These twenty or thirty branches leave the left side of the artery, at various points between the lower border of the duodenum and the origin of the ileo-colic artery; and pass outwards, or to the left side, towards their distribution on the small intestine.

The further course of all these branches towards the small and large intestine affords a remarkable instance of an arterial anastomosis; such as is almost unparalleled in the whole of the body for the freedom and frequency of its communications, and the size of the vessels by which they are effected. Each of the primary branches just alluded to bifurcates: and its two resulting branches unite with those above and below them, so as to form a set (*g*, *fig.* 277.) of arterial arches; from the convexity of which spring new trunks, to divide and inosculate in a similar manner. This arrangement, which prevails throughout all the mesenteric branches that supply the intestine, is carried to such an extent in the jejunum and ileum, as to offer, in many parts, four or five successive sets of arches; which become smaller and more numerous as they approach the bowel, and finally give off the minute arterial ramifications that enter and traverse the intestinal coats.

On reaching the intestine itself, the greatly diminished arteries break up into still smaller capillary branches. These inosculate freely with each other, by comparatively large branches of communication; and thus unite and anastomose to form a dense stratum or flattened network of vessels, which occupies the layer of loose areolar tissue that separates the muscular from the mucous coat. This vascular plexus gives off, on the one hand, the vessels of the mucous membrane; and on the other, the not very numerous branches which run between and amongst the unstriped bundles of the muscular coat.

The *inferior mesenteric artery* (*b*, *fig.* 278.), which supplies the descending and sigmoid portions of the colon, and the whole of the rectum, is also a branch from the aorta. It arises from the front and left side of this vessel (*a*, *fig.* 278.), about an inch below the place where it gives off the left renal artery, and nearly the same distance above its bifurcation into the two iliac vessels. From this origin it is directed downwards and slightly outwards, lying successively on the aorta, the left psoas muscle, and the left

Fig. 278.*

(*t c*, *a c*, *p*, *du*, as in *fig.* 279.)

* In several of the preceding microscopic figures, the artist has been indebted to Koelliker's beautiful woodcuts for some details, which require this specific acknowledgment.

common iliac artery. During this part of its course, it lies at some distance from the intestine. But below where it crosses the common iliac vessels, it occupies the double fold of peritoneum (*meso-rectum*) that attaches the rectum to the pelvis. This terminal portion of the vessel, which is called the *superior hæmorrhoidal artery* (*e*, *fig.* 278.), is continued to a point about opposite to the middle of the sacrum; where it ends by bifurcating into two branches, which ramify on the opposite sides of the bowel, and are distributed to its various coats. These branches inosculate freely with the ramifications of the *middle hæmorrhoidal artery*, which is itself given off to the rectum by the internal iliac artery, or some of its branches.

The only named branches of the inferior mesenteric are the left colic or *arteria colica sinistra* (*c*, *fig.* 278.), and the artery to the sigmoid flexure (*d*, *fig.* 278.). The former of these two vessels passes upwards and outwards, across the psoas muscle and left kidney, to reach the descending colon at about the middle of its height. The latter, which is sometimes double, also crosses the psoas, to enter the short meso-colon which attaches the sigmoid flexure of the bowel. The further distribution of both these arteries precisely recalls that of the similar colic branches from the superior mesenteric: each bifurcating into two branches; which, by uniting with the similar trunks above and below, form the origin of a set of arches that ramify in a second and third series. And as the union of the upper twig of the colica sinistra with the lower or left branch of the colica media unites the superior and inferior mesenteric arteries by a large anastomosing vessel (*g*, *fig.* 278.), all the arches of both these trunks have the most complete anastomosis with each other. So that it would be easy to trace out a continuous arterial channel of large size; which begins as the superior mesenteric, and passes through the ileo-colic, left colic, median colic, and sigmoid branches, to end in the superior hæmorrhoidal artery.

Veins of the intestines.—The veins of the intestinal canal are chiefly characterized by the fact, that the trunks formed by their convergence and union do not open into the right auricle, like the veins of the body generally; but undergo a second ramification and distribution, in their course from the capillaries of the intestine to the right side of the heart. This arrangement of course influences their distribution at two successive stages of their course. In the first place, their larger trunks fail to exhibit that close correspondence with the arterial channels which is seen in the case of most other parts of the body. And, secondly, instead of seeking the large vessels on the spine, these trunks converge into a single channel, the portal vein (*a*, *fig.* 279.), which passes upwards to the liver at some distance from the aorta and primary intestinal branches *

* See Art. VENOUS SYSTEM.

The veins of the intestines commence by a dense network, that receives the minute venous radicles into which the capillaries of the mucous and muscular coats return their blood. This plexus has the same submucous situation, and flattened shape, as the corresponding arterial network already mentioned; but, like the venous system in general, is composed of more numerous and larger branches. It gives off a number of veins; which leave the intestine, and gradually unite into the vessels that converge to form the various trunks. These branches have a tolerable correspondence with the primary ramifications of the arteries from the cœliac axis and the two mesenteric vessels. Many of

(The remaining letters indicate as in the preceding figures.)

them unite to form two chief trunks, the superior and the inferior mesenteric veins. While others open directly into the splenic vein; or into the *vena portæ*, which is formed by the junction of it and these mesenteric veins.

The *superior mesenteric vein* (*b*, *fig.* 279.), which receives the venous blood from that portion of intestine supplied by the artery of the same name, travels for some distance in company with the latter vessel; lying on its right side, and somewhat superficially to it, and surrounded by very numerous lacteals and nerves. But near the lower border of the third portion of the duodenum, it swerves towards the right side, from what was hitherto an almost vertical course upwards; and after crossing in front of the duodenum at nearly a right angle, ends by joining the splenic vein behind the pancreas. This junction gives rise to the portal trunk (*a*, *fig.* 279.).

The *inferior mesenteric vein* (*c*, *fig.* 279.), — the origin of which also corresponds to the region supplied by the artery of the same name — generally commences as a single trunk at or near the border of the pelvis. From hence it ascends almost vertically, but with a slight inclination inwards, beneath the peritoneum, and on the psoas muscle; until, finally, it crosses under the transverse meso-colon, to end by a junction with the splenic vein (*d*, *fig.* 279.). In the latter part of this ascent, it is of course unaccompanied by the inferior mesenteric artery: and even below where this vessel is given off from the aorta, the artery and vein diverge so as to be comparatively distant from each other. Its junction with the splenic vein (*d*, *fig.* 279.), is usually about one or two inches from the point where this meets with the superior mesenteric vein. But it occasionally approaches much more closely to the latter vessel, or even joins with it prior to its union with the splenic to form the portal vein.

The branches of both these mesenteric veins resemble those of the corresponding arteries in their number and size, and in the remarkable freedom of their anastomosis. And this copious and frequent inosculation, — which coincides with an absence of all valves, — not only holds good of the several primary branches which converge into the portal vein, but also applies in some degree to those smaller ramifications, by which the portal system inosculates with the general venous system at the two extremities of the alimentary tube. Thus many of the smaller veins at the lower part of the œsophagus communicate with both the azygos and portal veins. While the lowest branches of the inferior mesenteric vein establish a similar and much more extensive anastomosis of the two systems, by their junction with a dense venous network — the *hæmorrhoidal plexus* — which encircles the lower part of the rectum, and gives origin to the middle and inferior hœmorrhoidal branches of the internal and external iliac veins.

The foregoing peculiarities in the vascular arrangements of the human alimentary canal are at present only susceptible of a very imperfect explanation.

As regards the arteries, their great number and size, and their large anastomosing channels, would probably be attended by several advantages. The variety of these channels would concede to the circulation, not only a large supply of blood, but one such as no ordinary local accident could at all interfere with.* The muscular fibre contained in their walls would allow these numerous tubes to exercise an unusual control over the amount of blood

* Compare the remarks on the vessels of the stomach at p. 327.

they from time to time convey. While on very simple hydraulic principles, these repeated cross branches would so diminish the various resistances (of impact and adhesion) offered to the blood within the vessels, as to permit, either a greater rapidity of the current, and hence a more rapid renewal of the mass of blood contained in the capillaries; or a more forcible pressure upon the latter fluid; or even both of these effects simultaneously.

It is perhaps a corroboration of the above conjectures, to trace their close relation to those which might be gathered from an independent consideration of the circumstances of the portal system. The trunk vein of this set of vessels leads to a second set of capillaries in the liver; through which there is nothing to propel the portal blood, save the force of the heart, aided by a small amount of suction, which the thorax exerts as it expands during inspiration. And hence, however large a quantity of the original cardiac pressure may be again amassed by the convergence of the various intestinal veins, still there can be no doubt that at least so much of it will have been lost, as to require all the aid which the above disposition of the arteries can afford it. But in spite of all such assistance, it seems probable, that the current of the portal blood is both far slower, and much more feeble, than that which occupies any of the arteries. Still it is no doubt quite sufficient for the exigencies of the circulation in the liver; and especially for that secretion of bile, to which the various details of the organization of this gland chiefly refer.

The Food. — The function of digestion has for its chief object the replacement of that loss of substance which the body is constantly undergoing.

Even the hardest materials of the globe we inhabit experience a gradual disintegration; as the result of the various physical processes to which they are exposed. Such processes may be instanced in the attrition and solution of solids, the evaporation of liquids, and the diffusion of gases. And hence, when we turn from these inorganic substances to the animal fabric; and consider its slight cohesion, the friction which its locomotion implies, its large watery constituent, and the feeble chemical affinities which enchain its elementary atoms — we shall scarcely be surprised to find, that the rapidity of its waste far exceeds that of the inanimate solids around us.

But the rate of waste, and the consequent need of replacement, both depend, far less on simple physical causes of this kind, than on certain actions which are specific to the organized body. These actions, which, in the aggregate, make up what we term Life, do not so much imply, as actually consist in, a perpetual process of flux and metamorphosis. This multiform change engages the whole of the corporeal tissues; and conducts their various ingredients, through a number of successive phases of composition, to an effete and useless state, in which they are finally ejected from the organism.

And hence, whatever the share taken by the physical actions of diffusion, solution, friction, and evaporation, in the removal of the substance of the body, they are not in any sense the true causes of its process of waste; or the real sources of its *egesta* or losses. They are but, as it were, the janitors of the animal fortress; the nature and amount of the matters which pass out by them being controlled and regulated by the higher life that rules within.

The *ingesta*, which replace these *egesta*, and thus form the opposite extreme of nutritional life, are equally influenced by the general requirements of the animal. Excluding, for the present, all consideration of that preponderance of absorption which determines the growth of a young animal, or the converse excess of excretion which results in the decrease and decay of an old one; and limiting our attention to the mere maintenance of the adult body:—we shall find that it is the composition of its structures, and the rate of their wear and tear, that chiefly determine the kind of food it makes use of, and the quantity it consumes within a given space of time. While as regards the exact degree of this dependence, we shall further find that, here as elsewhere, the operations of organized nature are only limited by wide general principles; within which are apparently conceded great variety and fluctuation. The laws of nutrition are, so to speak, universal in their range, but elastic in their application.

In respect to the *nature* of the food, we may first notice, that by far the larger part of it is always derived from the organic, and never from the inorganic, world. In other words, the chemistry of the organism has little power of construction or synthesis. So that, although a proximate analysis of the tissues of the animal body presents us with compounds, which may be shown to consist chiefly of a few elementary substances united to each other in varying proportions, still the carbon, oxygen, hydrogen, and nitrogen, which surround or penetrate the living animal, are never directly built up into these tissues. On the contrary, the various substances which form the proximate principles of the several structures of the organism are themselves produced by the metamorphosis of kindred compounds introduced in the food; — compounds which have been in their turn derived from the vegetable kingdom; either directly, in the shape of plants, or indirectly, from substances constructed out of vegetable tissues by the organism of another animal. And the inorganic substances introduced into the body seem to be almost restricted to the subordinate (though equally indispensable) office, of combining with these products of vegetable life, and modifying their actions in obedience to the necessities of the existing individual.

The above statement as to the organic nature of the food suggests some interesting considerations.

In the first place, it seems to shew that the living animal of to-day pre-supposes another organization of yesterday ; — that its individual descent from two creatures of the same species is accompanied by a less evident, but quite as real, transmission of substance from several previous beings. In short, that the greater part of its entire mass might be regarded as the sum of various legacies, which have been bequeathed to the existing organism by the various plants and animals that lived before it.

In the next place, it indicates a fixed and definite relation between the plant and the animal. The former is thus the chief agent in the constructive chemistry of the latter :— a necessary link in that chain of processes which builds up organic principles, out of the elements of inorganic nature, or out of those simple products into which the particles of the animal body are finally converted by its waste during life, or its putrefaction after death. The carbonic acid given off by the living or dead animal may especially exemplify the latter remark ; converted as it is, by the vegetable, from a poisonous gas into a class of substances which are in the highest sense alimentary, and essential to the life of the animal.

And lastly, since animal and vegetable life are thus complementary to each other, alike in their broader features and their minuter details, we may conjecture that, in the present disposition of our planet, they form what is in fact a tolerably constant magnitude : — a sum of organized life, the amount of which is subject to but very slight variation from one time to another. Nay more, we may almost suspect that the total of animal existence — the composition of which ranges thus regularly through vegetable organization as an essential part of its cycle of metamorphosis — is in the main equally constant and fixed. Created by what even modern science must be content to own as a miracle, in the strictest sense of the word, it seems not improbable that animal, as well as vegetable life, is sustained in consonance with some vast law of this kind. According to such a law, each by each, and both together, would make up certain constant units ; the innumerable constituent fractions of which might vary within vast limits without exercising any effect on their respective sums. And thus the world of life around us would but parallel that perpetual flux, but unaltered quantity, which the chemist has long predicated of the various materials which compose the inorganic globe we inhabit.

But if, on the one hand, the animal is incapable of constructing its complex tissues from the simple elements of inorganic nature, still, on the other hand, it is not bound down by such rigorous chemical necessities, as to demand a food possessing an exact identity of composition with itself. A large proportion of the animal creation feed on a vegetable diet, the constituents of which deviate considerably from those of their own mass. And but very few of even the more carnivorous animals are in the habit of devouring their own species. Finally, though the blood forms the pabulum of all the tissues, and hence closely approaches their total composition, still it does not appear to form even an advantageous article of food, far less an indispensable one.

And while such considerations may suffice to show, that there is no true identity between the food and the tissues in general, the progress of modern physiological chemistry plainly indicates, that an identity of this kind would be equally impossible in detail. Thus it is not improbable, that the tissues of every individual possess chemical peculiarities more or less specific to himself. And it is all but certain, that the various proximate principles isolated by the chemist are not definite combinations of certain elements in equivalent proportions — as are the salts, acids, and alkalies of the inorganic world — but rather ever-varying mixtures. Those various forms of protein which it is so convenient to distinguish by the names of albumen, fibrin, and casein, may indeed be separated from the tissues of animals, and even of vegetables, by the same rough processes ; and may therefore respectively exhibit the closest resemblance in their composition and properties. But an accurate analysis would probably show, that the organic substance represented by either of these terms is never precisely identical in any two specimens. It is the total of a number of constituents, the result of a variety of processes, the end of a serial metamorphosis : rather than a definite and specific compound of carbon, oxygen, hydrogen, and nitrogen.

And not only is there no identity in the composition of the organism and the ingesta, but it would seem that there are some tissues of the body which have absolutely no representative in the food : no kindred substance to which their formation can possibly be referred. Such are the various tissues that yield gelatine ; a substance which, though it appears to escape assimilation when introduced into the organism from without, is yet constantly formed within it, from the metamorphoses of other parts of its substance.

The chemistry of nutrition therefore implies neither construction, on the one hand, nor identity, on the other ; but something midway between these two extremes. Its forces occupy, so to speak, a debateable ground between the prehension of old materials, and the formation of new ones. And the food submitted to its action is only required to possess such a similarity of composition with the body, as will concede these limited changes, without implying any wider process of metamorphosis.

Any exact definition of the degree of resemblance thus requisite, would be foreign to our present object. Indeed, in the existing state of our knowledge, it is impossible to specify the precise nature of those metamorphoses, which accompany the digestive act, and are bounded by the food and the organism as their respective beginning and end. It is enough to indicate, that they appear to be intermediate between the forces of chemical affinity on the one hand, and homogeneous and heterogeneous adhesion on the other; and that while they are sometimes * akin to the formation of hydrates, they occasionally resemble those still more recondite phenomena which are concerned in the production of isomeric or isomorphous compounds :— substances which, though identical in their composition, offer striking differences in their solubility, as well as in many of their chemical properties and reactions.

This very limited convertibility of the main components of the food, renders their variety almost as essential, as though each different tissue of the body had required the entry of its corresponding substance from without. In other words, within the range of the chemical parallelism just mentioned, the organism demands alimentary compounds containing all the different ingredients necessary to cover its own waste.

This fact receives a good illustration from that selection which the instinct of most persons would impel them to make. Left to himself, Man always chuses a mixed diet, composed of proper quantities of animal and vegetable, liquid and solid, matter. Nay more, that almost equally imperious instinct which urges him to vary his diet, though often confused with the morbid cravings of luxury, is essentially nothing less than an expression of the natural wants of a healthy organism.

Obscured, however, as these really natural instincts often are by the stereotyped tastes and habits of a highly artificial state of society, we gain a far better insight into the proper composition of food, by examining that store of nutriment which, in the shape of the yolk of the Bird's egg, or the milk of the Mammal, Nature herself provides for the maintenance of the young of these classes. Of these two substances, the milk is justly regarded as forming the very best example of a proper food :—both as regards the nature of its several ingredients, and the proportions in which they are mingled with each other.

Milk.— The alimentary properties of the milk are due to the presence of a number of proximate constituents, the more important of which may be enumerated as follows. — (1) A protein-compound, casein; (2) a hydro-carbon or fat; (3) a hydrate of carbon or sugar; (4) certain salts; and (5) the water in which the whole of these materials are suspended or dissolved. Of these five groups of substances, at least four are indispensable ingredients of every proper food. The hydrate of carbon and the hydrocarbon are, to some extent, capable of forming substitutes for each other. But with this exception, (an explanation of which will be attempted by and by), the absence of any one of these constituents, or even its presence in insufficient quantity, suffices to destroy the capacity of any particular food for maintaining life; so that an animal limited to such a diet ultimately dies with appearances of inanition. And *à fortiori*, the ingestion of but one of these alimentary ingredients, — such as albumen, fat, or sugar, — is soon attended with effects which still more closely resemble those of starvation. Such a diet does indeed essentially starve the entire organism, even while it supplies some of the constituents of its lost substance. For although the unchecked waste of the remaining constituents of its mass tells upon certain of its textures with greater rapidity and energy than on others, still it ultimately involves the whole in a common destruction: — a fact which need little surprise us, when we recollect the mixed composition of the simplest tissues, and the intimate mutual dependence of the most distant and isolated parts.

Constituents of food.—1. The first group, consisting of what are called the protein-compounds, includes a number of proximate principles, which are derived from both the animal and vegetable kingdoms of nature. The chief of these principles are albumen, fibrin, and casein. By digestion in solution of potash, and precipitation with an acid, either of these yields a substance called *protein*: — a name that alludes to the relation this principle is supposed to bear to all the compounds from which it is thus obtained. It is regarded as their common starting-point (πρωτεύω, *primas partes teneo*), and most essential component. And the slight differences of composition offered by each particular protein-compound, are explained as chiefly due to variations in the nature and amount of certain collateral ingredients, the addition of which to protein imparts the specific characters of albumen, fibrin, or the like. Hence the various protein-compounds are supposed to differ, not so much in elementary composition, as in certain characters which might almost be termed morphological: — namely, outward form, physical properties, degree of solubility, and the like.

The exact process by which one of these protein-compounds undergoes conversion into another is still a complete mystery. But that such changes do constantly obtain, cannot be doubted. And hence, while the quantity of albumen in the animal body, and the constancy with which it is present, assign to this proximate principle the leading position in the above group of proteinous substances, it is on its generic, and not its specific, properties that our attention ought chiefly to be fixed.

The protein of the food may be regarded as its most essential constituent. The reason why such an importance is ascribed to it becomes sufficiently evident, when we compare its composition with that of the body which it is intended to nourish. The highly azotized constitution it possesses ($C\ 54{\cdot}7 + H\ 6{\cdot}8 + N\ 14{\cdot}2 + O\ 24{\cdot}3 = 100$) closely approaches that of the solids of the organism generally. And it shows an equally important relation to most of the tissues in detail. It forms a large constituent of the blood; and therefore of the plastic nutritional fluid that

* Compare the remarks on the gastric juice at p. 337.

exsudes directly from this fluid. It is the main component of the muscles, which execute the various movements of the body. It is an equally important ingredient in the tissues of both the central and peripheric parts of the nervous system. It is probably the source of the gelatinous * tissues; which, in herbivorous animals, can only be derived from a kind of degradation or regression of the albuminous substances. And, finally, its large amount in the structures of the fœtus proves that it is just as important to the evolution and growth of the animal, as it is to its maintenance. In short, in protein and its various kindred substances, we recognize the principle, which forms the material exponent of all the structures and functions, and is the chief substantive agent of the chemistry of life.

The quantity of protein necessary for the proper maintenance of the healthy animal can only be estimated from very indirect and approximate calculations.

In milk, the albuminous compounds are chiefly represented by casein, which forms about $3\frac{1}{2}$ per cent. of its total quantity. But we can scarcely guess how much milk is daily consumed by the sucking animal, or what proportion this amount bears to the weight of its whole body. And we are justified in assuming, that a large fraction of the protein thus introduced into the system, is applied to exigencies of growth and development which have little or no place in the adult animal.

Assuming an exact maintenance of the adult organism, without increase or decrease, we might expect that an examination of its various azotized excretions would teach us how much nitrogen had been discharged from the system within a given time: and hence that, by comparing this quantity with the known elementary composition of protein, we might be enabled to calculate how large a quantity of the azotized constituent of the food ought to be added to the system, in order to replace its daily loss.

But here we are met by a difficulty connected with the process of nutrition itself:—with that chain of events of which food and waste constitute only the extreme links. The amount of nitrogen given off by the body does not depend solely upon the quantity excreted by its waste, but also varies in close correspondence with the quantity taken in its food. It is therefore greater in carnivorous, and less in herbivorous, animals.

Hence the true or essential waste of the organism, in respect of this constituent, can only be determined from an analysis of the excretions of animals which have been kept for a day or two, either without food, or on a diet altogether devoid of nitrogen. In both cases the results are the same. The nitrogen of the egesta drops to a certain minimum; at which it remains for a considerable period.

The quantity of nitrogen evolved by the lungs and skin is at any rate so small, as scarcely to form an important element of calculation. And even the larger quantity excreted in the biliary resin, hardly deserves notice. It is in the uric acid, and above all in the urea, of the renal secretion, that this element is chiefly dismissed from the body as an effete compound. And hence it is from the urea found in such experiments that we may best deduce the probable rate of daily waste in the albuminous tissues; and the corresponding quantity of protein which therefore has to be supplied in the daily food.

From observations of this kind on the human subject, we may infer that, in Man, the albumen of the adult organism undergoes a loss of about 2 ounces daily;—a quantity which corresponds to scarcely more than $\frac{1}{1200}$th of the weight of the body. While if we suppose that a new-born infant, weighing six or seven pounds, consumes daily about ten or twelve ounces of milk, containing $3\frac{1}{2}$ per cent. of casein, the quantity of protein thus introduced into its alimentary canal would amount to the larger proportion of about $\frac{1}{270}$th of its total bodily mass.

The larger proportion of albumen thus consumed by the infant probably depends upon at least two causes. As a smaller* animal, it is subject to a more energetic waste of substance. And as a growing animal, it not only lays aside in its body a constant surplus of its income over its waste; but possibly undergoes a more active metamorphosis, that still further increases the proportion of its effete materials.

But, apart from the influence of age or size, there is no doubt that a careful comparison of the azotized ingesta and egesta would always show a marked disproportion between the two. There are indeed obvious reasons, why the nitrogenous constituent of any suitable food should always greatly exceed that quantity which is required by the strict exigencies of the organism. A part of the casein which is contained in the milk taken by the sucking-child, is often found to pass through the alimentary canal without being absorbed into the blood. And in the case of many other varieties of food, the insoluble state of the protein-compounds actually present affords a still greater obstacle to their absorption. In a proper mixed diet, however, we may detect some approximation between the presumable gain and loss. Thus the daily rations of the British soldier on home service include little more than 5 ounces of albuminous substance;—a quantity which is therefore little more than double the amount

* Ignorant as we are, both of the nature of this metamorphosis, and of the various stages through which it is conducted, there are reasons for conjecturing that the formation of the chondrin radicle generally precedes that of the substance which yields gelatin by boiling.

Supp.

* From researches by Frerichs, Lehmann, Bidder, Schmidt, Boussingault, Valentin, and others, we may estimate the daily waste of albuminous compounds, relatively to the whole body, in the undermentioned animals, as follows:—Rabbit, $\frac{1}{140}$th; Cat, $\frac{1}{170}$th; Dog, $\frac{1}{330}$th; Horse, $\frac{1}{700}$th.

of this material, which the waste of his body probably dismisses from his system within the same period of time.

2. The next group of alimentary substances is that of the fats, the composition of which has led to their receiving the generic name of *hydro-carbons*. They are found in both animal and vegetable food. In the milk, they are represented by its butter; the quantity of which amounts, on an average, to about $3\frac{1}{2}$ per cent.

The great variety of different alimentary substances of this kind is such as to preclude even their enumeration. The most important are stearin, elain, and margarin. The composition of these three fats may be generally stated as almost corresponding to single equivalents of carbon and hydrogen:— or, more exactly, to ten atoms of each of these elements, *minus* one of hydrogen, and *plus* one of oxygen ($C_{10}\ H_9\ O_1$; or $C_{79} + H_{11 \cdot 4} + O_{9 \cdot 6} = 100$).

The uses sustained by these constituents of the food in the organism are easy to indicate, but difficult to specify. The protection afforded by the fat of the body to its temperature, and to the mechanical safety of its internal structures, might perhaps be accomplished without involving any rapid waste and replacement of the material by which it is afforded. But the vast quantity of fatty matter which enters into the composition of the nervous system, and the primary importance of this delicate and energetic organ to the maintenance of life, entitle us to infer, that its functions imply such a rapid metamorphosis of its substance, as can only be sustained by the continual supply of new materials to replace those rendered effete. And the numerical phenomena of nutrition further show, that the process of respiration is constantly dismissing from the body an amount of carbonic acid, the proportion of which to the azotized egesta proves that it must have been derived more or less directly from an oxidation of the fatty, as well as of the albuminous, tissues. The quantity of fatty matter contained in the healthy organism strongly confirms these views; and thus helps to account for its dietetic importance. For, including all their varieties in the tissues just alluded to, we can hardly estimate the total hydro-carbons of the human body at less than $\frac{1}{4}$th or $\frac{1}{5}$th of its weight. And since they scarcely form $\frac{1}{600}$th part of the blood, it follows, that even assuming this nutrient fluid equal to $\frac{1}{6}$th of the corporeal weight, its fatty constituent amounts to little more than $\frac{1}{800}$th or $\frac{1}{900}$th of the fat which is deposited in the central and peripheric structures of the nervous system, and stored up in the adipose cells of other parts of the body. Such an estimate further entitles us to conjecture, not only that the quantity of fat taken up at any one time by the digestive organs is limited to a very small one; but also, that it either undergoes some important metamorphosis before reaching the general mass of the blood, or is very rapidly eliminated from this fluid.

3. The *hydrates of carbon* form a class of nutritional substances, the elementary composition of which is still more exactly indicated by their name. In other words, they consist of carbon, united with hydrogen and oxygen in those equivalent proportions of these two elements which are necessary for the formation of water ($C_{12}\ H_{12}\ O_{12}$). This group is a very large one: and includes, not only the various forms of cane, grape, and milk sugar, but a number of kindred substances;—such as dextrin, gum, cellulose, inosit, and, especially, starch. All of these organic principles, however various their physical properties, have nevertheless the same chemical composition. And many of them are easily converted into grape sugar; either by the excitement of a limited metamorphosis by an azotized ferment, or by exposure to the action of dilute acids.

The sugary ingredient of the milk forms about $5\frac{1}{2}$ per cent. of its quantity; and is the only representative of the hydrates of carbon which it contains.

The average amount of the substances belonging to this and the preceding group of alimentary constituents will of course vary greatly in the different kinds of food. Speaking generally, however, these two groups may be stated to predominate by turns in the food derived from the two kingdoms of nature. Thus while the hydrocarbons are chiefly derived from the fat of animal food; the hydrates of carbon belong even more exclusively to the starch and sugar of vegetable food. But, in strictness, no such marked difference can actually be made out between the two kinds of food in this respect. The milk, the liver, and even the blood of the animal, all contain sugar: while inosit, a substance closely allied to sugar, forms an important constituent of its various muscles. And not only do many plants contain large quantities of oily matter stored up in various parts of their tissues, but even the seeds of the cerealia, which form the best vegetable diet, present an amount of fat ranging from ·2 to 2 per cent.

The purposes fulfilled by these hydrates of carbon in the animal economy, offer a marked contrast to those subserved by the two previous groups. The protein compounds form what is eminently the basis of the organism; — the plasma from which are developed the blood and the tissues. They are thus *histogenetic* and *hæmagenetic*, as the phrase is. The fatty matters of the body not only form a large constituent of the active nervous substance, but are also retained and stored up in the more inert and passive form of adipose tissue. While the grape-sugar, into which the various hydrates of carbon are all finally converted, appears never to assume any permanent form in the body, but to be always rapidly eliminated from the blood. In what shape, or after what metamorphoses, it leaves this fluid, is at present uncertain. It is, however, probable, that like the hydrocarbons, these hydrates of carbon are essentially a species of fuel for that process of calorific combustion, which pervades the whole body, and which discharges its resulting carbonic acid by means of the respiratory function. And Liebig has adduced numerical data from the fattening of animals, which lead him to suppose, that these substances are also capable of undergoing a process of deoxidation, that converts them into fat, and thus enables them to augment the adipose tissue. But this view rests on very insufficient foundations*: and is curiously contrasted with that oxidation† of hydro-carbons into sugar, which the researches of various recent observers seem to indicate as one of the chief functions of the liver.‡

4. The importance of the *water* of the food is such as justly entitles this liquid to the rank of a fourth alimentary constituent. For it forms about four-fifths of the entire corporeal mass: and undergoes, at the various excretory surfaces of the skin, the lungs, and the kidneys, a continual expenditure; the replacement of which is obviously necessary to the maintenance of the proper composition of the body.

The way in which this large aqueous constituent facilitates the action of the various organs is not very difficult to conjecture. Their merely physical properties of hardness, flexibility, and the like, often seem chiefly determined by the quantity of the watery ingredient which they contain. And their far more recondite vital properties seem quite as immediately under its influence. Thus not only do its solvent powers appear to be eminently useful in furthering the minute division, and the local transfer, of various organic substances, but we are justified in conjecturing that it gives a more specific chemical assistance to many of those processes of metamorphosis which are so intimately connected with life. In both of these respects, it would seem to afford a special aid to the function of digestion. While that act of absorption, which conveys the dissolved contents of the alimentary canal into the surrounding veins, is greatly facilitated by the heightened diffusive energy which the low specific gravity of water enables it to impart to the fluids with which it has been mixed. And finally, the use of water in relation to the opposite extreme of nutrition—namely, to excretion—may be well exemplified by the urine, in which a highly poisonous product of life is continually washed out of the system, through the instrumentality of a stream of this universal solvent.

The details of death by thirst afford a fearful commentary on the above remarks;—although, from reasons which will presently be mentioned, it will be obvious that even these cases rarely afford us true examples of the strict exclusion of all entry of water from without the body. After a period of agonizing thirst, the most distressing symptoms of which seem to be referred to the dry and inflamed throat and fauces, the deficiency of water is gradually revealed by a diminution—which is almost a suppression—of the various secretions that normally contain a large proportion of this liquid: namely, the sweat, the urine, and the fæces. Increasing muscular debility accompanies this change; and is soon followed by delirium and coma, ending in death.

And, conversely, the benefits afforded by water seem to receive an almost paradoxical illustration from its effects in the opposite states of starvation and of fattening. Thus, as regards the latter process, animals are stated to fatten much more easily and quickly when allowed the free ingestion of this liquid. And Becquerel and Lehmann state, that when water is taken in excessive quantity, an increased amount of urea is excreted from the system of the healthy human subject.* While the researches of Bidder and Schmidt† show that, even after the withdrawal of all other ingesta, the copious use of water concedes to the starving animal a longer duration of life;—diminishing, not only the waste of its protein compounds, but those collateral results of the vital processes, which are exemplified by the excretion of urea, carbonic acid, and salts.

Hence water, which forms about 85 per cent. of the milk, is a universal constituent of the food of animals; and varies only in the proportion which its amount bears to that of the solid ingredients mixed with it, or dissolved in it. In some of the lowest forms of animal life, its relative amount is so great, that the remainder of the food is only present in the state of a very dilute solution. In certain aquatic creatures of this kind, the medium around the animal seems to form a dilute alimentary solution, which only requires an act of absorption by the outer surface of its body. And even in the higher animals, in whom the other alimentary constituents are

* The increase of fatty matter supposed to have been derived from these hydrates was calculated by subtracting the fat added in the vegetable food from the increase of the animal's weight; — this surplus being set down as due to augmented adipose tissue. Hence any error in estimating the fatty constituent of this food, on the one hand—or any neglect to calculate the watery and proteinous constituents of the increased adipose tissue, on the other—would partially account for the difference observed. And it seems not unlikely that both of these inaccuracies actually occurred in these observations.

† Assuming that such a metamorphosis really obtained, it would not be difficult to explain most of Liebig's results. For it is surely not impossible, that the presence of an excess of sugar in the liver might diminish the energy of this act; in other words, that an excess of the product might lessen the activity of the process. Thus the copious ingestion of sugar might check its formation, and diminish the metamorphosis of the fat supplied to the liver in the portal blood. And this retention of the fatty form might not only affect the hydrocarbons of the food, but also those which are possibly developed in the organism from its own proteinous constituents.

‡ Compare the remarks on the liver, at p. 401.

* An effect which is probably due to its favouring the absorption of a larger quantity of protein from the same amount of food.

† *Op. cit.* p. 314.

always taken into a stomach, or internal cavity, part of the total quantity of water which really accompanies them into the system is often introduced by the same mode of absorption. So that, although the amount of water consumed by the organism has probably a definite relation to the activity of the vital processes, the amount of this liquid habitually swallowed by any animal is greatly affected by the quantity introduced in other ways: namely, by the proportion contained in its solid food, the amount formed by the combustion of hydrogen in its body, and the quantity absorbed by its skin from the vaporous or liquid water of the surrounding media. Thus the apparently dry food of many herbivora is explained by the large amount of water, which is present as a chemical constituent of such food, and which accompanies its few digestible parts into the system. And the small amount of drink taken by many of the Batrachian reptiles is chiefly due to the active tegumentary ingestion last alluded to.

The quantity of water contained in the various kinds of food ordinarily made use of, will be referred to hereafter. But we may probably fix its average at about 75 to 80 per cent. (or about 5 lbs.) of the mixed fluid and solid food (about 6·5 lbs.) of the human subject.

5. The *salts* of the food constitute the fifth and last group of its constituents, and that of which we may be said to know less than any of the others. For, while many of the more important are easily recognized in the ashes of the various fluid and solid aliments in which they are usually introduced into the body, still we are often at a loss to know the precise state of combination in which they are originally present in the food, far more that in which they enter into combination with the organism itself.

In the case of many salts, we can, indeed, trace the actual changes of composition which occur in the organism. Thus the salts composed of the various organic acids united with the alkalies, are converted into carbonates, prior to their dismissal from the body in the urine. And it seems possible that even the sulphates are occasionally decomposed in the alimentary canal; their sulphuric acid being deoxidized into sulphuretted hydrogen. while their bases unite with the carbonic acid formed in the system.

Hence, although a careful and repeated analysis of the salts contained in the organism and in its total excretions, might afford some clue to the qualities and quantities of the salts which ought to be introduced in the food, it would not by any means represent the details of these demands. While it is hardly necessary to add, that no such series of examinations has ever yet been made; and that, however carefully conducted, it might easily overlook very small quantities of important ingredients. Many discrepancies, however, it would probably clear up; such as why animals which in one region seem indifferent to salt, in others seek it with the greatest avidity; — why the diet which produces scurvy in one person, leaves another little affected;—and finally, why the roving population of the South American Pampas can maintain a robust health on the fresh meat of the wild cattle which range these plains, while an apparently similar diet on the flesh of tame cattle has been known to destroy English soldiers.

The more essential salts of the food seem to be the chlorides and phosphates of the alkalies; and especially, the chloride of sodium, and the phosphate of soda. Lime and iron are also important bases. All of these ingredients are present in the salts of the milk; together with some free soda and potash, which are probably combined with its casein. The phosphates are in large quantity; especially the phosphate of lime — the predominance of which is doubtless connected with the exigencies of ossification in the fœtus.

Varieties of food. — The above grouping of the various constituents of the food, will afford us a valuable clue to the composition of its principal varieties. For however widely these varieties may differ from each other, they always contain representatives from each of the preceding classes. And the best food for any particular animal will always consist of such a proportion of all these constituents, as best corresponds to the demands made by the waste of its whole body, and to the peculiarities of its organs of digestion.

The food most natural to Man is a mixed diet. But though thus far omnivorous, he readily adopts an exclusively animal or vegetable food, according to the circumstances in which he is placed. And there are probably but few of the carnivorous and herbivorous animals, most properly so termed, in whom careful experiments would not detect a similar, though scarcely equal, capacity for such a change of diet. Thus the herbivorous Horse and Cow may be brought to eat fish and flesh; and the carnivorous sea-birds can be gradually habituated to the far more difficult change implied in their feeding on grain. But many of the frugivorous Quadrumana seem little susceptible of such alterations of diet. While there seem to be numerous Insects, which are not only strictly limited to a vegetable food, but even to certain species of plants, or particular parts of their structure.

The influence of any special variety of food on the human organism depends chiefly on its physical and chemical properties: — in other words, on its mechanical arrangement and admixture; and on the constituents which it presents; either originally, or as modified by the operations of cooking. Hence these are the chief points which will be noticed in the following short description.

It is obvious that the division of the various alimentary substances into solid and liquid, or food and drink, is an incorrect one. For, on the one hand, even the driest articles of solid food contain a large proportion of water of composition. And conversely, the purest liquids ordinarily made use of contain a certain quantity of solids, in the shape of dissolved salts, which are by no means indifferent to the organism.

In the following cursory view of the ordinary articles of diet, we shall begin by contrasting the general characters of animal and vegetable food. We shall then sketch the chief varieties of each generally made use of. And, finally, we shall attempt to estimate the proportions of each contained in a suitable dietary of ordinary mixed food.

It is to animal food that we must on the whole assign the first rank as an article of diet. For not only do the tissues of one animal necessarily contain most, if not all, of the organic and inorganic substances required for the construction of another, and in something like the proper proportions of their respective ingredients, but they are generally devoid of all noxious constituents. Besides these advantages, they offer the equally important ones of possessing such a structure, arrangement, and solubility, as materially aid their entry into the organism. Hence they are not only much more nutritious than an equal quantity of vegetable food, but are also digested and assimilated with far greater ease and rapidity. It is for this reason that the use of animal food is so much to be preferred in all circumstances where it is our object to avert the speedy exhaustion of the vital powers.

Against these advantages, possessed by animal food, we must, however, set off the disadvantages, that it not only contains some substances which (like gelatine and the horny tissues) appear to be either useless or even to require a speedy excretion; but that, as a rule, it is deficient in those non-azotized elements, which are so important to the maintenance of the combustion and heat of the organism. For the limited quantity of fatty matters which it generally includes rarely suffices to make these hydrocarbons a proper substitute for the copious amylaceous and saccharine constituents of vegetable food.

The main disadvantages of vegetable food are equally obvious. It generally contains but a small proportion of the protein compounds. And even this limited quantity is often virtually diminished by their insoluble state; or by the indigestible form which is implied by their mechanical arrangement in the vegetable tissues. Many of its amylaceous constituents are also rendered useless in the same way: being enclosed in insoluble envelopes, which effectually shield them from the digestive process; or having a composition which requires to be altered by a chemical metamorphosis before they can be fitted for absorption. These objections can be to a great extent obviated by the ingestion of a larger quantity of such food, as well as by a more protracted sojourn in the alimentary canal. But, besides these disadvantages, the inorganic constituents of certain kinds of vegetable food appear to be insufficient for the replacement of the loss consequent on the waste of the animal. Thus the ash of many esculent vegetables is peculiarly deficient in the important ingredients of soda and the chlorides. The poisonous materials contained in the tissues of some plants constitute another objection to vegetable diet; — an objection which is, however, generally obviated by the instinct of animals, and by the experience of Man, or by the purification which the process of cooking often affords.

Animal food. — The muscular substance, accompanied by more or less of its interstitial and investing fat and areolar tissue, forms what is called *meat* or *flesh*, in the ordinary acceptation of these words.

The mechanical subdivision of a mass of meat would of course afford us the microscopic elements of the above tissues; — namely, sarcolemma, sarcous substance, white and yellow fibrous elements, fat, and blood vessels; together with a certain quantity of blood, and of the nutritional fluids which saturate each of these textures. Its chemical composition varies, not only with the nature, but also with the age, food, habits, and individual peculiarities, of the animal yielding it. Hence it is impossible to give any definite account of its quantitative chemistry. We can only enumerate its principal constituents; and, in the case of some of the more important of them, approximatively estimate their amount. The protein-compound, that forms by far the greater part of the muscular fibres, is a substance which possesses characters closely allied to those of fibrin, and has received the name of syntonin. It is usually present in a proportion of about 15 or 16 per cent. The albumen of the juice which soaks the whole muscular mass, and the gelatin which is extracted from it by boiling, may each be estimated at about 2 per cent. Its extractive, exclusive of salts, amounts to about 3 per cent.; of which nearly half is dissolved by alcohol, half by water. This constituent has a very complex composition: osmazom, lactic acid, inosit, kreatin, kreatinin, and a variety of other substances, having been detected in it by the labours of modern chemists. The salts of meat form about $1\frac{1}{4}$ per cent. of its fresh substance, or about 5 per cent. of its dried mass; nearly three-fourths of their quantity being phosphates of the alkalies, and two-thirds of the remainder phosphates of the earths, with a little iron. The chlorides of the alkalies are about one-fourteenth of the entire ash. They are remarkably contrasted with the chlorides contained in the ash of the blood, by the great proportion which the chloride of potassium bears to that of sodium.

It is impossible to estimate the quantity of fat contained in meat as usually eaten. But even after the removal of all visible adipose tissue, Von Bibra has found fractions ranging from one-twentieth to one-fifth; the smaller amounts corresponding to the flesh of the Hare and Deer, while the larger (in the beef of Oxen) were perhaps partially due to a more or less artificial fattening.

The flesh of Birds contains less water and fat, and more albumen, syntonin, and kreatin, than that of most of the Mammalia hitherto examined. The muscular substance of Fishes contains a still greater quantity of albumen. That of the young of most animals is softer, and its fibres smaller and more digestible, than the flesh of the adult.

The artificial preparation of animal food for the table probably induces a variety of chemical changes. But the full import of these changes has yet to be made out. At present, we know little except some of the more obvious physical results which attend the processes of cooking. These are best seen in the cooking of meat.

The increased digestibility of meat which has been killed some time previously to being eaten, seems to depend, partly on the more uniform and softer consistence imparted by the diffusion of its juices, and partly on the imperfect decomposition which it has begun to undergo. The latter change to some extent prepares it for digestion, by rendering it more soluble. But any approach to absolute putrefaction reverses this advantage;—at any rate, in the case of Man, whose natural judgment would probably in most instances lead him to reject putrid meat, as alike disgusting to the senses, hurtful to digestion, and dangerous to health.

In the operation of roasting meat, the heat applied to the exterior of the mass soon converts its superficial portion into a dense, hard substance. This compact crust consists chiefly of albumen which has been coagulated by heat. It is of essential service, not only in moderating the heat afterwards applied through it to the deeper portions of the meat, but also in retaining its various liquid and volatile products, which would otherwise be soon dissipated in the gaseous or vaporous form. The moderate heat which permeates the mass probably aids the various juices of the meat in diffusing themselves throughout its whole texture; increasing its uniformity of consistence, and dissolving much of its gelatinous tissues. Its albumen is always more or less coagulated by the heat; though, where much blood is present, the colour and fluidity which it sometimes retains, appear to indicate an imperfect character of this change.* A variety of empyreumatic substances, which are developed chiefly in the more heated exterior of the mass, next add the savoury odour and deepened colour, so characteristic of this method of cooking. If the process be unduly protracted, it will obviously burn the harder outside shell, and render the coagulated and contracted mass within too dense, tough, and insoluble for easy digestion; while, if conducted too rapidly, the same combustion of the outside is of course attended with the loss of all the advantages of cooking in the raw central portion.

The changes induced by boiling meat, partially resemble those which are caused by roasting it. For both of these processes are probably accompanied by a coagulation of albumen, a solution of osmazom, and a formation of gelatine in the mass itself. But they differ greatly from each other in many respects. From the lower temperature applied in boiling, no empyreumatic substances are developed; while the water which conveys the heat to the mass always extracts from it a certain proportion of its soluble constituents. This extraction may be to some extent diminished by suddenly plunging the meat into boiling water, so as to coagulate the albumen of its outermost layers; and conversely, the extractive process may be favoured, not only by increasing the surface of contact, but also by delaying the coagulation of the albumen, and prolonging the period of the solvent action. Hence, where it is chiefly the broth or watery solution of the meat which is intended to be used as food, the mass is preferably cut in very small pieces, and the temperature of the water raised very slowly to a degree of heat short of ebullition, and maintained there for a long time.

The various modes of salting and smoking meat are chiefly intended to protect it from decomposition; hence they scarcely require much notice here. In the former process, however, the qualities of the meat appear seriously damaged*, quite apart from the mechanical disadvantages which both it and smoking often impart.

Fat.—In a purely animal diet, the amount of this oleaginous constituent is of indispensable importance. For, with the exception of that minute quantity of inosit or muscular sugar which is proper to the sarcous substance, the fatty matters contained in the various tissues of the body are the only representatives of the two groups of the hydro-carbons and hydrates of carbon, which this kind of food possesses. Hence the fat of such a diet has to replace, as it were, the starch of the vegetables which usually enter into a mixed diet; and thus constitutes the sole non-azotized or respiratory element of animal food.

And even in what are often miscalled vegetable diets, a large quantity of this animal substance is commonly added to the other ingredients of the food. At least there seems to be a strong impulse towards such an admixture in most of the vegetarian nations and races of modern times: — an impulse which is well exemplified in the butter or ghee so copiously added by the Hindoo to the rice that forms his staple food.

The quantity of fatty matter which may thus be taken into the system can scarcely have any definite limit assigned to it. In the Arctic climates it appears to attain a very

* This imperfect coagulation has been supposed to prove that the heat (154°) at which the blood coagulates, has not been attained. But the appearances in meat boiled at 212°, and the temperature of roast meat itself, render such a view very doubtful.

* The liability of persons fed on such meat to scurvy, can scarcely be exclusively referred to the privation of vegetables. For large numbers of people appear to subsist with impunity on fresh meat only (see p. 388.).

large proportion. And it is impossible to avoid connecting this maximum of fat in the food, with the large amount of heat that has to be evolved from the body in these cold regions, as well as with the energy of the combustion on which this evolution of temperature depends. As a rule, however, but a small quantity of fatty matter can be really digested at a time. Any excess over this amount is merely expelled from the intestinal canal with the fæces.

The digestibility of fat depends chiefly on two circumstances: — its mechanical arrangement, and its chemical composition. In the adipose tissue, the fatty substances are enclosed in large nucleated cells; the membranous walls of which consist of a proteinous substance that is rather difficult of solution, and yet requires to be dissolved before its contents can enter the lacteals as chyle. And the three substances (stearine, elain, and margarine), which form the greater part of the fat of the Mammalia ordinarily slaughtered for food, possess very different degrees of solubility. Hence they are by no means equally easy of digestion; the first resisting its influence much more obstinately than either of the other two.

An animal which is fed exclusively on fat increases in size during a short period. Its nutrition, however, soon suffers; and it finally dies, with those appearances of inanition which have already been mentioned as attending all attempts to maintain life by the ingestion of only one ingredient of the normal food. In the later stages of this process of starvation, its body gives off a repulsive odour, which appears to be due to the evolution of volatile fatty acids from the skin and lungs. The production of these acids may be regarded as probably due to an imperfect oxidation of the hydro-carbons accumulated in the organism.

The alimentary properties of various other tissues and organs of the animal body may be passed over with a very brief notice.

The *blood* itself appears to be a far less valuable article of food than its composition would lead us to suppose: — abounding, as it does, in the important protein-compounds of fibrin and albumen. Some authors have supposed, that its digestion is rendered difficult by the dense state of aggregation which its fibrin is so apt to assume in the act of coagulation. But however this may be, still its large albuminous constituent appears to be in a condition such as would eminently fit it for fulfilling the requirements of the organism. We are thus left to remark upon its almost total want of hydrocarbons *: as well as upon the contrast offered by its salts † to those of the muscular substance.

The *brain* and nervous centres are so rich in albumen and fat, as to form highly nutritious articles of food; especially when they are mixed with other substances, which are more capable of affording the requisite mechanical stimulus to the digestive organs.

The various *glands* possess a dietetic value which is derived, partly from their physical structure and arrangement, partly from their chemical composition. Thus, the dense mechanical texture of the *liver* and *kidney* must decidedly oppose their usefulness as food: while the bile and urine which they respectively contain, necessarily superadd the properties of these secretions to those of the proteinous parenchyma that forms the bulk of their mass. And conversely, from both mechanical and chemical reasons, the *pancreas* is highly digestible and nutritious.

The hard solid texture of *bone*, and its large gelatinous and calcareous constituents, together render it of comparatively little use as an article of food.

The *eggs* of oviparous animals contain, in addition to the embryo itself, a quantity of nutritive matter, which is destined for its nourishment during the process of incubation. Hence, the large eggs of many Birds form an excellent article of food, the dietetic virtues of which resemble, to some extent, those previously attributed to milk. The white of egg contains about 15 per cent. of albumen. The yolk is composed of about 20 per cent. of the same protein compound; together with about 30 per cent. of fatty matter—chiefly margarin and elain — in a state of subdivision and admixture which eminently adapt it to digestive purposes.

The general composition of the *milk* which forms the food of young Mammalia has already been mentioned. It only remains for us to notice its chief varieties, and the products which its artificial preparation adds to the bill of fare of the adult.

The peculiarities exhibited by the various kinds of milk, are chiefly referrible to the species of the parent animal, the date of its lactation, the nature of its food, and its habits. Thus the milk of the Human female* contains about half the quantity of casein, and two-thirds the butter, of that of the Cow: while that of the Ass, which is still poorer in each of these constituents, greatly surpasses them both in the amount of its saccharine ingredients (being as 3 to 2). The rich colostrum which is yielded in the puerperal state † soon gives place to a milk which is

* See p. 386. of this article.
† Compare pp. 332. and 389.

* From some analyses of this secretion in two persons, L'Heritier concludes that the milk of *Brunettes* contains nearly twice as much casein, as that of *Blondes*; together with about one-half more butter, and one-sixth more sugar. This statement confirms a belief generally entertained as to the superior qualifications of women of dark complexion as nurses. But, without much more extensive observations, it cannot be accepted as an established fact. If true, it would remarkably complete what we may venture to call the structural and functional homologies of the mammary gland, all of which concur in regarding it as a highly-developed offshoot of the general integuments.

† The composition of the colostrum seems to indicate, that it is partly derived from milk which has been concentrated in the breast subsequently to its secretion, by the re-absorption of a portion of

poorer in all the solid ingredients: and the further continuance of lactation appears chiefly to increase its casein and salts, and diminish its sugar. The copious ingestion of fatty or starchy substances seems to increase the buttery constituent. The over-feeding of a wet-nurse causes her to secrete a milk abnormally rich in butter and casein, and injurious to a delicate child. Finally, vigorous exercise appears to diminish both these constituents, especially the former.

Butter.— The composition of the butter contained in milk is as yet but imperfectly known. That of the Cow is stated by Bromeis * to consist of about 68 per cent. of margarine, with 30 of elain, and 2 of fatty matters specific to butter. The exact nature of the latter constituents probably varies in different animals, as well as in different specimens of the secretion; and also seems very liable to be altered by that rancidity which butter so easily acquires from a short exposure to the air. Such circumstances quickly give rise to the formation of a variety of volatile fatty acids:—which are known under the names of butyric, caprylic, capronic, capric, and vaccinic acids.

The dietetic value of butter can scarcely be rated too highly. It is probably by far the best and most natural form in which hydrocarbons can be supplied to the healthy organism. It is not only attractive to the taste, but is easily assimilated:—even by children or adults, whose delicate digestive organs resent the introduction of the ordinary adipose tissue of animal food. The quantity which may be advantageously consumed will of course vary with the nature and amount of other food, and with the rate at which combustion proceeds in the body. But the very large amount of this substance habitually consumed by the Hindoos, and by the dairy-men in many of the Alpine highlands of Europe—in the latter case often reaching a pound daily—is a striking testimony alike of its harmlessness to the digestive organs, and its value to the system generally.

Cheese.— The substance known by this name consists chiefly of casein; which has been precipitated from the milk in company with a variable quantity of its buttery constituent. Its dietetic value is of course very high. But its digestive properties vary greatly; according to the proportion of fatty matter and salts which it contains, the mechanical aggregation of its mass, and the degree of decomposition which it may have experienced.

Thus as regards its admixture of butter, we may distinguish three varieties of cheese:—one which is made from cream, or from milk with the addition of cream; one from pure milk; and one from milk which has been skimmed or deprived of its cream.

its watery ingredient. This view is corroborated by the fact, that colostrum-corpuscles have been found in the milky contents of the male breast.

* Annalen der Chem. und Pharm. Bd. xlii. s. 46. *et seq.*

In respect to its salts, the chief distinction hitherto established appears referrible to the way in which the casein has been precipitated from its solution in the milk. Where the process has been effected by the addition of rennet, the caseous deposit contains a large proportion—about 5 or 6 per cent.—of phosphate of lime. But where the precipitation has been produced by the lactic acid which is gradually developed in milk as the result of its own spontaneous decomposition, the deposit contains scarcely one per cent. of this salt. In such a case, however, the smaller amount of phosphates appears to be partially compensated by the presence of some free phosphoric acid.

The changes which cheese undergoes by keeping are chiefly manifested in the formation of various volatile fatty acids, that generally communicate their characteristic odour to the whole mass. Such alterations are usually most marked in those varieties of cheese, in which but a small proportion of rennet has been used, and much fatty matter is present. Hence they seem at least partially attributable to a metamorphosis—probably an oxidation—of the buttery constituents themselves. In addition to this change, however, the casein also undergoes a somewhat similar fermentation; which is accompanied by the production of oxides of casein, and volatile fatty acids. Occasionally the process is carried so far as to constitute a kind of putrefaction, in which the nitrogen originally present is given off in the form of ammonia. The highly poisonous properties which decayed cheese sometimes possesses, and the repulsive odour which it often gives off, may illustrate these statements.

The value of cheese as an article of food may be to some extent inferred from the large amount of its proteinous constituent, which often forms more than 70 per cent. of its whole weight. This quantity of casein would correspond to about 11¼ per cent. of nitrogen: a quantity far beyond that contained in any other ordinary variety of azotized food. But just as this unexampled chemical composition may suffice to indicate how largely such a proportion of the "histogenetic" principles would require to be diluted with the "respiratory" or "combustible" substances, in order to constitute a food in the true acceptation of the term,—so it partially explains the fact, that cheese is anything but easy of digestion. With many persons even milk is only digested with difficulty; so that much of its casein may be traced through the bowels, but little changed by the action of the gastric juice. And the mechanical aggregation of many kinds of cheese—their extreme hardness, dryness, and density,—often enable them almost to defy digestion. But minute division, cooking, or careful mastication, will obviate one of these objections; and the other is easily met by a proper admixture of vegetable food. With such precautions, cheese becomes a most valuable article of food. So that we need be little surprised to find the extreme value and importance assigned to this variety of azotized aliment amongst rural populations where meat is scarce and expensive. Indeed, the diet on which tradition states old Parr to have attained his remarkable age can hardly have been very unwholesome. And the natives of a country which, like ours, still boasts of large cheese-fairs in some of its country towns, can find little to wound their national pride in the quaint fancy of Mueller:— that cheese and freedom flourish together.

Vegetable food. — The general characters of vegetable food have already been alluded to. They are, however, modified by all circumstances which materially affect the arrangement or composition of the vegetable tissues. Thus young plants, or the younger shoots of plants, are much more easily digested than the harder and less soluble textures of the older organism. While the approach of fruits towards their maturity determines a series of physical and chemical alterations, which have the result of rendering them much more nutritious. The mode of culture, and the peculiarities of the soil, also exercise important influences on the resulting vegetable produce. Thus a rich soil, a warm climate, or a highly azotized manure, have all been noticed to increase the per-centage of protein contained in the corn grown under their influence. And the influence of such circumstances will, of course, be in some degree extended to the persons and animals, whose staple food is thus partially dependent upon them.

Corn.—The seeds of the *cerealia* are not only the most important of all the varieties of vegetable food, but may even be ranked above all other alimentary substances, animal as well as vegetable. The history of mankind sufficiently attests the truth of this estimate,— an estimate which is confirmed by the appellation of "the staff of life," that is applied to their chief product as prepared for food.

An inquiry into their composition explains this remarkable value, by showing that the nutriment which such seeds place at the disposal of the vegetable embryo they contain, has a close resemblance to milk, both in the number and proportion of the alimentary principles of which it is composed.

The *proteinous* constituent of all the cereal grains forms a considerable proportion of their total weight. In wheat it even reaches 22 per cent. of the dried mass. But in rye, barley, oats, and maize, this amount is diminished to about 15 per cent. And in rice and buckwheat, it may be estimated at not more than 7 per cent. In respect to the varieties of protein which are present, we find substances resembling all three of its chief modifications in the animal kingdom. Thus wheat contains a large quantity of vegetable gluten, and vegetable fibrin, which are respectively analogous to casein and fibrin; together with a small portion of vegetable albumen.

The *amylaceous* or starchy constituent, which represents the calorific elements of the food, also varies in quantity; but to a smaller degree than does the protein. It forms about two-thirds of the four first kinds of grain above mentioned. In maize and rice, however, it rises to about 78 and 86 per cent. respectively; apparently replacing the protein which is diminished here. This starch is associated with a variable quantity of sugar, part of which may probably be regarded as produced from its own metamorphosis. And gum is also present in small quantity.

The *hydrocarbons* are only represented by a small quantity of fatty and resinous matter; the greater part of which, together with the cellulose also present, passes through the alimentary canal without undergoing any digestion.

The *salts* found in the ash generally make up about 1 to 3 per cent. of the whole vegetable mass. As regards their bases, they are chiefly characterized by containing little lime in comparison with magnesia. The quantities of potash and soda experience great fluctuations: — which are probably connected with the natural or artificial peculiarities of the soil in which the corn has been grown. The quantity of iron is generally considerable. As regards the acids of these salts, the phosphoric greatly predominates; while the sulphuric is in but small quantity. And the chlorides, so important to digestion and nutrition, are almost absent.

The ordinary preparation of these different kinds of grain is such as to introduce some slight changes of composition. The grinding of corn into flour strips away the outer husk of the grain; and thus has the disadvantage of removing a part of it, which contains a much larger proportion of protein than its more starchy interior. The subsequent process of fermentation and baking converts part of the starch into sugar and alcohol, with the formation of carbonic acid gas. The slow extrication of this elastic fluid gives the bread a porous or spongy character; which has the advantage of greatly increasing the effective surface that is subsequently exposed to the action of the digestive fluids. Part of the gluten of the flour is also lost in the process. But the whole amount of both gluten and starch which disappears is not very considerable; probably not more than 5 per cent. This trifling loss, and the addition of about 30 per cent. of water, constitute almost the only noticeable differences between the composition of pure wheaten bread, and that of the flour from which it is made. Their effect is, to exchange the composition already mentioned in speaking of wheat, for about 16 per cent. of protein, and 35 to 40 of starch, in bread of a moderate dryness. But the advantages afforded by the spongy texture, and the intimate admixture of water, which are brought about in the process of making bread, are still further increased by a mechanical change produced in the starch-granules themselves. For, under the influence of the moisture to which they are exposed, most of these swell up and burst, and thus place their contents in a state much more accessible to the changes which are subsequently induced in them by the salivary and pancreatic secretions.

The various *leguminous* seeds contain a quantity of the protein-compounds which may be estimated as forming, on an average, nearly 30 per cent. of their weight; or half as much again as that present in the cerealia. The quantity of their starchy constituent is, however, much less; being barely 40 per cent. They contain a somewhat larger quantity of gum. They have also a larger ($3\frac{1}{2}$) per centage of saline ash; the several ingredients of which, though almost identical with those of the cerealia, approach each other much more nearly in quantity. From the few analyses hitherto made, it would appear that the quantity of alkaline bases is very large: but that potash predominates over soda; and lime nearly equals magnesia. And though the phosphoric is still the predominant acid, sulphuric and hydrochloric are also combined with the above bases: — the latter chiefly with soda.

The value of these vegetables as food will of course depend on the preparation to which they have been subjected before being eaten. When ripe and dried, their small proportion of water, and their great density, together with the little surface they expose, together render them almost impregnable to the attacks of the various digestive agents. And even after moderate mastication, their larger fragments pass with little change through the whole of the intestinal human canal.

But after careful boiling, which bursts their starch granules, dissolves their gum, and softens and breaks up their various tissues, they assume the proper digestive value to which their composition entitles them. So prepared for eating, their large constituent of vegetable casein renders them a most efficacious azotized food. While their considerable quantity of starch, as well as their comparatively uniform admixture of the particular salts most important to nutrition, gives them a completeness for dietetic purposes, which even wheat can scarcely be said to possess. Hence we are entitled to suppose that, if suitably prepared by cooking, some of these legumes might form a food sufficient for the maintenance of health.* At any rate, we may presume, that their dietetic usefulness is rather under than overrated; so that, on physiological grounds, their consumption as human food might be advantageously extended far beyond those limits which the custom of modern European nations (and especially of the English) seems to have assigned them.

The *potato*, the starchy tuber of a plant belonging to the poisonous genus of the *Solaneæ*, is an article of vegetable food, the properties of which render it a remarkable contrast to the preceding group. We may best sum up its average composition as consisting of about 75 per cent. of water, and 25 of solids. Of the latter portion, only one-tenth is composed of protein, which is present in the form of albumen and asparagin. Three-fifths of these solids are starch. The salts of its ash amount to about 1 per cent. They are chiefly characterized by the fact, that though they contain little lime, and scarcely any soda, they include a large amount of potash; which, in the fresh tuber, is probably combined with some of the organic acids present. The quantity of phosphates is also very small: — barely, one-fourth of that contained in the various cerealia.

The above sketch of the composition of this vegetable sufficiently entitles the physiologist to range himself with the economist in determined opposition to the predominant use of this vegetable as the principal article of food. We may dismiss from our notice all consideration of the social and moral degradation which, since its introduction with this object, have steadily followed such undue use of the potato as the staple aliment in various parts of Europe. We may even set aside those fearful outbreaks of pestilence in Ireland which, though produced by the quantitative failure of one crop, must surely have been in some degree fostered by a peculiar state of the constitution — itself probably founded, in part, on the qualitative deficiencies of the previous food. Our objections to the potato find a better excuse in such a composition as the above. Rough as is the above estimate, it nevertheless claims to be based upon analyses of unusual number and accuracy. It shows that the food to which it refers is wanting in some of the most important saline constituents of the body;—such as the phosphates, which are hourly leaving the organism in comparatively large quantity. And that, in addition to this grave fault, it contains so small a proportion of protein, that we may calculate about thirteen pounds of potatoes as the quantity which a man ought to take into his stomach, in order to replace the waste of his body by a sufficient quantity of the histogenetic constituent of the food. At least this would be the amount corresponding to the protein which long experience has shown to be enough, and not too much, for the daily ration of a soldier: that is, for the food of an adult male, in good health, and habituated to moderate, but not excessive, bodily labour. Lastly, we need hardly add, that the form and arrangement of the protein contained in the potato are such as would scarcely ever allow it to be as well digested as the protein contained in the bread and meat of the soldier's ration. Hence its less suitable quality would require to be compensated by a still further increase of quantity.*

But the mixture of potatoes with other alimentary substances, and especially with meat or milk, removes all these objections, and restores it to its proper rank in the scale

* Compare Daniel, chap. i. verse 12.

* A great increase in the capacity of the stomach is regarded by Dr. Todd as a not infrequent result of an almost exclusive potato diet, so common among the lower classes of the Irish.

of food. While its saline constituents, its potash, and its organic acids, admirably adapt it for that use as an anti-scorbutic which experience points out as one of its most valuable qualities.

Succulent vegetables. — The various succulent roots, fruits, and herbs made use of as articles of food, possess a composition which, though different in each particular instance, may still be comprehended in one general description. With little protein or starch, they include a variable quantity of sugar, pectin, gum, organic acids, and salts; united with what is always a large proportion of water.

Thus in the class of roots* represented by turnips, carrots, and beet-root, the quantity of albumen is not inconsiderable; — ranging from 1 to 3 per cent.†: and the pectin itself, (C_{12} H_{16} O_{10}) is in much more considerable quantity. The organic acids of these and the various fruits are too numerous to specify; but the malic, which is also found in the potato, is one of the most frequent. The fruits contain still less protein and starch than the above roots. The young shoots and leaves of the several varieties of cabbage include starch, and some albumen, as well as sugar. The fixed salts of these various esculent vegetables are little known. In fruits their quantity is small. But in the green vegetables it is larger. And, finally, in the pectinous roots, they form about 1½ per cent. of ash; in which Boussingault has found most of the ordinary acids and bases, with proportions somewhat approaching those seen in the potato; — save that lime and soda are increased, while phosphoric acid is diminished.

The nutritive value of these vegetable substances is therefore very considerable. Deficient as most of them are in the proteinous principle, they are of course unsuited for the maintenance of nutrition without the admixture of other azotized substances. The precise way in which their pectin is applied to the uses of the organism cannot at present be explained. But its composition is so far akin to that of the gum and sugar which accompany it, that we may conjecture it subserves purposes similar to those accomplished by these hydrates of carbon. The salts of such vegetables replace those lost by the body; and, although deficient in phosphates, seem to form what is, in most other respects, a tolerable compensation for the waste of excretion. Finally, their organic acids disappear in the blood, in which they probably undergo an oxidation that ultimately converts them into carbonic acid and water.

With respect to the two latter constituents, — namely, salts and acids — it is important for us to recollect, that there are many phenomena of health and disease which teach us, far better than our present knowledge of physiological chemistry, what is the true value to the organism of such compounds. The incontrollable longing of Man after variety of diet, appears to find vent chiefly in the cultivation and consumption of esculent vegetables of this class. While scurvy, and other dangerous diseases of the same kind, which are still too prevalent among us, may serve to advise us that, within certain limits, this instinctive taste represents a bodily want, the satisfying of which is not so much a concession to the cravings of luxury, as a payment of the just claims of health.

The *seasonings* generally added to food are rarely alimentary in the strict sense of this word.

Chloride of sodium, or common salt, is, however, a marked exception to this rule; being habitually taken by most nations, and eagerly sought after by many animals, both wild and domesticated. Its use in reference to digestion may be presumed to depend chiefly on its relation to the acid* of the gastric juice. But the alleged results of its complete withdrawal from the food of criminals, are such as to suggest an antiseptic action of this salt on the contents of the stomach, even independent of that exerted by the gastric juice itself. And the office it subserves with reference to nutrition generally, appears to be a still more obscure one. Its habitual ingestion seems to facilitate the process of fattening, as well as to increase the amount of excretion. The large constituent which it forms in the ash of the blood and of most of the tissues, probably has some reference to all these details.

The other seasonings chiefly made use of in civilized life may be divided into two classes; — acids, and acrid substances. The former consist of various organic acids; especially acetic acid or vinegar, and lemon juice. These seem to act mainly by stimulating the stomach; perhaps increasing the acidity, and with this the solvent energy, of the gastric juice. The various acrid substances — mustard, pepper, capsicum, garlic, &c. — are also supposed to stimulate the secretion of this fluid, by exciting a violent determination of blood to the mucous membrane of the stomach. Many of them are irritant poisons, when taken in undue quantity.

Stimulants.—Tea, coffee, and alcohol, are substances which, though taken with the food, are scarcely alimentary in any truer sense than some of the acrid seasonings just alluded to. Indeed, were the practice of chewing tobacco as prevalent as the use of these substances †, the leaf of this highly poisonous narcotic would be equally entitled to rank in the category of food. Still their

* Botanically, of course these parts are not "roots," though usually so termed.

† Frerichs, *Op. cit.*

* Compare pp. 332. and 349.

† An instance of the partial starvation of a large ship's crew on a long voyage was lately brought under the author's notice, in which the chewers of tobacco were alleged to have endured hunger far better than the other sufferers: whilst the smokers of this narcotic did not enjoy the same advantage.

habitual ingestion in company with other articles of diet, and the manner in which they modify nutrition, forbid them to be passed over unnoticed.

Tea and Coffee.— Tea and coffee present a marked similarity, not only in their composition, but also in that action on the nervous system which is their chief physiological effect on the organism. Both consist of an oil, with a certain quantity of tannin, united to an azotized vegetable alkaloid; which is called thein, or caffein, respectively, but possesses the same composition in both ($C_{46} H_{10} N_4 O_4$). As regards their effects on the system, both produce sleeplessness and cerebral excitement. But coffee stimulates the circulation much more strongly, and in some persons excites diarrhœa. While tea is more apt to produce muscular tremors and irregular cardiac action; and generally causes a constipation rather than a relaxation of the bowels. The dietetic use of the two is very similar. How far they promote digestion is doubtful. They seem, however, to lessen the drowsiness and cerebral inaction which often follow the ingestion of a large meal. Like alcohol, they probably* diminish the rate of waste of the tissues generally.

Alcohol in all its various forms—whether of beer, wine, liqueur, or spirits—is equally undeserving of the name of food. It is not a nutritious article of diet; but rather a drug, which has a specific stimulating action on the nervous system. As regards its ultimate destiny in the organism, it seems certain that a part of it leaves the body, unchanged, in the exhalations of the skin and lungs.

The fermented liquors enumerated above are generally taken with the food. And in many of them, the alcohol is associated with small quantities of sugar and other alimentary substances. Their several tastes and odours are due partly to these, partly to other admixtures:—such as the bitter of the hop in beer, œnanthic æther in wine, and the various products of distillation in ardent spirits. The per centage of alcohol in these different liquids may be estimated as being, on an average, 3 to 7 in beers; 7 to 20 in wines; and 20 to 50 in spirits.

Dietaries.— In ending this cursory view of the different alimentary substances, we may briefly inquire into the quantity and quality of the food which would be the result of their admixture with each other, in the proportions best suited to the maintenance of health.

From what has already been stated, it is obvious that, in constructing such an ideal diet, or in estimating the proper daily ration which ought to form the food of any individual or class of persons, it should be our first care to ascertain the presence of all the alimentary principles in suitable proportions.

* Since the above was written, the experiments of Boecker, Lehmann, and others, on which this statement may now be regarded as based, have been well discussed in an article in the Medico-Chirurgical Review for January, 1855.

At first sight, it might seem easy to calculate an efficient scale of diet, from no other data but those which the above law affords us. With these data, it might even appear that such a knowledge of arithmetic as is implied in knowing the rules of simple addition and subtraction would enable us to calculate an infinite number of dietaries. For, it would evidently be easy for us to take any forms of protein, hydrocarbon, or hydrate of carbon, and compare the known per-centage of their elementary substances with the similar elements of the carbonic acid and urea which represent the most important products of the waste of the body. Adapting the quantities of the former to those of the latter, we might thus arrange thousands of formulæ, in which food would always cover waste, and income exceed expenditure:—formulæ which, provided the human organism were really made up of similar figures, would, no doubt, give us equally definite and satisfactory results when carried out into practice.

A variety of circumstances, however, concur to invalidate such calculations, and reduce them to their true value:—viz. the results of a mere process of addition and subtraction, that only distort and obscure the facts on which they are founded. Such circumstances prove, that the end of these sums in simple arithmetic is no better than the beginning:—that they do but repeat, in a less specific, and therefore less truthful form, the various statements of the skilful chemist, on which they are all based; and that, if carried any further, they can only mislead the physiologist.

For instance, not all our existing knowledge of the composition of most of the substances commonly used as food, would enable us to construct a diet which would be certain to contain an exact proportion of all the necessary salts. For, in the first place, we must recollect the probable importance of some which are only present in very small quantity; as well as the value that similarly appears to attach to minute proportions of certain organic acids, and their compounds with bases. In the next place, we must remember that, both in animals and vegetables, these saline constituents seem liable to vary, in nature as well as amount, according to the peculiarities of the soil from which they are ultimately derived. It is not by any means easy to insure their presence. And a good scale of diet ought to provide against any danger of their deficiency, by adding so much of various fresh vegetables as would cover all possibilities of such an occurrence. Indeed, nothing short of such variety would make the saline quality of any food perfect.

A similar argument will apply to the quantities of all the other ingredients. The mechanical state of the protein and hydrate of carbon will have at least as much influence in determining their requisite amount as the quantity rendered necessary by the waste of the tissues. Hence, to this latter estimate we have always to add a large excess; such as will be sufficient to cover the surplus protein which passes,—

undigested or indigestible—from the alimentary canal. And the same caution may be applied, with still more force, to that substitution of hydro-carbon, or fat, for hydrate of carbon, or starch and sugar, which some authors have regarded as so easy and natural an exchange. In all probability these substances are not by any means convertible or inter-changeable in any scale of diet. The cell-wall of the adipose tissue is dissolved with great difficulty; its liberated contents are next absorbed in but small quantities; and they then pass through glands which apparently have a slow but definite office to execute upon them, before they are admitted into the general circulating current of the blood. And, lastly, the rudest numerical contrast of their final combustive metamorphosis with that of the hydrates of carbon, shows that they require the combination of a much larger quantity of oxygen * before they can leave the body in the form of carbonic acid and water.

The total amount of food required by the body is also exposed to circumstances which are just as certain to baffle all such calculations. For this important quantity will evidently vary with the rate of waste sustained by each individual :— and hence with the activity of his life ; the nature of his habitual exertion; and the state of his mind ; as well as with the climate, race, temperament, and education, which help to form the microcosm of every man's personality. The degree of variation which may be brought into play by each of these circumstances it is impossible to specify ; though it would often receive no inapt illustration from a comparison of the habits of the various members of a family or other smallest social aggregate.

Hence the true value of physiological chemistry, in respect to the principles of dietetics, is that of being an admirable guide to the general composition of a proper food. In this capacity, it is not too much to say that its *veto* ought to be absolute. But with this negative function terminates its practical usefulness. Our choice of the exact quantities and qualities of alimentary substances necessary to construct a perfect scale of diet, may indeed be sometimes explained by chemistry. But it must always be dictated by experience. And the dietaries of gaols, workhouses, and hospitals, corrected, as they have too often been, by the ghastly hand of Death himself, have fixed the limits of the food necessary for health, with an accuracy which, considering the price of human life that has been paid for it, ought surely to satisfy the most rigid economist.

From such sources of information we may deduce, that a healthy adult male, of active habits, requires daily about two pounds of solid food. Of this food, six or eight ounces are, preferably, meat. While, if the quality of such a diet be lowered (as, for example, by the introduction of much potatoes or rice), its quantity ought to be proportionally raised, so as to compensate this diminution of its nutritious characters.

Relations of digestion to nutrition generally.—We have thus specified the various alimentary substances which are normally submitted to the action of the digestive canal. And the functions of the different segments and structures of this tube have already, so far as possible, been assigned to each.

All these functions, however, together make up but a small part of the complex act of digestion. Nay, more, digestion itself is only a part of a still wider and more complex process of nutrition. And, further, the relation borne by digestion to nutrition is by no means limited to an absorption of new matter into the body ; but also involves a revolution or cycle of much of the existing substance of the organism, between those acts of ingestion and egestion, which mark the respective extremes of its nutritional life. Hence it seems necessary to end this description of the alimentary canal by a succinct enumeration of (1st) the series of phenomena which constitute the digestive act, and (2nd) the share which digestion itself takes in nutrition generally.

We may best review the various stages of digestion generally, by supposing that we could track a mass of mixed food through the whole extent of the alimentary canal, and could observe the changes which it gradually underwent in this course. Such a food must of course be assumed to consist of proper proportions of all the alimentary principles, in the states in which they are ordinarily found in any diet suitable for the maintenance of health in the human subject.

The entry of such a food into the mouth would mark the end of what is generally described by systematic writers as the first stage of digestion :— namely, the act of *prehension*.

The food having arrived in the cavity of the mouth, is next subjected to the operations of *mastication* and *insalivation*.

Of these two processes, the first effects the mechanical division of the food :— reducing it to small particles ; increasing, therefore, its relative surface; and hence preparing it for the action of all those secretions to which it is exposed in its further course through the alimentary canal. The mechanism of this act is greatly aided by the simultaneous admixture of the saliva. This liquid is added to the food in quantities that vary, according to its dryness and the consequent need of such an addition, from 4 (apples) to 80 (bread) per cent. of the alimentary substance that is undergoing mastication.

But *insalivation* also adds an important chemical influence to the preceding mechanical advantage. The united secretions of the parotid, sublingual, and submaxillary glands, and the mucous membrane of the mouth, together furnish a liquid mixture, which converts starch into grape sugar with the greatest rapidity and energy. The perfect

* It would not be difficult to point out, how these views concur to explain the preference of fat as a calorific food, by the inhabitants of cold climates.

and instantaneous character of this change, which is only paralleled by the similar efficacy of the pancreatic juice, quite distinguishes it from that slower and less perfect metamorphosis which other animal secretions and substances are able to produce. The absence of the high temperature, and the evident putrefaction, which are generally associated with the action of these latter, still further distinguish the specific metamorphosis due to these secretions. But the substance and secretion of any one of the salivary structures, seems insufficient for the production of this agent. The submaxillary glands, and the mucous membrane of the mouth can, however, together furnish it without any aid from the parotid.*

The mastication and insalivation of the food is immediately followed by its *deglutition*, which propels the pulpy or semifluid mass it now forms into the stomach.

On entering this organ, it is subjected to a special act of *gastric digestion.*

The energetic action of the mixed saliva is not affected by the gastric juice secreted by the stomach. Much of the starch of the food is probably converted into sugar during the short sojourn of the aliment in this cavity. The sugar thus produced would seem to be absorbed by the vessels of the gastric mucous membrane with extraordinary rapidity. The water, salts, and soluble organic compounds of the food are similarly taken up. And the gastric juice attacks and dissolves the protinous element of the food. The perfectness of this process of solution depends on the mechanical state of the substances concerned, and the quantity and efficiency of the active liquid. Of the resulting solution or peptone, part is immediately absorbed by the gastric vessels, while part passes on into the duodenum, in company with portions of protein, which have not yet yielded to the solvent process. Many of these portions ultimately become dissolved, and with the peptone that accompanies them, are taken up by the veins of the intestine.

The *intestinal digestion* of the food is a still more complex act. The chyme that enters the duodenum probably contains all the alimentary principles originally present in the food. But it includes them in very different proportions compared with their original quantities. And these proportions have very diverse destinies in connection with the digestive process.

The watery ingredient of the food, and the salts it introduces, probably have but to complete their absorption. The soluble calcareous compounds appear, however, to decompose the bile ; and to combine with and precipitate some of its acids in the shape of insoluble salts of lime.

* The experiment on which Bidder and Schmidt (*Op. cit.* p. 281) claim a similar efficacy for that of the mucous membrane of the small intestine, appears scarcely to warrant such a conclusion. Should its accuracy be hereafter established, it would be interesting to determine how far the glands of Brunn were concerned in the process.

The protein-compounds probably continue their course through the intestine, still undergoing (or rather completing) a gradual process of solution under the action of the gastric juice which accompanies them. Whether any special intestinal juice* aids this process, may at present be looked on as doubtful. And whether the quantity of bile usually added in the duodenum can really hinder it, in the way in which Bidder and Schmidt † have found that it suspends the power of the gastric juice out of the body, remains equally uncertain.

The starch of the chyme would seem to be converted into sugar, by the addition of a further quantity of an agent, similar to that which is furnished by the mixed secretions of the salivary glands and mouth. At any rate, the secretion of the pancreas, which is poured out into the duodenum with the bile, is gifted with the capacity of inducing this change just as rapidly as the mixed saliva itself.

The fatty constituents of the food are probably absorbed by two channels, if not by two processes. But the quantitative share taken by each of these, remains at present unknown. That a certain portion of the fat contained in the food is taken up by the vessels of the alimentary canal, seems evident from the remarkable difference in the amount of this substance, which is found in the organic residuum of the portal blood, and that of the ordinary systemic veins.‡ But the quantity thus absorbed can scarcely be large. It appears to consist chiefly of the more fluid elain. And hence there seem no valid grounds for the supposition of much assistance being given to its transudation from the digestive canal into the veins, by means of a saponification with their alkaline blood. A much greater quantity of the fatty matter of the food is taken up by the lacteals of the villi, and is conveyed from these vessels into the thoracic duct. The microscopic details of this process have already been mentioned. Hence, it only remains for us to notice its chemical relations to the various secretions poured into the small intestine, in the lacteals of which segment of the canal the white or fatty chyle is chiefly found.

The experiments and observations of Claude Bernard would ascribe the formation of chyle chiefly to the *pancreatic juice*. This secretion appears to have the power of separating fats into their acid and base. But the fact, that such a saponification is prevented by an admixture of gastric juice, or any other acid, would justify us in doubting whether the change really occurs in the acid chyme of the living body. And all the appearances of the chyle in the lacteals of the villi concur in representing their fatty contents as being not saponified, but merely in a state of minute division. The production of this condition, — which closely corresponds to that of

* Compare p. 349.

† *Loc. cit.*

‡ See Heller's Archiv. vol. iii. p. 487.; vol. iv. pp. 15—37. 97—132.

oily substances when reduced to an artificial emulsion,—would seem to be one of the chief offices of the pancreatic juice.

The evidence adduced by Bernard* in support of his views appears very conclusive. His experiments gave him the means of obtaining large quantities of pancreatic juice from Dogs. A mixture of this secretion and oil, when shaken together, immediately produced an emulsion of the most intimate kind, such as no other animal fluid which he examined could imitate. A similar emulsion within the body could be seen in the Rabbit, when fed on butter. In this animal, the pancreatic duct opens into the intestine comparatively low down. And hence there is, under such circumstances, a long extent of bowel above the orifice of this duct, quite devoid of white chyle; while below, the lacteals are distended with this fluid. And, finally, experiments on the healthy animal†, and observations on human disease, tend to establish the same conclusion. Complete artificial obstruction of the pancreatic duct, diversion of its contents from the intestine, and extensive disease of the secretory structure of the gland,—alike prevent the formation of white chyle.

The small quantity of the pancreatic secretion would, perhaps, indicate that much of the metamorphosis of starch is effected by the saliva. And, taken in conjunction with the neutral or feebly alkaline reaction of the bile, and the apparently small amount of alkaline intestinal juice, it may at any rate be regarded as throwing great doubt upon the old theory of a direct neutralization of the acid chyme in the intestinal cavity.

The precise share taken by the *bile* in the process of intestinal digestion, is even more obscure than that of the pancreatic fluid. It may probably be stated as follows:—

The bile is not essential to the solution or absorption of any one of the alimentary principles. Nor, on the other hand, does its presence check the conversion of protein into peptone‡, or of starch into sugar. But from the appearance of the fæces in jaundice and biliary fistulæ, it would seem that its admixture with the food limits and modifies the putrefaction of its animal constituent, and the acid fermentation of its vegetable portions; and thus far aids in its proper assimilation. While the constipation generally observed in such cases, indicates that the bile is also a stimulus to the muscular action of the bowels.

The absorption of fatty matter is, however, materially influenced by the bile. So that, when this secretion is altogether diverted from its accustomed channel, its absence from the intestinal canal reduces the quantity of fat taken up here to about one-fourth of that normally absorbed.

The quantity of biliary solids discharged with the fæces is but a very small fraction of that poured into the bowel;—probably not more than $\frac{1}{10}$th or $\frac{1}{15}$th. And much of this may be regarded as a precipitate; which is produced, partly by an oxidation of a small part of the biliary fats into resinous matter, and partly by the combination of the fatty acids of the bile with the lime taken in the food.

The details of the assistance given by the bile to digestion, are very obscure. But assuming the accuracy of M. Bernard's views with respect to the pancreatic function, we may conjecture, that it is the venous, rather than the lacteal absorption of fat, which is furthered by the hepatic secretion. This view agrees with the known capacity of the soda in the bile to unite with fatty acids in the form of a soap. And that separation of the neutral fats of the food into acid and base, which would probably precede such a saponification, is sufficiently explained by their sojourn in the intestine at the ordinary temperature; or by the direct effect of this kind which the pancreatic fluid could produce, supposing it not overpowered by the gastric juice. But Bidder and Schmidt offer the further suggestion, that even neutral fat is aided in penetrating the villus by the moistening of its surface with bile:—a view which they confirm from experiments with capillary tubes and dead animal membranes.

The continuous absorption of these various alimentary principles constitutes the chief share taken by the remainder of the intestinal canal in the function of digestion. And as this absorption requires contact, too rapid a transit of the canal, or too limited an extent of digestive tube to be traversed, present much the same appearances in the food, and produce a very similar effect on the organism. Thus the fæces expelled in intestinal fistula, on the one hand, or in diarrhœa on the other, alike exhibit a large quantity of undigested starch, protein, and fat; with unabsorbed bile and water. And the fatal exhaustion which often accompanies both of these states, is evidence of the virtual starvation which may thus be brought about.

From the little change undergone by proteinous substances artificially introduced into the large intestine, as well as from the comparative development of this part of the canal in the carnivorous and herbivorous classes, we

* In a mere enumeration of the chief digestive changes, all controversial discussion would be out of place. I shall therefore content myself with saying, that having seen this eminent physiologist perform the more essential of his admirable experiments abroad, and repeated some of them at home, I entertain little doubt of their substantial accuracy. And to the ordinary disparity between the value of the negative and positive results of experiment, one may add, that none of Bernard's German antagonists appear to have succeeded in procuring large quantities of the pure secretion. Indeed I think that a detailed criticism of these negative results themselves, would amply justify the retention (for the present) of Bernard's view.

† The inflammation which sometimes follows these experiments on animals, may hinder the absorption of fat in two ways:—either by attacking the substance of the pancreas, or by engaging the tissues of the villi themselves.

‡ Compare p. 349., on the action of the intestinal juice.

may conjecture that its absorptive powers are chiefly intended to be exercised on the water of its contents; and on the sugar and lactic acid produced by that slow metamorphosis, which dense starchy substances would here continue to undergo. But in animals like the Horse, whose aliment passes quickly through the stomach and small intestine into an enormous colon, it is difficult to avoid believing, that a more or less modified gastric juice accompanies the insoluble albuminous compounds of the food into this segment of the canal, and continues its solvent action during their long sojourn in its interior. It would otherwise be almost impossible to explain the nutrition of such animals. How far the large intestine can take up fat remains unknown. But it seems certain that its share in the absorption of this alimentary principle is very slight compared with that of the small intestine.

The entire process of digestion might therefore be described as consisting in the application to the food of a variety of agencies, such as mechanical division, solution, and metamorphosis. In whatever manner these are applied (either to the food as a whole, or to the several alimentary principles which form its constituents), and whether they operate in succession or combination—in any case, they all work towards the same object: namely, that of preparing the food for absorption by the vessels and lacteals which occupy the walls of the digestive canal. With this act of absorption, the function of digestion terminates.

The chief agents of this process of division and solution, we have found to consist of certain liquid secretions; which are poured into the canal, either by the ducts of several glands, or by the vast compound mucous membrane that lines the various parts of its cavity. In short, the food received into the intestinal tube, mingles with a large quantity of a mixed fluid; which itself represents the aggregate contributions of the salivary glands, the pancreas, the liver, the stomach, and the intestine.

But the more accurate researches which have recently been made on the nature and amount of these secretions, confirm a suspicion that has long been entertained with respect to some of them by physiologists. Comparing their quantity and quality with that of the fæces and the food, we can now confidently state, that but a very small fraction of their whole mass leaves the canal with the excrements; by far the greater part of it being reabsorbed into the vessels of the alimentary canal.

This proposition — so important to a correct appreciation of the true office of the intestinal canal, and of the relation of digestion to nutrition — has lately been placed in the clearest light by the admirable researches of Bidder and Schmidt upon animals. From their toilsome and accurate experiments, it would appear, that the total quantity of matter which thus leaves and returns to the circulation of an adult man, may be estimated at little less* than 20 pounds of liquid daily; of which about 3 per cent. consists of solids in solution. The importance of these "recrementitious" secretions to the system, is well shown by the results which follow the establishment of an artificial biliary fistula. Unless the ensuing loss of bile is compensated by the digestion of a much larger quantity of food, the animal so operated on soon dies of inanition. And it is probable that the exhaustion produced by diarrhæa, or by the discharge of the intestinal contents through an abnormal opening in the bowel, may be partially due to a similar loss of this and other rich organic fluids, which ought to be reabsorbed.

Whether the secretions experience any change prior to absorption — whether any of them are really modified, and thus far *digested* by their colleagues — remains at present in doubt. It may be conjectured, however, that they are so altered. At any rate, it would seem that, by provoking these secretions †, the whole system of a starving animal may be for a time invigorated and restored. But the chain of these phenomena is at present too indistinctly seen, and their connection with various other organic processes much too obscure, to justify us in doing more than offering this conjecture, as one of the most immediate explanations of certain well-known facts.

But we know enough to state that, within the limits of ingestion and egestion, lie two corresponding acts of absorption and secretion. Each of these is, so to speak, the coefficient of two elements. Absorption takes up food and secretions: secretion pours out, not only materials newly devoted to this purpose by the system, but others which have, in all probability, already subserved it many times before. The great mass of the intestinal secretions is thus continually revolving in a cycle:—forming a circulation the channel of which, placed in the intestinal canal, leaves and returns to the blood that flows in its walls; and only allows a very small offshoot of its current to reach the outer world, bearing with it certain of its effete particles.

The important chemical details of this circulation have yet to be won by sedulous and thoughtful "questionings of nature." But since, for the acquisition of such results, the liver offers what will probably be the easiest prize, it may be useful to point out how little even the vast progress of modern chemistry has hitherto been able to establish respecting its true physiological import. The portal blood,

* From the greater proportionate waste of small animals, it is possible that this estimate (22 lbs. for an adult weighing 140 lbs.) is rather too large.

† Some of the American Indians are alleged to eat clay with the object of allaying hunger. The drinking of water is well known to have a similar effect, and has been shown to increase the quantity of these secretions without causing a converse diminution of their density. And the benefit which a starving person derives from the minutest portion of food is sometimes so sudden and remarkable, that we can scarcely avoid referring it to the same explanation. (Compare 1 Sam. xiv. 27. 29.)

charged with the water, fat, albumen, salts, and extractive, which it has taken up from the food, and from the secretions of the digestive organs, reaches a large gland. There it breaks up, as it were, into two streams of fluid: bile, and hepatic-venous blood. And hence, the composition of these two fluid products, compared with its own, might be expected to give us a clue to the process by which they originate, if not to the action of the secreting structure itself.

Such an examination would show that the hepatic blood has lost almost all the fibrin, half the albumen, much of the water, and half the fat (even more of the elain) present in the portal vein. It has gained in extractive, and especially (ten to sixteen times as much) in sugar. And its pale corpuscles are increased in number.

On the other hand, the organic constituents of the bile are chiefly fatty substances, especially the fatty cholic acid and its congeners. The quantity and quality of most of these substances show that they have probably been formed in the liver: and hence that their presence in the bile is not to be explained as a mere transudation of certain dissolved constituents of the blood, followed by their concentration in the gland, such as might be alleged in the case of most of its salts.

But here for the present we rest. Sugar on the one hand, and certain fatty acids on the other, appear to be formed in the liver; at the expense of fat, albumen, and fibrin. Until accurate quantitative researches establish whether the disappearance of the protein-compounds is sufficiently accounted for by the total increase of extractive and of pale corpuscles in the bile and hepatic vein, the exact source of these substances must remain a mystery. Schmidt, indeed, suggests, that the fat of the portal blood is decomposed in the liver into the sugar and cholic acid which its elements would exactly make up. But while we are justified in giving every consideration to a view which seems so consonant with the facts hitherto known, we must be careful to remember that it is on these facts, and not on the neatness of any formula, that its value entirely depends. Unsupported by them, it would be a mere arrangement of certain letters and figures, devoid of all real significance, and destined to the oblivion to which thousands of its predecessors in the literature — not the science — of chemistry are daily being consigned.

Development. — The development of the alimentary canal, like that of other organs, offers a series of complicated changes, the details of which often have but little visible or direct relation with the future function of the part. Hence any minute description of the process would be quite out of place in this essay. The author therefore limits himself to a brief sketch of its general outline; and for all further details begs to refer the reader to the article "Ovum."

Just as the completely developed intestinal tube might almost be described as the involution of an extremely vascular cell-growth, so its origin distinctly refers it to those two germinal layers of the embryo from which such mucous and vascular structures are respectively derived. The centre of the early ovum consists of three layers; the upper or serous, the middle or vascular, and the under or mucous, lamina. A portion of each of the two latter is folded inwards, to form the rudiment of the alimentary canal. And the whole history of the subsequent development of this tube is little more than a recital of the various steps and processes, by which these mucous and vascular structures are so arranged as to result in the characteristic form, the numerous segments, and the complex structure, which have been briefly described in the foregoing pages.

The formation of the tube begins by the separation of the united vascular and mucous layers from the serous lamina immediately above them. An increase of this separation prolongs their attachment to the serous layer into a simple and rudimentary mesentery. Each end of the canal is then mapped out, by the conjoined laminæ being bent downwards and inwards, so as to give rise to two shallow pits or fossæ: which are named the *fovea cardiaca, seu aditus ad intestinum anterior*; and the *foveola caudalis, seu aditus ad intestinum posterior*. These two fossæ, however, do not correspond to the future mouth and anus; but to the cardiac aperture of the stomach, and to the middle segment of the rectum respectively. And between them, a lateral inflection of the conjoined mucous and vascular layers gives the canal two sides, the *laminæ intestinales*; which, like the similar vertebral plates of the serous layer, bound a shallow groove. This groove, the *fissura intestinalis*, is rapidly converted into a tube, by the closing in of its inferior or open surface. The process of closure begins at each extremity of the groove, and runs rapidly towards its centre; but is arrested here, so as to leave an opening or umbilicus, by means of which the intestine is connected with the umbilical vesicle that replaces the vitelline membrane and yolk. But there does not seem to be any direct continuity of the vitelline and intestinal cavities with each other through the channel formed by this umbilical ("omphalo-enteric") duct: — at least not such an aperture as to allow of the yolk itself being immediately received into the intestine. As the umbilical vesicle gradually removes from the intestine, this duct undergoes a corresponding elongation. Its canal becomes obliterated prior to the degeneration and disappearance of the tube itself.

The simple straight cylindrical canal, the development of which has thus been traced out, resembles the permanent intestinal tube of many of the lower animals; with the exception that, as above stated, it is deficient in both terminal segments. These it next acquires. And at the same time that it does so, it assumes the length, form, and convolutions, proper to the perfect intestinal tube.

As it already occupies the whole length of the abdominal cavity, any elongation of the canal will of course give it a curved shape. And since, at this period of fœtal life, the abdomen opens by a wide vertical fissure in the situation of the future umbilicus, the first bend of the intestine renders it convex forwards, and then protrudes it through this aperture. Here it adjoins the base of the umbilical duct; which opens into the point or angle of this convexity, so that the bowel appears like a bifurcation of the duct itself. The two forks of this bifurcation are soon produced into a spiral coil of intestine; which still lies outside the abdominal cavity, and only recedes into it at about the middle of the third month of uterine life.

At this stage of its evolution, the intestinal canal may be conveniently described as consisting of three portions: an anterior, which extends from the beginning of the tube to the umbilical coil; a middle, which is formed by this coil itself; and a posterior, which reaches from the latter segment to the end of the canal.

The anterior of these three portions may again be subdivided into three similar segments. The first, which gradually elongates from the blind end that was formerly the *fovea cardiaca*, is developed during the evolution of the thorax, so as to form the œsophagus. And it finally opens into the cavity of the mouth; which is itself developed from an involution of the skin, and from the united ends of the anterior visceral arch. The second or middle segment dilates, turns on its left side, and then bends transversely to the axis of the body, to form the stomach. The pyloric valve is only visible some time after this change has occurred. And the third or lowest portion of this anterior segment is converted into the duodenum.

The middle, umbilical, or extra-abdominal, part of the canal, is developed into the jejunum and ileum, the cœcum, the vermiform appendix, and part of the colon. In this process, the change of form undergone by the small intestine is limited to a mere increase in its length and in the degree of its convolution: — an alteration which is accompanied by a further elongation of its mesentery. The upper boundary of the large intestine is first seen as a constriction and change of calibre, which occupy a point some distance below the insertion of the umbilical duct. Such a situation of the future cœcum conclusively shows, that the vermiform appendix is not that permanent intestinal end of the duct, which Oken supposed it to be. This commencement of the large intestine next enlarges into a projecting pouch of uniform width. But the lower end of this pouch soon ceases to enlarge, and remains as the vermiform appendix. While its upper part, increasing in size, becomes the cœcum. The valve appears at about the tenth week. But the proper shape and size of the cœcum are only acquired towards the end of fœtal life.

The colon is developed from the lower part of the second, and the upper part of the third portion of the rudimentary intestine. The ascending colon is at first a simple straight tube, which, commencing in the pouch just alluded to, runs forwards along the spinal column, lying to the left of the numerous coils of the small intestine. The succeeding backward bend of this tube has at first a median position, which renders it parallel with (and close to) the ascending colon. But this part of the canal soon elongates; and, passing outwards towards the left side, forms the transverse and descending portions, as well as the sigmoid flexure, of the colon. Finally, the blind end which corresponds to the rectum is continually moved downwards by a gradual lengthening of the tube; so that it meets, and at last opens into, a cavity, which is sent inwards from the skin to form the future anus. The sacculation of the large intestine only occurs in the latter half of uterine life. The valvulæ conniventes appear still later, and are but rudimentary at birth.

The development of the various microscopic constituents of the canal may be almost as briefly summed up. The cell-growth (which is derived from the mucous lamina), and the fibrous tunic (which is developed from the vascular lamina), are at first very loosely united to each other. Hence they may be easily separated into distinct and comparatively plane strata; of which the fibrous has about double or treble the thickness of the epithelial one. The cells of the latter affect an elongated or columnar form at a very early date of fœtal life (about the sixth week). The various offshoots of tubes and other glands which are contained in the wall of the canal, are developed from a mass of cell-growth, which sprouts from the external surface of the mucous layer, and gradually acquires the definite form and cavitary arrangement specific to these minute structures. The larger accessory glands of the liver and pancreas are produced from a similar mass which lies external to the bowel: and they ultimately prolong their ducts so as to open into the cavity of the intestine.

The fibrous layer, which is at first smooth and homogeneous, soon becomes roughened into little projections, which ultimately take the shape of conical processes. These, as they enlarge, pass upwards into the mucous or epithelial layer. Some of these projections not only separate the various tubes and glands from each other, but, by a farther advance and enlargement, carry before them the general surface of the cell-growth. They thus form the future villi. While others — and by far the majority — affect a lateral, instead of a vertical, growth; uniting with their neighbours by cross ridges, which soon form a network, that extends between the tubes at all parts of their height, so as to constitute a matrix for these and the other structures derived from the mucous lamina.

Finally, the unstriped muscular fibres, and the white and yellow fibrous elements, repeat the ordinary steps seen in the development of these tissues generally.

Abnormal Anatomy.

Malformations.— The malformations of the digestive canal may be conveniently arranged in three groups:— 1. Those which appear to depend on an arrested or deficient development. 2. Those which are attended by an excess of size. 3. Those which can only be referred to errors of development, the causes of which are unknown; or to malformations of adjacent parts.

(1.) A deficient development of the whole tube may diminish either its calibre, its length, or both of these dimensions simultaneously. But malformations of this kind are rarely seen, in that marked degree in which alone they can be distinguished from from the differences which doubtless obtain in different individuals.

Among the results of a local failure of development, by far the most common is one, which we might expect to be so, both from the history of the evolution of the digestive canal, and from the analogy of malformations in other parts; namely, the absence of one or both of the terminal orifices of the tube, together with more or less of its adjacent segments.

Thus the imperforate anus, which is sometimes limited to the mere occlusion of the lower orifice of the bowel by a thin membrane, is, in other instances, associated with the absence of a variable extent of the rectum, and even of the colon, ileum, or jejunum. In such cases, a cord of more or less dense fibrous tissue generally replaces a variable extent of the absent segment of tube. The canal itself is usually dilated above its closed extremity. It may, however, communicate with the neighbouring urinary or genital cavities; or it may even open at the umbilicus.*

The analogous deficiency of the œsophagus is of less frequent occurrence than the preceding, and is but very rarely associated with it. Here the pharynx ends below in a blind extremity; generally forming a pouch, which sometimes communicates anteriorly with the adjacent trachea. The œsophagus below this pouch begins in a similar but narrower sac, which is separated from the pharynx, either by a membrane, or by a fibrous cord, or by an absolute interval of varying length.

The deficiency of the stomach occurs chiefly in acephalous monsters. It is sometimes accompanied by the absence of the duodenum, or part of the jejunum.

An incomplete evolution of the remainder of the tube is evinced, either by a local narrowness of variable* extent and situation, or by a closure and interruption which (*mutatis mutandis*) repeat the various grades of this malformation seen in the occluded œsophagus and anus. Or it may exhibit a somewhat analogous tendency of the more complex parts of the canal towards the simply tubular shape. Thus the stomach may be devoid, either of its cardiac sac, or of its pyloric valve; or may present a cylindrical form, precisely like that of the small intestine. Or the valve or pouch of the projecting cœcum, or its vermiform appendix, may similarly disappear.† The maximum of this imperfection renders the whole intestine a narrow cylindrical tube, in which it is impossible to distinguish between the large and small bowel.

Almost all the foregoing malformations, where excessive, are accompanied by other deformities, which affect the neighbouring organs. Thus the deficiency of part of the rectum is a common coincident of the monopodous state, in which the two lower limbs are fused into one.

(2.) The excess of development to which we may refer the second class of malformations of the digestive canal, consists in an increased length or width of the whole tube, or of any particular part of it. In the latter case, the large intestine, the cœcum, and the stomach are the segments most frequently affected. The other local malformations which we may ascribe to such an excess, are those of subdivision of the canal on the one hand, and the production of diverticula or supplementary tubes on the other.

Very few of the transverse subdivisions of the tube can, however, be regarded as really belonging to the category of excessive development. For even where these, as in the stomach, subdivide the cavity of the canal by imperfect septa, into abnormal portions, still the latter generally exhibit a diminished, rather than an increased size.‡

The longitudinal division of the tube presents us either with a septum, which separates its interior into two channels, that communicate again below; or with a double canal, of variable length and position.

The double cœcum which has sometimes been observed, might be regarded, either as a bifid or double state of the canal, or as the

* In that class of double monsters in which the trunks are distinct below, but united above in the upper part of the belly, a variable length of their two small intestines is sometimes similarly fused into a single tube, which bifurcates above and below. The seat of the lower bifurcation is sometimes occupied by a (probably true) diverticulum.

* In rare instances this narrowing is so great as to constitute a virtual occlusion. Thus cases are sometimes met with, in which the whole of the intestinal canal below the duodenum or jejunum constitutes a tube, which retains the formal separation into large and small intestine, but evinces its checked development by its narrow calibre, and by the dilatation or pouch above it, that terminates the normal segment.

† In some of these latter cases it is probable that the projecting cul-de-sac, which appears to be the cœcum only, is in reality the undivided rudiment of both it and the vermiform appendix.

‡ Some of these transverse subdivisions of the tube possibly imply a mere arrest of development in the site of the imperfect septum, without any excess of this process in the contiguous parts.

co-existence of a diverticulum with the normal pouch of this part.

The *diverticula* of the intestinal canal seem to be of two kinds, which differ, not only in the frequency of their occurrence, but also in their situation, form, structure, and (in all probability) in their nature or import.

The least common variety form pouches of variable length, width, and shape; which may spring from almost any part of the canal, but are usually connected with the small intestine. Their structure varies; but, as contrasted with the bowel itself, they usually exhibit more or less deficiency of the muscular coat.*

The *true diverticulum* differs materially from these. It usually forms a short tube of intestine, which leaves the ileum at from 1½ to 2 feet above its termination; by what is either a right angle, or is such as gives it an inclination towards the lower part of the bowel. Its width generally approaches that of the ileum, with which its cavity is continuous, by an aperture that is sometimes valvular. It possesses the ordinary muscular and mucous coats. The former exhibits its usual transverse and longitudinal layers. The latter also presents its ordinary structure: being occupied by villi, tubes, and follicles; and sometimes, by valvulæ conniventes of remarkable distinctness for this region of the bowel. Its length is generally about three or four inches. Its shape is more or less cylindrical, oftener contracting than expanding towards its termination. It commonly sustains vessels, and is attached by a kind of mesentery. Occasionally it exhibits, in addition to these vessels, a cellular cord that evidently contains the degenerated relics of some large artery. And finally, it sometimes extends upwards towards the umbilicus; and, in rare instances, opens here. From all these circumstances there can be little doubt of its true import being that assigned to it by Meckel; namely, that it is a highly developed and persistent portion of the duct of the umbilical vesicle.

(3.) The third or remaining group of malformations includes most of the congenital displacements of the digestive canal. These, as already mentioned, may be ascribed to two very different causes. The transposition or displacement of the tube within the abdomen, whether total or partial, is a fact for which the history of its development affords no explanation or probable secondary cause.† While the situation of any part of the canal externally to the cavity of the belly, is, in most instances, the mere result of a deficiency of the abdominal parietes.

The partial displacement of the canal generally affects the transverse colon, or some other segment of the large intestine; and, more rarely, the stomach. Its total transposition inverts the position of all the abdominal viscera with respect to the median line: so that, for example, the pylorus, the cœcum, and the ascending colon occupy the left side of the belly; while the cardia, the descending colon, and its sigmoid flexure, are found on the right, or opposite side.

The congenital inguinal herniæ form the most familiar illustration of the second (or extra-abdominal) class of displacements. And when a similar arrest of development involves the anterior wall of the belly generally, the abnormal situation of the canal may assume any grade, from that of a limited umbilical hernia, to an external situation of almost all the intestinal canal. While the deficiency of the diaphragm may allow a variable extent of the canal to occupy the cavity of the thorax. From obvious reasons, it is the commencement of the small intestine, which usually experiences this displacement. The stomach, above the hernia, is sometimes dilated.

Morbid Conditions. —*Size.* — Alterations in the size of the alimentary canal, though they chiefly affect its calibre, are generally associated with changes in its walls.

Constriction. — Narrowing or diminution of calibre is sometimes general, but is more frequently limited to a part of the tube. Its causes are various.

1. It often results from a process of contraction, which specially engages the muscular coat. Such contraction, generally passive, is well exemplified in the narrow empty tube, seen where the canal has for some time received no contents. Thus in persons who have died of starvation, the intestines are sometimes reduced to a tube, with pale thick walls, and a narrow calibre, like a tobacco-pipe. While a more local change of the same kind is often found in the empty segment of the intestine immediately below an obstruction, or an artificial anus. During its *rigor mortis*, the dead intestine often presents similar appearances. These may, however, be distinguished by their originating in a more active contraction, by their exhibiting a more marked, but less permanent character, and by their involving a less extent of bowel. And lastly, various irritants and astringents have been found to excite the muscular coat to contractions, which can more or less imitate the diminution of calibre producible by the preceding causes.

2. Narrowing may also result from the contraction of other intestinal tissues, besides the muscular coat. The constriction produced by the immediate or local action of the corrosive poisons on the alimentary canal, may be partially ascribed to their direct chemical influence on the various textures with which they come into contact. Such poisons, for

* Hence some anatomists regard these pouches as constituting a kind of hernia of the mucous membrane. But unless this view imply that they are, at least in part, of mechanical origin, it can only amount to a circuitous statement (and often an exaggerated one) of the above fact. It is however probable, that some of these diverticula really are the results of accident.

† In rare instances, the stomach or colon take a vertical position, which, to some extent, suggest an arrest of their development. But little stress can be laid upon such a conjecture, unless it be confirmed by other appearances of the same kind in these or neighbouring parts.

example, absorb the water of these tissues, coagulate their albumen, and thus corrugate and condense their mass. The narrowing which is produced by inflammation or by morbid growths, may be regarded as more mechanical. It results, either from the exsudation or deposit directly engaging more or less of the cavity of the tube; or what has a similar effect, from its ultimate contraction first reducing the size of the diseased part, and then trenching upon that of the neighbouring healthy parietes. Where the deposit of the new substance has been preceded by a loss of the normal tissue, — as often occurs in inflammation and ulceration — the constriction which is thus subsequently brought about is of course much more considerable.

3. To the above causes of constriction intrinsic to the tube, we may add several which are extrinsic to it. These are chiefly important, either by the inflammation they excite, or by the obstruction which constriction beyond a certain limit is apt to produce. Hence they will be hereafter alluded to, in connexion with those displacements of the tube, by which obstruction is most frequently brought about.

Dilatation.— An increase in the calibre of the digestive tube may be the result, either of distention of its cavity, or of relaxation of its walls, or of both of these causes conjointly. Thus that segment of the canal which is immediately above an obstruction, is always found in a state of distention: its dilatation being obviously produced by an onward transmission of the intestinal contents, to the point where their progress is arrested. And even in the absence of direct morbid obstruction, constant distention of the tube can to some extent imitate this state. Thus the colon of persons habitually constipated, frequently becomes enlarged to a vast extent. And the stomach of the rice-eating Hindoo, or the potato-eating Celt, often acquires a similar increase of capacity.

In many of these cases it is, however, probable, that the passive distention of the organ is assisted by an actual relaxation of its walls. In the enlarged bowels of obese individuals there can be little doubt that this is the case. And most of the diseases at present associated under the name of *ileus* exhibit, as one of their characteristic changes, a relaxation of the bowel, which may be distinguished from the preceding by its rapid occurrence, its morbid nature, and its usually considerable amount.

Thickness.—It is seldom, if ever, that the walls of the intestinal canal are altered in their thickness only. Apart from the obvious physical effects of distention and constriction, by which their tenuity is respectively increased and diminished, the coats of the bowel rarely undergo changes in this respect, without presenting some other appearances, such as betray a more important lesion. Indeed, the foregoing alterations in calibre are often associated with changes of texture.

Thus, in persons who have died from slow starvation, the intestines become extremely thin, soft, and transparent. A similar change sometimes accompanies that atrophy of the tube, which is produced by tubercular peritonitis or by diarrhœa, and is attended by an anæmic pallor of the canal. The dilatation caused by obesity is usually associated with an increased thickness of the intestinal parietes; a condition which has been compared to hypertrophy. Here, however, a careful examination will easily show that the real nutrition of the tube has by no means undergone an increase commensurate with that of its bulk. The bowel is indeed enlarged: but its muscular coat is softer, paler, and weaker; and its whole appearances are those of a thickening, which is chiefly due to an increased effusion of fluids interstitial to the normal solid structures.

Situation. — Changes in the *situation* of various parts of the canal are by no means uncommon. We have already alluded to the great freedom of movement which is natural to the small intestine *; and have specified the various regions of the abdomen which distention of the stomach † or large intestine ‡ may cause these segments respectively to occupy. We have also briefly mentioned the more frequent congenital displacements. We have therefore only to enumerate those displacements which are independent of the above causes.

The abnormal positions of the different parts of the intestinal canal are naturally divisible into the *extra-abdominal*, and the *intra-abdominal;* in other words, into those in which they are placed externally to the abdominal cavity; and those in which their change ra situation is within the belly, and thus allows them still to be bounded by its walls.

The first of these classes includes the various kinds of hernia: in which an unnatural deficiency or weakness of some part of the abdominal parietes allows a portion of the canal to be protruded through them; forming a displacement which, according to the situation of the protrusion through the wall of the belly, is called inguinal, femoral, abdominal, umbilical, or diaphragmatic hernia.

Amongst the second class of displacements, or those which are included within the parietes of the belly, we may first mention some, which are attended with few, if any, symptoms during life; and are, at least in many instances, a mere adaptation of the canal to external pressure.

Thus the habit of tight-lacing sometimes gives the stomach an hour-glass shape, sometimes thrusts down its projecting cardiac pouch, towards the left hypogastric region and the pelvis. In like manner, the bulk of the organ may be forced aside into various unusual situations by the pressure of any tumour in its neighbourhood. Thus, during the latter stages of pregnancy, the uterus so far encroaches upon the stomach, that the latter impedes the descent of the diaphragm, and

* See p. 340. † See p. 309. ‡ See p. 362. *et seq.*

thus claims a considerable part of the trunk which generally belongs to the thorax. The duodenum is so fixed as scarcely ever to be displaced, except when it is dragged out of its normal position, by displacements of the stomach or small intestine.

It is in the large intestine that such deviations of position are most frequently found. In the cœcum, however, they are by no means common; or if present, are generally limited to a descent of its dependent left extremity into the pelvis. The more frequent displacements of the ascending and descending colon seem usually produced by changes, which principally engage the segments that immediately succeed them. Thus the transverse colon sometimes appears to be wanting; being converted into a narrow arch, with the convexity upwards, and having sides which are no way distinguishable from the ascending and descending colon. The reverse of this state is even more common, in which the arch, instead of being horizontal, has its centre depressed towards the hypogastrium, so as to form an abrupt vertical bend, with the convexity downwards. Here the neighbouring ascending and descending segments of the bowel are, as it were, drawn into the increased length of transverse colon, so as to be themselves greatly shortened. And finally, the displacements of the sigmoid flexure, which are even more common than the preceding, resemble them in the modifications which they impress on the normal length and curvature of the tube. Sometimes they merely exaggerate the natural curve of this part; sometimes they lengthen it at the expense of the descending colon, or even of the rectum; and occasionally the curve is, as it were, transferred to the latter bowel. Lastly, the sigmoid flexure is sometimes preceded by a long segment of tube, which carries it over to the right iliac fossa; where it is so fixed, that the rectum which succeeds it, shares its displacement, is attached to the right sacro-iliac symphysis, and only gains the median line towards the middle of the sacrum.

The origin of many of these displacements is scarcely at present ascertained. But there is little doubt that they are often produced by tight-lacing, as above alluded to. Such a conjecture is confirmed by the fact, that they are almost limited to the female sex. They seem to occur most frequently in persons who have borne children.

We have next to notice a form of accidental displacement, in which the change of situation, though limited in amount, is much more serious in its results, leading to an obstruction that is usually fatal. It includes the various kinds of torsion, and the intus-susception or inversion of the canal.

In the *torsion* of the intestine, a portion of bowel is more or less twisted, either around its own axis, or around a centre formed by a variable extent of the neighbouring mesentery. The parietes of the tube are thus brought into contact with each other, with the effect of completely occluding its calibre. In what way this twisting is effected, or why it is not soon effaced by the subsequent distention of the bowel, it would be incompatible with the limits of this sketch to inquire.

In *intus-susception*, the obstruction is effected by the passage of a longer or shorter segment of the canal, with a portion of its adjoining mesentery, into the cavity of the next or following segment.

The anatomy of this displacement may be best traced by a brief narrative of the steps of its occurrence; at any one of which death may intervene.

Mobility of the tube is an essential condition of its production. Hence intus-susceptions are generally found in the small intestine, and sometimes in the large intestine; but rarely or never in the duodenum.

Irregular contraction of the muscular coat seems equally essential to their occurrence. Hence we often find them in dead bodies, as a result of the intestinal *rigor mortis*. While their occurrence during life can often be traced to a casual diarrhœa, which seems to form at least their exciting cause.

They are almost invariably produced by the reception of a superior into an inferior segment of bowel. It would therefore seem that they "originate as a kind of perverted peristalsis:—that, the longitudinal fibres remaining quiescent, the intestine is surprized by a transverse constriction, the rapid advance of which hurries the contracting portion into the flaccid and dilated part immediately anterior to itself."* The whole of this process appears to be well illustrated by the ordinary action of the œsophagus, the lower end of which tube undergoes a temporary intus-susception into the stomach at the end of every act of deglutition.†

The way in which the transverse contraction of a segment of intestine furthers intus-susception, receives some illustration by its frequent occurrence in cases where a polypiform tumour is attached by a pedicle or stalk to the interior of the intestine. Here the traction exercised by the stalk of the tumour on the wall of the bowel from which it takes its origin, appears to assist the muscular contraction of the segment which immediately propels the tumour itself, in producing the intus-susception.

The mechanical obstruction produced by an intus-susception is probably always an indirect result. It is perhaps aided by the obliquity of the received portion, the open end of which is always inclined towards the mesenteric border of the bowel. This obliquity seems due, partly to the pledget of mesentery, which shares the occupation of the outer or receiving segment of intestine; partly to the greater distention undergone by the free margin of the bowel above. In large intus-susceptions, the mesentery thus forms a thick strong cord, that not only ties down the bowel by its inner margin, but constitutes the

* Author, *Op. cit.*, p. 17.
† See p. 311.

axis of the spiral and dilated segment of tube around it. The congestion and strangulation of the vessels of the peritoneal fold, as well as of those of the invaginated bowel itself, soon cause a swelling, that fixes the innermost segment firmly in its abnormal position. An exsudation of serum and lymph next increases its size, at the same time that it renders these changes of situation permanent. The dilatation of the preceding part of the canal, by the fluids passed into it from above, often further exaggerates the above changes.

The sloughing which from all these causes finally ensues, sometimes has the effect of setting free the intus-suscepted segment in the cavity of the canal. Hence, if the patient survive until this separation occurs, the discharge of this segment from the bowels may terminate all the symptoms of obstruction; and leave the bowel at the site of the intussusception occupied by a ring of lymph, which gradually contracts into a firm cicatrix of fibrous tissue.

From the preceding changes in the size, shape, and situation of the digestive canal, we pass on to consider the abnormal conditions of its texture.

Softening is the first of these conditions which claims our notice.

In rare instances, this change engages the whole of the digestive canal, to which it imparts a semi-transparent gelatinous appearance, and a pulpy diffluent consistence. In this general softening, the walls of the canal are usually diminished, scarcely ever increased in thickness. Their colour is generally pale enough to warrant us in regarding them as in a state of anæmia. But they sometimes exhibit those various shades of discoloration which are present in the more localized forms of softening.

The latter are usually found in the stomach, where they especially occupy the cardiac pouch. But they are sometimes seen in the large intestine:—indeed, in most subjects, the mucous membrane of this part of the canal has a somewhat softer consistence than that of the small intestine.

It is in the stomach, in which the process of softening occurs with most frequency and intensity, that we may best notice the details of this change, and the degrees in which it generally engages the different tissues of the coats of the canal. Of these the mucous membrane is that which always seems to suffer first and most; in which the process appears to commence, and to which it is often limited. At first, the only noticeable change is a diminution of its consistence: a change which either occupies isolated patches of its surface*, or is spread over a considerable extent of the cardiac sac, rendering it liable to break down on the application of the slightest pressure. Hence if a portion be taken between the blades of the forceps, it will come away between them on exercising a very moderate traction. The mucous membrane next becomes absolutely broken down; so as to form a granular pulp. This pulp covers the subjacent tissues with a layer of variable depth; the deficiency of which, here and there, lays bare the submucous areolar tissue. The process may next engage this and the muscular textures; either imparting to the latter a paler, softer, and thinner appearance than natural; or implicating the whole thickness of the gastric parietes, and giving them a gelatinous appearance. A considerable thinning of these parietes almost always accompanies this change, and is sometimes so great as to cause the rupture of the organ, and the effusion of its contents. Finally, in extreme cases, the contiguous tissues of the belly, and especially the muscular substance of the diaphragm, become involved in an extension of this process from the stomach.

* These are sometimes the projecting summits of the ridges formed by its mucous folds.

The colour associated with this loss of consistence is very variable. In some cases, there is a complete anæmia of the gastric coats; in others, this term is rendered somewhat less applicable by the presence of one or two large veins distended with blood. In other instances, we find the softened part of the stomach coloured a variable shade of brown, red, or even black; according to the quantity of blood it presents, and the degree in which its hue has been altered by the gastric juice. Finally, in many cases the organ offers no appreciable contrast in this respect with its normal state.

It is probable that these softened states of the digestive canal are capable of being produced by very different causes. Even after setting aside all those instances in which the softening has been preceded by symptoms of inflammatory action during life; and all those in which it has been due to the ingestion of poisons which exert a direct chemical action of this kind; we may trace the process to three causes, which often coincide in its production, and the exact share of which it is therefore often difficult to estimate in any particular specimen. These causes are, putrefaction, digestion, and altered nutrition.

The amount of influence which has been exerted by putrefaction, might seem very easy to determine. But we cannot always estimate it by the date which has elapsed since death, or the temperature to which the body has been exposed; since its access and rapidity vary remarkably according to the state of the organism, and the nature of the fatal disease.

The capacity possessed by the secretion of the stomach for digesting its coats after death is one which will obviously depend on the nature and amount of this fluid present: and will, other things being equal, attain its maximum in the case of the sudden death of a healthy person, soon after the ingestion of food.

The softened state of intestines, which is often found in diarrhœa, fever, and other disorders, — as well as the peculiar softening*

* The characters of this softening appear to in-

of the stomach, long known to occur in ill-nourished infants, or in cases of hydrocephalus or brain disease, — point just as decidedly to the influence of an abnormal state of nutrition in favouring this state.

Lastly, there are many cases of acute disease, in which the softened stomach is more or less coloured by blood that has stagnated in its walls, where we have the additional difficulty of determining whether this congested condition preceded or followed death.

Hyperæmia.—The hyperæmia of the digestive canal constitutes an abnormal state, the correct appreciation of which is of great pathological importance. Of course, even the loosest interpretation of the term would limit it to an increase in the quantity of blood present in the vessels of the alimentary tube ; and would thus exclude a condition which is capable of being confounded with it : namely, a transudation of the mere colouring matter of the blood from neighbouring parts.

But there are many circumstances which render it very difficult exactly to determine the amount of true hyperæmia present in any segment of the digestive canal after death.

Thus, while there is little doubt that hyperæmia is a stage of almost all the processes ordinarily regarded as inflammatory, as well as of those which result in the deposit of adventitious growths, the examination of the digestive canal after death shows that this condition by no means accurately coincides with these processes. On the contrary, it is often absent in the very cases in which the symptoms during life might best entitle us to expect it. And conversely, it is often present where death has been the result of accident, or of disease no way referable to the organ which is the seat of the congestion. We are therefore bound to conclude : (1.) that the presence of hyperæmia in any part of the digestive canal does not necessarily prove this part to have been the seat of disease during life ; and, (2.) that the absence of hyperæmia in the dead structure does not disprove its previous presence in the living organ. And we have therefore to inquire : — (1.) What causes can produce it in the healthy tube? (2.) What circumstances can efface it from the diseased tube? And (3.), what are the marks by which we may recognize hyperæmia in the corpse, as a true and characteristic relic of diseased action during life?

It is to the phenomena of death, as this process usually affects the organs of circulation, that we must first look for an answer to the above questions. A very cursory allusion to these phenomena may suffice to indicate, in what manner they can by turns imitate, modify, or efface the state of true hyperæmia occurring during life. The *rigor mortis* of the dying arteries flushes and distends the capillaries beyond them with an abnormal quantity of blood. The degree, date and extent of this arterial contraction in different vessels, will obviously be capable of imparting almost any moderate amount of distention or congestion to the terminal networks they respectively supply. And at a later period after death, the gravitation of the now stagnant blood may distend the vessels of any dependent part of the body. But the congestion of one part implies—other things being equal—the drain of some others which are immediately contiguous to it. And hence the very occurrences which can cause moderate hyperæmia in a healthy segment of intestine, may at the same time produce a certain amount of anæmia in another ; and may therefore diminish — and, when moderate, remove — a state of simple congestion due to disease.

It would be easy to accumulate instances of the fact last alluded to. The state of really intense, though healthy, hyperæmia, which is present during the periodic activity of the stomach or other parts of the canal, rarely leaves any traces after death, unless in animals who are examined very speedily after this event, and before these new adjustments of its circulating fluids have had time to take place. In like manner, the increased vascularity of the intestines which accompanies cholera or diarrhœa is often just as completely effaced after death : — disappears, in short, in the same manner in which the redness of erysipelas and various other cutaneous disorders rapidly fades away in the first few moments that immediately follow the last breath.

But, even with all allowances for such sources of error, the condition of hyperæmia is one of the highest significance in the pathology of the digestive canal. It is, generally, an important sign of disease. And, with proper attention to its collateral circumstances, its import need rarely be misinterpreted. Thus, as regards the extent of the process, an intense and minute congestion is almost always morbid ; and is obviously much less likely to be removed by the phenomena of death, than one of more moderate hyperæmia. Again, a long duration of the abnormal vascularity, as in the hyperæmia of chronic disease, generally brings about such a definite and permanent enlargement of the vessels concerned, as evidently tends to enable them better to resist the action of these cadaveric changes. In other instances, a similar result appears to be produced by a process of exsudation around the vessels; and by changes in the structure of these tubes themselves. It must, however, be confessed, that we do sometimes meet with specimens of tolerably intense congestion of a part of the alimentary canal, where it is only from the presence or absence of corresponding symptoms during life, that we can conjecture whether the state of hyperæmia has preceded or followed death.

Of course, the mere hyperæmia of any network of capillaries may be determined in two ways : — either by an increased afflux, or by a diminished reflux, of the blood. But the

dicate that although it is probably preceded and assisted by an unhealthy state of the tissues of the stomach, the gastric juice is at least the chief immediate agent of the change.

first or "active" form of congestion may generally be distinguished from the latter or "passive" variety. The active hyperæmia is immediately attended by an enlargement in the calibre of the afferent arteries; the passive, by a diminution in that of the efferent veins. Again, the former usually has the colour of a tolerably scarlet or arterial blood; the latter, that of a darker and more venous fluid. Lastly, the active form affects chiefly the minute arterial branches and the capillaries; the passive is most prominent in the veins which come from these ultimate vessels. The hyperæmia of enteritis and of cirrhosis respectively, might well illustrate this contrast.

Amongst the varieties of hyperæmia, we may notice a more or less complete limitation of this state to the capillaries of particular tissues. Thus the microscope sometimes reveals a congestion of the gastric or intestinal mucous membrane, that specially engages those capillaries which surround the mouths of its tubes. In other instances, their blind extremities exhibit a similar state of injection. The exact cause of such partial hyperæmia is scarcely known. But the first of these varieties appears to be generally connected with a very limited amount of congestion. In accordance with this fact, it seems frequently to occur during or after death.

Hæmorrhage.—Hæmorrhage is by no means an unusual morbid occurrence in the digestive canal.

Of course, the mere presence of blood in some part of the alimentary tube, affords no proof that it has been derived from the vessels which occupy its walls. The blood which reaches the pharynx in cases of hæmoptysis, or of lesions of the nose, mouth, or pharynx, is often swallowed, and is thus introduced into the stomach or bowels. In like manner, blood effused into the ducts of the liver or pancreas, may be carried onwards through these tubes, so as to simulate hæmorrhage into the intestinal canal; or the blood extravasated into cysts, abscesses, and tumours, may find its way, through some abnormal opening, into the cavity of the bowels.

It was formerly supposed that, in many cases of hæmorrhage, the walls of the vessels remained uninjured; or, at least, unaffected by any definite solution of continuity: the blood being set free from its channels by "exhalation" through their porous walls. But we now know that this doctrine is incorrect; that the walls of even the finest capillaries have no pores of appreciable magnitude, such as are necessary for the transit of blood-corpuscles: and hence that the "extravasation" of these structures is, *ipso facto*, a proof that some blood-vessel has been ruptured. That, amongst the myriads of these minute tubes present, we often fail to detect the exact seat of the lesion, need, of course, little surprise us.

The frequency with which hæmorrhage occurs in the digestive canal, seems related chiefly to the number and delicacy of its vessels, to the nature of its tissues, and to the mode in which these structures are arranged with respect to each other. Amongst such predisposing causes we may especially notice, that the greater part of its large vascular supply breaks up into a vast and dense network of capillaries, which is placed in the closest proximity to the free surface of the mucous membrane. While the latter structure not only has a consistence which disease can readily reduce below what is necessary for the mechanical support of these delicate vessels; but is the constant seat of muscular movements, which agitate it in almost every conceivable plane.

The extravasated blood may either occupy the interstices of the intestinal tissues, or may make its way into the cavity of the canal.

The former case is much the less frequent of the two. As we might infer from the anatomy of the tube, the areolar tissue around the submucous stratum of vessels is by far the most frequent situation of such interstitial hæmorrhage.

The blood which is effused by hæmorrhage into the cavity of the tube itself may be either fluid or coagulated, arterial or venous, pure or mixed, changed or unchanged. With respect to the latter alternative, we may point out, that blood effused into the digestive canal not only becomes mingled with the various ingesta and secretions which may chance to be present, but gradually undergoes a kind of digestive process, that often has the effect of greatly modifying its colour and consistence. Hence, where the extravasated blood has been sufficiently exposed to this action, it will generally be found to have acquired a dark, grumous, or even black colour, and a peculiar tarry or almost pultaceous consistence. While conversely, if the effusion be excessive in quantity, or recent in occurrence, it may be pure enough to testify to its arterial or venous source. A small quantity of blood thus altered by digestion sometimes simulates the colour and appearance of inspissated bile. But by diluting the sanguineous mass with water, its dark-purple or blackish hue may be at once distinguished from the rich yellow colour which is proper to the biliary secretion. And a microscopic examination would, of course, assist (or even replace) this means of diagnosis.

The nature of these intestinal hæmorrhages is very various. Apart from mechanical injuries of the canal by foreign bodies applied to it from within or from without, we may classify (but scarcely separate) them into hæmorrhages from two sources: — from abnormal states of the vessels themselves; and from diseased conditions of the contiguous tissues.

As examples of the former variety, we may adduce the hæmorrhage produced by the rupture of an atheromatous artery; or the extravasation which occurs in cirrhosis from obstruction and distention of the portal veins.

The hæmorrhage of inflammation, of ulceration, of atony, may be referred to the second variety. But even here, just as it is evident that lesions of the vessel themselves always constitute the immediate cause of the extravasation, so we can hardly doubt that such lesions may (and often do) form a predominant, though not an exclusive, element in the process.

Inflammation. — Inflammation constitutes the most frequent and important of all the morbid conditions of the alimentary canal. Indeed, there are very few of these conditions with which it is not more or less directly concerned. It is generally, if not always, preceded by hyperæmia; often by downright hæmorrhage; and itself usually precedes the occurrence of ulceration and gangrene. It is the necessary result of mechanical injury to the various tissues of the tube; and is often an immediate consequence of the diseases or injuries of neighbouring organs. There is little doubt that it is often concerned in the production of those conditions which we at present include under the name of hypertrophy. And it is also capable of being evoked by the presence of adventitious growths, even though their origin may be regarded as independent of its presence. Finally, it constitutes one of the most characteristic phenomena by which various diseased states of the blood declare their influence on the system.

Such a diversity in the forms of the inflammatory process, as it affects the intestinal tube, might well lead us to expect variations at least as considerable and numerous in its nature. These, however, the space allotted to the present article will not allow us even to sketch. As little can we enter upon the difficult subject of its true pathological relations to the other morbid processes just alluded to. We must be content to accept the term inflammation as it is ordinarily made use of; and to enumerate its appearances, as they are usually seen in the dead body.

The mere existence of congestion we have already found to be no certain indication of the inflammatory state; but, on the contrary, one which would often deceive us, if viewed in this light. And though the presence of an exsudation forms a test which is far less frequently fallacious, yet even it requires some qualification, before it can be accepted as tantamount to proof of inflammation. For just as, to speak physiologically, it is the very office of the blood-vessels to mediate and permit an exsudative process of definite nature and amount, so slight differences of the exsuded fluid in both these respects, from that normally poured out, are not even incompatible with health, much less characteristic of inflammation. Hence, in saying that "exsudation" is a main feature of inflammation, we are using the word, not so much to express an isolated fact, as to imply a comparison: — an exsudation, of such a quality, and in such a quantity, as to offer a marked contrast with the specific fluid which is poured out by a secreting organ, on the one hand; or with the healthy nutritional fluid which bathes the interstices of its tissues, on the other. Of the two contrasts thus implied, that of quality is obviously much the more important. Thus, while the copious interstitial juices of the swollen but flaccid intestine of a very corpulent person, offer little difference from those of the typical healthy adult, save in their (so to speak) more diluted state, — or while the intestine of a dropsical abdomen is chiefly enlarged by an increase of the ordinary fluid of its submucous tissue, — the vessels of the inflamed alimentary tube take on what is more or less a new, as well as an increased action; by virtue of which they pour out, into the tissues or the cavity of the canal, fluids which are very different to those normally present in this situation. Using the term "exsudation" in this restricted sense, we should scarcely do wrong in regarding it as the chief feature of the inflammatory process; and as an appearance which, when seen accompanied by the ordinary marks of hyperæmia, quite entitles us to affirm that the part in which it is situated, was the seat of inflammation during life.

And not only does the presence of exsudation form the characteristic mark of inflammation, but the basis of the classification under which we may best arrange the varieties of this process.

Thus according as the characters of mucus, pus, or amorphous protein, predominate in the exsudation poured out, we distinguish the process which has given rise to it as *catarrhal*, *puriform*, or *croupy* inflammation. The rapidity of its effusion is at least a frequent and important element of these peculiarities which are summed up in the epithets "*acute*" and "*chronic*." And finally, as regards its extent and situation, it not only ranges from an inflammation of the mucous surface only, to one which successively involves the subjacent muscular and peritoneal coats, but may even specially affect the submucous areolar tissue of the canal, or engage certain parts of its secretory apparatus in the shape of its tubes or follicles. Each of these modifications will be noticed in a few words.

The *catarrhal* inflammation of the mucous membrane offers precisely the appearances seen in catarrh of other mucous surfaces. The numerous vessels of the membrane exhibit a state of more or less intense hyperæmia, giving it a corresponding shade of that red colour which is generally producible by vascular injection. This increase of vascularity is stated by Rokitansky to be chiefly visible, sometimes in the villi, sometimes around the follicles. But it seems to me that its being limited to the latter is often due to the contraction of the villi * having thrown back the blood they contain, into the adjoining follicular network with which they anastomose. The exsudation thrown out in this form of inflammation, may be traced in two situations: — in the textures of the canal itself, and in

* Compare p. 54.

its contents. In the former, it gives a softened, swollen, relaxed, and watery appearance to all the coats of the tube, and especially to its epithelium and submucous areolar tissue. In the latter, we notice certain changes in the fluids poured out upon the inner surface of the tube. The contrast between these fluids and those which are present in health is probably closely analogous to that which obtains in other catarrhs. The specific normal secretion is arrested, and is replaced by a variable (usually a large) quantity of a thin watery fluid. The effusion of this fluid coincides with the detachment of the proper epithelium of the mucous coat from the subjacent basement membrane ; a process that is generally followed by the shedding of large numbers of imperfect or abortive cells, which take their origin in the same situation. The admixture of this cell-growth imparts to the catarrhal exsudation its well-known gelatinous or mucous characters, and viscid consistence; properties which the microscope shows are partially due to the solution and rupture of these delicate cells, causing the escape of their contents into the surrounding fluid. The latter is either transparent, or of a cloudy, whitish, reddish, or grayish colour. The last of these appearances, when not due to an admixture of foreign ingredients, is mainly derived from the quantity of these cells, many of which generally assume more or less of the characters of pus. The reddish hue is due to an admixture of blood, by that process of hæmorrhage which so frequently results from congestion in the delicate mucous membranes.

The *puriform* variety of inflammation might, at first sight, seem scarcely worthy of distinction from the catarrhal. For the two merge into each other by innumerable gradations in the character of their exsudation. And the general tendency of catarrh of the mucous surfaces, to end in the production of pus, is too well known to require any comment. But while there always seems sufficient reason for distinguishing it as a separate stage of the inflammatory process in the digestive canal, there are circumstances which render it not improbable that the mucous and puriform inflammations of the intestinal canal are often distinct, both in their origin and nature. Thus there are some catarrhal affections of the bowels, in which lapse of time seems to have no effect whatever in exchanging mucus for pus ; while there are others in which this morbid product appears to be formed very speedily, or even at once. And that there are many cases which we should find it difficult to assign to one or other of these divisions, is an objection which would equally apply, not only to all the other varieties just alluded to, but to almost all the classifications we are compelled to use in describing the various results of disease on the healthy organism.

The presence of pus in any considerable quantity, is of course easily recognized by the glairy consistence and yellow colour it imparts to the exsuded fluid, as well as by its microscopical characters. It is usually accompanied by a swollen and sodden state of the various textures, such as greatly exceeds that noticed in the catarrhal inflammation. The redness and vascularity of these tissues is sometimes also increased in intensity. Often, however, the bowel acquires a grayish or ashy gray hue; or a dark reddish brown, or even slate-colour. The latter appearances are chiefly characteristic (as Rokitansky points out) of the duration of the disorder. It may be conjectured that these varieties of colour depend upon phenomena of at least three kinds. The paler tint, where not due to an interstitial deposit of pus, seems dependent on an abnormal influence which the disease exercises upon the circulation of the part, obstructing in some way the flow of blood in its vessels; an obstruction which the microscope permits one to suspect is rarely due to the mere physical effects of the surrounding exsudation. The various shades of red and brown appear to be determined by the changes undergone by blood, which has either stagnated within the vessels or — what is much more frequent — been extravasated from them. And the darker bluish or blackish tints are evidently caused by a variable quantity of black pigment, which probably forms the last relics of a similar degeneration of the blood, in the shape of masses of accrete (and now insoluble) colouring matter. With ordinary care, an admixture of biliary colouring matter can rarely be mistaken for these abnormal products. The production of pus may, however, take place in a less diffuse form, and by a much more rapid process, than that which causes the discharge of puriform mucus from an inflamed intestinal surface. These acute local suppurations, as we may call them, often at once strip off the whole of the cell-growth that normally covers the basement membrane of the mucous coat ; and then immediately proceed to erode and ulcerate the subjacent textures. These ulcerations seem peculiarly liable to form sinuses, by extending in various directions through the loose and yielding submucous areolar tissue. In rare instances, scattered abscesses are found in this situation ;—abscesses which are occasionally so isolated from each other, as to appear due to a process of purulent infection by means of the vessels themselves, and not to any mere extension of a continuous suppurating cavity. Finally, in extreme cases, the whole of the tunics become so infiltrated with pus throughout, as to form a soft or pulpy yellowish-gray mass ; which breaks or tears up on applying the slightest violence ; and, if life be sufficiently prolonged, becomes converted into a rotten membranous slough.

The *croupy* or *diphtheritic* variety of inflammation is distinguished, as its name implies, chiefly by the greater consistence of its exsudation ; which, in well marked cases, forms a more or less solid, opaque, white, or yellow mass, and is generally moulded to the shape of the inflamed surface, as a false membrane of variable thickness. It is almost always the result of a rapid or acute inflammatory process. Hence it is for the most part found connected with an intense redness and vascularity of the whole depth of the mucous membrane. And this appearance, which often extends to all the other tunics of the bowel, in some instances rapidly merges into a sloughy or even gangrenous state.

The exsudation of this croupy lymph occurs in a variety of morbid conditions. As an idiopathic disease of the canal, its effusion is very rare. In some of the exanthemata, and especially in scarlet fever, it is occasionally poured out over a very large extent of the inflamed mucous surface of the alimentary tube. In the tuberculous cachexia it is also now and then effused. In the inflammation produced by mechanical injuries, we may generally observe it; mingled, of course, with blood, where there has been any lesion of the blood-vessels. Finally, in cases of poisoning by irritant substances, its presence is by no means uncommon. Here, however, it is important to distinguish it from the false membrane which is often produced by the chemical effect of the poison on the membrane itself, and on the exsudation it subsequently pours out.

The morphology of the proteinous mass poured out under these very different morbid states, seems to be even more variable than its physical and chemical properties. The observations which the author has hitherto been able to make, would lead him to infer the following conclusions: —(1.) The croupy exsudation of the intestinal mucous membrane generally contains a considerable proportion of a cell-growth; which is an abortive epithelium, homologous with that of the healthy structure. (2.) The amount of this constituent attains its maximum in the tough white lymph thrown out during the acute inflammation of a previously healthy organism; for example, in the lymph of the inflammation that follows mechanical injuries of the bowel, or in the croupy casts of the intestine, sometimes voided in the earlier stages of scarlet fever or cholera. (3.) The form of this constituent is never that of the columnar cell proper to the healthy membrane; but, even when best developed, rarely exhibits more than its cytoblast, devoid of an outer cell-wall. (4.) The degeneration of these cytoblasts, as marked by the disappearance of their distinct nucleus, and the appearance of more refractile and granular contents, mark their transition to the characters of true pus-corpuscles; which thus become admixed with the croupy substance, and communicate to it the softer consistence and yellower colour of pus. (5.) The minimum of this modified cell-growth is found in the chronic forms of inflammations of the mucous membrane, and in the cachetic states of the system;—for example, in the exsudation associated with the tuberculous state. (6.) The bulk of such deposits is a mass, which generally has a yellowish colour, and is rarely mixed with small masses of black pigment. This mass possesses a soft friable consistence, and presents an amorphous granular appearance under the microscope. In exceptional cases, it varies from this description :— in the firmer deposits, by offering an indistinctly fibrillated texture; in the softer, by exhibiting numerous highly refractile (and probably fatty) molecules of variable size. (7.) The application of re-agents under the microscope, seems to indicate a corresponding variety of composition in these various forms of the croupy exsudation. At any rate, this very imperfect mode of examination permits us to conjecture that these exsudations consist in great part of protein-compounds, which possess very different degrees of solubility in different cases, and are capable of undergoing a partial degeneration into a fatty material.

The *acute* and *chronic* varieties of inflammation, like the preceding, merge into each other by infinite shades of resemblance. But they are contrasted by a number of circumstances, all of which seem more or less dependent on the rate and duration of the process.

Thus the *acute* inflammation presents a maximum both of hyperæmia and effusion; the latter having usually either a croupy appearance, or a more or less purulent composition. It involves a greater depth of the mucous membrane ; and often spreads to the subjacent muscular and peritoneal coats, so as to cover various portions of the latter with lymph. In its most intense form, it may even convert the whole of the intestinal parietes into a comparatively uniform mass, of a dirty-red colour, and a rotten (or almost friable) consistence.

The *chronic* variety of inflammation chiefly testifies to its duration by the presence of some one or other of the following peculiarities : — Its colour varies from pale red to dark brown or blackish red ; variations which are due to the exsudation being mixed with more or less of blood or pigment, as before alluded to. Its consistence is less regularly affected, but is often increased by a kind of hypertrophy. The exsudation is, on the whole, in smaller quantity; and of a less croupy or albuminous quality. And finally, it is exceedingly prone to pass into ulceration.

Concerning the inflammations of the various microscopic constituents of the mucous membrane, it must be confessed that our knowledge is at present very limited.

In most instances, the *villi* and *tubes* appear to share pretty equally in the disease. Of the two involutions of the mucous surface, however, the villi seem the most liable to suffer; a fact for which it would be easy, though scarcely justifiable, to assign a mechanical explanation. In some instances, the blind extremities of the gastric or intestinal tubes appear to suffer disproportionately, as compared with their upper extremities, and with the general surface of the canal. In such cases we may often see the capillaries around these blind extremities deeply injected, or their blood extravasated into the cavity of the tube; and in other instances, their natural cell contents may be seen exchanged for a dark softened granular mass. Precisely similar changes are often seen in the matrix of the tubes and of the villi; in which latter situation they are generally accompanied by a loss of the investing epithelium.

The closed *follicles* of the alimentary canal are the seat of various changes: some of which are obviously connected with an inflammatory state; while others probably have an equally definite, though less direct, relation to it.

An unusual number of these follicles seems to be one of their most frequent abnormal conditions. In such cases we may often find them strewn thickly through the submucous areolar tissue of the stomach, the small intestine, the large intestine, or even the entire alimentary canal.

But not only may it be doubted whether this increase in their number is due to an inflammatory process, but even whether it is a real occurrence. For in many instances there can be little question, that these follicles are not so much really multiplied in number, as revealed in increased numbers by their universal and extreme distention.

We have seen* that their apparent number varies greatly in different individuals; that, in children, they are generally very numerous and distinct; and that even that healthy afflux of blood, which obtains during the act of digestion, renders them unusually prominent and visible.

Hence it is to the presence or absence of other circumstances indicative of disease, that we must look for evidence as to the really morbid character of an increase in the number or size of these follicles. Wherever we find these alterations associated with a general dyscrasia, or with marks of congestion, hæmorrhage, or inflammation in the surrounding tissues, or with a change in the character of the contents of the follicle itself, there we are entitled to regard them as indicative of a morbid process. And conversely, where none of these appearances are present, we must be content to suspend our judgment on this point.

In typhoid fever, these follicles become the seat of a definite morbid process; which not only constitutes a specific element of the disease, but furnishes the pathognomonic lesion, which seems to dictate many of the details that distinguish the typhoid from the other varieties of fever.

The typhoid process in the intestine is almost limited to these follicles, of which it engages both the agminate and solitary varieties. Amongst the agminate follicles, those are most affected which lie nearest to the ilio-cœcal valve. The same rule applies to the solitary follicles, both in the small and the large intestine. In the latter segment of the canal, the change rarely extends beyond the follicles of the cœcum and ascending colon.

The process appears to commence by a stage of congestion or hyperæmia. This is at first general, and engages the whole mucous membrane of the lower part of the ileum. It subsequently increases in intensity, and at the same time becomes limited to the neighbourhood of the affected follicles; so that these are surrounded with minute rings of injected vessels, which are visible from the mucous surface, or can be seen gleaming through the transparent peritoneum as dark vascular points or streaks. The microscope traces this congestion into the small vessels (and especially the veins) which intervene between the several follicles.

The latter phase of congestion marks the access of the next stage: which corresponds to the exsudation and deposit of a new substance within the follicles, and (to a lesser extent) in the submucous tissue of their immediate neighbourhood. The infiltration distends the several follicles with a mass, which gives them a grayish, grayish red, or bluish-red colour; and a more or less firm or pulpy consistence. They thus acquire a thickness (1—2 lines) that raises them considerably higher than the adjacent surface, and causes them to stretch the mucous membrane above. Below, they rest on the muscular tunic. Of course the shape, extent, and situation of the follicles thus brought into view, is that of the original structures. Thus, in the case of the agminate follicles, we see an oval or elliptical patch that runs lengthwise along the free margin of the bowel. While in the solitary follicles, we find small round granules, of about the size of a millet seed, or a very small pea, irregularly scattered over the intestine.

The mass itself exhibits under the microscope, the ordinary constituents of the normal pulp of the follicle: mingled, however, with a variable quantity of blood; and with an amorphous granular substance in larger quantity, and of a browner hue, than natural.

The softening and breaking up of this pulpy mass constitutes the next stage of the change. In general, it occurs simultaneously over the whole of the agminate follicle: and thus detaches from the subjacent muscular tunic, not only the new deposit, but the follicles themselves; together with the areolar tissue by which they are connected to each other, and the tubes and villi of the mucous membrane by which they are covered. In other instances, the several follicles are softened and detached separately, or in clusters of two or three only; so as to leave some of the tubes and villi which normally occupy their intervals. In some cases, a portion of the patch undergoes a modified process; in which the contents of the follicle seem to make their exit through small openings at their projecting summit, with little or no disturbance of the adjacent tissues. Finally, in certain instances, more or fewer of the follicles are said to undergo a retrograde change, in which their contents undergo absorption, without either sloughing or dehiscence.

The removal of the new deposit leaves the characteristic typhoid ulcer; the shape, size, and situation of which are therefore precisely

* See p. 360.

indicated by the preceding description. The floor of the ulcer is formed by the muscular coat of the bowel, covered by a very thin stratum of areolar tissue. Its margin, somewhat irregular in outline, is a reddish or bluish-gray edge of mucous membrane: which was formerly raised and almost detached from the subjacent tissue by the distended and projecting follicles in its neighbourhood; but has now fallen down upon it, so as to form a perfectly flat, loose, and relaxed border, around the shallow ulcerated fossa of the patch.

In its further progress, the ulceration may extend in two directions. In the horizontal plane, it generally follows the shape, and rarely much exceeds the size, of the original patch. In the vertical plane, it may gradually destroy the muscular and peritoneal coats, and thus give rise to perforation. Such a deepening of the ulcer is accompanied by a narrowing of its width, so that the aperture in the serous membrane is generally of very small size.

The cicatrization of the ulcer, which follows the cessation of the local and general malady, takes place by the development of a firm, but very delicate layer of fibrous tissue, on the floor of the ulcer. This merges, by a gradual increase of its thickness, into the thickened margin before alluded to, where the original mucous membrane becomes intimately blended with the new fibrous cicatrix. The latter exhibits under the microscope the ordinary characters of this variety of fibrous tissue, and is generally covered by one or two layers of irregular flattened cells. The junction of the old and new structures is often marked by wrinkles and puckers, which appear to radiate from the new tissue of the cicatrix; and thus, as it were, measure and express its contraction. In very rare instances, this contraction gives rise to an obstruction of the canal. That it does not oftener do so seems due, not only to the limited extent of the ulcer around the bowel—an extent which scarcely ever exceeds $\frac{1}{3}$d or $\frac{1}{4}$th of its circumference—but also to the little injury generally inflicted on the textures subjacent to the ulcer, and to the amount and situation of the new tissue of the cicatrix. So little of this is deposited, and so exclusively is it limited to the surface of the ulcer, that the process of repair might almost be regarded as resulting in a mere condensation of those superficial layers of the original areolar tissue which are left intact by the ulcer.

The above series of morbid changes in the solitary and agminate follicles, is accompanied by a somewhat similar alteration in the lymphatic or mesenteric glands connected with the affected segments of intestine. This process closely resembles the preceding, except in the fact that it scarcely ever ends in the ulceration of the structures it engages. A stage of hyperæmia is soon followed by one of enlargement; the latter being due to the deposit of a substance, which gives to the glands affected, much the same grayish or reddish colour, and soft firm consistence, as that seen in the follicles. This deposit next undergoes a limited degree of softening: which is sometimes accompanied by hæmorrhage, rarely by suppuration, ulceration, or peritonitis; and is followed by its gradual absorption. The latter process slowly restores the glands to their normal size and colour.

Among the various inflammations of the different segments of the alimentary canal, there are only two to which we need accord any notice, apart from the general description as given above. These are, the gastritis produced by the ingestion of irritant (or rather caustic) mineral poisons; and the dysenteric inflammation which affects the large intestine.

In the *acute gastritis* caused by caustic substances, the stomach presents appearances of two kinds: — one, which forms a series of effects produced by the mere chemical action of the poison on the tissue, and which might therefore be to some extent imitated by introducing it into the stomach of a newly killed animal; and another, which represents the subsequent vital reaction of the tissue against the poison, constituting the phenomena of inflammation, properly so called.

The first of these will of course vary, not only with the nature of the poison, but also with a variety of other circumstances; especially with its quantity, concentration, and solubility, as well as with the amount and duration of its contact with the stomach. Thus according to the nature of the poison, the organ may either undergo softening and solution, or hardening and coagulation; may either be blanched, or carbonized; coloured, or deprived of its colour; swollen by an imbibition of fluid, or contracted by the loss of its own water of composition.

The second or inflammatory class of appearances will necessarily depend upon the extent in which the first preceded them; since it is chiefly in the tissue beneath the destroyed part, that the reactive inflammation is set up. Thus if the epithelium be the only structure which has been acted upon by the poison, it is soon replaced by the development of a new layer in the exsudation poured out; a process which implies but a moderate hyperæmia, and leaves no traces in the structure of the part. While, if the direct action of the poison involve all the coats of the organ, it may give rise to a more or less extensive (and generally fatal) perforation.

The intermediate degrees of this action are followed by a set of appearances which, with great differences in particular poisons and individual cases, may be summed up as follows. The vascular changes consist chiefly in the production of an intense congestion or hyperæmia. The blood-vessels thus injected communicate to the mucous membrane a colour which takes every conceivable shade, from intense red to almost black. In the latter case, the microscope will often show that the blood is coagulated within the vessels, and here and there forms patches of hæmorrhage externally to them. The exsudation which accompanies this congestion, renders the mucous membrane swollen, soft and relaxed; — a change which is generally due to the interstitial effusion of a large quantity of bloody serum. A similar fluid is also poured out into the interior of the organ in variable quantity; and its effusion is generally attended with the detachment of the sloughs previously caused by the direct action of the poison. The exsudation also often distends the submucous areolar tissue, so as to separate the muscular and mucous tunics from each other. Sometimes the former of these two tunics is only rendered paler and more yielding than natural. But in other cases, the whole parietes of the organ ultimately become converted into a rotten, brown, or reddish mass, in which scarcely any structure is distinguishable.

The details of those changes by which the moderately inflamed gastric membrane returns to a healthier state, are equally variable with the preceding. The separation of one or more flat sloughs lays bare what may be regarded as an ulcerated surface. The establishment of suppuration on this surface precedes the formation of the reparative tissue. When fully developed the latter substance exhibits the ordinary fibrous structure of cicatrix. And since the process of exsudation previously extended to some little distance from the ulcer, the margin of the cicatrix blends gradually with the surrounding healthy mucous membrane; while its base generally exhibits similar gradations of structure with the subjacent tissues. The subsequent contraction of the new tissue may materially alter the shape of the organ, and diminish its size. Indeed, where there has been much loss of substance at one point, it may even cause a more or less complete obstruction or occlusion of its cavity.

In *dysentery*, although the morbid changes appear to begin in the follicles, and often predominate here, still the relation of these structures to the process is far less intimate and specific than in typhoid fever. The dysenteric state may rather be regarded as an intense inflammation of the whole of the mucous membrane; which engages these closed sacs with a rapidity and severity that seem to be not more than proportionate to their vascularity, and to the facilities which, as it were, their very construction offers to the exsudative process.*

The morbid appearances chiefly affect the large intestine; and generally exhibit an increase in severity from the cœcum towards the anus. In a subordinate degree, however, they not unfrequently involve the adjoining segment of the ileum.

The process begins as an enlargement of the solitary follicles of particular parts of the bowel, which is quickly followed by appearances of inflammation in the adjacent mucous membrane. Red, swollen, and injected streaks are seen occupying the most projecting parts of some of the transverse folds of the bowel. And on examining these streaks, we find that the epithelium is here and there raised from the subjacent tissues; either as a grayish flake, or as a semi-transparent vesication enclosing serum. Beneath this cell-growth is the raw and denuded mucous membrane; which is softened, reddened, and infiltrated (especially in its submucous areolar tissue) with a bloody serum, that easily exsudes on making pressure. The above change soon extends, from these isolated streaks, to larger portions of the mucous surface; so as to involve, not only the projecting folds of the bowel, but also their intervening depressions. The detached epithelium, which has a dirty gray colour, becomes mixed with the subjacent reddish exsudation. The latter is generally thick and glutinous: but is sometimes of a denser and more croupy consistence; which permits it to be detached and expelled as a more or less perfect cast of the inflamed segment of the bowel. The mucous membrane itself acquires a pale, or dirty-red, or even somewhat yellowish, colour; as well as an increased thickness, and a pulpy gelatinous consistence. The submucous areolar tissue beneath it also becomes infiltrated with an exsudation that has the characters of bloody serum; its enlarged follicles ulcerate or rupture; and its interstices are here and there raised by effusion into protuberances, which give a mammillated aspect to the free inner surface of the intestine. In extreme cases, these projections multiply, enlarge, become confluent, and thus proportionally thicken the whole texture.

These changes are usually accompanied by a more or less considerable dilatation of the intestine; the cavity of which contains, in addition to a large quantity of gases, a mixture of fæces, blood, epithelium, and lymph, in variable proportions.

An increase in the intensity of the above appearances rapidly converts the inflamed membrane into a sloughy or mortified mass. Prior to this event, it becomes dark red, brown, or almost black, from congestion and extravasation of blood. Where less ecchymosis is originally present, and the blood poured out undergoes alterations after its effusion, it frequently offers a dirty gray or almost greenish colour. Subsequently to the separation or dissolution of the sloughy membrane, the denuded submucous tissue may be seen occupied by black masses of altered and coagulated blood, and by more or fewer of the vascular trunks formerly distributed to the destroyed tissues. And at this stage of the process, if not previously, the adjacent muscular and peritoneal coats exhibit every evidence of their sharing in the disease. The former becomes infiltrated with blood, or serum, and of a dark, gray, or ash-coloured hue. While the peritoneum loses its smooth and shining appearance, acquires a dirty reddish colour and an injected state of its vessels, and often has its surface visibly occupied by a more or less purulent or sero-purulent exsudation. In extreme cases, these changes bring about an adhesion of the diseased bowel to neighbouring segments of

* See p. 357. *et seq.*

the large or small intestine. The lymphatic glands connected with the diseased intestine are also altered; becoming swelled, injected, and of a red or bluish-red colour. These alterations seem chiefly due to their irritation.

The changes by which the diseased portions of intestine are restored to a healthier state, of course vary with the intensity of the process, and with the extent to which it has proceeded. Thus, in slighter cases, the process is one of mere resolution. While, after the occurrence of sloughing and loss of substance, the reparative act is much more imperfect. It is effected by the development of a cicatrix; which is gradually formed in the suppurating ulcer that is left by the detachment of the gangrenous portion of membrane.

This cicatrix, though similar in structure to that noticed in the typhoid process, is very different both in its amount and arrangement. Its smooth (and apparently serous) surface often has to fill up the intervals of the irregular islands or isthmuses of mucous membrane which are left by the process of sloughing; and hence the latter are often seen as thick projecting nodules, surrounded by a basis of new tissue. The base of the cicatrix extends to a variable depth in the subjacent coats of the bowel; and, in chronic cases, often forms a thickened base, that sustains an ulcer of long standing and variable size. Finally, the great loss of surface which the cicatrix replaces, concurs with the two preceding circumstances to render its subsequent contraction of great influence on the shape and diameter of the bowel. Thus the ordinary situation of the sloughs in milder cases — on the projecting folds of the mucous membrane — seems at least a partial explanation of the frequency with which the contracted cicatrix takes the form of a cord or fold, itself more or less transverse to the axis of the tube, and hence very liable to cause obstruction of the canal.

Ulceration constitutes a frequent termination of the various inflammations of the alimentary canal. In this tube, as in most other parts of the body, it is associated with inflammation, chiefly as a secondary result; which is conditionated, not so much by mere intensity of the process, as by a certain slow and chronic rate of its progress. Thus in many of the abnormal conditions already alluded to, the sloughing occasioned by rapid and violent inflammation is often replaced by this interstitial mode of destruction, during the subsidence of the earlier and more acute symptoms. While, in milder and more chronic cases, it occurs independently of the gangrenous process. How far it is due to the vascular disturbance which inflammation produces; or to the direct effects of the exsudation; or finally, to a mere increase of the ordinary destructive absorption, or a decrease of assimilation; — it would be irrelevant to this sketch to inquire.

The specific ulceration of typhoid fever has already been mentioned, as well as the secondary ulceration to which it often gives rise. The ulceration of tubercle and of cancer of the canal will be hereafter alluded to; as being essentially due to the metamorphosis of certain deposits in the tissues of the organ, and to the reaction excited in the latter by their presence. Hence we need here only enumerate one or two of the remaining forms of ulceration most frequently seen in the stomach and intestines.

It is but rarely that we find ulcerations of the tube which can be attributed to mechanical causes.

In certain instances, however, the mere pressure of a neighbouring tumour, or of some diseased viscus, results in this process. But in such cases, the access of ulceration is usually preceded by the occurrence of exsudation and adhesion, which limit the amount of original substance it removes, and thus to some extent obviate the danger of its perforating the walls of the tube.

The impaction of solid masses in the canal more frequently leads to such a result. In rare instances, these masses find their way into the canal from neighbouring organs; as is the case with gall-stones. In still rarer cases, they seem to be formed solely by the concretion of the liquid contents of the canal; resulting in intestinal calculi. In most instances, however, they are due to the introduction, from without, of various foreign bodies; such as cherry-stones, pins, needles, or nails. In all cases, the ulceration depends, not only on the size, but also on the shape and surface, of the mechanical irritant. The most familiar examples of such ulceration are seen in the vermiform appendix: where it is not uncommon to find perforation produced by an impacted mass; which, on examination, proves to be some one of the small solids just alluded to, encrusted with rough calcareous matter, that has been derived from the contents of the canal.

Ulcer of the stomach.—In the stomach and the first portion of the duodenum, the ulcerative process is often present in a peculiar form: namely, that which is usually called the simple or perforating ulcer. Of these two epithets, the first refers to the slight appearances of inflammation often present in the neighbourhood of such ulcers; the last, to the frequency with which they extend to such a depth, as to perforate all the coats of the organ.

The size of these ulcers varies from that of a fourpenny piece, to that of a crown piece, or even larger. Their shape is usually circular; sometimes elliptical: occasionally, however, more irregular. In some instances, this irregularity of outline is due to the fusion of two or more neighbouring ulcers into one, by an extension of their adjacent margins. But in a majority of cases, only single ulcers are present.

The ulcer is generally situated, either in the neighbourhood of the pylorus, or near the lesser curvature of the organ: more rarely in front than behind; and least frequently of all, in the cardiac sac.

The mucous membrane in the neighbourhood of the ulcer is sometimes a little swollen: and the immediate margin of the excavation is often indurated and raised above the level of the adjacent mucous surface. But it offers no other appearances worth mentioning as indicative of inflammatory reaction in the contiguous tissues.

The mode in which the ulcer penetrates the various tissues is somewhat characteristic. The smooth, sharp and vertical edge by which it passes through the mucous membrane, and reaches the submucous tissue, is here exchanged for a less regular one; which forms a circle of smaller diameter than the opening in the mucous coat. In like manner, when the ulcer has gradually eaten its way through the muscular coat, it reaches the peritoneal coat, at a point which about occupies the centre of this smaller circle. Hence, the whole depth of the ulcer forms a cone; the base of which is at the free or internal surface of the stomach, while its apex occupies the peritoneum. The latter membrane is scarcely ever destroyed by mere ulceration, except in those instances in which it has previously been strengthened and defended by an exsudation of lymph. Where this has not been deposited, the peritoneum becomes converted into a yellow slough; the rupture or detachment of which gives rise to perforation of the stomach, and allows its contents to escape into the abdominal cavity.

The process by which the gastric ulcer originates is at present unknown. Rokitansky thinks it probably begins as a hæmorrhagic erosion, or a circumscribed slough; and that it gradually extends by its basis throwing off a succession of laminated sloughs, or exfoliations. Some such process he has indeed observed in a few instances. On the other hand, if we may venture to regard that ulcer of the duodenum which sometimes occurs in severe burns, as analogous to the gastric ulcer, we should probably find reason for concluding, that the ulcerative process may sometimes occur, without being preceded by hæmorrhage, sloughing, or any appreciable exsudation, in the situation of the affected part.*

The cicatrization of such ulcers may take place at almost any stage of their course. The precise details of its occurrence vary with the amount of destruction which has preceded it. Where the destructive process has been limited to the mucous membrane, there is little more than a condensation and thickening of the subjacent areolar tissue; which ultimately forms a scar that has a shape similar to the ulcer. But where the muscular coat has been partially destroyed, its remaining lamina, and the subjacent peritoneum, are generally more or less folded or crumpled up, so as to bring the margins of the ulcer nearer to each other. Hence the resulting cicatrix has a much more irregular form; and often contracts into a kind of thickened cord, with radiating extremities, which seriously affects the shape and diameter of the whole organ. The amount of contraction thus impressed upon the stomach varies, other things being equal, with the size and shape of the ulcer.

The extension of the ulcerative process would always end in perforation, were it not this event is, in most instances, to some extent guarded against by the occurrence of adhesion. From what has been already stated, it is evidently very doubtful whether the ulcer originates in an inflammatory state. And in many cases, it certainly seems devoid of all the ordinary appearances of inflammation during its progress. But it is often accompanied, not only by swelling and induration of its mucous margin, but by exsudation and hardening at its base, and by adhesive inflammation of the neighbouring tissues. Thus the peritoneal coat at the bottom of the ulcer becomes inflamed, and pours out upon its free surface a stratum of coagulable lymph; by means of which the stomach may become united to any adjacent viscus. In this manner the liver above the organ, or the pancreas behind it, may become attached to the outer surface of the stomach, at a point corresponding to the situation of the ulcer in its interior. But the more mobile diaphragm and anterior wall of the belly are less frequently the seat of such adhesions.

The adhesion does not, however, replace the loss of substance in the gastric coats. And hence, in many of these cases (just as in adherent wounds of the stomach, attended with much loss of its parietes) the mucous membrane around the edges of the ulcer becomes prolapsed and protruded into it; and thus comes into contact with the surface of the adhesion at its base. The substance of the adhesion itself may either ultimately become converted into a cicatrix: or it may be gradually drawn out by the constant traction which the stomach exercises; so as to form a hollow funnel-shaped tube, that is lined by a smooth surface having the appearance of a serous membrane.

The efficiency of the adhesion, as a means of protection against perforation, varies with its situation, and still more with its structure. Where it is a mere thickening of a delicate fibrous network by inflammatory lymph, as is generally the case when it occupies the omentum, it is of little avail in this respect. While where the exsudation possesses a fibro-cartilaginous character, such as is often seen in the adhesions which unite the stomach with the liver, it forms a much more efficient protection against such an event.

But in many instances, a continuance or renewal of the ulcerative process attacks and destroys the new tissue itself: and either penetrates the viscus (pancreas, liver, or spleen)

* See Pathological Transactions, vol. i. p. 258, for an instance brought forward by Mr. Prescott Hewett; where one of these ulcers seemed to be commencing as "a slight depression in the surface of the mucous membrane, which in their neighbourhood presented some traces of increased vascularity."

to which this is attached; or, by extending laterally, and opening into the peritoneum beyond the margin of the adhesion, leads to perforation.

Hæmorrhage to a considerable extent generally occurs at some stage or other of the ulcerative process. In the earliest periods of the ulcer, this hæmorrhage seems to proceed chiefly from smaller vessels. But after the coats of the stomach have once been penetrated, the larger vessels which run on its exterior surface become very liable to be attacked, eroded, and laid open. The hæmorrhage thus produced is a frequent cause of death in this disease. The peritonitis produced by perforation is, however, still more frequently fatal.

Lientery.—A peculiar ulceration of the follicles of the large intestine has been described by Rokitansky, under the name of *lientery.* Like other ulcerations of this segment of the canal, diarrhœa is a constant symptom of its presence. The process begins by a distention of the follicles, which is accompanied by a dusky-red injection of the vessels on and around their summits. The contents of the follicle next suppurate ; and are discharged from the resulting "follicular abscess," through an ulcerated or ruptured opening in the summit of the follicle itself. The follicle thus emptied is next removed by a process of ulceration ; the limits of which subsequently extend, so as to form a round or oval ulcer, which has the size of a pea or a small bean. The mucous membrane at the margin of these ulcers is relaxed; and of a pale, grey, or livid colour. And the cellular tissue which forms their base exhibits similar appearances, which are sometimes combined with the various results of slight extravasation of blood.

The subsequent enlargement of these ulcers in various directions, and the fusion of several into one which may thus be brought about, constitute a secondary ulcerative process, which often lays bare a large surface of the submucous or muscular coat. The bases of these irregular secondary ulcers present characters like those of the primary ulcers just mentioned. Like the dysenteric process, this follicular ulceration increases in intensity from the cœcum onwards towards the rectum. And in acute cases, it sometimes extends upwards into the ileum.

Hypertrophy.—The *hypertrophy* generally described by authors as one of the abnormal conditions of the intestinal canal probably includes, under one name, a variety of states ; which differ widely from each other, both in their nature and results.

(1.) That thickened state of the tunics of the tube which is generally found behind an obstruction of gradual origin or long standing, is the best (if not the only) instance, to which we can really apply the word hypertrophy ; in its strict sense of an excessive nutrition of tissue. Here the propulsive powers of the tube have to struggle against the increased resistance which is offered by the constricted or obstructed part : and this increased activity results in an exalted nutrition of the unstriped muscular fibres, which materially adds to their bulk. Such a true hypertrophy of the muscular coat may be seen in certain cases of simple stricture of the rectum or œsophagus. And a similar condition is not unfrequently associated with the scirrhous constriction of the pylorus; as a moderate hypertrophy of this tunic over a large part of the stomach.

But a careful examination into the minute anatomy of this hypertrophy would generally show, that it can hardly be regarded as due to a mere exalted nutrition of previously existing tissues. On the contrary, even in those instances in which it appears, to the naked eye, almost limited to the circular fibres of the muscular coat, the microscope often reveals evidence of a more extended change. The neighbouring submucous areolar tissue is always infiltrated with an exsudation, in larger quantity, and of more gelatinous consistence, than the nutritional fluid proper to the part. The partitions of areolar tissue by which the bundles of the unstriped fibres are normally separated from each other, are increased both in solidity and bulk. And, finally, the fibre-cells themselves not only present a more variable, as well as a generally increased size; but are in many places surrounded by a more or less perfect layer of what seem to be developmental forms of these structures.

(2.) In other cases of what is often called hypertrophy, a more partial and imperfect process of the same kind appears to take place, incidentally to the exsudation of a plasma, which may doubtless be referred to an inflammatory origin. In such instances, an examination of the tunics of the canal generally shows all of them to be more or less infiltrated with a proteinous substance ; which renders them much thicker, whiter, and more resisting than natural. Mingled with this deposit, we often find an unusual quantity of the unstriped muscular fibre. But it is not always easy to verify the exact amount of true muscular hypertrophy that has taken place. For the exsudation, which generally predominates in the submucous and subserous coats, has also a great tendency to involve the fibrous sheaths of the various bundles of the unstriped fibres; and is thus capable of communicating to the muscular coat an increased thickness, which by no means implies a proportionate hypertrophy of its characteristic fibres.

The author is inclined to conjecture, that, in these instances of interstitial exsudation, the muscular fibres are capable of being affected in either of three ways. In some instances they seem to be really hypertrophied ; a process which is possibly the indirect result of the immovable and thickened condition of the tube, being such as to demand increased contractions, and stronger muscular structures, in order to effect its various movements. In a second class of instances, they seem to be but little affected. Finally, in others — and especially in those cases in which the copious exsudation has subsequently contracted, so as to diminish the calibre of the tube,— the muscular fibres themselves seem to undergo a process of atrophy, which ends in their complete disappearance.

(3.) The above remarks may serve to illustrate a brief allusion to a third (and very frequent) variety of what is called hypertrophy of the digestive canal, in which it is still more difficult to determine the exact change that has taken place. In these cases an albuminous plasma exsudes into the coats of the canal: either pretty equally throughout; or with a more or less marked preference for the submucous or subserous areolar tissue, and with marks of inflammation in the neighbouring mucous membrane or peritoneum respectively. When examined under the microscope, this albuminous plasma generally exhibits all the appearances which attend the abnormal development of fibrous tissue. But the fibres thus developed as the product of a diseased (and often an inflammatory) action, offer marked differences in their structure and arrangement from those of the normal areolar tissue among which they originate. While, as regards the changes undergone by the latter or healthier texture, it is often impossible to decide whether it has been augmented or hypertrophied; or whether it has not rather experienced such an interference with its nutrition, and such a loss of its substance, as amounts essentially to its atrophy.

Polypi.—The tumours which have received the name of polypi agree in the common character of projecting into the cavity of the digestive canal, by means of a peduncle or stalk of variable length, that attaches them to its walls. Their size varies from that of a pea to a pigeon's or hen's egg. They are almost always covered by the mucous membrane: in the submucous areolar tissue beneath which they appear to be generally formed.

It can scarcely be doubted that the shape of these polypi — like that of the papilliform tumours on the external integuments — is sometimes determined by a definite arrangement or development of the plasma out of which they are constructed. It is, perhaps, chiefly in this way that isolated malignant growths under the mucous membrane so frequently assume the pedunculated or polypoid form. But it seems certain that, in many instances, their form is partly the result of a mechanical traction, such as the muscular contractions of the alimentary canal itself might exercise on almost any small tumour projecting from its mucous surface. The pedicle* of the tumour is thus continually drawn out and lengthened. And the intussusception of that segment of intestine from which this pedicle arises, sometimes affords a remarkable testimony of the mechanical activity of the bowel.

The interior of the non-malignant polypiform tumours generally consists of a more or less completely developed fibrous tissue. In some cases, however, they contain a mass of adipose tissue, which causes them to resemble appendices epiploicæ. In very rare instances, their contents approach the amorphous character, and friable consistence, of a tuberculous deposit. And finally, they sometimes constitute true mucous polypi; which are distinguished by their lobulated form, their great vascularity, and their erectile and dilatable texture.

The various small tumours which occasionally occupy the submucous tissue of the bowel scarcely require any separate description. Cysts are comparatively rare in this situation. Fibrous, or fibro-cartilaginous masses are less infrequent. The latter rarely become the seat of a process of true ossification. The inorganized earthy matters oftener found in their interior are formed, either by obsolete tubercle, or by the cretified contents of old abscesses, the pus of which has undergone a partial absorption.

Tubercle. — The digestive canal is more frequently the seat of tuberculous deposit than any other organ of the body, the lungs only excepted. The pulmonary tubercle is, however, far more frequent than the intestinal. And the latter is not only generally preceded by the former; but is rarely seen to any extent, before the tuberculous matter deposited in the lungs has already reached the stage of softening and suppuration.

The different segments of the canal are affected by it in the following order of frequency: the lower part of the ileum; the cœcum; the large intestine generally; the upper part of the ileum; the jejunum; the duodenum; and (very rarely) the stomach.

Both forms of tubercle are met with in the intestinal canal. In a vast majority of instances, none but the crude, yellow, or caseous tubercle is detected. But in cases in which the disease has taken an unusually chronic course, the grey granulations are sometimes met with. The latter appear gradually to assume the caseous form; the change beginning at their centre, and extending thence to their circumference.

The deposit usually begins by engaging the agminate and solitary follicles of the lower third or half of the ileum; filling and distending their cavities with crude tubercle. A marked (and often intense) redness of this segment of the bowel usually accompanies the deposit; and remains, as a more or less distinct hyperæmia, during the remaining stages of the process.

The caseous tubercle contained in these follicles next undergoes the process of softening. The summit of the sac bursts or ulcerates; and its contents escape into the cavity of

* The movements of the intestines upon each other often seem to exert a similar mechanical influence on tumours or deposits attached to their peritoneal surface.

the canal. The follicle itself is thus either evacuated or destroyed: and its situation is then occupied by a small excavated ulcer, varying in size from a millet-seed to a pea.

This primary ulcer now becomes the seat of a process of secondary ulceration, which extends its size in the two directions of width and depth. Its superficial extension causes several of the small primary ulcers to become fused into one; and sometimes widens the resulting secondary ulcer, so as to form a patch of ulceration that more or less encircles the bowel. Its vertical progress successively engages the submucous and muscular coats, and thus finally reaches the peritoneum. The latter membrane, if not strengthened by the lymph of adhesive inflammation, now sloughs or ruptures; with the result of a fatal perforation.

This extension of the ulcerative process, and the means by which it is effected, together constitute the chief characteristics of tubercular disease in the intestinal canal: and render the loss of substance it brings about in the walls of this tube, strictly analogous to that by which it excavates the tissues of the lung. The base and margins of the tuberculous ulcer have a ragged swollen appearance; are surrounded by a gelatinous infiltration; and are themselves the seat of an interstitial deposit of cheesy tubercle. The softening of this deposit, and the suppuration of the original tissues in which it is entangled, continually increase the size of the ulcer; and the inflammation thus produced tends as continually to increase the deposit of new tubercle. Hence the tuberculous ulcer assimilates, so to speak, the adjacent tissues to itself: and is never bounded by healthy or heterogeneous tissues; like those which adjoin the gastric ulcer, or the specific follicular ulcer of the typhoid process.

As the tubercular ulceration extends, the intervening submucous tissue, even where hitherto healthy, generally becomes the seat of a similar deposit and destruction. Hence, in well marked instances of acute intestinal tuberculosis, these ulcerations occupy a large proportion of the affected surface of bowel; leaving only small insulated patches, or fungous projections, of the original mucous membrane. And in extreme cases, they may even remove this tunic from a large continuous segment of the bowel.

The cicatrization of such ulcers is rarely seen, except in cases where the process has ceased in one part, while it has still been going on in another. In such instances, the removal of the softened mass already present ceases to be followed by any further interstitial deposit of fresh tubercle in the margin of the ulcer; and a plasma, which exsudes on the bare and ulcerated surface, is ultimately developed into a cicatrix of the ordinary structure and appearance. The subsequent contraction of this cicatrix is of course proportional to the loss of substance which it has had to replace. The zonular direction of the previous ulcer often gives it a form more or less approaching that of a cord or imperfect septum; which lies transversely to the axis of the tube, and materially narrows its calibre. In rare instances, the cicatrix contains fragments of the cretaceous or other varieties of obsolete tubercle.

Cancer. — Cancer affects the intestinal canal under all three of its chief forms; namely, scirrhous, medullary, and colloid or areolar cancer. And even its villous and epithelial varieties are occasionally present. The latter is, however, very rarely met with.

In most instances the cancerous growth is at first seated chiefly in the submucous areolar tissue; from which it gradually advances towards the inner and outer surface of the canal, so as ultimately to involve the whole of its coats. But the three forms of cancer fall with various degrees of intensity on different parts of this areolar layer. The scirrhous variety begins in its deepest stratum; and in those fibrous septa of the subjacent muscular bundles which are connected with it. The areolar or colloid variety chiefly affects the middle and looser laminæ. While the medullary and the villous variety generally occupy the immediate neighbourhood of the basement membrane of the mucous tunic. Finally, in the epithelial variety, there seems to be a definite metamorphosis of all the histological elements of the mucous membrane itself.

Those rare instances in which the cancer seems to begin in the subserous areolar tissue are in reality cases of cancer of the peritoneum; which membrane they almost always involve in its visceral reflexions (omentum and mesentery), as well as in some parts of its parietal laminæ.*

The cancerous growth is generally primary; but is sometimes secondary to a deposit in some neighbouring organ. In the latter case, the intestinal canal may either be involved by a mere extension of the disease from absolute contact; or it may be affected through the intervention of the lymphatic glands and vessels. The first of these contingencies may be illustrated by the way in which the stomach is sometimes involved in a cancerous tumour of the liver: the second, by the far more numerous instances, in which the large intestine becomes cancerous, as the result of similar disease occupying the neighbouring lymphatic glands.

The above varieties of the cancerous growth occur with very unequal frequency. The scirrhous is by far the most common, the medullary less frequent, and the colloid or areolar rarest of all. And while the former is usually primary, the two latter are more frequently secondary; or are often admixed, in varying proportions, with what was originally a scirrhous growth. In the latter instances, the scirrhus is sometimes said to have undergone a transformation into medullary cancer.

* Compare Art. PERITONEUM.

But it is very rarely, if ever, that such a metamorphosis really occurs. In general the process thus designated consists merely in the deposit of new cancerous matter within, and especially around, the scirrhous mass; and not in any true metamorphosis of the latter growth itself.

The cancerous disease of the intestinal canal is often associated with the existence of a limited amount of hypertrophy. For the deposit of scirrhus in the coats of the canal not only thickens and hardens their substance; but, by the annular form it affects, has a special tendency to obstruct the calibre of the tube. Where it does this slowly, and with little disturbance of the general health, the obstruction is often partially compensated by a true conservative hypertrophy of the muscular coat behind the diseased part. But, for similar reasons, this hypertrophy is often associated with dilatation: — an alteration which is indeed sometimes carried to an enormous extent; so that the stomach, for example, fills almost the whole abdominal cavity.

Of the various morbid conditions already alluded to, there is only one which is very liable to be mistaken for cancer; namely, that fibrous thickening of the gastric and intestinal parietes which is usually termed hypertrophy. This state offers so many points of resemblance to the scirrhous deposit, that it seems worth while to enumerate the chief points of contrast between them. Of these we will only premise that, though they generally afford ample materials for a satisfactory decision, they occasionally leave us in great doubt as to the fibrous or scirrhous character of the particular specimen under examination.

Comparing these two states in their ordinary form, as seen in the stomach, we may sum up their chief differences as follows:— 1. The scirrhus affects the submucous tissue in a greater degree than the hypertrophy, which is more evenly distributed throughout the three coats. 2. The scirrhus often presents a similar irregularity of distribution in the horizontal plane of the gastric coats themselves, which it thus renders uneven and protuberant; while the hypertrophy forms what is generally a larger and more uniform expanse. 3. The appearance of the scirrhus is white, hard, and gristly or cartilaginous; that of the hypertrophy is yellower, tougher, and more elastic. 4. The muscular substance is involved in hypertrophy chiefly by the atrophy or enlargement of its bundles, within their thickened cellular sheaths. But in scirrhus, it undergoes a characteristic metamorphosis; by virtue of which its structure may almost be * said to approach that of colloid cancer. The fibrous septa become the seat of a development of new fibres; while in their loculi or intervals, the muscular fibres are replaced by a reddish-yellow gelatinous substance, which consists of characteristic cancerous cells, in various stages of development. 5. The scirrhus fuses and confounds the various tunics; which, in the hypertrophy, generally remain tolerably distinct. 6. In scirrhus, ulceration is of more frequent occurrence, of earlier access, and of wider extent, than in hypertrophy. 7. In scirrhus, the neighbouring glands and organs generally become at length affected by an enlargement and deposit, which itself partakes of the cancerous characters. 8. The microscopic characters of the two morbid products are usually decisive; the scirrhus almost always offering the cell-forms characteristic of cancerous growth, in some part or other of its mass. Thus, for instance, even where the fibres of the central and cartilaginous substance are so numerous and well-developed as to obscure the cells they involve, the gelatinous matter enclosed within the meshes immediately around this harder mass will generally yield an abundant cell-growth; or the still softer periphery of the tumour will afford the unmistakable cells of medullary disease.

* Marked specimens of this kind are, I believe, sometimes mistaken for the rarer true areolar cancer.

Of the various segments of the digestive canal, the stomach is by far the most frequent seat of cancer. The large intestine stands next to it in liability to this disease, the liability diminishing successively from the rectum through the sigmoid flexure, to the remainder of the colon. In the cœcum, however, it seems somewhat increased. The small intestine is very rarely affected, except in acute and general cancerous cachexia; in which the mucous membrane, and its submucous tissue, are sometimes infiltrated with medullary deposit in the situation of the agminate follicles.

In the *stomach*, cancer generally occurs as a scirrhous deposit which surrounds the pyloric extremity of the organ. The cancerous growth is strictly limited towards the duodenum, by the pyloric valve; but it extends a variable distance along the right side of the organ, generally favouring the lesser curvature. The neighbouring gastric surface is often occupied by small isolated deposits of cancerous matter, which lie beneath the mucous membrane. And the healthy muscular coat, as before mentioned, is also frequently hypertrophied over a large extent of the same locality.

The chief peculiarities of the scirrhous mass have been enumerated in speaking of the differential diagnosis between it and hypertrophy of the stomach. Beginning in the submucous tissue, and the subjacent muscular coat, it rapidly involves both of these structures in a white cartilaginous-looking mass; the more opaque and fibrous parts of which often seem to give off bundles of fibres, that pass completely through the muscular coat. The anatomy of these fibrous bundles has already been mentioned. The disease advancing, involves the subserous tissue and the peritoneum, on the one hand; and the mucous membrane on the other. The latter of the two extensions is generally both earlier in date, and more considerable in amount. After the disease has thus fused into one mass the muscular and mucous coats, the distention and vascular disturbance undergone by the latter gradually effects its disorganization. Its epithelium becomes detached; its surface ulcerates or sloughs; and more or less hæmorrhage is excited. At this time, if not before, the cancerous process is generally so far modified, as to give rise to the deposit of the medullary instead of the scirrhous variety. The eroded surface of the tumour thus becomes the site of a bleeding fungous growth; the hæmorrhage from which, more or less altered by the fluids of digestion prior to its being ejected from the stomach, gives rise to the characteristic coffee-coloured vomiting which is almost always present in the latter stages of the disease. The metamorphosis of the cancerous mass is generally followed by sloughing or ulceration, either of which may end in the perforation of the organ. But this event is sometimes prevented by the adhesion of the peritoneal surface of the stomach to neighbouring structures; and is, perhaps, still more frequently staved off by the continuous deposit of new cancerous matter beneath and around the ulcerating mass. The perforation of the gastric parietes may give rise to an abnormal communication between the stomach and some neighbouring segment of the canal:—for example, the transverse colon, or some part of the small intestine. Or it may even open on the exterior of the belly; or penetrate the thoracic cavity.

The medullary form of cancer, which is not unfrequently seen as a secondary deposit at the surface and margins of the scirrhous mass, sometimes occurs independently, as a continuous or discrete deposit in the submucous areolar tissue. It offers its ordinary characteristic structure and appearance.

The areolar form is also more frequently secondary than primary. It is by no means uncommon to find the hard scirrhous texture of the centre of the cancerous pylorus merge into a fibrous network as it approaches the inner surface of the organ; — a network the large meshes of which are filled with a gelatinous mass. The fibres which constitute these meshes are generally long, pale, and extremely delicate; and their narrow outline is here and there bulged by persistent developmental cells. The gelatinous mass which they enclose consists of cells, which are often large and compound; sometimes caudate, or pigmentary. It is possible that this structure is to some extent produced by a true metamorphosis of the previous scirrhus: its fibres being multiplied, at the same time that they are enlarged and distended by the deposit, between and amongst them, of a soft mass of cells. In some instances we find evident traces of a development of new fibres, which gradually break up the primitive loculi into secondary cells. The most superficial or internal of these loculi project from the mucous surface into the cavity of the stomach; where they often become the seat of a medullary or fungous growth, which undergoes ulceration and hæmorrhage.

Stricture of the intestine. — The most frequent cancerous affection of the large intestine is a scirrhous deposit, which more or less encircles the tube. The extent to which it passes round the circumference of the canal is determined chiefly by its primary or secondary nature. In the former case, it is a complete circle. In the latter case, it generally forms but part of a circle; and occupies that side of the intestine, which is nearest to the gland or other neighbouring texture, from which the disease may have been derived.

In either kind of scirrhous stricture, the deposit may subsequently extend, for a variable distance, in the direction of the length of the canal. But so long as it remains limited to a simple annular mass of gristly scirrhus occupying the submucous tissue, its chief effect is that of narrowing the canal. The influence of this narrowing on the neighbouring segments of the bowel is at first merely the mechanical obstruction which it offers to the transit of the intestinal contents. Where this obstruction amounts to a complete occlusion, it is speedily fatal: the intestine above the stricture becoming enormously distended by its contents; and undergoing inflammation, gangrene, or even rupture, as the result of this distention. A slower process of constriction, or a less complete obstruction, generally give rise to a combination of a similar dilatation, with a variable degree of hypertrophy; the latter change being often carried to such an extent as greatly to increase the thickness of all the coats of the bowel, and especially of the muscular tunic.

The obstruction is often increased by the way in which the diseased part of the intestine becomes abnormally united with neighbouring viscera or walls of the belly. In the secondary form of scirrhus, the mass is of course attached and fixed, almost at the very commencement of the process of deposit. But in the primary form, it may remain free until a comparatively late period of the disorder; when the weight of the tumour often causes the bowel to gravitate into a more or less unnatural position. In either case, its occurrence often alters the course of the canal, by bending it at an acute angle opposite to the adherent part. The bowel is thus placed at a still further disadvantage for the transmission of its contents.

The subsequent progress of the disease requires little notice. The growth of a medullary fungus, or the deposit of a colloid or areolar mass upon the surface of the ulcerated stricture, may of course increase the obstruction which the latter produces. Or, conversely, its sloughing or ulceration may restore the permeability of a previously almost occluded canal. Finally, the extension of the disease upwards, into the dilated segment of intestine above the stricture, may convert this part into a large receptacle, which is bounded by thick and solid cancerous walls. Where the lower outlet of this cavity remains patulous, life is sometimes preserved under such an unfavourable condition during a considerable period of time.

(The NERVES of the Stomach and Intestine are described in the article "SYMPATHETIC NERVE.")

(*William Brinton.*)

SYMPATHETIC NERVE.—The term sympathetic nerve is applied to denote a series of ganglia arranged along each side of the spinal column, connected by intermediate bands of nerve fibres, so as to present the form of two gangliated cords. These extend from the upper part of the cervical region to the lower extremity of the sacrum, where the cords of opposite sides are united in a single ganglion or plexus situated in front of the coccyx. The ganglia in each cord correspond in number to the vertebræ, except in the cervical region, where only three ganglia commonly exist. The gangliated cord of either side forms communications with all the corresponding spinal nerves along its course. Branches are also sent upwards from the superior cervical ganglion into the head which communicate with nearly all the cranial nerves, and with which several small ganglia, arranged in different parts of the skull, are connected. From the gangliated cords branches also pass inwards for the supply of the bloodvessels, as well as to almost all the different viscera in the body. These branches are remarkable for their tendency to form plexuses, from which subsidiary branches are sent off to the various viscera in their vicinity. Connected with these plexuses, as well as with the branches which pass off from them, are numerous ganglia of different sizes.

This nerve has been variously named by authors. The older anatomists described it under the name of the great intercostal nerve. From the fact of its being chiefly distributed to the viscera belonging to the circulatory, digestive and generative systems, it was termed by Chaussier the trisplanchnic nerve; and under the supposition that it alone influences the organic processes, it was termed by Bichat the nervous system of organic life. The name sympathetic, or great sympathetic, was given it by Winslow, from its being believed to be the channel through which are effected the different sympathies sometimes found to exist between distant organs when in a morbid condition.

For the sake of description the sympathetic may be regarded as consisting of two portions; the one corresponding to the right and left gangliated cords situated on each side of the vertebral column, the other to the different plexuses occurring on the branches which are sent inwards for the supply of the viscera and bloodvessels. It is commonly further subdivided into a cervical, thoracic, lumbar, and sacral portion. In the following account of its descriptive anatomy it is proposed to describe, 1st, the gangliated cord of the sympathetic, and 2nd the different plexuses formed by its branches in the several regions of the body already specified.

I. *Cervical Portion of the Gangliated Cord.*—The cervical portion of each gangliated cord lies in front of the vertebral column, separated from it by the rectus capitis anticus major and longus colli muscles. It is situated behind the internal and common carotid arteries, the internal jugular vein, and pneumogastric nerve. It presents commonly but three ganglia, named, according to their situation, superior, middle, and inferior.

1. The *superior cervical ganglion* is situated at the upper and lateral part of the neck, in front of the transverse processes of the second and third cervical vertebræ, upon the rectus capitis anticus major muscle, behind and to the inner side of the internal carotid artery and the pneumogastric and glossopharyngeal nerves, with the sheath of which it is more or less intimately connected by some cellular tissue. It is the largest of the ganglia in the sympathetic cord; it varies considerably in its form and size. In general it presents an elongated oval, or spindle-shape, and measures from 4 to 8 lines in length, 2 to 3 in breadth, and about 1½ in thickness. According to Flourens it is generally bifurcated at its lower extremity, and frequently presents a constriction about its middle which appears to divide it into an upper and lower portion. The branches connected with this ganglion are the following:

(*a*) *Communicating branches* pass between it and the three or four upper cervical nerves. They vary in number, and are connected with the posterior aspect of the ganglion. It also forms communications with the pneumogastric, hypoglossal, and glossopharyngeal nerves. The branch of communication with the ninth, or hypoglossal nerve, consisting of one or two delicate filaments, joins it near the base of the skull. This communication is regarded by Sœmmering, Cloquet, Hirzel and others as very rarely existing. In twelve bodies examined by the latter, he found it present only twice. Arnold, Longet and others regard the communication as constant. The communication with the pneumogastric nerve is twofold. One small branch passes between the superior cervical ganglion itself and the ganglion on the trunk of the vagus; another branch, also of small size, passes upwards from the ascending branch of the superior cervical ganglion, and divides at the base of the skull into two filaments, one of which becomes connected with the ganglion of the root of the pneumogastric, while the other terminates in the petrosal ganglion of the glossopharyngeal nerve.

(*b*) *Ascending or Carotid Branch.*—This branch may be regarded as a prolongation upwards of the sympathetic cord. It is soft, and presents a more or less greyish-red aspect. On approaching the inferior orifice of the carotid canal in the temporal bone, it commonly divides into two branches which pass along the canal with the internal carotid artery, the one being situated rather to the inner, the other to the outer side of the vessel; they form numerous intercommunications with each other, giving rise to what is termed the internal carotid plexus.

(*c*) *Pharyngeal Branches.*—These, from three to six in number, leave the upper and inner margin of the ganglion, pass inwards and downwards, and unite with the pharyngeal branches of the glossopharyngeal and vagus nerves to form the pharyngeal plexus.

(*d*) *External lateral Branches.*—These vary in number; sometimes there are only two present; at other times as many as six or eight. They have a greyish-red colour, and from the softness of their texture were termed by Scarpa nervi molles, from their being chiefly distributed to the blood vessels, they were named by Sœmmering vascular branches. They arise from the front of the ganglion, and pass downwards along the internal carotid artery to the point of division of the common carotid, where they give rise to the external carotid plexus. Some filaments also unite with the superior laryngeal nerve.

(*e*) *Superior or long cardiac Nerve*, named also the superficial cardiac branch, varies in thickness, and is sometimes absent. It arises from the anterior and lower portion of the superior cervical ganglion, sometimes from the intermediate cord between that and the middle cervical ganglion, and sometimes it derives filaments from both sources. It runs downwards upon the longus colli muscle and to the inner side of the sympathetic cord, and passes behind or in front of the inferior thyroid artery. In its course through the neck it forms communications with the external laryngeal and descendens noni nerves; it also communicates with the vagus and recurrent laryngeal nerves, and sometimes with the phrenic. Not unfrequently it is joined by the cardiac branches, which leave the middle and inferior cervical ganglion. It passes into the chest in front of or behind the subclavian artery, and along the arteria innominata, to terminate in the cardiac plexus. The nerve of the left side, after entering the chest, runs along the left carotid artery to the arch of the aorta, passing sometimes in front and sometimes behind that vessel.

(*f*) *Communicating cord between the superior and middle cervical Ganglia.*— The connecting cord between the superior and middle cervical ganglia is commonly single, but occasionally consists of two distinct portions. It passes from the inferior extremity of the superior cervical ganglion, which sometimes seems to be prolonged downwards into it, along the surface of the rectus capitis anticus major muscle, behind the carotid artery, and rather to the inner side of the pneumogastric nerve, as far as the inferior thyroid artery. Before sinking into the middle cervical ganglion it sometimes divides into two portions, one of which passes in front, the other behind the vessel just mentioned. The communicating branches with the third, fourth and fifth cervical nerves frequently join it instead of passing to the cervical ganglia. There is also, according to L. F. Meckel, sometimes formed upon it, above the inferior thyroid artery, a small ganglion termed by some the superior thyroid ganglion, and by others the middle cervical ganglion.

2. *Middle cervical ganglion*, smaller than the superior ganglia of the same name, presents an irregularly oval or triangular shape, and is situated on or near the inferior thyroid artery. Communicating branches pass between it and the fifth and sixth cervical nerves; it is also sometimes connected by filaments of communication with the vagus and phrenic nerves. From the inner side of the ganglion several delicate greyish filaments pass off which surround the inferior thyroid artery forming a plexus, which is termed the inferior thyroid plexus. These branches communicate with the recurrent and internal laryngeal nerves, as well as with the upper cardiac nerve. The middle cervical ganglion also gives a branch which is sent to the cardiac plexus. This branch, termed the middle or deep cardiac nerve, arises from the ganglion by from two to four roots which unite into a single or double stem. It passes into the chest in front of the subclavian artery, but sometimes behind that vessel, and runs along the arteria innominata to the deep cardiac plexus. On the left side it enters the chest between the left carotid and subclavian arteries.

3. *Inferior cervical ganglion*, varies in its size and form, which, in general, is more or less semilunar; its convexity being directed downwards, its concave margin upwards. It is situated between the transverse process of the seventh cervical vertebra and the neck of the first rib, behind the subclavian artery, and behind and to the outer side of the root of the vertebral artery. (*a*) Branches of communication pass between the ganglion and the seventh and eighth cervical nerves, as well as the first intercostal nerve. It also sometimes communicates with the phrenic nerve and recurrent laryngæal. (*b*) From the ganglion proceed several fine twigs, which surround the subclavian artery as well as its branches, forming small plexuses about them. One of these accompanies the vertebral arteries; according to some it passes up along with the artery into the cranium, subdividing into as many secondary plexuses as there are branches of the artery. Blandin states that he has followed the branches of the nerve along the basilar artery, upon the posterior cerebral and cerebellar arteries. Whilst situated within the canal in the transverse processes of the cervical vertebra it communicates with several of the cervical nerves. According to M. De Blainville several ganglia occur on this branch, equal in number to the cervical vertebræ, and hence he regards the vertebral branch as the continuation up-

wards of the sympathetic cord. According to Bourgery*, the common sympathetic trunk may be regarded as dividing at the inferior cervical ganglion into an anterior and a posterior portion; the former, corresponding to the continuation of the cord in the neck, he terms the carotid track, the latter, corresponding to the vertebral branch, he terms the posterior or vertebral track. He describes it as arising from the plexus formed around the subclavian artery: it is quite visible to the naked eye at its origin, but higher up its filaments become microscopic in point of size: the vertebral branches, or tracks of opposite sides, unite together in the groove lodging the basilar artery, and communications are also formed between them and the anterior, or carotid track, by means of filaments which pass backwards with the posterior communicating arteries. The vertebro-basilar nervous apparatus, as it is termed by him, supplies nerves to the vessels, which ramify on the cerebellum and posterior lobe of the cerebrum.

(*c*) *Inferior or small Cardiac Nerve.* — The inferior cardiac arises by one or two roots, passes inwards behind the subclavian artery, and terminates in the deep cardiac plexus. It forms communications with the middle cardiac nerve, as also with the cardiac branch of the recurrent laryngeal. Frequently, especially on the left side, the lower cardiac branch becomes united with the middle cardiac, giving rise to what has been termed the Nervus cardiacus crassus. The communicating branch between the lower cervical and first thoracic ganglion is very short, sometimes wanting, the two ganglia running into one another.

II. *Thoracic portion of the Gangliated Cord.* — The thoracic portion of the gangliated cord of the sympathetic lies on each side of the spinal column, in front of the transverse processes of the vertebræ and heads of the ribs, and beneath the pleura. It is continuous above with the cervical portion, and below it passes into the abdomen, between the pillars of the diaphragm and superior extremity of the psoas muscle, outside the splanchnic nerves, becoming continuous with the lumbar portion of the sympathetic cord. The number of the ganglia varies: they are commonly eleven, rarely twelve, on each side. They are, in general, situated between the heads of the ribs in front of the transverse processes of the vertebræ, and present commonly a more or less triangular form. The cord connecting the ganglia of either side runs in front of the heads of the ribs, and is generally single, though sometimes it is double. The branches connected with the thoracic ganglia are the following: —

(*a*) Communicating branches pass between each of the ganglia and the corresponding intercostal nerve: these are commonly double, sometimes three, short, and pretty strong.

(*b*) Branches of small size pass from the ganglia to the descending aorta, forming a plexus around it; others pass to the pulmonary and œsophageal plexuses; branches are also described by Krause as passing between the ganglia of opposite sides in front of the bodies of the vertebræ.

(*c*) The chief branches leaving the thoracic ganglia are the greater and smaller splanchnic nerves. These are situated to the inner side of the main cord of the sympathetic, and also more anteriorly, upon the lateral and anterior surface of the bodies of the vertebræ. They are formed of branches derived from the six lower thoracic ganglia, and pass through the diaphragm into the abdomen. The greater splanchnic nerve derives its roots commonly from the inner part of the sixth, seventh, eighth, and ninth, thoracic ganglia; it often also receives a branch from the fifth, and, according to Dr. Beck, from the different ganglia as high up as the first. It passes obliquely downwards and slightly inwards upon the sides of the vertebral column, in front of the intercostal vessels, and covered by the pleura. It enters the cavity of the abdomen by perforating the pillars between the middle and internal crura of diaphragm, rarely through the aortic opening, and terminates in the semilunar ganglion of the cœliac plexus. The smaller splanchnic nerve, which is sometimes double, springs from the tenth and eleventh thoracic ganglia: following the same course as the greater splanchnic nerve, it is directed obliquely downwards and inwards upon the body of the twelfth dorsal vertebra, passes through the diaphragm between the greater splanchnic nerve and the communicating cord, which unites the last thoracic to the first lumbar ganglion, or pierces the middle crus of the diaphragm. It terminates in the cœliac and renal plexuses; the branch to the latter being generally stronger than that to the former.

(*d*) The communicating cord between the last thoracic ganglion and first lumbar enters the cavity of the abdomen between the middle and external crura of the diaphragm, or penetrates the latter.

III. *Lumbar portion of the Gangliated Cord.* — The lumbar portion of the sympathetic cord generally contains five ganglia, sometimes only three or four, and is situated upon the lateral and anterior aspect of the bodies of the lumbar vertebræ, in front of the psoas muscle, behind and to the left of the aorta on the left side, and behind and to the right of the vena cava on the right. The branches connected with the lumbar ganglia are: — (*a*) Branches of communication with the lumbar nerves: these are commonly two in number for each; they are longer than those in the thoracic region, and pass between the heads of the psoas muscle.—(*b*) Branches also pass off from the ganglia to the aortic, spermatic, renal and superior hypogastric plexuses. — (*c*)

* Mémoire sur l'extremité céphalique du grand sympathetique dans l'homme et les animaux mammifères. Par M. I. M. Bourgery. Comptes Rendus, vol. xx.

Krause describes branches as passing across the bodies of the vertebræ, forming a communication between the ganglia of opposite sides.

IV. *Sacral portion of the Gangliated Cord.* — The sacral portion of the sympathetic cord is situated towards the inner side of the sacral foramina. The ganglia are commonly four in number, are smaller than those in the lumbar region, and decrease in size from above downwards: the cords of opposite sides converge as they pass to the lower extremity of the sacrum, and unite together in front of the coccyx, there being frequently present at their point of union a small ganglion, from which one or two filaments of communication pass to the fifth sacral and coccygeal nerves. The branches connected with the sacral ganglia are communicating branches with the spinal nerves, commonly two in number for each. Several delicate filaments are also sent to the inferior hypogastric plexus.

PLEXUSES OF THE SYMPATHETIC.

A. *In the Head.* — The chief plexuses of the sympathetic which exist in the head are the *internal carotid plexus*, *cavernous*, and *external carotid*. There are also present in different parts of the head several ganglia: the principal of these are the ciliary ganglion, spheno-palatine, otic, and submaxillary. These ganglia have been already described in this work in the articles on the different nerves with whose branches they are connected.

1. *Internal Carotid Plexus.* — The internal carotid plexus is formed by the ascending branches of the superior cervical ganglion, and surrounds the internal carotid artery during its passage through the carotid canal. The ascending branch of the superior cervical ganglion, as was already stated, divides into two portions, one of which passes along the outer and anterior aspect of the artery, while the other lies on the inner and posterior aspect of the same vessel. The external portion is chiefly concerned in the formation of the carotid plexus, the inner in forming the cavernous plexus. The carotid plexus is thus situated chiefly on the outer side of the artery between its second and third bends. The branches connected with the plexus are, —

(*a*) Two or three filaments of communication with the sixth pair of nerves; they join the nerve as it passes along the cavernous sinus. One of these, stronger than the others, was formerly regarded as one of the roots of the sympathetic nerve. One filament is said sometimes to run only a short distance with the sixth nerve, when it leaves it and passes to the ciliary ganglion, or to the spheno-palatine.

(*b*) *Great or deep Petrosal Nerve.* — This branch, commonly termed the deep branch of the Vidian nerve, may be regarded as passing from the fifth pair to the sympathetic, or *vice versâ*. Regarding it as the latter, it may be described as passing out by the superior orifice of the carotid canal, traversing the cartilaginous substance which occupies the anterior lacerated foramen to reach the pterygoid canal, where it becomes associated with the cranial division of the Vidian, along with which it traverses the canal from behind forwards, and terminates in the ganglion of Meckel. In the interior of the pterygoid canal, the two nerves are merely placed side by side with each other, and after leaving the canal are connected separately with the ganglion. The greater or deep petrosal nerve was formerly regarded as the second of the two roots by which the sympathetic was supposed to begin.

(*c*) From three to five delicate short branches pass through the outer wall of the cavernous sinus and join the Gasserian ganglion on its inner surface. One or two of these have been described as passing backwards to the tentorium cerebelli, and have been traced by Arnold to the walls of the transverse sinus. The filaments to the Gasserian ganglion are sometimes supplied by the cavernous plexus.

2. *Cavernous Plexus.* — This name is applied to the plexus formed around the internal carotid artery as it lies in the cavernous sinus; it is situated rather towards the inner surface of the vessel, at the point where it makes its highest turn.

The branches which leave the cavernous plexus are the following: — (*a*) Filaments which join the third nerve; they are two or three in number, and become united with the nerve before its entrance into the orbit. Hirzel regards the communication as rare, having found it only in ten bodies; in some cases he found that the supposed nerve filaments consisted merely of cellular tissue. Bock, Longet, and others regard it as constant. (*b*) Branches of communication to the fourth nerve; they are either derived from the cavernous plexus or from the carotid, and join the nerve as it lies in the cavernous sinus. (*c*) Communicating filaments with the ophthalmic ganglion, one or two in number, emerge from the anterior part of the cavernous plexus, and enter the orbit on the inner side of the ophthalmic division of the fifth nerve, either ending directly in the posterior border of the ophthalmic ganglion, or joining the long root derived from the nasal branch of the ophthalmic. Occasionally one filament enters the posterior border of the ganglion, the other along with the long root derived from the nasal branch. (*d*) One or two delicate filaments have been observed by Fontana, Hirzel, and Arnold to pass from the cavernous plexus to the pituitary body. As this body is said to receive filaments from the sympathetic cords of either side, it has been supposed to hold the same relation to these as the ganglion impar or coccygeal ganglion at the opposite extremity of the trunk. Bock regards the filaments, however, which have been described as entering the pituitary body, as solely destined for its vessels, terminating in their coats. Weber states that he has examined with the greatest care the supposed communication between the sympathetic and pituitary body in mammals and birds, but failed to convince himself that any such communication exists. (*e*) Arterial branches, accompanying the branches of the internal carotid arteries. These are described by Chaussier* and Ribes as passing not only along the anterior and middle cerebral arteries, but also along the branches of the ophthalmic artery, forming minute plexuses upon them. One of these plexuses is described by these authors, as well as by Rusel† and Langenbeck, as accompanying the central artery of the retina into the eyeball. Ribes has also traced filaments from the cavernous plexus upon the anterior communicating arteries, by means of which the sympathetic cords of either side are united, there being at their point of junction a small ganglionic enlargement; this arrangement has been denied by Lobstein and others.

3. *External Carotid Plexus.*—The external carotid plexus formed as already mentioned by the union of the nervi molles from the superior cervical ganglion, commences at the origin of the external carotid artery. There is sometimes a ganglionic enlargement present, which from the fact of being situated at the point of bifurcation of the common carotid artery, was termed by Arnold the intercarotidean ganglion. The external carotid plexus extends along the artery of the same name, encircling it with numerous branches, on which frequently occur small ganglionic enlargements. At its commencement numerous communications are formed between it and the branches of the glosso-pharyngeal and vagus nerves, which go to form the pharyngeal plexus. It also forms connections with the upper cardiac nerve, and, higher up, as it passes with the artery through the parotid gland, branches are given off for the supply of this organ, and also others, which become connected with the facial and auriculo-temporal nerves. Offsets are sent from it along the divisions of the external carotid artery, forming a number of plexuses around them, which are named according to the arterial branches which they accompany. One of these accompanies the superior thyroid artery into the substance of the thyroid gland: it communicates with the superior laryngeal and upper cardiac nerves. Another accompanies the ascending pharyngeal artery, and is intimately connected with the pharyngeal plexus. The lingual plexus encircles the artery of the same name, giving off filaments to the sublingual gland, and forming communications with the lingual branches of the glosso-pharyngeal nerve. The facial plexus surrounds the facial artery and its branches, one or two filaments, which accompany the submental artery, pass to the submaxillary gland, and communicate with the ganglion of the same name. Small plexuses accompanying the occipital and posterior auricular arteries seem to terminate chiefly in the parotid gland. Most of the branches which accompany the superficial temporal artery appear to pass along the arteries going to the ear and eyelids. Numerous filaments, presenting here and there ganglionic enlargements, proceed upwards on the external carotid artery as far as its division into the temporal and internal maxillary arteries; many of these appear to terminate in the parotid gland, while others accompany the temporal and internal maxillary arteries. Of the latter, one is described by Arnold as emanating from the plexus surrounding the middle meningeal artery, and passing to the posterior part of the otic ganglion. Subsidiary branches accompany the different divisions of the internal maxillary artery.

From the external carotid plexus several filaments pass downwards upon the common carotid artery, forming, with others derived from the middle cervical ganglion, a plexus around the vessel, which accompanies it and forms communications with the inferior thyroid plexus, as well as with the superior cardiac nerve and cardiac plexus.

B. *Thoracic Plexuses of the Sympathetic.*—The plexuses occurring in the thorax in connection with the sympathetic are the cardiac plexus, and the plexus surrounding the thoracic aorta: it also contributes to the formation of the pulmonary and œsophageal plexuses.

1. *Cardiac Plexus.*—The cardiac plexus is formed by the union of the cardiac branches of the sympathetic already described, and by numerous filaments derived from the recurrent laryngeal, as well as from the vagus nerve itself; a branch from the descendens noni nerve accompanies the superior cardiac nerve, and also terminates in the plexus. The superior cardiac nerves, the branches from the recurrent laryngeal and vagus nerves terminate in the upper part of the plexus; the middle cardiac branches of both sides terminate commonly in its middle portion, while the inferior cardiac branches, with some of those derived from the recurrent laryngeal nerve, end chiefly in its lower part. The plexus is asymmetrical, and is situated in the upper part of the thoracic cavity, extending from the transverse portion of the arch of the aorta to the base of the heart: it consists of a widely-meshed network of moderately fine filaments, some presenting a greyish, others a more or less white appearance. About the centre of the plexus, behind the arch of the aorta and in front of the bifurcations of the trachea, at the point of division of the pulmonary artery there is commonly present a ganglionic enlargement. This which is termed the cardiac ganglion (Ganglion cardiacum Wrisbergii), presents a greyish colour and irregular shape, generally more or less angular or oblong, and measures from one to two lines in length. That portion of the cardiac plexus which is

* Mémoires de la Société Méd. d'Emulation, vol. vii. p. 97.

† Tiedemann's Zeitschrift. für Physiol. band ii. p. 227.

formed by the branches of the sympathetic which pass down in front of the arteria innominata on the right side, and the arch of the aorta on the left side, corresponds to what is termed by some the superficial cardiac plexus, while the portion formed by the branches of the sympathetic and vagus which descend behind the arch of the aorta between it and the trachea, is termed the deep cardiac plexus. The branches which proceed from the cardiac plexus are the following:—(*a*) Numerous filaments pass off from the upper part of the plexus and surround the arch of the aorta, as well as the large arterial trunks which spring from the same. (*b*) Others pass along the right and left pulmonary arteries, and terminate in the pulmonary plexus. (*c*) Offsets are also sent along the coronary arteries, forming the anterior and posterior coronary plexuses. The anterior coronary plexus is chiefly derived from the superficial portion of the cardiac plexus, and accompanies the anterior or right coronary artery and its divisions; the posterior coronary plexus, chiefly derived from the left side of the deeper portion of the cardiac plexus, is situated at first behind the aorta and pulmonary artery; it then passes in front of the left division of the pulmonary artery to the base of the heart, and reaches the posterior coronary artery, around which it forms an interlacement of filaments. Numerous filaments are distributed by it to the left side of the heart, especially to the left ventricle: the filaments of the anterior coronary plexus are chiefly distributed to the right ventricle. The nerve filaments which leave the coronary plexuses do not all accompany the branches of the coronary arteries, as was formerly supposed; by far the greater number of them run separately from the vessels, and are distributed to the muscular substance of the heart. As regards the arrangement of the nerves on leaving the coronary plexuses, they appear to be much more numerous on the ventricles than the auricles. The filaments distributed to the former are very numerous; they are directed from the base to the apex of the ventricle; those on the anterior surface passing obliquely downwards from left to right, those on the posterior surface from right to left; they thus in general cross obliquely the direction of the muscular fibres of the ventricles, and often also that of the blood vessels. Where they cross the latter, especially in the heart of the young ox, they appear to bifurcate, so as to enclose the vessel in a loop; and at this point there is frequently, as is represented by Dr. Lee, a small enlargement which occasionally contains ganglionic matter.* In their course along the surface of the ventricles, neighbouring filaments frequently unite, there being here also small ganglionic enlargements. According to Dr. Lee there are distinctly visible on the anterior surface of the young heifer's heart about ninety of these ganglia or ganglionic enlargements. The left ventricle appears to be more abundantly supplied with nerves than that of the right side: on the former they can be traced, extending from base to apex, on the surface of the latter they generally extend but a little way down, when they sink into the muscular substance.

2. *Plexus of the Thoracic Aorta.* This consists of delicate filaments which are derived from the thoracic portion of the gangliated chain of the sympathetic; several filaments also pass between it and the œsophageal plexus. Above, it is continued into the cardiac plexus, from which it derives some branches, and below it accompanies the vessel through the aortic opening in the diaphragm, to terminate in the cœliac plexus.

C. *Abdominal Plexuses of the Sympathetic* — The abdominal plexuses of the sympathetic are larger and more numerous than those occurring in any of the other cavities of the body. They correspond in number with the branches of the abdominal aorta, and accompany them in their course to the different viscera. From the plexuses occurring on the larger arteries, off-sets pass, which form a number of subsidiary plexuses upon the smaller vessels. The chief abdominal plexuses are the *cœliac*, *superior mesenteric*, *renal*, *inferior mesenteric*, and *superior* and *inferior hypogastric* plexuses.

1. The *cœliac*, *solar*, or *epigastric plexus* is the largest of the plexuses of the sympathetic. It is situated in the upper part of the cavity of the abdomen, on both sides of the aortic opening in the diaphragm, extending across the anterior part of the aorta, and is covered in front by the stomach. It surrounds the cœliac axis, and extends downwards as far as the origin of the superior mesenteric artery. It usually contains two ganglia; these present a somewhat crescentic form, and have on this account been termed the semilunar ganglia. They are situated one on each side of the plexus towards its upper part, and are commonly surrounded by a number of smaller ganglia. The solar plexus receives the splanchnic nerves, also some branches from the posterior gastric plexus of the pneumogastric; it likewise receives filaments from the plexus which has been described as surrounding the thoracic aorta, as well as others from the three or four upper lumbar ganglia. The offsets from the plexus present the same plexiform arrangement as the plexus itself, and are named according to the arteries which they accompany; they are the phrenic, or diaphragmatic, superior coronary, hepatic, splenic, and renal plexuses.

(*a*) The diaphragmatic plexuses are two in number, a right and left, and consist of several delicate filaments derived from the upper part of the semilunar ganglia. They often present several small ganglionic enlargements, and accompany the diaphragmatic arteries, sinking with them into the muscular

* Dr. Lee, on the Ganglia and Nerves of the Heart. Phil. Trans. 1849.

substance of the diaphragm, where they communicate with branches of the phrenic nerve.

(*b*) The superior coronary plexus accompanies the left coronary artery of the stomach, along its upper border, and is distributed to the anterior and posterior walls of the organ, its filaments uniting with the branches supplied by the pneumogastric nerves, chiefly with those which are distributed to the posterior wall of the stomach. It extends to the pyloric orifice, where it joins branches of the hepatic plexus.

(*c*) The hepatic plexus, of considerable size, ascends along with the hepatic artery; it receives some filaments from the pneumogastric nerve, and also communicates, as has been already mentioned, with the superior coronary plexus of the stomach. Branches leave it for the duodenum and head of the pancreas; and others pass with the right gastro-epiploic artery, along the greater curvature of the stomach, forming the inferior coronary plexus of the stomach. On entering the transverse fissure of the liver, the hepatic plexus divides into a right and a left portion, which accompany the divisions of the hepatic artery and vena portæ, ramifying upon them—an offset from the hepatic plexus passes to the gall-bladder, along with the cystic artery.

(*d*) The splenic plexus surrounds the artery of the same name, passing with it and its branches to the spleen. Offsets pass from the splenic plexus to the pancreas, and to the stomach, which form the pancreatic and left gastro-epiploic plexuses.

2. *The superior mesenteric Plexus* appears as a prolongation downwards of the cœliac plexus, and is the largest of the offsets furnished by it: it also receives some filaments from the right pneumogastric nerve. It surrounds the superior mesenteric artery, forming for it a close plexiform sheath, and sends offsets along its branches, which accompany them as they pass between the layers of the mesentery to the duodenum, small intestine, cœcum, and ascending and transverse colon. The highest of these unite with the nerves which pass along the pancreatico-duodenal artery, while those which are distributed to the transverse colon communicate with the nerves derived from the inferior mesenteric plexus. The nerves which accompany the arteries to the intestines present at first a plexiform arrangement but in their course through the mesentery, several of them are seen to run alongside the vessels, sometimes separated a short distance from them. Communicating branches pass between them in the same way as between the arteries. On reaching the intestine they enter it at the part where the mesentery is attached, and dividing into finer twigs, soon disappear in the substance of its coats. Many appear to become lost in the muscular coats, while some may be traced through these, ending apparently in the mucous coat, or in the sub-mucous cellular tissue.

3. *Renal Plexuses.*—The right and left renal plexuses are formed by branches which proceed from the cœliac and superior mesenteric plexuses, and likewise derive filaments from the aortic plexus. In their course along the renal arteries they receive filaments, which are sent off from the smaller splanchnic nerves, and others from the superior lumbar ganglia. Several small ganglia are present in the nerves of the renal plexus. They divide along with the branches of the renal artery, each arterial branch being generally accompanied by two nervous twigs. From the renal plexus filaments are sent off, which, with others derived from the cœliac and phrenic plexuses, form the supra-renal plexus destined for the supply of the supra-renal capsule.

4. *Spermatic Plexuses.*— The right and left spermatic plexuses consist of some delicate nervous filaments, which are derived from the renal plexus. As they pass downwards with the spermatic arteries, they receive some additional filaments from the aortic plexus, and appear to give off several filaments to the ureters; in their course to the testes they are connected with the nerves which accompany the vas deferens. In the female they are distributed to the ovaries and uterus.

5. *The aortic plexus*, situated along the abdominal aorta, and extending from the superior to the inferior mesenteric arteries, consists of filaments derived from the superior mesenteric and renal plexuses. In its course downwards it also receives branches from the lumbar ganglia: it terminates in the inferior mesenteric and superior hypogastric plexuses, and also, as has been already stated, contributes to the formation of the spermatic plexus.

6. *Inferior Mesenteric Plexus.*—The inferior mesenteric plexus, formed by the left lateral portion of the aortic plexus, is less dense and less distinct than the superior plexus of the same name: its fibres present, however, the same whitish aspect and firm consistence, and sometimes have small ganglionic enlargements developed upon them. It accompanies the inferior mesenteric artery, dividing along with it, and forming secondary plexuses around its branches, which pass with them to the descending colon, sigmoid flexure, and upper half of the rectum. Above, the branches of the inferior mesenteric plexus form communications with those derived from the superior mesenteric, and below, with others derived from the superior hypogastric plexus of the left side.

7. *Hypogastric Plexus.*—The hypogastric, a single plexus, situated in front of the fifth lumbar vertebra and promontory of the sacrum, between the two common iliac arteries, presents an irregularly quadrilateral and flattened aspect. Nervous branches, about twelve in number, pass down to it on each side from the aortic plexus, and additional filaments are derived from the lumbar ganglia. From the plexus small offsets proceed along the common iliac arteries, and a few join the hemorrhoidal filaments derived from the superior mesenteric plexus: it then divides into a right and left

portion, which are continued forwards along the sides of the rectum, to form the inferior hypogastric plexuses.

8. *Inferior Hypogastric Plexuses.* — These consist of a right and left plexus, formed in the manner just mentioned: they contain several small ganglia. Filaments are likewise sent to them from the sacral ganglia, as well as from two or three of the sacral nerves. These plexuses are situated upon the sides of the rectum, the plexuses of opposite sides being united by cross branches. From the plexus proceed the following branches. (*a*) Some hæmorrhoidal branches: these are termed the inferior hæmorrhoidal nerves; they are very delicate and unite with the superior hemorrhoidal branches derived from the inferior mesenteric plexus, and go to supply the rectum. (*b*) Vesical plexus. The nerves proceeding to this plexus come from the lower and anterior portion of the inferior hypogastric plexus, and pass to the sides and lower part of the bladder. The nerves are most numerous near the neck of the organ, and have several minute ganglia developed upon them. From the neck numerous branches pass upwards on the sides of the bladder, and are chiefly distributed to its muscular coats; a few, however, may be traced through the muscular to the mucous coat. From the vesical plexus, filaments are given off which pass to the vesiculæ seminales, around which they form a plexus; others pass to the vas deferens and ramify around it, communicating on the spermatic cord with the nerves of the spermatic plexus, while a third portion passes to the prostate gland. The branches which pass to the latter are of considerable size, and form connections with the plexus around the vesiculæ seminales. Some of the branches sink into the substance of the gland, others are continued forwards to the erectile tissue of the penis, constituting the so-called cavernous nerves, or cavernous plexus. From these branches are distributed to the membranous portion of the urethra. They then continue forwards, passing beneath the arch of the pubis to the root of the penis. By Müller*, they are divided into nervi cavernosi minores, and nervus cavernosus major. The former penetrate the crus of the corpus cavernosus penis, and spread out upon the cells of the erectile tissue: the latter runs along the dorsum of the penis between the dorsal artery and vein. About the middle of the penis it divides into a number of branches and forms communications with the dorsal branch of the pudic nerve: some of the branches accompany the dorsal vessels and unite with those of the opposite side; the greater portion, however, penetrate the corpus cavernosum and are distributed to its substance.

9. *Uterine Plexus.*—The nerves destined for the supply of the uterus are derived from the upper and posterior part of the inferior hypogastric plexus, and also from the superior plexus of the same name. They pass between the folds of the broad ligament in company with the uterine vessels; before reaching the uterus, however, the greater portion of them separate from the vessels, and are distributed to the substance of the neck and body of the organ. The portion derived from the superior hypogastric plexus appears to be chiefly distributed to the fundus of the organ: a filament also passes, according to Dr. Beck*, from the ovarian artery to the fundus of the uterus. Besides the branches above mentioned there are others, according to Dr. Beck, derived also from the hypogastric plexus, which assume a plexiform arrangement around the vessels, and are characterised by the presence of several minute ganglia.

Fig. 280.

Small ganglion from the posterior wall of the cervix of an impregnated uterus of the Cow.

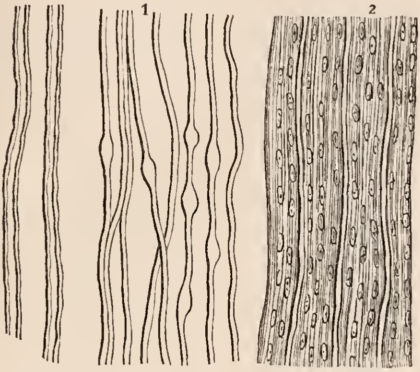
Minute Anatomy. — The branches of the sympathetic nerve present to the naked eye certain characters which, more or less, distinguish them from the proper cerebro-spinal nerves. They have a dull greyish-white appearance, different from the white shining aspect which characterises the nerves belonging to the other class. This appearance is better marked in some parts of the nerve than in others, and is best seen in the branches which accompany the blood-vessels. By Valentin this gray appearance of the sympathetic nerves was attributed to the presence of the ganglionic corpuscles: this, however, as Remak observed, cannot be the case, inas-

* Ueber die organischen Nerven der erectilen männlichen Geschlechts-organe. Berlin, 1836.

* On the Nerves of the Uterus. Phil. Trans. 1846.

much as the ganglionic corpuscles are not distributed throughout the whole extent of the nerve, but are confined to certain limited parts. Remak believed it to be due to the presence of structures termed by him *organic nerve fibres:* Volkmann and Bidder also believed it to be owing to a peculiar set of fibres, different,

Fig. 281.



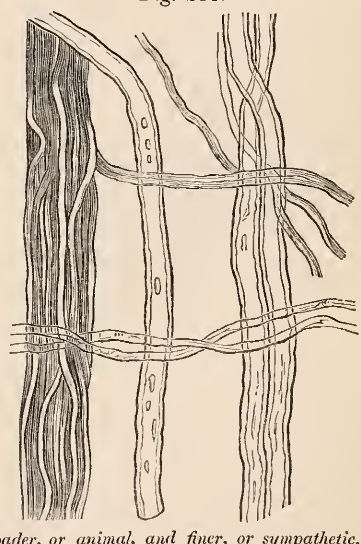
1. *Tubular nerve-fibres from the thoracic portion of the sympathetic cord in Man.*
2. *Fibres of Remak (gelatinous fibres) and fine tubular nerve-fibres, from the nerves of the spleen in the Sheep.*

however, from those of Remak. Whether it be due to the fibres of Remak or not, it seems to be, at least, best marked in those branches of the sympathetic in which these fibres are most abundant. The sympathetic also differs from the cerebro-spinal nerves in consistence as well as in its appearance, being much softer and more readily torn across than the latter. This may be partly due to the want of the strong distinct fibrous sheath possessed by the latter, and partly also to a difference in the character of the nerve fibres themselves. The nerve fibres of the sympathetic are moreover not arranged into distinct fasciculi, but lie together imbedded in a mass of fibrous tissue which accompanies them, serving the purpose of a sheath.

As regards the constituents of the sympathetic nervous trunk, when a portion of one of the main cords is examined with a power of 250 diameters, it is found to be composed of the following elements: 1st. Tubular nerve fibres; 2nd. Structures which present a homogeneous flattened appearance, and contain a number of oval nuclei imbedded in them at intervals; and, 3rd. a quantity of white fibrous tissue.

The tubular nerve fibres which are present in the sympathetic, differ much in point of breadth from one another. Some of them measure about $\frac{1}{2000}$ to $\frac{1}{1600}$ of an inch in diameter: their contents present the arrangement of *double contour* and *axis cylinder* which characterise the fibres occurring in the cerebro-spinal nerves. Besides these fibres there are others present which have also the character of the tubular fibre, but are much finer, measuring only from the $\frac{1}{9600}$ to the $\frac{1}{4500}$ of an inch. They present distinct margins, but have a paler aspect than the above, and do not possess the double contour which is seen in the broader tubular fibres, and many of them often have a tendency to the formation of varicosities. When running in bundles they have, according to Volkmann* and Bidder, who first called attention to their anatomical characters, a yellowish grey hue instead of the white pearly aspect of the cerebro-spinal nerves. Sometimes the two sets of fibres are intermingled and run side by side with each other, at other times they run in bundles more or less distinctly separated. The number of fine fibres which are present much exceeds that of the broader or coarser variety. The two classes of fibres do not, however, appear to be distinctly marked off from one another, there being present fibres which possess partly the characters of the one and partly those of the other. When one of the finer variety is examined at the same time with one of the coarser variety, and the two compared, the points of distinction are sufficiently

Fig. 282.



Broader, or animal, and finer, or sympathetic, primitive nerve-fibres, from the common trunk of the vagus in the Frog. (*Bidder and Volkmann.*)

marked, but a gradual transition from the fibres belonging to the one set to those belonging to the other may, in some parts of the sympathetic, generally be traced. The finer the nerve tubules are, the less distinctly do their contents appear to be separated into central portion or axis cylinder, and white substance of Schwann.

2. In regard to the structures No. 2. which have been mentioned as occurring in the sympathetic, Remak†, their discoverer, describes

* Die Selbständigkeit des sympathischen Nervensystems von F. H. Bidder und A. W. Volkmann, Leipzig; 1842; p. 19. et seq.

† Observationes Microscopicæ, &c. Berol, 1838. §§ 6. 13.

them as being destitute of a sheath, naked, transparent, almost gelatinous, as presenting a number of longitudinal streaks, and as breaking up into delicate fibrils, which in their course present oval dilatations or swellings, and have moreover a number of round or oval corpuscles arranged upon them at intervals. Apparently, the same structures have been described by Henle under the name of "gelatinous fibres." According to him they are flat homogeneous fibres, measuring from the 0·002‴ to the 0·003‴ in diameter, and characterised by the presence of numerous nuclei, some round, others oval, their long diameter being directed in the longitudinal axis of the fibre. They are dissolved by acetic acid, the nucleus becoming at the same time more distinct. The fibres in question are well seen in the branches of the sympathetic which go to the spleen or kidney in the sheep or ox, as well as in the trunk of the sympathetic nerve itself. In the former situations they appear as a more or less transparent, slightly granular, pale mass, and marked by indistinct longitudinal lines into fibres presenting a diameter of about $\frac{1}{7000}$th to $\frac{1}{4000}$th of an inch, and characterised by the presence of round, oval, or elongated nuclei. On the addition of acetic acid they swell out, becoming perfectly transparent and indistinct, while at the same time the nuclei are brought more clearly into view. When treated with tartaric or citric acid, the effect produced upon them is much the same: solution of soda also causes them to swell out and become indistinct, the nuclei being at the same time also rendered more or less indistinct. The nuclei generally measure about the $\frac{1}{4000}$th to the $\frac{1}{2000}$th of an inch in length, and about $\frac{1}{6000}$th to the $\frac{1}{4000}$th of an inch in breadth, presenting the same characters and behaving towards reagents in the same manner as the nuclei occurring in most other tissues. They are much softer than the tubular fibres, and are not easily separated from one another. In some parts of the peripheral branches of the sympathetic these fibres present a much smaller diameter, measuring about $\frac{1}{9000}$th of an inch, are finer and distinguished with difficulty from the white fibrous tissue present. In the nerve they are placed parallel to one another, and are seen, when the preparation is pressed between the glasses, running along each side of the tubular fibres, which latter seem to be imbedded amongst them. They differ from the tubular nerve-fibres in their flattened appearance, want of distinct margin, and in the effects produced upon them by reagents, but are especially characterised by the presence of their nuclei. They are most abundant in the more grey-looking branches of the sympathetic, and seem to be the cause to which this appearance is chiefly owing. Sometimes when one of the smaller filaments of the sympathetic is examined, it seems to be entirely composed of these fibres, no tubular nerve fibres being at first seen; solution of soda, however, which, as has been stated, renders the gelatinous fibres transparent, brings into view more or fewer fine tubular fibres. There can be no doubt that in many parts of the sympathetic, especially in the branches distributed to the arteries, the fibres of Remak, or gelatinous fibres, make up the greater portion of their constituents, the tubular nerve fibres existing only in comparatively small numbers Sometimes more or less grey and white bundles of fibres may be seen running alongside each other: such an arrangement is not unfrequently seen in the branches of communication between the sympathetic and the spinal nerves. In such cases, while the white chiefly or entirely consists of tubular nerve fibres, the grey contains a large number of gelatinous fibres, and always in addition to these more or fewer fine tubular fibres.

The gelatinous fibres are present in different proportion in different parts of the sympathetic: they appear to be more abundant in the neighbourhood of the ganglia than in other parts and in the larger peripherical branches they also exist in considerable proportion, but in the final distribution of these they either do not exist at all or only in small number. They appear to be more abundant in the sympathetic of the higher animals than in that of the lower vertebrata. In mammals and birds they exist in considerable quantity: in amphibia, according to Kölliker, they are present but only in small proportion. In some fish, as in the common Ray, the sympathetic ganglia and branches contain a very large proportion of structures which agree with the fibres of Remak in some respects, such as in their relation to the ganglionic corpuscles and tubular nerve fibres, as well as by the presence of a number of small oval nuclei; they differ from them, however, in not being so much affected by acetic acid and in being firmer: the number of tubular fibres occurring in the sympathetic is very small compared with the number of these structures.

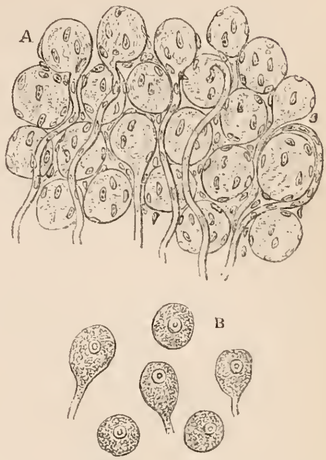
3. The quantity of white fibrous tissue present in the sympathetic trunk and branches is generally considerable; the fibres are arranged in the longitudinal direction for the most part; other fibres, which from their relation to reagents appear to belong to the yellow elastic tissue, encircle the nerve, binding together, as it were, its constituents. After addition of soda or acetic acid the circular fibres are well seen; at the parts where they occur there is frequently observed a distinct constriction, the nerve being swollen out above and below by the reagent applied.

With respect to the nerve fibres occurring in the sympathetic, many of them present undoubtedly the same characters as those occurring in the nerves of the cerebro-spinal system. It has been maintained that the sympathetic also contains fibres which differ in their anatomical characters from the fibres of which the latter class of nerves are composed, and which have been termed organic or vegetative nerve fibres.

Ehrenberg appears to have regarded the fine varicose tubular fibres which are present in the sympathetic, as constituting the peculiar organic nerve fibres. According to Purkinje *, the ganglionic nerve-fibres are much finer than those belonging to the cerebro-spinal system or animal fibres. He describes the latter as containing two substances,—an outer, which runs in the form of a tube through the elementary fibre immediately within its sheath, and an inner, which occupies the hollow interior of the former. The tubular sheaths of the elementary fibres of the ganglionic system contain, on the other hand, no double substance ; their contents are homogeneous, and appear to correspond to the axis cylinder or central portion of the animal nerve-fibres ; their sheaths are much stronger than those of the nerve-fibres of the cerebro-spinal nerves, and resist mechanical influences in a high degree. In the fœtus the animal nerve-fibres cannot, according to Purkinje, be distinguished at a certain stage of their formation from those which are characteristic of the sympathetic in the full-grown animal ; and hence he regarded the latter as a less highly developed stage of the former. Pappenheim also appears to have recognised the fibres described by Purkinje, as constituting the peculiar fibres of the sympathetic system.

According to Remak†, the fibres which have been described above as the gelatinous fibres or fibres of Remak, constitute the peculiar organic or sympathetic nerve-fibre, all the tubular nerve-fibres being considered by him as belonging to the cerebro-spinal system. The fibres in question do not take their origin, according to him, from the cerebro-spinal centres, but arise from the ganglionic corpuscles contained in the different ganglia, and then run along with the tubular fibres sent to the sympathetic by the cerebral and spinal nerves. It has been disputed, however, whether the fibres described by Remak are entitled to the character of nerve-fibres, and are not rather to be regarded in the light of accessory structures which serve as a sheath to the true or tubular nerve-fibres. Valentin ‡, who adopts the latter view, states that the fibres in question do not arise from the ganglionic corpuscles themselves, as was believed by Remak, but are continuous with the nucleated substance which forms the sheath or capsule of these bodies, and are thence prolonged upon the nerve-tubes, and are to be viewed as merely discharging the part of a protecting covering or envelope to the latter. They do not, according to Valentin, present the most distant resemblance to nerve-tubes, which could scarcely be the case were they in reality a mere variety of the same structures : in their microscopic character, on the other hand, they agree in every respect with certain forms of white fibrous tissue, especially at certain stages of its formation ; and they are

Fig. 283.



From the semilunar ganglion of man.

A. Ganglionic corpuscles included within their nucleated capsules.
B. Ditto liberated.

entirely wanting, or occur only in small numbers, in the main cord of the sympathetic, where the fibrous tissue is, as well as in many of the peripherical branches of the same, deficient. In the horse the fibres of Remak, which are present in the nerve-branches passing along the mesentery, were seen by Valentin to cease one or two feet from the point at which the nerves enter the intestine. Bidder * and Volkmann also appear to regard them merely as a variety of areolar tissue, observing that their anatomical characters are so different from the known elements of the nervous system as to exclude them from the character of true nerve-fibres. In the mammalia, according to these authors, the areolar tissue which is interposed between the different organs is very abundant, and in this class of animals the fibres of Remak also abound. In birds, where the quantity of such areolar tissue is smaller, these fibres are not so numerous ; and in the cold-blooded animals, where there is very little interposed areolar tissue, the fibres of Remak either fail altogether, or they exist only in very small numbers. From this it would appear that they regard the fibres of Remak as holding the same relation to the tubular nerve-fibres that the areolar tissue holds to the different organs between which it is interposed. They also agree with Valentin in regard to the very marked resemblance between these fibres and white fibrous tissue at certain stages of its formation, and accordingly adopt the view that they are rather to be regarded as white fibrous tissue which has not reached its full development than true nerve-fibres. They find, moreover, as will be afterwards noticed,

* Müller's Archiv. 1839, p. 203. Valentin's Repertorium, band v. p. 78. See also Bidder and Volkman, op. cit.

† Loc. cit.

‡ Ueber die Scheiden der Ganglienkugeln und deren Fortsetzungen, in Müller's Archiv. 1839. Also Valentin's Repertorium, band iii. p. 76. *et seq.*, and band v. p. 79., &c.

* Op. cit. § 12.

that the increase in point of thickness of the nerves leaving a ganglion over those which pass to it is due, not to the presence of a greater number of the fibres of Remak, as might be expected were these true nerve-fibres arising from the ganglionic corpuscles, but to an increased number of fine tubular fibres.

Kölliker * likewise agrees with the authors already mentioned in the view that the fibres of Remak are not to be regarded as true nerve-fibres, but rather as enveloping structures or sheaths to the tubular fibres. He believes, with Valentin, that they are not connected with the ganglionic corpuscle itself, but with its sheath, and are thence continued along such of the tubular fibres as arise from the corpuscles, forming for them a protecting envelope or sheath. The capsules of the ganglionic corpuscles are, according to Kölliker, a species of fibrous tissue; and so also the fibres of Remak, which are continuous with them, must be regarded as partaking of the same nature. Again, whilst, on the one hand, these fibres are very abundant in the neighbourhood of the ganglia, in the finer branches, on the other hand, they are much fewer in number, and in the ultimate distribution of the nerve do not exist at all. Similar structures have also been observed by him accompanying the very fine branches of some of the spinal nerves; such, for example, as those going to the skin, while, at the same time, they are not to be found in the main or larger branches of the same.

The chief grounds, then, on which it is held that the fibres of Remak are to be regarded as enveloping structures, and not as true nerve-fibres, are, 1. the anatomical differences between these and the true or tubular nerve fibre; 2. their resemblance to certain varieties of white fibrous tissue; 3. their connection with the sheaths of the ganglionic corpuscles, and not with these bodies themselves; 4. their absence in the final distribution of the nerve; 5. the increase in the thickness of the nerves *leaving* a ganglion being due, not to an increased number of fibres of Remak, but of fine tubular fibres.

On the other hand, it has been stated that the anatomical difference between the tubular fibres and the fibres of Remak is not a sufficient ground for believing that the latter are destitute of the properties of nerve-fibres. All the nerve-tubes in the embryo, even after it is considerably advanced in development, present much the same character as these fibres, and even after birth nuclei may be occasionally found existing in them. Again, as noticed by Todd and Bowman, the nerve-fibres in the olfactory nerve resemble the fibres of Remak in containing nuclei, and also in the want of double contour, as well as in their soft homogeneous appearance. When a nerve is divided, and a portion of it removed, the structure by which its continuity is restored presents much the same appearance as the fibres of Remak, and this for some time after the part supplied by the nerves has, to a certain extent, regained its functions, showing that impressions may travel along structures not differing from the fibres in question. In reply to the second objection, it is stated that the difference between the fibres of Remak and white fibrous tissue is such as to preclude the notion of the one being a mere variety of the other. In the third place, it is said that it is by no means determined that the fibres of Remak are connected merely with the capsules of the ganglionic corpuscle, and, supposing they were so, that these also may be possessed of the properties of nerve-tissue.

As regards the relation between the ganglionic corpuscles and the fibres of Remak, the tubular nerve-fibres which leave the ganglia may not unfrequently be observed to have structures running along each side, which present the same characters as the fibres of Remak; sometimes only a single row, at other times a double row, of nuclei are placed along each side of the tubular fibre, indicating one or two fibres of Remak. These, on being

Fig. 284.

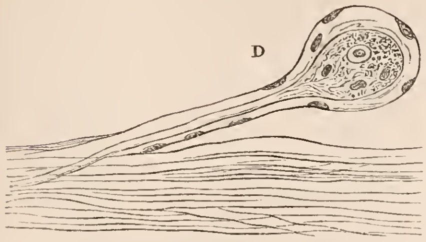
C. Cell freed from capsule.

traced inwards to the ganglionic corpuscle, are found to be distinctly continuous with the capsules of these bodies. When the ganglionic corpuscles are seen separately from one another it is found that these structures are connected only with such of the corpuscles as are still included in their capsules, those which are isolated from their capsules never having any such attached to them (see A, B, and C. *fig.* 284.) In their general aspect, as well as in their relation towards reagents, the fibres of Remak correspond with the capsules of the corpuscles; moreover Kölliker has seen and distinctly figures the capsules of these bodies as directly continuous with the fibres of Remak. As regards their dissimilarity to white fibrous tissue, there can be little doubt that when

* Mikroskopische Anatomie oder Gewebelehre des Menschen, von A. Kölliker; Leipzig, 1850; zweiter band, p. 530.

characteristic specimens of either are examined the difference is sufficiently marked; yet in

Fig. 285.



From a branch of the coccygeal nerve inside the dura mater of Man. (*Mag.* 350 *diam.*) *After Kölliker.*

some parts of the branches of the sympathetic in the higher animals it is difficult to limit the two species of tissue, and between the most characteristic of the fibres and many embryonic tissues the most marked resemblance exists. In the ultimate distribution of the sympathetic there seem to be, as Kölliker observes, none but fine tubular fibres present.

If, then, the fibres of Remak be kept out of consideration, as not being possessed of the properties of nerve-fibres, are there any fibres in the sympathetic which can be regarded as differing in their anatomical constitution from those occurring in the nerves belonging to the cerebro-spinal system? In 1842 Bidder and Volkmann described particularly the distinction in point of structure between the tubular fibres, which have been mentioned as being present in the sympathetic. They measured the tubular fibres, and found that while some of them had a diameter of 0·00046 to 0·00068 of an inch, others measured only 0·00012 to 0·00022; and between the two sizes they observed no fibres of intermediate breadth. They also measured the branches which enter and those which leave the ganglia in the frog. The latter were found to exceed the former in point of thickness, which could only be attributed to the addition of structures arising in the ganglia, and on examination they observed that the increase in thickness of the one over the other was due to the presence of a greater number of tubular nerve-fibres belonging to the finer variety; and hence it was concluded that these are the peculiar organic or sympathetic fibre. The coarser variety they regarded as arising in the cerebro-spinal centres, while the fibres belonging to the finer variety always, according to them, take their origin in the ganglionic system. They describe these fibres as being about half the diameter of those belonging to the cerebro-spinal nerves; they are further distinguished by their paleness; the absence, under all circumstances, of the double contour, and the small quantity of curdlike contents which they present even when examined some time after death, and by their yellowish-gray colour when in bundles. The distinctions between the broad and fine tubular fibres, as given by Volkmann and Bidder, were denied by Valentin, who stated that the fibres of these authors were merely fibres of Remak. Reichert, on the other hand, confirmed the observations of Bidder and Volkmann as to the difference in point of size and structure between the cerebro-spinal nerve-fibres and the sympathetic or organic fibres. The description which is given by Remak of the gelatinous fibre does not, as Volkmann and Bidder maintain, apply to the fibres which they have described: they are much finer, ten times finer, than the cerebro-spinal fibres, whereas the fibres of Bidder and Volkmann are generally only a half narrower than these fibres. The relations of the two structures towards reagents as well as their general characters are also very different.

Kölliker agrees with Bidder and Volkmann that there are nerve fibres in the sympathetic which are not derived from the cerebro-spinal system, but arise from the ganglionic corpuscles; he farther confirms the observation of these authors, that all the fibres which arise in the sympathetic belong to the finer variety of tubular fibres, and that they present the characters which they were described by Bidder and Volkmann as possessing; he denies, however, that they are peculiar to the sympathetic system. Fine fibres agreeing with these in structure arise, according to him, in the cerebro-spinal system, as well as in the sympathetic. Again, the diameter of the coarser and finer varieties of the tubular nerve fibres is by no means so strictly limited as Bidder and Volkmann believed, there being transitions from the finer to the broader or coarser variety. Besides occurring in the sympathetic, they are likewise present in the anterior and posterior roots of the spinal nerves, especially in the latter; and in the brain and spinal cord they exist in large numbers. Another objection to the views of Bidder and Volkmann as to the peculiar nature of these fibres is derived from the fact that it is by no means uncommon for the broader tubular fibres to divide into finer fibres during their course to the periphery, becoming narrower and narrower, and at the same time losing their distinct double contour; and hence in their ultimate distribution they consist almost entirely of fine fibres, which cannot be distinguished from those described by Bidder and Volkmann as constituting the peculiar fibres of the sympathetic system. Volkmann himself now admits that the distinction between the broad or animal nerve-fibre and the fine or organic is by no means always strictly defined, and also that the broad tubular or animal fibres, in their peripherical distribution, assume the characters of the others. It would appear, then, as Kölliker maintains, that there is no absolute distinction between the fibres of the sympathetic and those belonging to the cerebro-spinal system; the difference is merely one of relation and degree: while the nerves of the latter system consist *chiefly* of broad tubular fibres, the sympathetic is *chiefly* composed of fine ones.

Ganglia. — The ganglia occurring on the sympathetic are, as has been already stated, very numerous, constituting the most distinguishing character of this nerve. There are also ganglia present on the posterior roots of all the spinal nerves, as well as on several of the cerebral nerves; and by many these are classified along with those of the sympathetic, constituting what has been termed the ganglionic system of nerves. The ganglia present the appearance of nodules or swellings occurring on a nerve during its course. When examined with the naked eye, they appear to consist of opaque and more or less pellucid portions, present a greyish colour, and are possessed of considerable consistence. Sometimes they occur in the course of a single nerve, as is the case with the ganglia in the posterior roots of the spinal nerves. The sympathetic ganglia commonly present the appearance of masses of various sizes connected with several nerve-branches which appear to pass off from them in different directions. The ganglia situated in different parts of the body are all more or less connected by means of bundles of nerve-fibres passing between them. As already noticed, many of them are arranged alongside the spinal column; others are situated on the different plexuses which are formed by the branches passing off from these, while numerous others of smaller size occur in the substance of the organs supplied by the sympathetic. All of them consist essentially of a number of bodies presenting peculiar characters and termed ganglionic corpuscles, and of nerve-fibres in more or less intimate connection with these.

Ganglionic Corpuscles, ganglion-vesicles (Germ. *Ganglienkugeln*). — These bodies appear to have been first noticed by Ehrenberg*, and were afterwards more fully described by Valentin.† They vary in size from the $\frac{1}{1800}$th to the $\frac{1}{280}$th of an inch. Those in the ganglia of the cerebro-spinal nerves are generally considerably larger and not so delicate as those in the ganglion of the sympathetic. They commonly present a round or oval form; sometimes they are more or less pear-shaped. Their contents consist of a delicate clear fluid holding in suspension numerous finely granular particles, which give the cells a more or less grayish aspect. This substance is possessed of considerable viscidity, as shown by the fact that when removed from the corpuscle it does not separate into distinct particles, but remains coherent in a single mass which flattens out somewhat. Each of the ganglionic corpuscles contains a distinct rounded nucleus which in appearance resembles the corpuscle itself, only its contents are clearer. These measure from the $\frac{1}{3000}$th to the $\frac{1}{1300}$th of an inch in diameter, and are commonly situated rather towards one side of the cell. Within the nucleus there is commonly a third body, which presents a clear rounded appearance like the nucleus, and may be regarded as the nucleolus. Sometimes there are two such bodies present. In the ganglionic corpuscles there is also frequently contained a mass of pigmentary matter consisting of particles which are much coarser and darker than the rest of the contents. This mass is sometimes situated at a little distance from the nucleus, at other times it partly covers it, and occasionally it conceals it entirely from view. Its quantity varies much in different cells: it appears, as Kölliker observes, to be more abundant in the ganglion-corpuscles of old people than in those of the young. Sometimes he has observed it present in such quantity as to fill the entire cell. In the Gasserian ganglion of a man aged about sixty I observed several bodies present, which in size and shape corresponded with the ganglionic vesicles: they appeared, however, to be less delicate, and presented a dark-brown colour, and in all probability were ganglionic corpuscles filled with dark pigmentary matter such as Kölliker notices. Connected with many of the ganglionic corpuscles are one or two delicate processes of different lengths, and presenting the same delicate finely-granular appearance as the vesicle itself of which they appear to be a prolongation. In the corpuscles occurring in the ganglia these do not present the same branching character as they have been described to do in the brain and spinal cord by Purkinje, Remak, Hannover, and by Todd and Bowman, who in their description of these bodies, which by them were termed "caudate nerve-vesicles," hinted at the probability of the processes being continuous with nerve-tubes. The actual continuity of the process of the ganglion-vesicle with the nerve-tube was, however, first observed by Kölliker* in the ganglia of the amphibia. He found that on tracing the process onwards from the cell it became continuous with a nerve-tube presenting distinct dark margins. The observation of Kölliker in regard to the connection of the nerve-tube with the ganglion-corpuscle has since been confirmed by many other observers, and especially by Wagner and others in the ganglia of the fish. Some of the ganglionic corpuscles appear to be destitute of any such process; others have a single process passing off from them, while others present two such processes, passing off at either extremity (A. G. *fig.* 286.). Occasionally the two processes pass off from a round cell, not at either extremity, but at a short distance from each other on one side of the body (*fig.* 291.). The ganglionic corpuscles which are not connected with any process, or, as may be safely said, with any nerve-tube, have been termed by Stannius *apolar* cells; those from which one tube proceeds are termed *unipolar*, while the cells with which two such are connected are called by him *bipolar* ganglionic corpuscles or cells. The nerve-tube which is connected with the unipolar cell is always found to run peripherically, *i. e.* from the centre. In regard to the bipolar

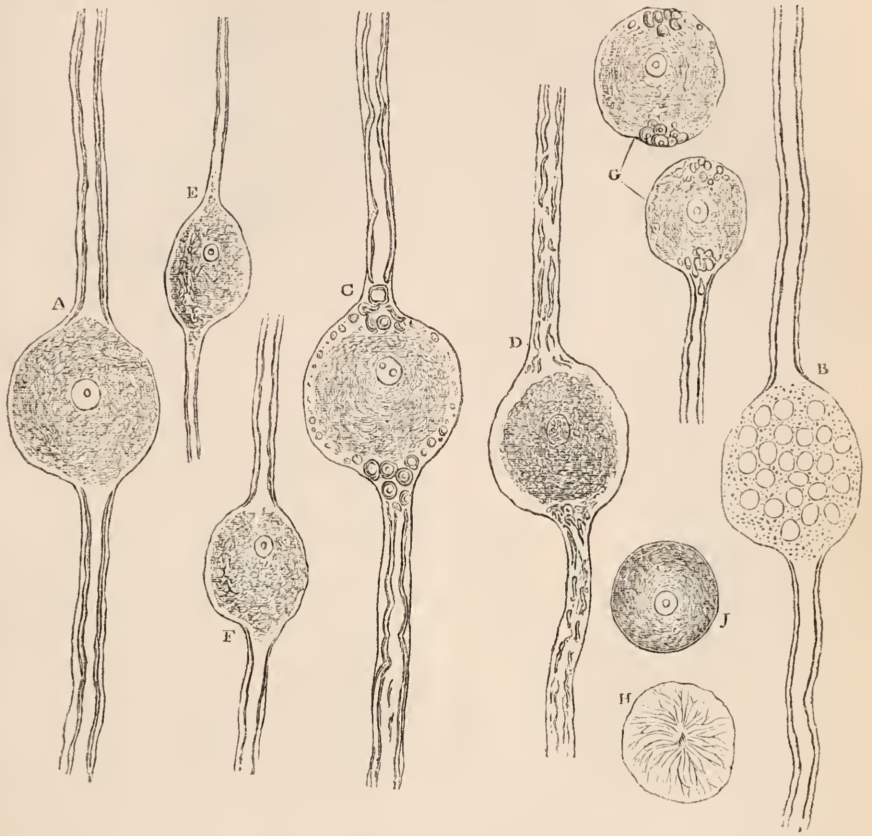
* Poggendorf's Annalen, band xxviii. p. 458., as quoted in Brun's Anatomie.

† Nova Acta, band xviii. p. 127., as quoted in Brun's Anatomie.

* Mikroskopische Anatomie, p. 508., zweiter band.

cells, when the nerve-tubes come off at either extremity, as they generally do, while one of them runs towards the periphery, the one at the opposite runs towards the nervous centres.

Fig. 286.



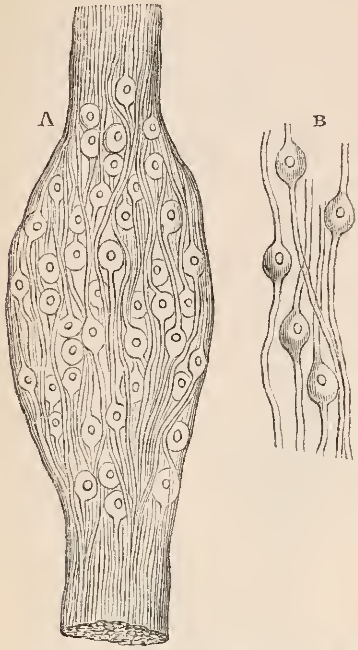
Ganglionic corpuscles from one of the spinal ganglia in the Ray.

In A, the granular contents reach quite to the margin of the vesicle; B, ganglion-corpuscle with a layer of clear round delicate bodies on the inner surface of its wall; C, showing a clear space between the granular contents and the cell-wall, occupied by particles of oily matter similar to the contents of the nerve-tubes; D, a corpuscle which has been treated with chromic acid; E, ganglionic corpuscle of smaller size, with narrower nerve-fibre attached to it; F, one intermediate in size between the larger and smaller corpuscles; G, apparent apolar and unipolar corpuscles; H, collapsed membrane of a ganglion-corpuscle; *j*, liberated contents of the same.

When both nerve-tubes pass off, not at opposite extremities, but from one side of the corpuscle, they both run, according to Bidder, in the direction of the periphery. As regards the mode of connection between the ganglionic corpuscle and nerve-tube, the cell-wall of the former appears to be directly continuous with the membrane of the latter, while the contents of the vesicle seem to be prolonged downwards into the nerve-tube, becoming continuous with its contents. The nucleated substance forming the capsule of the ganglionic corpuscle is also, according to Kölliker, prolonged along the nerve-tube which arises from the corpuscle itself (*fig.* 288. and 289.). All the nerve-tubes which are thus connected with the ganglionic corpuscles in the ganglia of the sympathetic belong to the finer variety of tubular fibres already described. In the spinal ganglia, according to Kölliker, the nerve-tubes arising from the corpuscles are at first fine, measuring about 0·0015—0·0025 of a line; but in their further course many of them increase in diameter up to 0·003—0·004 of a line, or even to 0·005—0·006 of a line, so as to represent broad nerve-fibres, or fibres intermediate between the broader and finer varieties.

Most of the cells which are seen in examining the ganglia of the mammalia belong either to the apolar or bipolar variety. It is possible, however, that many of them, as Wagner, Robin, &c. maintain, although apparently apolar, are really unipolar or bipolar cells, from which one or both processes have broken off during the process of preparing them for examination. That the bipolar cell exists in man and other mammalia, is proved by the observations of Schrœder van der Kolk in

Fig. 287.

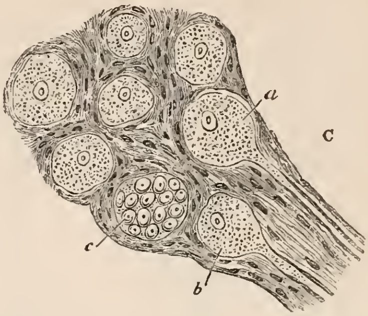


A. Spinal ganglion from the Ray. (40 diam.)
B. Portion of the same more separated.

regard to the cervical ganglia of man, as mentioned by Donders and Harting. Schaffner also describes a bipolar cell in the ganglion Gasseri of the sheep; and similar cells have been observed by Corti* and Pappenheim in the acoustic nerve of the pig, and by Frey in the Gasserian ganglion of the cat. In the common trunk of the pneumogastric and sympathetic nerves in the middle of the neck, in the young calf, oval cells may be seen which have distinctly attached at their peripherical extremity a nerve-fibre; and some of them also appear to be connected with one at the opposite or central extremity.

The different cells composing a ganglion are each surrounded by a more or less clear, homogeneous substance, in which are contained a number of round or oval nuclei. These are seen to form a single or double row around the margin of the ganglionic vesicle, their long axis being directed in the axis of the circumference of the cell (*fig.* 288.). They are also seen upon the surface of the corpuscle (*c*, *fig.* 288.). This substance not unfrequently presents a more or less fibrous aspect, as if composed of spindle-shaped corpuscles. It resembles much (as has been already stated) the fibres of Remak. The nuclei measure from the $\frac{1}{6000}$th to the $\frac{1}{4000}$th of an inch in breadth, and about $\frac{1}{4000}$th to $\frac{1}{1500}$th of an inch in length. The structure in question is closely connected with the walls of the included ganglionic corpuscle, and appears to hold much the same

Fig. 288.



From the gastric ganglion of the Ray, shewing ganglionic corpuscles embedded in a nucleated fibrous tissue.

relation to it that the fibres of Remak hold to the nerve-tubes. It has been termed the capsule of the ganglionic corpuscle. The capsules surrounding the different ganglionic corpuscles are also closely united to each other, so as to form a kind of framework, in the loculi of which the ganglionic corpuscles are placed (*fig.*288.). It would appear also to be prolonged along the nerve-tubes connected with the ganglionic corpuscles for some distance, forming for them an investment or sheath similar to that which it forms for the corpuscles themselves. The quantity of this substance which is present varies in different circumstances. It appears to be more abundant in some cases than in others, and is commonly more so in the sympathetic ganglia than in those on the posterior roots of the spinal nerves.

As regards the arrangement of the nerve-fibres in the ganglia, when one of the entering branches in the ganglia of small animals, such as the mouse, is traced into the point at which it joins the ganglion, it is found to spread out somewhat, and soon breaks up into its component fibres. These separate from one another, running amongst the ganglionic corpuscles, either singly or in bundles of two, three, or more. The nerve-fibres belonging to one bundle leave it and join neighbouring bundles, so that a more or less complete interchange of the fibres contained in the different bundles takes place; and at the same time there is formed a sort of plexus or network, in the meshes of which the ganglionic corpuscles are imbedded (*fig.* 287.). Sometimes, as Valentin observed, one or more of the fibres of one of the entering bundles are seen to wind round the ganglionic corpuscles, and appear again to pass into another entering bundle, thus pursuing apparently a retrograde course. The fibres which thus surround the ganglionic vesicles were termed by Valentin *umspinnende fasern*; whether they again really leave the ganglion in the direction in which they entered it, and in this way may be regarded as terminating in a looped arrange-

* Kölliker's Mikroskopische Anatomie, band ii. p. 519.

ment in the ganglion, it is difficult to determine. Kölliker* has observed that the nerve-tube arising from a ganglionic corpuscle frequently makes one or two turns around it before pursuing its course towards the periphery; and it appears probable therefore that many of the so-called *umspinnende fasern* may be of this description. That the nerve-fibres connected with the ganglia do not merely pass through it between the ganglionic corpuscles, as was formerly supposed, but enter into intimate organic connection with these bodies, either arising from them, or having these bodies developed upon them in their course from the centre towards the periphery, as seems to be the case with most of the bipolar cells, is quite certain.

Aves. — In the bird the ganglia present much the same structure, both as regards the ganglionic corpuscles and nerve-fibres, as those of the mammalia.

Reptilia. — In the frog, the animal in this class which has been most frequently examined, the ganglionic corpuscles present the same general characters as those in the higher animals. The existence of apolar and unipolar ganglionic corpuscles is much better seen in examining the small ganglia in the heart or bladder of this animal than in the ganglia of the mammal or bird. Bipolar cells have been described by Schiff; Valentin† has also described and figured bipolar ganglionic corpuscles the nerve-tubes of which ran in opposite directions, one towards the centre, the other towards the periphery. They were found by him both in the small ganglia of the heart, and also in the ganglia occurring in the main chain of the sympathetic. The nerve-tube connected with these he describes as clear and transparent, differing from the broad nerve-fibres in its colour and general appearance, especially in its not presenting any oily contents, and thus appearing to belong to the fine variety of fibres. Kölliker describes the unipolar ganglionic corpuscles as being pyriform, and at their narrow extremity drawn out into a delicate process. This presents the same pale and finely-granular appearance as the corpuscle itself, and measures from the $\frac{1}{10000}$th to the $\frac{1}{7000}$th of an inch in diameter: after running a short distance from the ganglionic corpuscle it acquires a dark margin and slightly granular contents; becoming, in short, a fine nerve-fibre (see *fig.* 289. A). Bidder has also observed in the ganglia of the heart of the frog bipolar cells, which, however, resembled the unipolar in the fact that both nerve-tubes ran in the direction of the periphery. In the ganglia of the frog there is a much smaller amount of the substance present, which has been described as constituting the capsules of the ganglionic corpuscle, and there are also very few of the fibres of Remak.

Pisces. — In certain animals belonging to this class, especially in the cartilaginous fishes, the connection between the ganglionic corpuscles and the nerve-tubes is much better seen than in any of the preceding classes. In the torpedo and ray the bipolar variety of ganglionic corpuscles was first discovered by Wagner, and shortly afterwards by Robin. Similar observations were also made by Bidder and Reichert, both as regards the cartilaginous fishes, and, by the latter observer, in the cod, perch, and certain species of salmon, as well as in the pike.* In the common ray the ganglionic corpuscles, as occurring in the spinal ganglia, are generally more or less round or oval, and are much larger than in any of the higher animals. They measure from $\frac{1}{400}$th to the $\frac{1}{200}$th of an inch in diameter, and contain a more or less clear viscid fluid with finely molecular matter. On the addition of diluted acids or spirit, they become dark and granular. Each of the cells contains a clear round nucleus, in which there is also present one, sometimes two, nucleoli. The contents of the nucleus, like those of the cell itself, become dark and granular on adding the reagents above mentioned. In several of the cells there are seen, apparently on the inner surface of their wall, a number of round corpuscles, generally clear and transparent, but sometimes more or less dark and granular. They measure about the $\frac{1}{1200}$th of an inch in diameter, and seem, as Wagner and Robin describe, to form a single layer on the inner surface of the ganglionic corpuscles. The larger of the ganglionic corpuscles are generally more or less spherical; the smaller, on the other hand, present commonly a more oval shape. Sometimes between the outer cell-wall and the contents of the vesicles there is, as Bidder describes, a clear space, varying in breadth, generally broadest at the points where the two nerve-tubes are connected with the corpuscle; at other times this space does not appear to exist, the granular contents of the vesicle coming close up to the cell-wall (see A. and D. *fig.* 286.). The wall of the corpuscle appears to be much stronger than that of those in the higher animals, and is distinctly prolonged at either extremity into the membrane of the nerve-tube, the two constituting one continuous structure, agreeing both in anatomical characters and in their relation towards reagents. When the ganglion-vesicle is ruptured, so as to allow its contents to escape, its cell-wall collapses more or less, and often presents the appearance of lines passing outwards towards the circumference, from a central point (H. *fig.* 286.): this appearance is evidently due to folds in the membrane. In the clear space which has been mentioned as sometimes existing between the cell-wall and the contents of the ganglionic corpuscle, there are often observed a number of particles, most abundant at the two poles of the vesicle, which resemble in appearance the curd-like contents of the nerve-

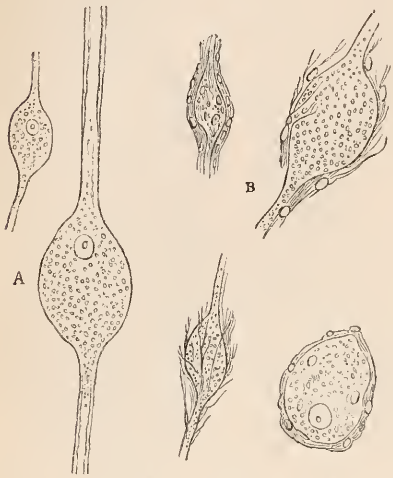
† Valentin, Lehrbuch der Physiologie. Braunschweig, 1848; band ii. p. 602. *et seq.*

* Canslatt's Jahresbericht, 1847, also Wagner's Handwörterbuch der Physiologie, band iii. p. 361. *et seq.*

tubes, and are evidently continuous with the same (C, *fig.* 286.). Sometimes the granular contents of the vesicle appear to be prolonged downwards into the nerve-tube (A. *fig.* 289.),

Fig. 289.



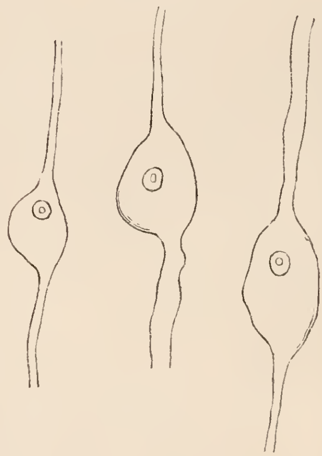
Ganglionic corpuscles from the gastric ganglion of the Torpedo. (After Wagner.)

Showing, B, several of the cells still surrounded by the fibro-nucleated tissue. A, other cells denuded of it.

while at other times, the oily contents of the latter reach quite up to the corpuscle, and seem either to become blended with the granular contents of the same, or are prolonged into the clear space. Wagner* believes that the normal relation between the nerve-tubes and corpuscles is, that each primitive nerve-fibre coming from the centre, retains its appearance of double contour up to the ganglion-cell, where its contents are interrupted by the finely granular matter of the latter; at the peripherical extremity of the cell, the nerve-fibre commences in a quite similar manner. Thus then, according to Wagner, the oily contents of the nerve-tube cease on reaching the ganglionic corpuscle. Bidder†, on the other hand, regards the clear white space between the cell-wall and the granular contents as a thin sheet of nervous matter, which serves as a connecting medium between the contents of the nerve-tube on either side of the ganglionic corpuscle.

As regards the sympathetic ganglia in this animal, they appear in some parts to be almost entirely composed of a fibrous structure and of a quantity of granular matter resembling, as Wagner and Robin observe, the gray granular matter of the nervous centres, and containing a number of bodies of a brownish-yellow granular appearance, which do not disappear on addition of acetic acid. In other parts the ganglia contain corpuscles similar to those already described as occurring in the spinal ganglia, with the exception that they are in general perhaps somewhat smaller. They are imbedded in a fibrous structure, which seems to hold the same relation to them as the nucleated substance forming the capsules of the ganglionic corpuscles in the higher animals. It is difficult to ascertain how far the ganglionic corpuscles in the abdominal ganglia are unipolar or bipolar; according to Wagner, they are the same in this respect as the corpuscles in the spinal ganglia, being all bipolar; one tube entering while another leaves the corpuscle. The nerve-tubes which are connected with them belong both to the broad and fine varieties; in general, the narrower fibres are connected with the smaller corpuscles, the broader fibres with those of larger size (*fig.* 290.).

Fig. 290.



Ganglionic corpuscles from the 26th spinal ganglion of the Torpedo, drawn in outline in order to show the different size of the nerve-tubes. (After Wagner.)

It has been already seen that it is almost certain that all the ganglionic corpuscles occurring in the ganglia on the posterior roots of the spinal nerves, at least in this animal, belong to the bipolar variety; it remains to inquire whether all the nerve-fibres in the posterior root are connected with ganglionic corpuscles. When the ganglion, after addition of dilute solution of soda, is examined with a power of about 30 or 40 diameters, it is observed that while many of the fibres soon disappear among the ganglionic corpuscles, several of them can be traced from the point at which they enter the ganglion almost to its opposite extremity, without being connected with corpuscles; but I have never been able to trace them in this manner quite past the ganglion. Wagner, who counted the nerve-tubes contained in the posterior root of the nerve and also the ganglionic corpuscles, found that the number of each corresponded pretty closely,

* Handwörterbuch der Physiologie, band iii. p. 361. *et seq.*

† Zur Leben von dem Verhältnisz der Ganglien, körper zu den Nervenfasern, Leipzig, as quoted in Canslatt's Jahresbericht, 1847.

so that he believes each of them is connected with one of these bodies.

Invertebrata.—The ganglionic corpuscles in the ganglia of the invertebrata appear to be the same in their essential characters as those of the vertebrate animals. Will* recognises two kinds of ganglion-corpuscles in the lower animals. The one he describes as consisting of a membrane and nucleus, the space between the two being occupied by a clear transparent fluid, which becomes granular on the addition of water; in the other variety there are imbedded in the clear transparent fluid numerous small round cells in which no nucleus is visible. The cells belonging to the former variety have always but one process attached to them which consists of a single tube, presenting no division so far as it can be traced, and thus corresponding to the unipolar variety of corpuscle. In the second kind of corpuscles there are several such processes present; the processes attached to some of these cells all run in one direction; in others they pass off at either extremity and run in opposite directions. In the leech, according to Bruch †, there are also two kinds of ganglion corpuscles. The one variety are round and are apolar; the others are connected with nerve-fibres. The latter are situated towards the lower part of the ganglia, and are more numerous than the former: they are more or less pyriform, their wider extremity being directed outwards; their narrower, terminating in a process, is directed towards the ganglia and the nervous cord. Peripherical ganglia, consisting of from one to six or seven cells, are always found at the points where the branches of the nerves divide. Ganglionic corpuscles were also seen by him in the interior of the nerve-tubes, and corresponding to the view taken by Bidder ‡ of the constitution of the bipolar ganglionic corpuscle. Apolar and unipolar cells have also been described by Hannover and Leydig in several other invertebrate animals.

From the fact that in such animals as the torpedo and ray, where the ganglionic corpuscles are easily isolated from each other, they are all found to belong to the bipolar variety, Wagner, Robin, and Bidder believe that all the ganglionic corpuscles in other animals are also bipolar. Kölliker, on the other hand, while he admits that the bipolar cell is most frequent in the fish, maintains that the opposite is the case as regards the higher animals, most of the corpuscles in them belonging either to the apolar or unipolar varieties; and so far as actual observation goes, the views of Kölliker seem to be perfectly correct, inasmuch as, while apolar and unipolar cells are very frequently seen in these animals, the bipolar variety has been seen very seldom. It is possible, however, that many of these unipolar and apolar cells may, as Wagner and Bidder, &c. hold, be really bipolar cells, one or both nerve-tubes having been broken off during the manipulation required for submitting them to examination. In the spinal ganglia of the ray the cells are very easily isolated from each other, whereas in the abdominal ganglia it is very difficult, owing to the amount of surrounding fibrous structure, to isolate them. Now in the former only bipolar cells are seen, whereas in the latter, most of the cells, when isolated, appear to be unipolar and apolar, although it would appear from the observations of Wagner and others, that they are all bipolar, like those in the spinal ganglia. In the higher animals, especially in the mammalia, the ganglionic corpuscles are isolated from one another with as much difficulty as those in the abdominal ganglia of the skate; and hence the probability that many at least of the unipolar and apolar cells which are seen in them, belong to the bipolar variety in reality. On the other hand that apolar and unipolar ganglion-corpuscles really exist, and that too in considerable numbers, in the ganglia of the higher animals, and also in those of the invertebrata, seems to be shown by numerous observations on the smaller ganglia, where no preparation is required, and where, consequently, the above source of fallacy cannot intervene. In the sympathetic cord of the frog, according to Valentin *, groups of ganglionic vesicles may be observed, without a single nerve-fibre connected with them: Ludwig † has also observed in the auricle of the frog's heart small ganglia in which there were eleven ganglionic corpuscles, and only four or five nerve-tubes; in a nerve passing to the bladder of the frog, and consisting of only two nerve-fibres, Valentin counted as many as seven ganglionic corpuscles, ‖ while another, consisting also of only one or two nerve-fibres, was surrounded by twenty-four ganglionic corpuscles.

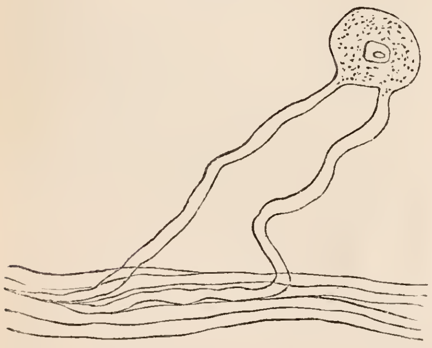
In accordance with the view adopted by Wagner, that all the ganglionic corpuscles are bipolar, the nerve-tube connected with either extremity of the cell running in opposite directions, one towards the centre, the other peripherically, Robin believes that all nerve-tubes arise exclusively from the brain and spinal cord; neither the spinal ganglia nor those of the sympathetic give origin to nerve-tubes; the ganglion-cells are merely organs developed upon the nerve-tubes, between their central and peripherical termination, and several such may be present on a single nerve-fibre during its course. From what has been already stated, however, it seems probable that unipolar as well as bipolar cells exist in the ganglia, and consequently that nerve-tubes do originate in them. That nerve-fibres arise in the ganglia, is further shown by the accurate measurements of Volkmann and Bidder of the nerves passing to and those leaving the ganglia. The ciliary, Gasserian, and spinal ganglia in the frog were found by them to give off a far greater number of fine nerve-

* Müller's Archiv. 1844, p. 76. also in Canslatt's Jahresbericht, 1847.
† Ibid. ‡ Ibid.

* Lehrbuch der Physiologie; Braunschweig, 1848; band ii. p. 602.
† Müller's Archiv. 1848, p. 142.

fibres on the one side than they received on the opposite side. So also in the septum between the auricles of the frog's heart Bidder has seen small ganglia, which gave off on the one side eight nerve-fibres more than they received on the other side. The observations of Bidder and Volkmann have been confirmed also by Kölliker. Engel*, moreover, describes a peripheral ganglion, to which no nerve-fibres passed, while a number of fibres left it; an observation which, if correct, places beyond a doubt the question as to the origin of nerve-fibres in the ganglia. The ganglion in question he describes as being pear-shaped, and about 0·096 of a line in diameter; it occurred in the perichondrium of the tracheal cartilage, and consisted of fourteen ganglionic corpuscles, with seven efferent nerve-fibres, each measuring about 0·0012 of a line in diameter. Even in regard to the bipolar ganglionic corpuscles, it does not appear to be at all certain that they are all merely organs developed on the course of a nerve-fibre arising in the brain and spinal cord. On the contrary, it would appear that several of the cells belonging to this variety must also be regarded as giving origin to nerve-fibres in the same manner as the unipolar cell. Thus Bidder has seen bipolar cells, the nerve-tubes connected with which did not run in opposite directions, one towards the brain and spinal cord, the other towards the periphery, but both ran in the latter direction (*fig.* 291.) : so also Stannius, as mentioned by Kölliker, has

Fig. 291.



Bipolar ganglionic corpuscle, both nerve-fibres connected with which run peripherically. From the spinal ganglion of a Fish. (After Bidder.)

seen in the ciliary ganglion of Trigla, a bipolar cell, both nerve-fibres of which were directed peripherically. The same observer has also seen ganglionic corpuscles in the fish which gave origin to or had three nerve-tubes connected with them.

That most of the bipolar cells are, however, as Robin maintains, organs developed on nerve-fibres of cerebro-spinal origin, in their course towards the periphery, there is no reason to doubt; and moreover that several of these may occur in the course of a single fibre between its central and peripherical termination is also shown by the observations of Stannius on the fish, and by Valentin on the frog. Wagner has also observed two ganglion-corpuscles occurring in the course of a single nerve-fibre, at short distances from one another.

Robin* divides the ganglionic corpuscles into two distinct classes, a larger and a smaller: the larger he finds always occur on broad nerve-fibres, or fibres of animal life, while the smaller are always connected with nerve-fibres belonging to the finer variety, or fibres of organic life; and in this way, according to him, we have a good mark by which to distinguish the animal from the organic nerve-fibres. In the ray, according to Robin, the larger variety of corpuscles measure 0·095 to 0·150 mm. in diameter, are spherical, and often flat at both poles; the smaller measures 0·080 to 0·115 mm. in length, and 0·050 to 0·070 mm. in breadth, and are commonly oval. In the larger cells there is a layer of clear round bodies, without nuclei; in the smaller ganglionic corpuscles the outer membrane is finer, and each of the cells, on their inner surface, is provided with a central dark nucleus. Bidder † also agrees with Robin in separating the ganglionic corpuscles into two groups. In the pike the one set measure 0·042‴, while the other set do not measure more than 0·018‴: the former chiefly occur in the ganglia of the cerebro-spinal nerves, the latter in the ganglia of the sympathetic; the former are always connected with broad fibres, the latter with fibres belonging to the fine variety. The views of Robin and Bidder are opposed by Kölliker, Valentin, and apparently also by Wagner. The latter admits that in general the ganglionic corpuscles are smaller than those occurring in the spinal ganglia, and that the smaller corpuscles have, as Robin observes, an oval shape, while the larger are more or less spherical: there are, however, according to him, cases where broad nerve-fibres are seen passing off from small cells, and where the large cells are connected with small or narrow fibres. Sometimes, indeed, the ganglionic corpuscle has a narrow tube on one side, and a broad one on the opposite side (see *fig.* 290.); and sometimes the broad, sometimes the narrow, runs peripherically. Stannius has, as mentioned by Kölliker, observed in *Petromyzon* cells present, of the fibres connected with which the one was six times broader than the other. Although, however, there does not appear to be a distinct demarcation between the ganglionic corpuscles belonging to the two sizes, there can be little doubt that the cells occurring in the sympathetic ganglia are generally smaller than those occurring on the cerebro-spinal nerves, both in the fish and also in the higher animals. The larger cells in the spinal ganglia of the

* Engel in Zeitschrift der Wien. Aerzte, iv. p. 307., as quoted in Kölliker's Mikroskopische Anatomie, p. 532.

* Annales des Sciences Naturelles, tom. septième, 1847, p. 282.; also Canslatt's Jahresbericht, 1847.

† See Canslatt's Jahresbericht, 1847.

ray appear, as Robin states, to be (in general at least) connected with broad fibres, while the smaller cells are connected with narrow fibres: this, however, does not appear to be invariably the case. In the sympathetic ganglia there are sometimes seen connected with narrow fibres cells as large as some of those in the spinal ganglia, which are connected with broad fibres. Moreover, as already stated, there appear to be transitional sizes between the larger and smaller variety of corpuscles. Kölliker also calls attention to the fact that small ganglionic corpuscles occur in other parts than in the sympathetic, as for example those in the brain and spinal cord. It would seem, then, that just as the finer variety of tubular nerve-fibres cannot be regarded as characteristic of the sympathetic system, so also the smaller variety of ganglionic corpuscles cannot be regarded as peculiar to it either.

It has been already stated, that the nerve-fibres which compose the posterior root of the spinal nerves in the ray, &c., have all, according to Wagner, ganglionic corpuscles developed upon them. He concludes from this, that all sensory fibres are so constituted, and that we have thus a good mark by which a sensory nerve-fibre may be distinguished from one possessed of motor properties. To this view, however, it is objected by Kölliker, that in the higher animals at least, so far is it from being the case, that all the fibres in the posterior roots of the spinal nerves are provided with these structures, that not one of the fibres proceeding from the spinal cord enters the ganglion at all, the nerve fibres connected with the ganglion being fibres which arise in it and run peripherically, not one of them passing in the opposite direction towards the spinal cord. In examining the spinal ganglia of the mouse, after addition, as Kölliker directs, of dilute solution of soda, I have often had no difficulty in observing, that a great portion at least of the fibres in the posterior root run past the ganglion without forming any connection with its corpuscles, and, moreover, that the fibres of the ganglion appear to be directed peripherically, as he states.*

Connection between the Sympathetic and Cerebro-spinal Systems. — By the older ana-

* A paper on multipolar ganglion-cells has been published by Remak in the Monatsbericht der Königl. Preuss. Akademie der Wissenschaften zu Berlin für Januar., 1854, translated also in the Edinburgh Monthly Medical Journal for April, 1854. He mentions that it was first made known by Stilling's discovery of the so-called nerve-nuclei in the pons Varolii of man and of the mammalia, that the multipolar ganglion-cells discovered by Purkinje, Müller, and himself (1837), in the central organs of the vertebrata are connected with motor nerve-fibres. It has also been ascertained by Wagner (1847), that each of the large multipolar ganglion-cells of the electric lobes in the torpedo becomes continuous by means of a process with the axis cylinder of a fibre of the electric roots of the n. vagus and trigeminus. The other branched processes of these cells, distinguished by their granular or striated appearance, serve the purpose, according to Wagner, of connecting the cells with each other. Remak could not, however, in an examination of the Torpedo marmorata find such connections. On treating the fresh brain with a solution of sublimate or of double chromate of potash, the electric lobes are easily separated into their constituents. All the ganglion-cells are multipolar, surrounded by delicate nucleate sheaths, and occupy the meshes of a network formed of wide vessels with thick walls. The processes destined for the formation of the electric roots of the vagus and trigeminus collect themselves at the base of the cerebral lobes into strong bundles visible to the naked eye. The remaining branched processes, becoming surrounded by a thin medullary sheath, form nerve-tubes with dark borders, which pass into the medulla oblongata. A connection of the cells with sensory fibres has not as yet been demonstrated; the sensory roots of the vagus and trigeminus do not pass into the electric lobes; rather those of the former pass into the medulla oblongata, those of the latter into a gray appendix of the cerebellum (feuillet restiforme of Lerres and Lavi), which in its structure, particularly in the size and form of its multipolar ganglion-cells, agrees with the cerebellum, but not with the electric lobes.

He mentions that he has in his possession transverse and longitudinal sections from the spinal cords of man and of the ox, prepared by Stilling, in which, as mentioned by the latter, the passage of nerve-fibres belonging to the motory roots into multipolar ganglion-cells of the anterior gray column is observed. He finds also in the transverse sections small bands of broad nerve-fibres with dark borders, which seem to unite the anterior and posterior roots. From the place of entrance of the anterior roots into the anterior gray columns, or commencing at the outer circumference of the latter, they run as far as the posterior surface of the substantia gelatinosa, where the posterior roots enter the latter. Here they are connected with the ganglion-cells, which send one of their processes to the sensory roots, while the chief mass of the latter radiates in broad thick bands through the gelatinous substance into the posterior gray columns as far as the seat of the large multipolar ganglion-cells. These circular bands of fibres may be presumed to indicate one of the paths on which in decapitated animals the stimuli applied to sensory nerves gives rise to reflex movements. It is remarkable in this respect, that the long axis of the largest ganglion-cells has the same direction as the long axis of the spinal cord, and that besides the lateral processes by whose means they are connected with the fibres of the roots of the nerves, they send out branched processes at both poles towards the cephalic and caudal extremities of the spinal cord.

In the spinal ganglia the multipolar cells discovered by Remak in 1837 in the ganglia are not found. They consist rather, as he observed, in fresh plagiostomes, without exception of the bipolar cells simultaneously described by Robin and Wagner (1846). These constitute, as shown by Leydig in Chimæra monstrosa, nucleated swellings of the axis cylinder, and are surrounded by a sheath consisting of an epithelial layer, and of a firm membrane, which is continuous with the sheath of the nerve-tube. Bipolar cells may also be obtained from the spinal ganglia of man and of the mammalia. They frequently appear unipolar when the two processes leave the cell close to one another. More frequently, however, as Kölliker observes, are cells seen with a single process; this probably divides after a short course into two fibres. He finds at least in the spinal ganglia of the mammalia (ox), not unfrequently, divisions of nerve-tubes with dark borders, which he misses in the plagiostomes.

Of the ganglia, it is exclusively the sympathetic which are made up of multipolar ganglion-cells. The sheath of the latter consists, as in the spinal ganglia, of a delicate layer of cells and of a strong tomists, the sympathetic was described as a continuation of the fifth and sixth cranial nerves, reinforced by fibres sent to it from the different-cerebro spinal nerves along its

membrane. The number of processes varies between three and twelve; by speedily branching they may be increased threefold and upwards. The number is regulated by the number of nerves connected with the ganglion; and hence it is smaller in the main cord than in the solar plexus. The processes have in general the optical and chemical properties of the axis cylinder of the nerve-fibres. In the solar plexus there are found, however, ganglion cells whose processes are distinguished from one another in a similar manner to those of the ganglion cells in the electric lobes of the torpedo. Besides the multipolar ganglion cells, bipolar cells are also observed in the plagiostomata and mammalia. They differ from those of the spinal ganglia, however, in this, that both processes branch, thus coming to agree essentially with the multipolar cells. The same holds of the unipolar cells which, in the animals mentioned, are sometimes found along with multipolar, and which in the batrachia and osseous fishes, as well as in the head of the mammalia, almost alone constitute the sympathetic ganglia. In transverse or longitudinal sections of the thoracic or abdominal sympathetic ganglia in the mammal or plagiostome, the simple (generally very broad) processes of such a unipolar cell are seen after a short course to divide into numerous fibres, which pass off from one another in different directions. That all the processes take a peripherical course cannot, according to Remak, be demonstrated, and is, from what follows, improbable.

He has ascertained, namely, that in the mammalia the multipolar ganglion-cells of the ganglia in the main cord of the sympathetic in the abdomen and thorax become continuous by means of their processes with the axis cylinder of nerve-fibres with dark borders, of such, too, as pass from the spinal ganglia into the ganglia of the main cord. In man and in the mammal, each ganglion in the main cord is connected, by at least two branches, with spinal nerves. The under branch (ramus communicans sympathicus s. revehens) is, according to his observations, gray, contains very fine (the fibres of Bidder and Volkmann) nerve-fibres, and very many ganglion-fibres: it joins a spinal nerve for peripherical distribution after it has at its place of entrance, sometimes close to the spinal ganglion, formed another ganglion consisting of multipolar cells. The upper branch (ramus communicans spinalis, s. advehens) is white: it contains the fibres which, according to Wützer, &c., may be followed to both roots of the spinal nerves. Remak has as yet succeeded in seeing fibres of this branch enter merely into the anterior root; the remainder, generally the smaller number, are lost in the spinal ganglion. The sensory fibres destined for the sympathetic nerve must, therefore, as it appears, become connected with cells of the spinal ganglia before they pass into the main cord of the sympathetic. The fibres of this spinal communicating branch either pass directly into the ganglia of the main cord, or they form in part separate white bundles, which apply themselves to the cord, and are lost in the next ganglion behind. Since, now, as transverse sections of the glangia in the main cord show, all entering spinal fibres become connected one after another with multipolar glanglion-cells, it follows that if the anterior roots of the spinal nerves contain merely motor fibres, the posterior merely sensory, the multipolar cells in the ganglia of the main cord are found as well in the course of sensory as of motory nerve-fibres. From these cells there pass off in the peripherical direction both broad nerve-fibres with dark borders, and fine fibres (fibres of Bidder and Volkmann), likewise others in which no dark borders can be observed. All these peripherical fibres may be named sympathetic, in opposition to the spinal fibres with which they are connected by means of the multipolar ganglion-cells. There are no grounds for the assumption that (human) sympathetic fibres exist which do not stand in connection with spinal fibres, and consequently not in connection with the great central organs of the nervous system. So also in the nerves passing off from the sympathetic ganglia to organs no spinal fibres have as yet been demonstrated in whose course no sympathetic ganglion-cells are found.

By the above results, it is merely established that in the sympathetic ganglia the angles of branching, or points where sensory and motor fibres divide, contain ganglion-cells. The ganglia are not, however, thereby established to have the function of central organs, so far as we make them dependant on the conflux of sensory and motor fibres, and so long as there is no ground for supposing that among the peripherical fibres passing from a sensory or motor sympathetic ganglion-cell, as well sensory as motor fibres are found. Ganglion-cells have been observed by Leydig in the angles of branching of sensory fibres in Carinaria Mediterranea.

In the angles of branching of motor fibres ganglion-cells are only known in the great central organs. This of itself gives ground for the question, whether the sympathetic ganglia have the function of central organs; that is, whether in them there are distinct sensory and distinct motor cells, or whether each multipolar cell serves as a medium of connection between sensory and motor fibres. On the spinal communicating branches, the question has not hitherto been determined, because they are too long, and a trustworthy microscopic distinction between the two kinds of fibres is wanting. On the other hand, other observations favour the view that the multipolar cells are connected both with motor and sensory fibres. In ganglion-cells whose long axis is the same as the long axis of the ganglion, there are frequently seen two fibres entering at one pole and two passing off from the other. If all four fibres were of the same kind, the cell would then form an anastomosis between fibres of the same kind, as has only once hitherto been observed by Leydig, as a variety of the bipolar cells in the Casserian ganglion of Chimæra monstrosa. If, moreover, in a small multipolar ganglion taken from the solar plexus of a mammal (ox), the number and direction of the nerves passing to and from it be compared with the number and the direction of the processes of the cells, as seen on a transverse or longitudinal section of the ganglion, the fullest correspondence is found to exist between them; that is, in such a multipolar ganglion each ganglion-cell is connected with nerve-fibres of all the nerves which are connected with the ganglion. That in these cases, each of the nerves entering or leaving the ganglion contains only sensory or only motor fibres is, however, improbable for this reason, that in other multipolar sympathetic ganglia, — for example, the ciliary, otic, and spheno-palatine,—we know that the entering nerves contain sensory as well as motor fibres.

If the sympathetic ganglion-cells serve as connecting media between sensory and motor fibres, then the impressions made upon sympathetic sensory fibres may be transferred by these ganglion-cells to sympathetic motory; through the medium of the spinal sensory communicating fibres they will also be enabled to act upon the great central organs (brain and spinal cord), and thence through the spinal motory upon the sympathetic ganglion-cells and their motor processes. Besides the sympathetic sensory and sympathetic motory fibres, the assumption of a third set of sympathetic fibres, serving immediately for nutrition, is not required by any fact in physiology, since it is possible to explain the dependence of nutrition upon the nerves by the action of the latter upon the contractile walls of the blood-vessels.

course. The communicating branch between the carotid plexus and the sixth nerve, and the deep or carotid branch of the vidian, were regarded as the roots by which the nerve commenced, while the different branches passing between it and the other cerebral and spinal nerves, were believed also to be entirely composed of fibres sent by the latter to the sympathetic.

According to Bichat, the sympathetic is an independent system of nerves ; the cords which pass between it and the cerebral and spinal nerves are not entirely composed of fibres sent to the sympathetic, but are partly branches transmitted by it to these nerves.

The observations of Petit and Fontana* had already shown that the communication between the sixth nerve and the sympathetic did not consist of fibres sent by the former to the latter, inasmuch as the sixth nerve was found to be thicker beyond the point of junction with the filament than before.

In 1827 Retzius† showed that in the trifacial nerve in the horse there was present a gray fasciculus of fibres distinct from the white, and which seemed to take its origin in the ganglion. Somewhat similar observations were made by Varrentrap and Müller on the branches of the trigeminus, and by Giltay on the glosso-pharyngeal, vagus, and superior spinal nerves of the fish, &c. It was afterwards noticed by Remak that the gray portions of the communicating branches consisted of fibres which were sent by the sympathetic to the cerebro-spinal nerves to be distributed peripherically with them. On microscopic examination it was found by him that the sympathetic contained a large number of fibres presenting a peculiar structure : these he regarded as the proper organic or sympathetic nerve fibres, and believed that while the sympathetic derived from the brain and spinal cord all the tubular fibres contained in it, the grayer portions of the *rami communicantes* were composed of organic or sympathetic fibres, which were sent by the sympathetic to the cerebro-spinal nerves, to be distributed peripherically with them. The same view was also adopted by Müller and others. Valentin, as has been already stated, rejecting the fibres of Remak as being destitute of the properties of nerve-fibres, believed that the *rami communicantes* consisted entirely of fibres sent by the brain and spinal cord to the sympathetic. Volkmann and Bidder, though agreeing with Valentin in regard to the fibres of Remak, still maintained the opinion, that the *rami communicantes* are of a compound nature, containing fibres which are sent to the sympathetic from the cerebro-spinal nerves, and also others which are sent to the latter by the sympathetic, and which belong to the fine variety of tubular fibres already described as probably arising in part from the ganglionic corpuscles.

On examining the connection between the sympathetic and cerebro-spinal nerves in the frog, they find that all the anterior branches of the spinal nerves communicate with the sympathetic. The filament of communication with the first spinal nerve at its entrance into it divides into two portions, one of which proceeds towards the spinal cord, the other towards the periphery : when it consisted of two portions, the one was directed towards the centre, the other ran peripherically. Connected with the second spinal nerve they found several communicating filaments, the smaller portion of the fibres of which ran towards the centre, while the larger portion was directed towards the periphery. The fibres connected with the third nerve also ran in both directions, the chief portion, however, towards the centre. The fourth communicating branch sent its fibres both towards the centre, and also towards the periphery, the portion running centrally, however, being much more considerable than that running towards the periphery. So also in regard to the fifth ; the portion, however, directed towards the centre did not exceed that passing peripherically so much as in the former. Sometimes they found that the central and peripherical portions were about equal. The sixth communicating branch sent about an equal portion of its fibres in either direction. In regard to the seventh, they found that by far the greater portion was directed peripherically, while only a very small bundle took the direction of the centre. Between the eighth nerve and the sympathetic there are frequently two communicating filaments : their fibres are directed almost exclusively towards the periphery, only a very small portion being directed towards the centre ; and sometimes even this is wanting. Between the ninth nerve and sympathetic there are commonly two, often also three, filaments of communication with the sympathetic ; and in one case they found as many as six : the course of the fibres here is similar to what it is in the eighth ; perhaps, however, the portion sent inwards towards the centre is even smaller, and not unfrequently fails altogether. The communication with the tenth nerve they found was not constant : sometimes three communicating filaments were observed ; at others no communication appeared to exist. When present, they always ran almost exclusively in the direction of the periphery. Thus, then, of the rami communicantes in the frog there appear to be none which consist of fibres entirely derived from the spinal cord, while, on the other hand, some of these consist almost exclusively of fibres which run towards the periphery, and which therefore must be regarded as exclusively consisting of fibres which are sent by the sympathetic to the spinal nerves. The five upper spinal nerves give to the sympathetic in the frog more fibres than they receive from it, while, on the contrary, the five lower receive from the sympathetic more fibres than they send to it. As regards the communicating

* Selbständigheit des Sympathischen Nervensystems von Bidder und Volkmann, p. 29.

† Ibid. ‡ Ibid.

branches between the sympathetic and cerebral nerves, they also regard it as probable that the greater number of the fibres in the communicating branches run peripherically. In the fish and bird they also found that the fibres of the communicating branches were directed partly towards the centre and partly towards the periphery. In small animals belonging to the class mammalia, such as the rat and mole, as well as in small dogs and cats, they found, on examining the communicating branches with the microscope as before, that the fibres passed both inwards towards the centre, and also outwards towards the periphery, and that the latter in many cases exceeded the former.

As already mentioned, there are commonly two branches of communication between each of the spinal nerves and the sympathetic in the higher animals. The one of these presents a white appearance, resembling more or less the ordinary nerves of the cerebro-spinal system; the other has frequently a more gray aspect, approaching in this respect the appearance of the sympathetic nerves. Sometimes the white cord presents the appearance of being composed of a white and a grayer portion running together. As regards the minute structure of the rami communicantes, the whiter portion consists entirely of tubular nerve-fibres, both of the coarser and finer varieties ; there are also not unfrequently present fibres which appears to be intermediate in point of breadth. In general the broader variety of fibres appear to be more numerous than those which belong to the finer variety. According to Kölliker, the relation between them is much the same in point of number as in the posterior roots of the spinal nerves. The gray portion, as is stated by Todd and Bowman, contains a large proportion of fibres belonging to the gelatinous variety : in young animals it is often entirely composed of structures agreeing in character with the gelatinous fibre. In the full-grown animal also it often, when examined without addition of reagents, presents the appearance of being altogether composed of these fibres. Addition of dilute solution of soda, however, always brings into view a number of tubular nerve-fibres, which belong to the finer variety. The relation between the tubular fibres and those of the gelatinous kind as regards number, is much the same as in many of the branches of the sympathetic, especially in the smaller twigs distributed to the blood-vessels. Occasionally, however, especially in the rabbit and cat, this portion is found to be almost exclusively composed of fine tubular nerve-fibres : the gelatinous fibres being present only in small numbers. In its appearance as seen by the naked eye, as well as in its microscopic structure, the grey portion of the rami communicantes agrees in character with the branches of the sympathetic, and would appear to be an offset from the same to the cerebro-spinal nerves. This is rendered more probable by the observation of Dr. Beck, that the grey portions on leaving the ganglia send off small branches to the neighbouring vessels, and are reduced in size before reaching the spinal nerves. Moreover, Kölliker has sometimes observed a small ganglion present upon them, which, on examination, was found to present the structure of the sympathetic ganglia, and which gave origin to the fibres with which it was connected.

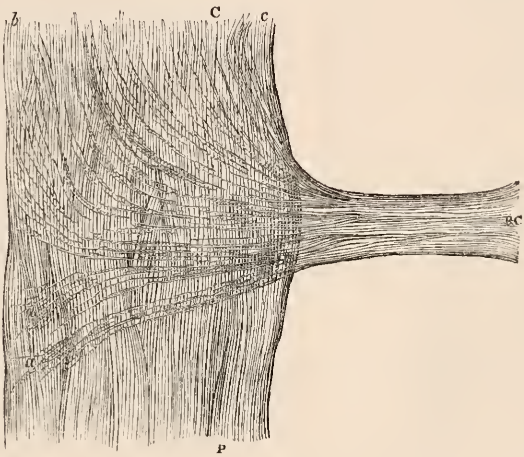
Fig. 292.

From a gray communicating filament between the sympathetic, and one of the lumbar nerves in the Cat, treated with acetic acid, showing fine nerve-fibres, and nucleated fibres of Remak. (*Mag.* 250 *diam.*)

As regards the white portion of the rami communicantes, there can be no doubt that all the broad tubular fibres contained in it are fibres which are transmitted from the nerves of the cerebro-spinal system. This is proved by the fact that all the tubular fibres which are supposed to originate in the ganglia do not belong to the broader, but to the finer variety. In regard to the finer variety of tubular nerve-fibres occurring in this portion, inasmuch as similar fibres are present both in the anterior and posterior roots of the spinal nerves, they may be regarded either as fibres sent from the spinal cord to the sympathetic, or they may be fibres which are transmitted from the latter to the cerebro-spinal nerves. On tracing the white portion of the *rami communicantes* backwards to the spinal nerve, it is found to apply itself to the latter generally in a direction more or less central. On attempting to separate the two by means of needles, though several of the fibres break across, yet the direction of these, as well as of the others, appears to be towards the centre. When the corresponding spinal nerve, along with its communicating branch, is dissected out, and examined, after addition of dilute solution of soda, with a power of 40 diameters, it is not difficult to observe, in the cat or other small animals, that the fibres composing the white portion run towards the centre. Many of them bend directly inwards to the cord, while others sink into the spinal nerve, more or less obliquely, still, however, in the direction of the centre. That the fibres in question are not to be regarded as fibres sent from the sympathetic to the cerebro-spinal nerves is rendered further probable by the fact that they can all be traced beyond the corresponding sympathetic ganglion into the cord above and below. Moreover Kölliker has traced them not only past the ganglia in the main chain of the sympathetic, but into the peripherical branches, and, in small animals, even through the ganglia occurring upon these latter He also finds that the fine fibres in question differ from those which arise in the sympathetic ganglia in presenting a darker contour and in being somewhat broader.

As regards the proportion between the fibres in the communicating branches which may be regarded as proceeding from the sympathetic to the cerebro-spinal nerves and those which are sent by the latter to the sympathetic, we have already seen that in the frog, according to the observations of Bidder and Volkmann, the former exceed the latter considerably. In the higher animals it would appear that the reverse is the case; in the rabbit, according to Kölliker, by far the greater portion of the *rami communicantes* run towards the centre. In man also, according

Fig. 293.



Connection between the sympathetic and the sixth intercostal nerve in the Rabbit.

R C, communicating branch; C P, intercostal nerve; C, its central extremity; P, its peripheral extremity. Most of the fibres of the communicating branch run towards the centre; several of these, *a*, *a*, disappear among the fibres of the intercostal nerve, rather in the direction of the periphery. (Mag. 60 diam.)

to the same observer, much the greater number of the fibres contained in these branches run inwards towards the spinal column. I examined most of the rami communicantes in a fœtal calf about 2½ feet in length, and have little hesitation in saying that in this animal the proportion of fibres which are directed towards the spinal cord greatly exceeds any that appear to run towards the periphery. At the point of junction with the spinal nerve the communicating branch, when examined with a power of 40 diameters, was seen to spread out somewhat, most of the fibres bent directly inwards towards the spinal cord, others passed into the nerve, either obliquely or at right angles to it, and then curved inwards towards the spinal cord. In some of the communicating branches, a few of the fibres were seen to join the nerve in the direction of the periphery. In the cat also, the fibres of many of the communicating branches were found to run exclusively in the direction of the spinal cord.

The fibres in the different communicating branches, as shown by Wützer, Müller, and others, are connected both with the anterior and posterior roots of the spinal nerves, and it seems probable that the fibres which are sent from the cerebro-spinal system are derived from both. Volkmann*, however, as will be afterwards noticed, believes that all the fibres sent to the sympathetic are derived from the posterior root alone.

As regards the further course of the fibres which are derived by the sympathetic from the cerebro-spinal system, Valentin†, holding the view that this nerve is entirely composed of such fibres, believed that on joining the

Fibres from the root of intercostal nerve of a Rabbit.

Towards C (in *fig.* 293.), the nerve chiefly consisted of fibres similar to those indicated by B; towards *b* it consisted chiefly of broad fibres, A; C fibres from the communicating branch. (Mag. 250 diam.)

tremity, none passing upwards towards the cephalic extremity. After thus running for a greater or shorter distance in the main cord, they then pass off from it in the peripherical branches, the point at which they leave the cord being always situated lower down than the point at which they entered it. This arrangement was termed by him the *lex progressus*: he endeavoured to support it by experiments on the motory action of the fibres contained in the sympathetic, showing that when different parts of the cerebro-spinal axis, as well as the rami communicantes, are irritated, the contractions produced in the viscera follow a certain order, which favours the opinion that the fibres are disposed in the manner he states. This view is opposed by Bidder and Volkmann*, on the ground that it is at variance with what is actually observed in regard to the course of these fibres on joining the sympathetic. On examining with the microscope the communicating branch at its point of junction with the sympathetic, they find that in so far as it consists of cerebro-spinal fibres it divides into two portions, one of which is directed downwards in the direction of the pelvis, while the other passes upwards towards the head. In small animals, such as the rabbit or mouse, it is not difficult, when one of the thoracic communicating branches is examined with the microscope, to observe that the fibres are disposed in the manner in which Volkmann and Bidder describe, some passing upwards, others downwards into the main cord of the sympathetic, and in which they may be traced for some distance, and, according to Kölliker, into the peripheral branches. That they all gradually pass off from the main trunk of the sympathetic into its peripheral branches is probable, as Kölliker observes, from the fact that most of these contain a greater or smaller number of fibres resembling those in question.

Peripherical Distribution. — The different branches of the sympathetic contain the same structures as those which have been already described as constituting the main trunk of the nerve, viz. broader and finer tubular nerve-fibres and fibres of Remak. These, however, vary in the proportion in which they are present in the different branches. In the whiter branches of the sympathetic, such as the splanchnic nerves, the number of tubular nerve-fibres, as compared with the number of the fibres of Remak, is much the same as in the main trunk. The grayer branches, on the other hand, such as the ascending or carotid branches of the superior cervical ganglion, the nervi molles as well as the arterial branches generally contain a large number of the fibres of Remak. Many of them appear to be entirely composed of these and fine tubular fibres. The nerves which are distributed to the heart are also chiefly composed of fine tubular fibres and fibres of Remak. In the heart of the sheep many of the branches which run along the surface of the ventricles are chiefly composed of the latter variety of fibres, there being few tubular fibres present. As already mentioned, numerous small ganglia have been described by Remak as occurring on the cardiac nerves, both on the surface and also in the substance of the organ. As regards the fibres on the inner surface of the heart, they cannot be distinguished by the naked eye. If, however, the lining membrane is dissected carefully off from the muscular substance, and then, after addition of diluted solution of soda, examined with a power of 250 diameters, they may frequently be observed. They consist of tubular nerve-fibres belonging to the finer variety, and are arranged

* Die Selbständegkeit, &c., p. 31.

in bundles containing from six to three nerve-tubes forming a widely-meshed network. The rami intestinales present much the same characters as the nerves of the heart. Many of

(*After Bidder and Volkmann.*)

the fibres seem to become lost in the muscular coats of the intestine; a few slender twigs, particularly in the stomach, can be traced through these to the mucous or submucous coats. The nerves of the unimpregnated uterus also contain a considerable number of the fibres of Remak. In the impregnated uterus of the cow, some of the twigs which run along the cervix of the organ consist almost entirely of fine tubular nerve-fibres; in others the fibres of Remak are more numerous than the tubular nerve-fibres. Ganglia have been observed by Remak on the nerves distributed to the muscular substance of the cervix uteri in the pig. Small ganglia are also present in the impregnated cow's uterus, both on the nerves passing to the organ and also in the twigs which pass upwards along the posterior wall of the cervix of the uterus. Some of them contain as few as from six to nine ganglionic corpuscles: they seem to be more numerous, and are larger near the point where the cervix uteri becomes continuous with the vagina. Divisions of the fine tubular nerve-fibres have been observed by Kilian*; he describes a fibre belonging to the finer variety as dividing into two branches, and each of these, after running a short distance, as again dividing. As regards the nerves of the urinary bladder, in that of the ox they are very numerous, especially towards the neck and posterior aspect of the organ, and present a more or less white appearance. Some run beneath the peritoneal coat, others between the deep and superficial layers of muscular fibres; and some may be traced through these to the mucous coat. At first the branches contain both broad and fine tubular fibres: in their farther course, only fine fibres appear to exist. There are present, especially towards the cervix of the organ, a number of small ganglia similar to those in the uterus. Ganglia have also been described by Müller as occurring on the nerves distributed to the cavernous tissue of the penis.

The branches of the sympathetic which pass to the different glandular organs also consist chiefly of fine nerve-fibres and fibres of Remak. In general there are more or fewer fibres belonging to the broad variety also present. In the substance of the organs they run in company with the blood-vessels and with the ducts of the glands, and appear to be chiefly distributed to these: at least no nerve-fibres have as yet been discovered running separate from the vessels or ducts in the parenchyma of the organ. In the finer ramifications of the nerves, the broader tubular fibres gradually disappear. The fine fibres also lose their distinct dark margins, and become pale and more or less indistinct. Their exact mode of termination has not been determined. Pappenheim, however, describes the nerves of the kidney as terminating in a looped arrangement. Small ganglia occur on the nerves distributed to

* Henle and Pfeuffer's Zeitschrift, p. 222.

many of the glands: they have been seen by Ludwig on the nerves of the kidney; also by

Pappenheim on the nerves distributed to the supra-renal capsules. Schaffner* has also observed ganglionic corpuscles from which nerve-tubes proceeded, in the substance of the lymphatic glands. Small ganglia have also been described by Remak as occurring on the nerves distributed to the bronchi: they have also been observed by Kölliker. The latter observer believes that he has seen nerve-tubes arise from them.

From the observations of Purkinje* it would appear that numerous fibres of the sympathetic pass to the cerebro-spinal membranes. In the dura mater of the cranium he describes the nerves as most abundant in the neighbourhood of the trunks of the three meningeal arteries. Most of them accompany the vessels; but there are also others which leave them and ramify in the membrane. In the pia mater of the cerebellum the nerves which branch separately from the arteries are not so numerous as in the pia mater of the cord. The nerves in the pons and cerebrum belong exclusively to the arteries: no trace of nerve-fibres was seen in the choroid plexuses. Around the vena Galeni magna they form a dense plexus which passes into the tentorium cerebelli, and seems to belong to it rather than to the venous system. The nerves in the pia mater of the cord unite with those of the cerebellum and pons. In the pia mater of the spinal cord the nerves are more abundant than in any other part of the cerebral membranes; they run singly or in bundles of two and three; others contain from thirty to fifty filaments. Sometimes fibres leave the bundles, forming loops and returning to the same or to a different bundle. The largest bundles are situated near the anterior spinal artery, which they entwine; and some pass from this into the process of the dura mater in the anterior fissure, and form loops in the same. Other large bundles, running mostly in a longitudinal direction, are situated near the ligamentum dentatum and posterior median line of the cord. Near the origins of the spinal nerves the bundles of sympathetic fibres are not so numerous and are also smaller. Some of these fibres spring from the cerebro-spinal nerves, and enter with the arteries through the intervertebral foramina. In the peritoneum nerve-fibres have been described by Bourgery* as existing in considerable numbers. They have also been observed by Luschka.† Nerve-fibres are also abundant in the periosteum, both that which invests the shafts of the bones and the articular extremities of the same, as shown by the observations of Pappenheim.‡ They are chiefly situated in the outer part of the membrane, and either run in company with the vessels or are situated upon them. They terminate in loops. Nerves also exist, according to the same author, in the cellular tissue which surrounds the ligaments, penetrating these along with the arteries, and terminating in a series of plexuses and loops. In the tendons they are also sometimes present. Wherever (according to Pappenheim) vessels pass to ligaments or tendons, nerves pass also.

Development. — In the cow's embryo of $8\frac{1}{2}$ lines in length, the gangliated cord of the sympathetic in the thorax was observed, by Kiesselbach §, on either side of the spinal column in the form of a thick cord, presenting numerous inequalities. In the pig's embryo, eight lines in length, it presents, according to Valentin, the same aspect. It seems, at this period, to consist of a series of small ganglia placed almost in juxta-position to each other, the interval between the individual ganglia not being very distinct. In another embryo, measuring about thirteen lines in length, Bischoff found the gangliated chain distinctly formed, not only in the thoracic, but also in

the cervical region: the superior cervical ganglion presented the aspect of a small round nodule. In the cow's embryo, measuring about $1\frac{1}{2}$ inches in length, I found the ganglia in the cerebral and spinal nerves, as well as those of the sympathetic, very distinct. The superior cervical ganglion of the sympathetic appeared as a small reddish grey mass, of an irregularly oval form, measuring about $\frac{1}{25}$th of an inch in its longest diameter, soft and breaking down readily. It was situated close to the pneumogastric, a narrow indistinct whitish line passing downwards from the lower part of the ganglion to that nerve. The lower cervical ganglion presented a more elongated form, and appeared to be prolonged into the first thoracic: the other thoracic ganglia appeared as minute greyish particles between the heads of the ribs, and measuring about $\frac{1}{30}$th of an inch in diameter. The ganglia in the lumbar and sacral regions presented in general a more elongated form, and were not so distinctly separated from one another: the connecting cord, especially in the sacral region, being short and thick, and looking as if it were a prolongation of the one ganglion into the other. None of the branches which are sent inwards from the sympathetic cord, nor the ganglia occurring upon them, could be accurately distinguished from the surrounding structures. As regards the ganglia occurring on the cerebral and spinal nerves, they were much more distinct than those of the sympathetic. The Gasserian ganglion presented the form of a greyish white body, situated beneath the still soft and transparent dura mater: it measured about $\frac{1}{15}$th of an inch in diameter, and presented an irregularly oval or triangular shape. It appeared to consist of several opaque portions, separated from one another by an intermediate more or less transparent substance, thus presenting the appearance of being composed of several minute lobules. The ganglia on the posterior roots of the spinal nerves were also very distinct: they were arranged along the interior of the spinal canal, on each side, and rather anteriorly towards the bodies of the vertebræ, and concealed by the spinal cord. They presented an oblong or oval shape, measured about $\frac{1}{25}$th of an inch in length and about $\frac{1}{30}$th in breadth, and presented the same characters in regard to colour, &c., as the Gasserian ganglion.

Fig. 297.

Sixth thoracic ganglion of the left side, from the sympathetic of a Rabbit, treated with soda, and magnified forty diameters.

Tr, main cord of sympathetic; Rc, Rc, communicating branches, each dividing into two portions; Spl, splanchnic nerve; S, small nerve proceeding probably to the blood-vessel; G, ganglion-cells and fibres, passing into the main cord of the sympathetic. (*After Kölliker.*)

In embryos from seven to eight inches in length, the superior cervical ganglion presents the same oval shape and reddish grey appearance as before: it is larger, however, measuring about $\frac{1}{12}$th of an inch in its long diameter: it consists, as before, of a number of opaque round or oval portions: the intermediate substance exists in much smaller quantity. It is surrounded by a highly vascular sheath. From its lower part the communicating cord is seen passing downwards for a short distance, when it is applied to the trunk of the pneumogastric. The cord presents a flattened aspect, and is of a greyish red colour. The ganglia in other regions of the body, as well as the intermediate cord, are well formed, and much larger than before. The first sacral ganglion of either side appears to be amalgamated into a single ganglion situated in the medial line.

The splanchnic nerves and solar plexus, as well as its offsets, are distinctly visible. The rami communicantes are also present; so also the plexus on the abdominal aorta and epigastric plexuses. The ganglia on the cerebral and spinal nerves present the same characters as before, with the exception that they are considerably larger.

In embryos measuring seventeen or eighteen inches in length, not only can the parts which have been already mentioned be distinctly seen, but also most of the peripherical branches of the sympathetic. The superior cervical ganglion presents, as before, a more or less oval shape, and measures about $\frac{1}{6}$th of an inch in its long diameter. It has still the appearance of being composed of a number of round or oval opaque greyish-white masses: there appears, however, to be very little of the intermediate transparent substance present. Its sheath is very vascular, and numerous vessels also pass into the interior of the ganglion between its lobules: it is possessed of considerable consistence. Its branches of communication with the different nerves are also distinctly seen: they have a more or less greyish red appearance. The lower cervical ganglion presents an irregularly oblong shape, about $\frac{1}{5}$th of an inch in length and $\frac{1}{10}$th of an inch in thickness, and still has the appearance of being prolonged downwards into the first thoracic ganglion. The thoracic ganglia are much smaller, measuring about $\frac{1}{10}$th of an inch; and are more or less triangular in shape, presenting the lobulated aspect above described. The connecting cord between the different ganglia has a reddish grey colour, is flattened, measuring about $\frac{1}{25}$th of an inch in breadth, and presents the appearance of consisting of distinct bundles of fibres. A portion of these can be traced over the surface of the ganglia, others appear to sink into them, while a considerable number can be traced into the rami communicantes. The latter are very distinct; some of them in the thoracic region appear to be almost as thick as the cord of the sympathetic itself, and all of them present the same greyish red appearance. On turning inwards to the sympathetic, many of their fibres are seen to be prolonged into the main cord of the sympathetic, and merely run along the sides of the corresponding ganglia: these pass both upwards towards the head, and downwards in the direction of the pelvis. They join the spinal nerves at the point where the anterior and posterior roots become united into a common trunk. By far the greater portion of the fibres in the rami communicantes run inwards towards the spinal cord.

The splanchnic nerve, which is about $\frac{1}{4}$th of a line in thickness, has a whiter aspect than the main cord of the sympathetic.

The nerves on the surface of the heart are very numerous and distinct, presenting the same arrangement as has been already described. The cœliac and epigastric plexuses are also large; the latter containing several ganglia. There are also several small ganglia in the plexus upon the abdominal aorta.

The ganglia on the cerebral and spinal nerves present much the same appearance as those in the animal after birth, only they are softer and have a redder colour.

As regards the development of the sympathetic in the human subject, it would appear from the observations of Lobstein*, that in the embryo of the 14th week, about three inches in length, the main cord of the nerve was very apparent. In the chest it constituted a thick cord of a red colour, the ganglia being closely approximated towards one another. The superior cervical ganglion was very well formed, and about two lines in length, and half a line in thickness. The great splanchnic nerve existed as a very delicate filament: the semilunar ganglia were almost imperceptible.

In an embryo male, about five months, old and measuring six inches in length, Lobstein found the trunk of the sympathetic very distinctly developed. It constituted an uninterrupted cord extending from the base of the cranium to the pelvis. The superior cervical ganglion was rounder than in the adult: it was three lines in length, and about half a line in thickness. The greater splanchnic nerve was very distinct, but very delicate, and arose by three roots. The semilunar ganglia were small, indistinct, and measured only about half a line in their greatest diameter. They were adherent to the supra-renal capsule and to the vessels. The thoracic ganglia, with the exception of the first, constituted little enlargements about half a line thick. According to Kiesselbach, the solar ganglia do not make their appearance until about the 7th month. At the 5th month, he found the ophthalmic and submaxillary ganglia formed; and about the 6th month, the spheno-palatine ganglion appears; and in the 5th month, according to the same author, the communicating branches between the sympathetic and cerebro-spinal system appear.

In the fœtus of eight months, the superior cervical ganglion, according to Lobstein, measures about five lines in length, and a line and a half in breadth. The greater splanchnic nerve is very distinct, but very fine, and terminates in an imperfect semi-lunar ganglion.

In the fœtus, at the full period, the superior cervical ganglion, according to Lobstein, measures about $8\frac{1}{2}$ lines in length, and furnishes four filaments to the branches of the external carotid, while a fifth is lost on the crico-thyroid artery. The thoracic ganglia are well formed, and measure about a line in diameter, with the exception of the first, which measures about 5 lines. They are of a red colour; and nearly all of them receive two branches from the intercostal nerves. The trunk of the sympathetic is very thick; the interval between the ganglia is about $\frac{1}{5}$th of a line. The lumbar ganglia are very apparent. The semilunar ganglia are of small size compared with the other ganglia. Lobstein failed to find the coccygeal ganglion in the child immediately after birth; according to Kiesselbach, on the other hand, it appears about the fifth month.

A, ganglionic corpuscles from the Gasserian ganglion of a calf $1\frac{1}{2}$ inch in length; B, nerve-fibres from the same; C, from one of the thoracic ganglia of the sympathetic in the same animal.

With respect to the minute structure of the ganglia and nerves in the fœtus, the Gasserian ganglion in the fœtal calf, $1\frac{1}{2}$ inch in length, consists of the following elements: 1st, bodies measuring from the $\frac{1}{4000}$th to the

* De Nervi Lympathici humani fabricâ, usu, et morbis, cap. iii. p. 47.

$\frac{1}{3500}$th of an inch in diameter, and presenting a slightly granular surface (most of them are round; others have more or less an oval shape); 2nd, distinct cells measuring from the $\frac{1}{2000}$th to the $\frac{1}{1200}$th of an inch in diameter: they contain a finely molecular fluid, and also a nucleus. The latter, which is frequently situated towards one side of the cell, is round and granular, and generally contains a nucleolus. With the exception of their smaller size, they resemble ordinary ganglionic corpuscles. The nerves in the ganglion present the aspect of flattened bands of blastema, consisting almost entirely of corpuscles resembling those first described, arranged close together in linear series in a somewhat granular matrix. They vary in breadth considerably. The ganglia on the posterior roots of the spinal nerves present the same structure.

The sympathetic ganglia appear to be entirely composed of structures similar to those first described, imbedded in a more or less granular transparent blastema.

In embryos of 6 to 8 inches in length, the sympathetic ganglia still contain a large number of corpuscles similar to those in earlier embryos. There are also present a number of bodies larger than these, and consisting of a distinct cell-wall inclosing, besides a nucleus, a finely-granular fluid. They are commonly round; some are more or less egg-shaped. The nucleus in the latter is generally situated towards the wider extremity of the cell, while its narrow end is prolonged into a delicate, granular process about the $\frac{1}{5000}$th of an inch in breadth. The nerves in the ganglia do not differ much in appearance from those in the Gasserian ganglion of the embryo of $1\frac{1}{2}$ inches in length. The sympathetic cord and branches present the same structure. In the ganglia of the cerebro-spinal nerves, the ganglionic corpuscles are larger and more distinctly formed than in the sympathetic ganglia. Many of the cells have processes similar to those above described; and in several of these, at a short distance from the corpuscle, there is a small oval nucleus such as Kölliker describes in the human embryo of 16 inches. The nerves belonging to the cerebro-spinal system are also much further developed than those in the sympathetic. Those in the brachial plexus present the appearance of being composed of a slightly-granular transparent blastema, marked by longitudinal striæ, and containing embedded in it oval granular nuclei. The striæ are arranged parallel to one another, and evidently correspond to the margins of the nerve-fibres. The nuclei are arranged at intervals, and occupy the entire breadth of the fibres. There is no trace of the white substance of Schwann.

Fig. 299.

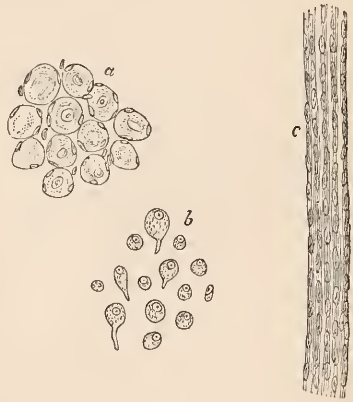
Fig. 300.

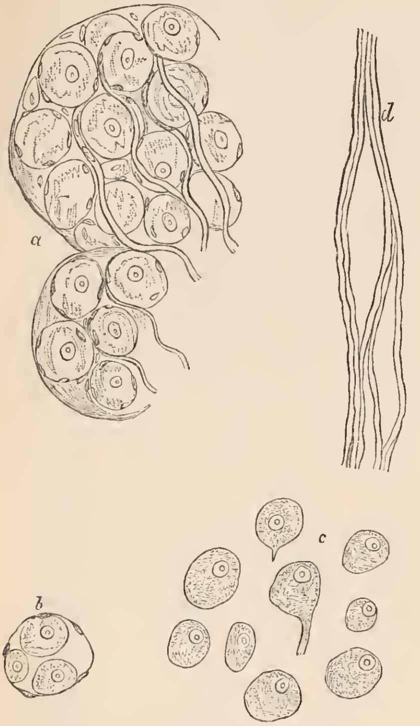


From the semi-lunar ganglion of a Calf 18 *inches long.*

a, portion of ganglion; *b*, corpuscles isolated; *c*, nerve-fibres connected with the ganglion.

In the sympathetic ganglia of embryos measuring 18 or 19 inches in length, there are still present a considerable number of granular corpuscles measuring from the $\frac{1}{4000}$th to the $\frac{1}{2500}$th of an inch in diameter, similar to those already described. They are chiefly composed, however, of cells resembling those in the ganglia after birth, only smaller and more delicate. The nerve-fibres in the ganglia have much the same appearance as those already described in the brachial plexus of embryos from 6 to 8 inches in length. In the ganglia occurring on the posterior roots of the spinal nerves, the Gasserian ganglion, and the ganglion on the trunk of the pneumo-gastric, the ganglionic corpuscles differ from those in the perfect animal only in point of size. Most of the nerve-fibres connected with the ganglia present the same tubular character as the perfect nerve-fibre. The nerve-fibres in the roots of all the cranial nerves present the distinctly tubular character also ; in those of the 3rd, 4th, and 7th, the double contour is more

Fig. 301.



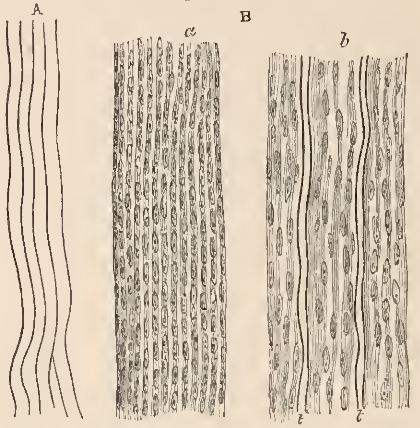
From the Gasserian ganglion of the same animal as the preceding figure.

a, portion of ganglion with corpuscles *in situ*; *b*, three corpuscles included within a single capsule; *c*, ganglionic corpuscles freed from their capsules; *d*, nerve-tubes connected with the ganglion.

or less distinctly visible. The optic nerve consists of fine tubular fibres mingled with small round or oval bodies. The nerve-fibres in the brachial plexus also present the character of perfect tubular fibres; they are narrower than in the adult animal. So also the fibres in the trunk of the pneumogastric; throughout the entire extent of the trunk of this nerve, in the neck and upper part of the thorax, there were embedded amongst its fibres ganglionic corpuscles similar in their character to those occurring in the ganglia of the cerebro-spinal nerves. Sometimes a single corpuscle lay imbedded in a bundle of nerve-fibres; in other parts two were seen, one situated above the other; and in some parts there were as many as six, all arranged close together in linear series; some of them were seen to give off a nerve-tube at one extremity; and once or twice the corpuscle was seen to be connected with two such, one passing towards the centre, the other in the direction of the periphery.

The main cord of the sympathetic appears to be entirely composed of fibres presenting the nuclear character, similar to those already described in connection with its ganglia, and representing an early stage of the development of the cerebro-spinal nerve-fibres. Addition of dilute solution of soda brings into view a few tubular nerve-fibres similar to those in the spinal nerves. The splanchnic nerves present the same structure as the cord of the sympathetic, containing a few tubular nerve-fibres, but being chiefly composed of the other structures. In one of the nerve-filaments from the surface of the right ventricle of the heart,

Fig. 302.



A, nerve fibres from the brachial plexus of a Calf 18 inches long. B. *a*, nerve-fibres from the sympathetic cord in the thorax; *b*, the same treated with dilute solution of soda, showing the presence of tubular nerve-fibres, *t t*, similar to those in the cerebro-spinal nerves.

there were no tubular nerve-fibres present; it consisted entirely of structures similar to those already described. As regards the communicating branches, all of them contained more or fewer tubular nerve-fibres ; some appeared to be entirely composed of these, while others consisted chiefly of the partially-developed nerve-fibres. The difference in point of structure between the fibres in the cerebro-spinal nerves and those occurring in the sympathetic is at this period of embryonic life very remarkable : while the former present for the most part the tubular character of the perfectly-formed nerve-tube, the latter appear to consist of a mass of blastema with numerous granular nuclei imbedded in it, corresponding, in short, to the fibres of the cerebro-spinal system in the fœtus measuring 6 to 8 inches in length. This also applies, though perhaps in a less degree, to the ganglia of the sympathetic as compared with those on the cerebro-spinal nerves, the latter being more fully developed, both as regards their ganglionic corpuscles and nerve-fibres, than the former.

As regards the further development of the nerve-fibres of the sympathetic, it would appear, from the observations of Volkmann and Bidder, that they undergo little further change during the whole period of embryonic life.

At least, in embryos near the full time, they observed little change in the sympathetic nerve-fibres.

It has been already stated that in the sympathetic of embryos of 18 or 19 inches in length there are some tubular fibres present; these, probably, are to be regarded as fibres sent from the cerebro-spinal system.

PHYSIOLOGY.—The actions which take place in the animal body may be divided into two classes. Those which are included in the one class are entirely under the guidance of volition; those which belong to the other not only take place independently of any effort of the will, but are also more or less completely removed beyond its control. The movements which occur in the muscles of the limbs, and in most of the muscles of the trunk, form examples of the former; while the movements of the internal muscular organs, such as those of the heart, intestinal canal, and genito-urinary organs, afford examples of the latter. To the latter also belong the acts of nutrition, secretion, &c., commonly termed the vegetative processes. Several of the latter, as the movements of the heart, go on without interruption during the entire life of the individual; while others, as the movements of the intestinal canal, take place at irregular intervals, depending apparently on the application of external stimuli to the free surfaces of the organs in which they are manifested. The exercise of the former class of actions is moreover attended by sensation; that of the latter, in the normal condition, not. The impressions which are constantly being made by the blood upon the inner surface of the heart and vessels never reach the sensorium; we are also insensible to the impressions made by the food upon the free surface of the intestinal canal, as well as to the contractions thereby induced. In like manner, the acts of nutrition and secretion take place entirely without our knowledge. The feeling of weariness also which ensues after exertion of the voluntary muscles, is never felt so far as the heart is concerned, although its action is constant, and just as little in regard to the other organic muscles.

The organs in which the former class of actions takes place are supplied with nerves which proceed directly from the brain and spinal cord; those whose actions belong to the second class derive their nerves chiefly from the sympathetic.

Guided by this difference in character between the vital phenomena, Bichat divided life into animal and vegetative; the former characterised by the circumstance of its phenomena coming within the range of sensation and volition; the latter including those acts which are more or less completely removed beyond the sphere of the will and of the consciousness. In accordance with this division, he also separated the nervous system into two portions: the one corresponding to the cerebro-spinal system, presiding over the functions of animal life; the other corresponding to the sympathetic, presiding over the involuntary movements, and over the processes of nutrition and secretion, or functions of vegetative life. The sympathetic and its ganglia are, according to the views of Bichat, entirely independent of the cerebro-spinal system of nerves. The various ganglia of the sympathetic he regarded as so many distinct nervous centres, each presiding over the actions of the parts to which it sends nerve-filaments, and each discharging its functions without any relation to the brain or the spinal cord. The involuntary nature of the processes which take place in organs supplied by the sympathetic, as well as the circumstance that the normal impressions which are made upon the free surfaces of these do not reach the sensorium, rendered the views of Bichat highly probable. In diseases of the brain and spinal cord, as in tetanus and chorea, where the muscles supplied by cerebro-spinal nerves are all thrown into a state of more or less violent contraction, the muscular organs which derive their nerves from the sympathetic, such as the heart, continue their movements as before. So also a stimulus applied to the brain or spinal cord, causes contractions in the muscles which derive their nerves from these parts, but does not, according to Bichat, produce any effect on the movements of parts which are supplied by the sympathetic. The fact that embryos in which the central masses of the nervous system are wanting may reach an advanced stage of development, showed that the processes of vegetative life might go on perfectly, independently of the influence of the cerebro-spinal system, while the circumstance that in these the sympathetic system of nerves was always present, and in a high state of development, seemed at the same time to indicate the connection subsisting between it and the processes in question.

The views of Bichat were generally adopted by physiologists until comparatively recent times, when they were ably combated by Valentin, who endeavoured to establish the doctrine, commonly held before the time of Bichat, that the sympathetic and cerebro-spinal nerves do not constitute two distinct and independent systems, but that the former is dependent upon the latter for all its properties, and is in this respect to be regarded as one of the cerebro-spinal nerves. The involuntary and apparently spontaneous nature of the movements which take place in organs supplied by branches of the sympathetic, affords no argument, according to Valentin, for supposing that their action is not regulated by the brain and spinal cord, or that the sympathetic is independent of these parts of the nervous system, inasmuch as the same character is also presented by the movements of certain organs which are undoubtedly supplied by cerebro-spinal nerves. This, for example, is the case with the rhythmical movements of the muscles of respiration. Again, there are organs which are supplied by nerves of cerebro-spinal origin, and which notwithstanding resemble the organs supplied by the sympathetic in the circumstance that the normal impressions which are made upon them do not reach the sensorium. Thus, the greater part of the mucous membrane which lines the bronchial tubes, as well as that of the œsophagus, receives its nerves from the eighth pair; the lacrymal glands receive filaments from the fifth nerve ; and from the fifth and seventh nerves fibres are distributed to the salivary glands : and yet all these organs present the same relations in regard to sensibility as the pancreas or other glands which derive their nerves from the sympathetic. The fact of certain parts being beyond the control of the will, and from which the ordinary impressions they receive are not conveyed to the sensorium, does not so much depend on any peculiarity in the nerves with which they are supplied, as upon their anatomical constitution. Such is the case, for example, with the muscular fibres presenting the same characters as those which are found in the walls of the ducts of the various glands, as well as with those which are present in the coats of the blood and lymphatic vessels. That the impossibility of influencing these structures by any effort of volition, as well as the fact of their being removed from the sphere of sensation, do not depend on any peculiarity in the properties of their nerves, is shown, Valentin says, by the fact that the greater part of the nerves for the salivary glands are derived, as above stated, from the fifth and seventh cerebral nerves. The same thing also holds true, according to him, of the mammary glands, the nerves supplied to which proceed chiefly from the supra-clavicular and intercostal nerves. As regards the argument which is drawn in favour of the views of Bichat, from anencephalous fœtuses, Valentin remarks that there is no evidence to show that in the development of the various organs in the fœtus nervous influence is at all concerned ; and, moreover, that the phenomena of growth and nutrition are not dependent on the sympathetic is shown by the circumstance of few or no sympathetic fibres being sent to the extremities. The sympathetic is moreover capable of transmitting stimuli to and from the cerebro-spinal centres, in the same manner as the ordinary nerves arising from these, though in a less degree; stimulus applied to the spinal cord being capable of exciting contractions in the heart and intestinal canal, while on the other hand stimuli applied to the latter may also be transmitted to the former. This is shown by the severe pain which is felt in organs supplied by the sympathetic, when affected with disease, as well as by the circumstance that irritations of the intestinal canal not unfrequently give rise to contractions in the muscles of animal life : as is not unfrequently the case with children, when the presence of worms in the intestinal canal gives rise to impressions which are conveyed along the centripetal nerves to the spinal cord, and are there transferred to the motor nerves which pass to the voluntary muscles, exciting them to contractions. As already stated, Valentin believes that all the true nerve-fibres which are present in the sympathetic, are derived from the brain and spinal cord ; on entering the sympathetic they pass through a greater or smaller number of its ganglia, and are then distributed to the different organs, in the same way as the ordinary cerebro-spinal nerves. The sympathetic is therefore, according to him, a cerebro-spinal nerve, possessed of the same properties, and deriving these from the same source as the other cerebro-spinal nerves ; the only peculiarities in the sympathetic being its numerous points of origin, as well as the large number of ganglia which it presents. Similar views are also held by Longet*, and others.

After the discovery of the gelatinous fibres in the sympathetic, it was held by some, that while motion and sensibility in the organs supplied by this nerve depended upon the tubular nerve fibres sent to them through the medium of the branches of the sympathetic by the brain and spinal cord, the processes of nutrition depend upon the gelatinous or proper sympathetic fibres. Moreover, as these fibres are found in the cerebro-spinal nerves also, it is supposed that they pass to the extremities along with the cerebro-spinal nerves, where they in like manner preside over the nutrition of these parts. According to these authors, the ganglia are so many centres, from which nerve fibres, possessing peculiar properties, pass off in different directions ; some to the viscera, others to the extremities, along with the cerebro spinal nerves, and by means of which the nutritive processes are regulated. Thus, while the internal viscera receive sensory and motor nerve fibres from the brain and spinal cord, they, as well as the organs of animal life, receive the nerve fibres which regulate the nutritive processes from the sympathetic. Such seems to be the view of Remak †, R. Hall ‡, and others.

Volkmann § adopts the same view as was held by Bichat, regarding the sympathetic as constituting a system of nerves distinct from and independent of the cerebro-spinal system. Under the term sympathetic, he includes not only the sympathetic, commonly so called, but also the ganglia which occur on the posterior roots of the spinal nerves, as well as those which are present on several of the cerebral nerves. All the finer nerve fibres are regarded by him as sympathetic fibres. These originate in the different ganglia ; some of them pass inwards to the viscera, over whose movements and nutrition they preside, while others pass along with the cerebro-spinal nerves to the extremities, and serve as the nerves of nutrition to these parts. Each of the ganglia he regards as a nervous centre.

‡ Edinburgh Medical and Surgical Journal, July, 1846, &c.

§ Wagner's Handwörterbuch der Physiologie Zehnte Lieferung, p. 499.

By the term centre, Volkmann seems to mean an organ which serves as a regulating apparatus, and by which several separate and simple acts are combined into a single complex organic act. The contraction of a muscle is a simple act; in the act of respiration we have the contractions of many muscles combined into a single complex act, their combination being dependant on a power situated in the medulla oblongata, which part of the nervous system is therefore termed their central organ. The question then in regard to the independence of the sympathetic is, whether, in the sphere of the organic nerves, there be such combinations, and whether these have their centre in the brain and spinal cord, or in the sympathetic. The brain is the centre of all psychical acts; it is therefore evident that the sympathetic, in so far as regards all the phenomena of sensation occurring in its sphere, must be regarded as dependent on the brain. But after the brain and spinal cord have been destroyed, does the sympathetic still remain active, and in such a state of activity as implies the co-operation of a central organ? Muscular motion implies the activity of the motor nerves, and the activity of those muscles which are supplied by the sympathetic must imply the activity of sympathetic nerve fibres. The action of the heart, however, as well as the circulation, sometimes continues for weeks after the destruction of the central masses of the nervous system. Thus Bidder removed with great care the arches of the second cervical vertebra, so that little blood was lost during the operation, and then completely destroyed the spinal cord. Frogs treated in this way often lived six weeks, sometimes ten, the circulation, as seen in the web of the foot, remaining at the same time active, and not differing from that in uninjured frogs. The heart beat powerfully and quickly: in a freshly-killed frog, in winter, the heart pulsated thirty-five times in the minute; while in a frog, the spinal cord of which had been destroyed twenty-six days previously, the pulsations were forty per minute. When the brain and spinal cord were destroyed, the medulla oblongata being left, frogs were retained in life until the sixth day; and when the entire central organs of the nervous system were removed, they lived until the second day; the rapidly ensuing death in the latter case being due, according to Volkmann, to the effects produced upon the respiration. Within a few weeks after the destruction of the spinal cord the muscles of animal life were found to have lost their irritability in a marked degree, and still later no contraction could be produced in them by application of chemical or mechanical stimuli; the heart, however, in such cases still continued to pulsate eleven times in the minute, and retained its property of responding to external stimuli. The intestinal canal, in like manner, retained its irritability; application of stimuli giving rise to contractions which were sometimes of a local nature, at other times extended for a considerable distance on either side of the part stimulated. Digestion, in like manner, suffers but little from destruction of the central parts of the nervous system; healthy frogs, and others, which had been operated upon, were, after being starved for a considerable time, fed with worms, and kept in separate glasses. In the one, as well as in the other, the worms were found after twenty-four hours to be fully digested, and the stomach and duodenum were filled with coloured mucus; such was observed to be the case even in animals whose spinal cord had been destroyed twenty-six days previously. The secretion of urine also continues: when in animals in which the brain or spinal cord had been removed, the bladder was emptied by external pressure upon the walls of the abdomen, in a short time it again became filled and distended to an enormous size, unless emptied in the way just mentioned. It had been observed by Valentin and Stilling that after destruction of the spinal cord in the frog, different derangements in the nutritive processes ensued; there were frequently observed dropsical swellings, especially of the limbs. On these also, sores formed, which often penetrated as far as the bones. In reference to these results, Volkmann states that they are, as shown by Bidder, chiefly accidental. Bidder found that when the bottom of the vessels in which the frogs were kept was covered, not with water, but with moist grass or moss, no such degenerations ensued. The rapid death which ensues in warm-blooded animals, when operated upon in the above manner, depends, according to Volkmann, upon the difficulty of sufficiently keeping up the respiration by artificial means, as well as upon the loss of blood and diminution of animal heat. The circumstance, then, that a certain number of the vital phenomena disappear suddenly and irrevocably after destruction of the spinal cord and brain, while others continue for a greater or shorter time, and this very perfectly, can only depend, according to Volkmann, upon the circumstance that the brain and spinal cord is a necessary condition for the existence of the former, but not for that of the latter. If the latter depend upon certain nervous organs, and if the nerves of the vegetative organs do not require, as a fundamental condition of their activity, the presence of the brain and spinal cord, the only possible centres on which they can depend for this are the ganglia of the sympathetic. The sympathetic and its ganglia, then, constitute, according to Volkmann, an independent whole, from which proceed the impulses to as well as the regulation of those actions which continue after the brain and spinal cord have been destroyed, and which notwithstanding require the co-operation of a central organ. That the movements in question require such an organ, and are not produced by the mere stimulus of the blood, fæces, air, &c., in the same way as the twitchings of the muscles in a frog's leg are produced by galvanism, is shown, according to Volkmann, by the different characters exhibited by the two. When stimulus acts immediately on motor nerve fibres, contraction ensues only in that muscle or part of the muscle to which these are distributed; when it affects the whole trunk of such a nerve, many muscles are excited to contraction; the contraction so produced, however, is a mere quivering, quite different from the combined and plan-like movements of the muscles of respiration, &c., or those reflex movements which are produced artificially. In these, there is a certain unity and plan, in the others not; the difference depending on the circumstance that in the one a regulating principle associates the muscular movements for the attainment of an organic object or purpose; in the others this does not take place. When the regular and plan-like manner in which the pulsations of a heart removed from the body take place, is compared with the tumultuous and purposeless quiverings of a diaphragm similarly circumstanced, it is hardly possible to suppose that the two kinds of movement proceed from the same principle. Irritability acted on by the stimulus of the blood, or air, might explain the mere contraction of the heart; the regular order, however, in which this takes place, implies the existence of a regulating principle; and a regulating principle implies the existence of a regulating apparatus. While the regular movements of the voluntary muscles suddenly cease when the brain and spinal cord are destroyed, those of the organic muscles continue; and hence their regulating apparatus cannot lie in the brain and spinal cord, and can only, therefore, be situated in the ganglia of the sympathetic.

The heart, according to Volkmann, is more flabby after death than it is during life: the intestines, in like manner, are collapsed in the dead body, and appear like so many flattened bands; while in the living body, at least in small animals, they present more the aspect of tubes; the looseness of the skin and of the scrotum in the dead body is also remarkable, compared with the appearance they present in the living. These differences depend upon a loss of tone. The tone of the involuntary or organic contractile structures does not, however, depend on the brain or spinal cord, inasmuch as it does not cease after these parts have been destroyed, but may continue in the amphibia at least for months thereafter. It depends, according to Volkmann, upon the sympathetic; and from this he derives another argument in favour of the view that the activity of the sympathetic or ganglionic nerve-fibres does not depend upon the brain or spinal cord. After division of a motor nerve, the muscles immediately became relaxed, which shows, according to him, 1st, that the tone depends on an active contraction of the muscle; 2nd, that the mere irritability of the muscle is not alone sufficient for the restoration of this contraction, but also requires an exciting cause or motor impulse; 3rd, that the nerve conveys this motor impulse to the muscle; 4th, that the place where this motor impulse arises or originates is not the nerve itself, but is a central organ. If now, after destruction of the brain and spinal cord, the tone in the organic muscles and many other contractile tissues continues, it follows from this that, besides the brain and spinal cord there must still be another centre from which motor impulses proceed, and this can only be the ganglia of the sympathetic.

In regard to this question, so far as our knowledge of the anatomical constitution of the sympathetic extends, the most probable view would seem to be that it is partly independent, in its action, of the brain and spinal cord, partly dependent. The circumstance that there are present in its branches numerous nerve-fibres which are derived from the brain and spinal cord, would appear to indicate that the organs to which such fibres proceed must be to a certain extent influenced by the central masses of the nervous system. From the circumstance, however, that it probably contains other nerve-fibres which do not arise in the brain and spinal cord, and more particularly from the circumstance of gray nervous matter being present in different parts of its extent, it seems not unreasonable to suppose that the influence which it exercises over the parts to which it is distributed originates, partly at least, not in the brain or spinal cord, but in the gray or ganglionic matter mentioned. If we attribute to the gray matter of the brain or spinal cord a certain property of originating nervous force, it seems unreasonable to deny similar properties to the gray matter occurring in other parts of the nervous system. Whatever properties are possessed by the one, analogous properties are, it is to be expected, possessed by the other. Besides, no other hypothesis which has been proposed to account for the function of the ganglia appears to harmonise so closely with known facts as that which regards them as so many distinct peripherical nervous masses endowed with properties similar to those which are commonly attributed to a nervous centre.

Properties of fibres of sympathetic. Sensory properties.— In regard to the sensory properties of the sympathetic, different statements are made by authors. Bichat, Magendie, Dupuy,* and others, observed that section of the branches of the sympathetic was attended with few or no signs of pain. Dupuy states that he has removed the superior cervical from the horse without the operation appearing to call forth any marked expression of pain. Section of the sympathetic cord in the neck may often be performed in the rabbit without any indication of sensibility being given. Haller found, on the other hand, that irritation of the hepatic plexus in the dog gave rise to distinct signs of pain: the same results were also obtained by Meyer from irritation of the solar plexus. When he made incisions into the superior cervical ganglion, he found, contrary to what had been observed by Dupuy,

* See Longet. op. cit. tom. ii.

that clear indications of pain were elicited. From ligature applied to the renal nerves, as well as from the application of chemical or mechanical stimuli to the semilunar ganglia, animals suffered great pain. So, also, Flourens* found that on irritating the semilunar ganglion in dogs the animals exhibited distinct signs of pain, and the same results were obtained by Brachet †, from irritation of the thoracic ganglia. Frequently, according to Brachet, stimuli, when first applied to a part of the nerve, do not give rise to pain; afterwards, however, when the part has been exposed to the air for some minutes, if irritation be now applied distinct signs of pain are elicited. Longet ‡, in like manner, found that on irritation of the semilunar ganglia the animal almost invariably exhibited indications of more or less pain being produced. In other animals, where the lumbar ganglia were subjected to experiment, he found, like Brachet, that it was only after prolonged irritation that signs of pain were evinced. So, also, according to Valentin §, when the cavities of the thorax or abdomen are opened as quickly as possible, and pressure applied to the semilunar ganglion, to the splanchnics, or to any other branch of the sympathetic, sometimes no signs indicative of sensibility are evinced. When, however, they have been exposed to the air for a short time they generally exhibit these properties in greater or less degree. The severe pain which frequently attends *diseases* of parts supplied exclusively by the sympathetic nerve, also affords still better evidence than can be derived from experiments of the existence of sensory nerve fibres in the sympathetic.

Different parts of the nerve appear to exhibit the property of sensibility in different degrees. In regard to this point, Valentin ‖ gives the following as the results of his experiments. 1st. The very grey branches which have passed through several ganglia do not, when the stimulus applied to them is slight, give rise to any signs which would indicate that pain was produced. Such branches are those which pass along the mesentery to the intestine; strong stimuli, however, such as the application of a ligature or of chemical irritants, cause, when applied even to these branches, distinct signs of pain. 2nd. Irritation of the ganglia themselves is followed by signs of pain either immediately or after a short time. 3rd. The connecting cord of the sympathetic is similarly circumstanced in regard to sensibility as the ganglia. 4th. The rami communicantes are as highly endowed with sensibility as the posterior roots of the neighbouring spinal nerves. He found that section

‖ Op. cit. band ii. p. 422., as quoted by Longet.

of a communicating branch did not destroy the sensibility of the corresponding ganglion: the main cord of the sympathetic must also be divided above and below the ganglion before this ensues. In the lumbar region Brachet* found that, when the communicating branches of three successive ganglia were divided, the central ganglion was deprived of its sensory properties. The greater the number of ganglia intervening between the point of the branches of the sympathetic, to which the irritant is applied, and the cerebro-spinal centres, the less distinctly, according to Valentin, does it give rise to signs of pain. Hence, the peripheral branches are the least sensitive, while the rami communicantes are the most highly endowed with this property, the connecting or main cord of the sympathetic and ganglia being intermediate in this respect between these two. The nature of the stimulus applied has also an influence on the results produced: when the ganglia are merely pricked, or their branches quickly divided, sometimes no sign of sensibility is evinced, whereas pressure, application of nitric acid or potash to the same parts give rise to distinct expressions of pain.

In regard to the experiments which are made with a view to ascertain the sensory properties of this nerve, it is to be observed that in general it is only by application of very powerful stimuli that the phenomena of sensibility are elicited: they seem to act by producing a more or less abnormal condition in the part of the nerve to which they are applied, and hence the effects they produce may be regarded as belonging to the same category as the phenomena observed in diseased conditions of the organs supplied by this nerve. In the normal or healthy condition the fibres of the sympathetic seem to be almost entirely destitute of the property of communicating impressions to the sensorium. We do not know, as Volkmann observes, whether the organic muscles be at rest or in motion; whether the glands secrete in larger or in smaller quantity; whether the gall-bladder be full or empty. We are sensible of the impressions made by the particles of food so long as they remain in the mouth, but, as soon as they reach the stomach or intestinal canal, we are no longer aware of their presence.

Motor properties.—That the sympathetic contains motor nerve fibres there can be no doubt; irritation of its branches being followed by movements in the different muscular organs to which they are distributed. Thus irritation of the splanchnic nerves in the living animal, or immediately after death, is generally followed by more or less extensive contractions in the small intestine. Müller observed that the same result followed irritation of the semilunar ganglion: the same observation has also been made by Kürschner.† Mechanical or chemical irritation, but especially galvanic

* Op. cit. p. 360., as quoted by Longet.

† Abhandlungen über das Nerven System, von M. Hall. Aus dem Englischen von D. C. Kürshner, Marburg, 1840, Nachtraege, p. 182.

stimulus applied to the filaments of the sympathetic which pass to the heart, have the effect of accelerating the pulsations of that organ and of exciting it to renewed contraction after it has ceased beating. As movements very frequently arise in organs supplied by the sympathetic, especially in the intestines, spontaneously, at least under the stimulus of the atmospheric air, it is sometimes difficult to determine whether the contractions which follow the application of a stimulus to any of the nerves be really caused by this, or whether they may not belong to those just mentioned. Frequently, however, the contraction follows the irritation so regularly as to leave no doubt that the two are connected; if, moreover, the abdominal muscles in the cat or rabbit be removed, so that the thin and transparent peritoneum alone remains over the viscera, application of mechanical or chemical irritants to the splanchnic nerves in the thorax may still be observed to be followed, in many cases at least, by contractions in the intestine. In such experiments the air is prevented from acting upon the viscera by the intervening peritoneum, and in this way the fallacy above mentioned is less liable to occur.

It remains to consider the motor influence of the sympathetic in reference to the different muscular organs supplied by it.

Heart.— The heart, as has been already stated, derives its nerves from the sympathetic and pneumogastric. That the branches which are supplied by the sympathetic exercise an influence over the movements of the heart, is shown by what has been already stated, that after it has ceased to beat, irritation of the branches which pass to it from the cervical ganglia will again excite it to contraction. Similar results frequently follow irritation of the ganglia themselves. When the galvanic stimulus is applied to the cardiac branches of an animal in which the heart has not yet ceased pulsating, the effect is to augment the number of beats, and at the same time to increase their strength. In a rabbit in which the heart's action had ceased, Valentin * found that when the wires of the magneto-electric apparatus were applied, about $\frac{1}{4}$ of a millimetre distant from each other, upon the second thoracic ganglion of the right side, a very powerful contraction in the auricles immediately ensued: the experiment was repeated several times, and with the same result. This also took place when the same stimulus was applied to the first thoracic ganglion. When, on the other hand, the wires were laid upon the aorta at the distance of $\frac{1}{4}$th of a millimetre from the heart, or upon the surface of the right ventricle, no effect was produced. He concludes, therefore, that the stimulus when applied to the nerves was, in this case, more effectual than when applied to the muscular fibres themselves. As regards the function of those filaments which are sent by the pneumogastric to the heart, E. H. Weber † believes that they exercise a restraining influence over the movements of the organ; stimulus applied to the pneumogastric, according to his experiments, having the effect of retarding or altogether stopping its movements. When the stimulus of the electro-magnetic rotation apparatus was applied to the bulbus arteriosus in the frog's heart,—the part of the organ around which the fibres derived from the sympathetic are, according to him, chiefly distributed,—he found that the pulsations were increased in number as well as in strength. When, on the other hand, the same stimulus was applied to the upper portion of the inferior vena cava, where the filaments of the pneumogastric are mainly distributed, the effect produced was not an acceleration but a retardation or stoppage of the heart's action. When a defined part of the vagus has been stimulated for some time continuously, the heart again begins to pulsate: when a portion of the nerve above this point is now stimulated, no effect is produced; when, on the other hand, the stimulus is applied to a portion further down, nearer the heart, a cessation of its movements is again produced. The circumstance that the heart, after the stimulus has been applied to the pneumogastric for some time, again commences to beat, is attributed by Weber to the part of the nerve becoming exhausted, or losing its restraining influence, when the heart, being thus freed again, begins to pulsate. Budge*, however, attributes the cessation of the movements of the heart, produced by the application of galvanic stimulus to the pneumogastric, not to any restraining power exercised by that nerve, but rather to a temporary exhaustion produced by the strength of the stimulus. In support of this view, he states that, although the movements of the iris chiefly depend upon the oculo-motor nerve, yet Weber found, when the wires of the magneto-electric rotation apparatus were applied to this nerve within the cranium, that the pupil became dilated, remaining so for a considerable time after stimulus had been withdrawn, and then again slowly contracting. The effects thus produced upon the iris are, according to him, analogous to those produced upon the heart by application of the galvanic stimulus to the pneumogastric. Moreover, the nerves which are sent to the heart of the frog do not present the arrangement which Weber has described. No other filaments than those which pass from the vagus are distributed to the heart of this animal, at least no others have been demonstrated. The vagus nerve becomes united with the sympathetic in the ganglion, which is situated about one line from the root of the pneumogastric; and from this ganglion, which contains fibres of the vagus and sympathetic, springs, amongst other branches, a slender filament which is destined for the heart. This runs downwards on the inner aspect of the lungs, and passes along the veins to the auricles and ventricle, the former receiving the greater number of the nerve fibres. The branch in

* Loc. cit. p. 427.

† Wagner's Handwörterbuch der Physiologie, band iii., Abtheilung ii. p. 45.

* Wagner's Handwörterbuch, band iii. p. 415.

question contains fibres derived both from the sympathetic and also from the pneumogastric. Again, such a restraining power must hold an opposite relation to the moving power in the normal condition ; the moving power would therefore express itself only in part, according as the other is in a latent state or in a state of activity, and consequently section of the vagus nerve ought, did it exert the restraining power in question, to be followed by an acceleration in the movements of the organ, which is not the case. Budge, therefore, seems to regard the fibres which are sent to the heart in the frog by the pneumogastric, as possessed of motor and sensory properties.

Schiff also found that when the heart's action has been made to cease by application of the wires to the groove between the auricles and ventricles, this effect cannot be counteracted by applying them to the bulbus arteriosus. The phenomenon of the cessation of the heart's action, produced by the application of the galvanic stimulus to the pneumogastric, he explains by supposing that its fibres are in a state of activity during the systole of the corresponding part of the heart, but quickly become exhausted, thus allowing the diastole to take place: thereafter, their activity being again renewed, a second systole results. When therefore, strong galvanic stimuli are applied to the nerve the state of exhaustion continues longer and in the same proportion the diastole, or cessation of the heart's action, is also longer.

In accordance with the above views, Valentin * in like manner holds that the sympathetic has no influence over the movements of the heart in the frog, neither giving rise to acceleration nor stoppage of its action.

In regard to the connection between the central masses of the nervous system and the action of the heart, it is evident, from what has been above stated in regard to the effects which are produced by the application of the galvanic stimulus to the pneumogastric nerve, that a certain influence must be exercised by these. By Willis †, and others, it was held that the movements of the heart, as well as of the other inorganic muscles, depend upon the cerebellum. This they believed from the circumstance that the nerves which preside over the involuntary actions were supposed to take their origin from this part of the nervous system, and also from observing that wounds upon the back part of the head proved speedily fatal. Haller ‡, again, endeavoured to show that the action of the heart is entirely independent of nervous influence, and is due merely to the inherent irritability of the muscular fibres. From the circumstance that sudden destruction of the spinal cord immediately produces an interruption of the heart's action, Legallois concluded that its movements are not due to inherent irritability, as Haller maintained, but depend upon the spinal cord. The cessation produced in the way just stated, although indicating that an influence may be exercised through the central nervous masses upon the movements of the heart, by no means implies the conclusion which was drawn from it by Legallois, inasmuch as the heart may sometimes in such cases again begin to pulsate. That the heart may be influenced in its action through the medium of the central masses of the nervous system is also shown by the effects which are produced by the application of the galvanic stimulus to these parts. Thus, in the frog, as shown by the experiments of Weber *, Budge †, Valentin ‡, and others, it may be made to cease pulsating by applying the wires of the magneto-electric rotation apparatus to either side of the medulla oblongata. Unless there has been much loss of blood in exposing the parts the heart becomes dark-red, and is very much distended; where the large blood-vessels have been previously cut the heart still ceases to pulsate when the stimulus is applied as above: it does not, however, present the dark-red distended appearance, but is more or less collapsed and pale. The experiment, according to them, seldom or never fails. If the electric stimulus has been applied for too long a time the heart again begins to beat, in the same way as takes place when the stimulus is applied to the trunk of the pneumogastric nerve. The same stimulus also sometimes produces more or less change in the rhythm of the organ. According to the Webers, the portion of the central nervous masses which, when stimulated in this manner, gives rise to a cessation in the action of the heart, is that extending from the corpora quadrigemina to the posterior extremity of the calamus scriptorius. Budge found, in his experiments, that the corpora quadrigemina were not so intimately concerned in the production of these effects as the medulla oblongata. Tiedemann § appears to regard the cerebellum and the medulla oblongata as the parts through which the cessation of the heart's action may be induced, while stimulus applied to the corpora quadrigemina produces no effect. Valentin believes that while the corpora quadrigemina and cerebellum exercise a certain influence, the medulla oblongata is the part chiefly concerned. In nine mice, which were rendered insensible by chloroform, and whose hearts and medulla oblongata were laid bare, Valentin endeavoured to ascertain the parts of the central nervous masses which, when stimulated in the way above mentioned, give rise to cessation of the heart's action, as also the effects which are produced by the same stimulus when applied to the spinal cord. In none of them did he observe any

stoppage of the heart's action when the cerebellum, or corpora quadrigemina were the parts to which the stimulus was applied: when applied to the medulla oblongata, on the other hand, this effect was invariably produced. The cervical part of the spinal cord, when stimulated, gave different results. In a mouse, which had been under the influence of the narcotic for 2½ minutes, the heart was repeatedly made to cease pulsating when the wires were applied upon either side of the spinal cord in the region of the third to the fourth cervical vertebra, and also when applied to the part between the first and second cervical vertebræ. After repeating this experiment several times, and with the same result, he cut the spinal cord across in the region of the second to the third vertebra; when the stimulus was now applied to the lower cut extremity of the cord the heart's action was accelerated. The cessation produced by application of the stimulus to this part of the spinal cord in the former experiment was, therefore, according to Valentin, probably due to its being transferred along the spinal cord to the medulla oblongata. In two other animals it was found that the two lower thirds of the cervical portion of the cord in like manner gave rise to no cessation in the heart's action, but rather, after the first few seconds, caused it to be accelerated. A young rabbit was strangled, the head separated from the body at the articulation between the occipital and first cervical vertebræ, and artificial respiration kept up. When the wires of the battery, moderately loaded, were now applied to the upper part of the spinal cord, in the region of the first cervical vertebra, the heart, which was before at rest, commenced pulsating. The spinal cord was laid bare from the first cervical to the eighth thoracic vertebra. When the wires were inserted in the region of the fifth cervical to the second thoracic vertebra, the heart's action was distinctly accelerated. When the spinal cord was removed, the same result still followed upon application of the wires, because the roots of the nerves were stimulated. When the heart was cut out of the body, and again placed *in situ*, the above experiment was repeated without effect.

Just as stimulus of the sympathetic branches in the mammalia is followed by acceleration of the heart's action, while stimulus of the pneumogastric causes it to cease pulsating, so also Valentin concludes, from the above experiments, that stimulus applied to the spinal cord gives rise to the former result, while from stimulus applied to the medulla oblongata the latter result ensues. In the frog, according to Valentin, the spinal cord has no influence over the movements of the heart. He also holds, as already stated, that in this animal, the sympathetic, in like manner, exercises no influence in this respect.

In a pigeon, he found that when the wires of the magneto-electric apparatus were inserted into the cerebellum, the heart's action became more or less laborious: when applied to the spinal cord, in the region of the first cervical vertebra, forwards, towards the medulla oblongata, the heart's action was repeatedly brought to a stand.

The cessation in the heart's action by application of the galvanic stimulus to the medulla oblongata most readily ensues, according to Valentin, when the wires are applied to its sides, or to the under surface in the vicinity of the roots of the eighth pair, and in no instance does it ensue when the wires are applied to any part of the central nervous masses after removal of the medulla oblongata.

The influence exercised upon the heart's action by the central nervous masses is also shown by the diminution in the number as well as in the strength of its pulsations, which ensues when these are removed, especially on removal of the medulla oblongata. That the diminution in question does not depend entirely upon the stoppage of the respiratory process consequent on the destruction of the medulla oblongata, has been shown by Budge. When, in the frog, the anterior portion of the medulla is left, the lungs continue to act; and yet, according to him, the pulsations of the heart diminish very rapidly both in strength and in frequency. He finds that, although removal of the other parts of the central nervous masses produces little immediate effect on the heart's action, it seldom continues for any length of time after the removal of the medulla oblongata. The effects which follow disease of these parts in like manner illustrate the influence which they exercise over the movements of the heart. In compression of the brain, as well as from lesion of the upper part of the spinal cord, the pulsations are frequently diminished: the effects of shock in altogether stopping its action also illustrate the same thing.

From the experiments above mentioned, Valentin and others hold that the nervous centre upon which the heart's action depends is the medulla oblongata. The particular rhythmical order in which its different parts contract is due, according to some, to peculiarities in the manner in which they are acted upon by the blood, the contact of arterial with the lining membrane of the left cavities of the organ, that of venous blood with the lining membrane of those of the opposite side, furnishing the proper stimuli, in obedience to which these parts contract. The successive contraction of auricles and ventricles is in like manner explained by the blood first entering the former, and causing them to contract. By their contraction it is propelled into the ventricles, and stimulates these to contraction also, while the contraction of the ventricles causes the auricles to become again filled with blood from the veins, and so on indefinitely. This rhythmical order in the movements of the organ has also been attributed to peculiarities in the mode of arrangement of its muscular fibres. The muscular fibres of which it is composed, as may be seen on examining with the microscope the auricles in the heart of the frog or other small animal, do not lie parallel to one another, as in the ordinary muscles, but cross one another in different directions, many of the bundles being at the same time observed to present a more or less branching character. The branches or divisions of one bundle cross those of neighbouring bundles. In this manner the fibres form a number of reticulated layers laid over one another, while at the same time bundles pass from one layer into the adjacent layers, so that a more or less complete intermixture of the fibres takes place. The fibres composing the ventricles also present more or less of this reticulate arrangement. Moreover, many of the fibres of the auricles pass into those of the ventricle, and *vice versâ*. In virtue of such an arrangement of the fibres, stimulus applied to one part of the heart gives rise to a contraction in the bundle to which it is applied: since this crosses neighbouring bundles its contraction acts as a stimulus to these, in obedience to which they also contract. In this manner, the contraction is not limited to the fibre, or bundle of fibres, to which the stimulus is first applied, but extends over the entire mass. So also the contraction of the fibres, which are described as passing between the auricles and ventricles, stimulate the fibres of which the latter are composed, giving rise to a general contraction in them also; and in this way the successive contraction of auricles and ventricles is produced. According to Schiff, as mentioned by Valentin, the movements of the heart may be reduced to the peristaltic or vermicular type. He holds that in a certain part of the muscular substance are contained the nerves which preside over the movements of neighbouring bundles. When this contracts, a stimulus is thereby given to the nerves which supply the portion of the muscular substance immediately succeeding; so that in this manner a number of progressive contractions of the successive bundles of fibres are produced. The contraction of the auricles or ventricles is thus not a single simultaneous act; but is made up of a great number of contractions succeeding one another, in the same manner as is seen in the contraction of the intestine. It is the rapidity with which they follow one another that gives rise to the appearance of their being simultaneous. These contractions travel from auricle to ventricle, giving rise to the successive contractions of these parts. He finds that when a ring of the muscular substance at the base of the ventricle in the frog's heart is brought, by local application of the galvanic stimulus, into a state of continued or spasmodic contraction, the due rhythm between the contraction of the auricles and the part of the ventricle below the contracted portion ceases. When a spasmodic contraction is produced in a part of the ventricle by external stimulus this part may be irritated without giving rise to any general contraction. He also finds that when a portion of the ventricle of a heart which still retains its irritability, is stimulated, the contraction is sometimes seen to take place in this before it takes place in the other portions; the stimulated portion is also the part which first becomes relaxed in the diastole of the organ.

In opposition to the view above mentioned Volkmann* maintains that the movements of the heart cannot depend upon the central nervous masses. It continues its pulsations after the brain and spinal cord have been removed. When, however, the rhythmical movements of a part depend upon a nervous centre, they cease immediately after the connection between these parts and the nervous centre is broken. The rhythmical movements of the muscles of respiration depend upon a nervous centre, the medulla oblongata. So soon as this is destroyed they cease. In like manner the heart, were the medulla oblongata, or any other part of the central masses of the nervous system the centre upon which its movements depend, must also cease pulsating so soon as it is removed from the influence of these. According to the experiments of Bidder, however, already mentioned, frogs may live for six weeks after the spinal cord has been destroyed, the circulation, as seen in the web of the foot, going on as livelily as before, and presenting no difference when compared with that in the healthy animal. So also when the entire central masses of the nervous system are removed the heart still continues its pulsations until the second day. The movements exhibited by the heart, after the central masses of the nervous system have been destroyed, cannot, according to Volkmann, be explained as mere movements of irritation, due to the inherent irritability of the muscular fibres, acted on by the stimulus of the blood or of the atmospheric air. Mere irritability, acted on by the stimulus of the blood, or of the air, cannot explain why both auricles or both ventricles should contract at one and the same time; and just as little can we in this way explain the successive contraction of auricles and ventricles. To explain the rhythmical order in which these contractions take place it is necessary to suppose that they, like movements of a similar kind, such as those of the respiratory muscles, are regulated by a nervous centre. The fact that the heart's movements continue after it has been removed from the body indicates, moreover, that the centre upon which its movements depend must be contained in the organ itself. It has been already mentioned that in different parts of the heart are found small ganglia. These are believed by Volkmann to be the centres on which its movements depend. These, according to him, act as organs from which the impulse to contraction proceeds: they are also so connected with one another as to act in concert, the impulses proceeding in such directions as to give rise to the regular succession in which the contractions of the different parts take place.

The effects produced upon the heart's action by stimuli applied to the central masses of the nervous system, and upon which the

* Loc. cit. p. 616. &c.

view that its movements depend upon these parts is chiefly founded, are explained by Volkmann as taking place by reflex action through the medium of the sympathetic ganglia. The fibres which pass from the spinal cord to the ganglia stand to the proper sympathetic fibres arising in these in the same relation in which the ordinary sensory fibres stand to the motor fibres of the muscles of animal life.

A conclusive way of determining whether the movements of the heart, as well as the order in which these take place, depend, or not, upon the ganglia contained in its substance, would be to ascertain whether they still continue after the ganglia have been extirpated. These, however, are so small, and apparently so numerous, as to render such an experiment impossible. That the continuance of these movements after the brain and spinal cord is destroyed, as well as when the heart is removed from the body, cannot be attributed to mere irritability of the muscular fibres acted on by the stimulus of the blood or of the atmospheric air, but must be connected with nervous influence, is rendered probable by several circumstances, but especially by the observation first made by Henry, and afterwards by Müller *, that solution of opium or of other narcotic substances, when applied to the outer surface of the heart, does not produce any obvious alteration in its action, whereas when introduced into its cavities so as to be brought into contact with its inner surface, their almost immediate effect is to cause this to cease. Again, when stimulus is applied to one of the ventricles of a heart which has just ceased pulsating, the contraction thereby produced does not commence at the point irritated, as might be expected were the irritability of the muscular fibres alone concerned, but in the auricles, and is followed by contraction of the ventricles. Sometimes, indeed, stimulus applied to the ventricles is followed by contraction of the auricles alone. Even when the stimulus is applied to the apex of the organ, the contraction still commences in the auricles, and sometimes limits itself to these. The regular order in which its movements take place, so different from those produced in the ordinary muscles by direct application of external stimuli, would imply that the impulse by which they are produced must be conveyed in a certain definite direction to the different muscular parts of which the heart is composed; and this can only be supposed to be effected through the medium of its nerves. The mere arrangement of the muscular fibres of the heart seems insufficient to account either for the general contraction of auricles and ventricles or for the order in which these succeed one another. If, in the case of the heart, the contraction of a single bundle of the muscular fibres may act as a stimulus to the neighbouring fibres, by which they also are excited to contraction, the same thing ought to take place in the muscles of animal life: the bundles in these, though presenting a different arrangement from those in the heart, are, notwithstanding, in as close contact with one another as are the latter, and have equal facility for stimulating the neighbouring bundles to contraction. The dependence of the rhythmical movements of the heart upon a certain arrangement of its nerves, and moreover that there are certain portions of the same from which the stimuli to contraction proceed, is further indicated by the effects, as shown by Volkmann, which follow incisions made into the heart's substance. When a transverse incision is made through the heart, between its auricles and ventricles, the former have been found to continue their contractions much longer than the latter; and if a longitudinal incision be made gradually proceeding from apex to base, the rhythm is preserved in both portions until the heart has been divided half way; when the incision is continued further, however, the movements of either part become irregular. When the ventricle is divided transversely into two portions, that towards the apex either ceases its contractions immediately or continues the same only for a short time, whereas that which is still in connection with the auricles goes on contracting as before.

It has also been observed that in the heart of the frog there is one portion of the septum between the auricles which continues its contractions much longer than any other part; and in this portion the greatest number of the cardiac ganglia and nerves are situated. It was also observed by Kölliker that the transverse groove in the frog's heart in like manner exercised a marked influence on its rhythmical contractions; and here also the ganglionic corpuscles and nerves are very abundant. In young kittens and rabbits also, Valentin has likewise observed that the groove in question affects the movements of the heart very much.

The opinion of Volkmann, therefore, that the rhythmic contractions of the heart are connected with a nervous centre, and moreover that this nervous centre is the sympathetic ganglia contained in the heart's substance, seems highly probable. At the same time there cannot be the least doubt that an influence may be exercised over these movements by the central masses of the nervous system.

Intestinal canal. Œsophagus. — The œsophagus receives nerve-fibres both from the pneumogastric and sympathetic. The former is, according to Longet *, the source of its sensibility as well as of its motion, while the sympathetic presides over the secretion of the mucus with which its inner surface is lubricated. Valentin, however, as mentioned by Longet, found, on irritating the cervical portion of the main cord of the sympathetic in the rabbit, that movements were produced in the middle portion of the œsophagus; and contractions were also produced in the thoracic portion of the same tube when the inferior cervical ganglion or either of the first four thoracic ganglia was irritated.

* Müller's Archiv. 1845, p. 423, et seq.

* Op. cit. p. 607.

Longet, on repeating the experiments of Valentin, failed to observe any contractions, and concludes that Valentin must have irritated the pneumogastric as well as the sympathetic. It is only (according to Longet) when the pneumogastric or spinal nerves are irritated, that such contractions ensue; and, moreover, section of the eighth pair is attended by complete paralysis of the œsophagus.

Stomach.—The stomach, like the œsophagus, is supplied by branches of the pneumogastric and sympathetic. Irritation of the former is almost always followed by contractions in this organ. Irritation of the splanchnic nerves, or of the semilunar ganglion, according to Longet *, produces no such effect. Valentin, on the other hand, found that stimulus applied to the main cord of the sympathetic in the neck, or to the inferior thoracic ganglia, in the rabbit, gives rise to contractions in this organ. Volkmann † has also found that when the stimulus of the electro-magnetic rotation apparatus is applied to the thoracic portion of the sympathetic in the cat it gives rise to powerful peristaltic movements in the stomach. He also observed still more lively contractions excited in the stomach of a young dog when the same stimulus as in the previous experiment was applied to the sympathetic cord in the thorax, or to the greater or smaller splanchnic nerves before they enter the semilunar ganglion. It would seem, therefore, that, besides the motor filaments which are sent to the stomach by the pneumogastric, it also receives others through the medium of the sympathetic.

As regards the movements of the small intestine, &c., it is almost invariably excited to contraction by irritation of the splanchnic nerves or semilunar ganglion. After the movements produced in the intestine by the stimulus of the air, acting upon them when the cavity of the abdomen is laid open, have subsided, contractions extending over the greater part of the gut may still be produced, as was first shown by Müller, by application of chemical irritants, such as potash, to the solar plexus. According to Valentin, the movements produced by irritation of the splanchnic nerves are chiefly confined to the duodenum and upper part of the jejunum, while irritation of the solar plexus, on the other hand, is followed by contractions which extend over the whole of the small intestine. Irritation of the sympathetic cord in the thorax as high up as the fifth or sixth ganglion, and also in the lumbar region, gives rise, according to Valentin, to distinct contractions in the small intestine, while stimulus applied to the lumbar and sacral portions acts very energetically upon the great intestine and rectum. The influence of the sympathetic over the movements of the intestines is also shown by the observation of Valentin that when the branches which pass along the mesentery are irritated, contractions are produced in the particular portions of the intestine to which they are distributed, while the rest of the gut remains quite motionless.

* Op. cit. p. 609.

† Müller's Archiv. 1845, p. 414., &c.

Budge observed that movements were excited in the cœcum of the rabbit when the trunk of the vagus-nerve in the neck was stimulated by means of the electro-magnetic rotation apparatus.

As in the case of the heart, so also in regard to the intestinal canal, stimuli applied to the central nervous masses have been observed to exercise a greater or less influence in exciting contractions in the intestine. In animals newly killed, Valentin has frequently observed movements produced in the intestines by division of the anterior and posterior roots of the spinal nerves. In such experiments, however, it is difficult to ascertain whether the contraction be due to the stimulus applied to the nerves, or whether it may not be owing to the stimulus of the air acting directly on the intestines themselves. The application of galvanic stimulus leads to more decisive results. When, according to Valentin*, the wires of the magneto-electric apparatus are applied to the corpora quadrigemina or medulla oblongata, lively contractions are excited in the stomach and intestine. Contractions were also produced in the small intestine, great intestine, and rectum, by application of the same stimulus to the spinal cord. In *Cyprinus tinca*, Weber has shown that very powerful contractions may be excited in the stomach by application of the wires of the electro-magnetic rotation apparatus to the posterior part of the cerebellum or to the medulla oblongata. The same stimulus applied to the spinal cord in the animal above mentioned, as also in dogs, he observed to be followed by movements in the intestinal canal.

From the experiments of Valentin it appears that the movements which are excited in the intestinal canal by stimulus applied to the central masses of the nervous system, are not produced through the medium of the pneumogastric alone. In a rabbit which had been bled to death, and in which the abdominal muscles were removed without injuring the peritoneum, he found, when the wires of the magneto-electric apparatus were inserted into the cerebellum, that very lively movements ensued in the small intestine, although the two vagi nerves had been previously divided in the neck. Budge, however, finds that it is only when the two vagi nerves have been left that movements can be excited in the cœcum of the rabbit by application of the galvanic stimulus to the medulla oblongata.

The constipation and tympanitis which frequently attend diseases of the spinal cord, in like manner indicate that the central masses of the nervous system exercise a certain influence over the movements of the intestinal canal.

These movements, however, like those of the heart, still continue after the brain and spinal cord have been destroyed. Bidder, as

* Op. cit. p. 466., &c.

cited by Volkmann, fed several frogs with worms and immediately destroyed the spinal cord: on opening the animal twenty-four hours afterwards, the stomach was found distended with tough slimy matters: if, on the other hand, forty-eight hours were allowed to elapse before the stomach was examined, it was found almost empty, part of the contents having been probably absorbed, while part had passed downwards into the intestinal canal. The continuance of the movements of the intestinal canal after the brain and spinal cord have been removed, would seem to indicate that these are not the immediate centres on which their contractions depend. The contractions which take place may be explained as due to the inherent irritability of the muscular fibres, while their type may be said to be owing to a peculiar arrangement of these, by which the contraction of one bundle acts as a stimulus to the neighbouring bundles, exciting these to contraction also, and in this way giving rise to the vermicular movements of the gut. It seems probable, however, that they are regulated by the ganglia of the sympathetic, especially since it has been observed by Henle*, that in pieces of the intestine which have been cut away close to the line of attachment of the mesentery, the contractions produced by application of local stimuli extend but a little way on either side of the point irritated, and are comparatively feeble. When a part of the mesentery is removed along with the portion of the intestine, they are more powerful and more extended, and are most so when the intestine and mesentery are left in their normal relations.

Genito-urinary organs. — Contractions of the ureters have been frequently observed by Valentin † to follow irritation of the abdominal ganglia of the sympathetic. They present the same peristaltic character as those of the intestines, and pass downwards from the kidney towards the bladder. In the bladder contractions are more easily produced than in the ureters: sometimes shortly after opening the abdominal cavity of an animal newly killed, the bladder contracts so powerfully as to give rise to an expulsion of its contents. Contractions may be excited in it, according to Valentin, by irritation applied to the sympathetic cord in the abdomen or pelvis, or to the lower lumbar and upper sacral ganglia; the contraction commonly commencing on that side of the bladder on which the nerves have been irritated. The last lumbar and first sacral ganglia are described by him as having most influence over its movements. In the vas deferens powerful contractions have been observed by Valentin when stimulus was applied to the two last lumbar ganglia: the rabbit and guinea-pig were the animals on which this experiment was made. In the latter animal the vesiculæ seminales were also excited to contraction by irritation applied to the lower lumbar and upper sacral portions of the sympathetic, sometimes so powerful as to expel the contents through the opening of the urethra. Stimulus applied to the same parts in the female gives rise to contractions in the Fallopian tubes. The uterus may, according to the same observer, be excited to contraction by stimulus applied to the lower lumbar and upper sacral ganglia, or to the branches given off from these. The contraction in such cases passes downwards from the Fallopian tubes towards the vagina.

In regard to the influence of the central parts of the nervous system over the movements of these organs, it would appear, from Valentin's experiments, that contractions may be excited in the urinary bladder by stimulus applied to the spinal cord. The ureters are also said to exhibit contractions when the wires of the magneto-electric apparatus are brought into contact with the medulla oblongata, or with the spinal cord in the cervical or thoracic regions, as also when they are applied to the right optic thalamus. The same also holds true, according to him, regarding the vasa deferentia, Fallopian tubes, and uterus. He has further observed, that often when the stimulus is applied to one side of the central nervous masses, it is the organ on the opposite side which is excited to contraction: thus stimulus applied to the right optic thalamus not unfrequently acts on the ureter of the left side; in like manner, when the right hemisphere of the cerebellum is the part irritated the contractions sometimes take place in the Fallopian tubes or vas deferens of the left side.

These organs, however, like those already mentioned, exhibit their usual contractions after they are removed from the influence of the brain and spinal cord. The fact that in paraplegic women delivery has taken place, would appear to show that the contractions of the uterus are not dependent upon the central masses of the nervous system: this is also shown by an experiment of Segalas*, that division of the spinal cord in the lumbar region in the rabbit does not prevent the completion of the labour. Moreover, it would appear, from a series of experiments made by Professor Simpson of Edinburgh, that the whole process of labour may be completed, although the spinal cord has, in great part, been previously removed.

Pupil. — It was long ago ascertained by Pourfour du Petit †, that section of the main cord of the sympathetic in the neck is very quickly followed by contraction of the pupil, besides certain other phenomena. The same experiment has since been made by Molinelli, Dupuy, Reid, Valentin, and others.‡ Molinelli regarded the effect produced upon the pupil not as an immediate effect of the operation, but as an after result;

* Allgemeine Anatomie, p. 724.
† Op. cit. p. 468.

* Bulettin de l'Academie de Medicine, tom. ix. p. 1124.
† Histoire de l'Academie, 1727, 1729, Paris, p. 5. et seq.
‡ See Budge, in Vierordt's Archiv. für physiologische Heilkunde, 1852, Ergänzungs Heft.

by Dupuy, on the other hand, it was described as the immediate consequence of the same. Reid found in his experiments that the contraction of the pupil invariably takes place in the dog and cat, but in the rabbit the result is not so constant. Reid also showed that it was not the section of the trunk of the vagus, but that of the sympathetic, that was the cause of the contracted state of the pupil. According to Valentin the effects produced differ considerably in different animals: in the dog the pupil becomes very much contracted: the contraction is not immediate, but ensues within about half a minute after the nerve has been divided. Stimulus applied to the nerve still causes the pupil to dilate, but in a few minutes it again contracts, until it is not larger than the head of a pin, and remains so for months. The contracted pupil has generally a circular form; there are, however, occasionally seen particular inequalities in its margin which change from time to time. When belladonna is applied the contracted pupil dilates, but does not reach the size which the sound pupil attains under similar circumstances. When the aqueous humour is tapped the contracted pupil becomes slightly widened, while at the same time it assumes a longish round form. In the sound eye when treated in this way the pupil becomes diminished in size.

Biffi found that slight dilatation of the pupil followed irritation of the ascending or carotid branches of the sympathetic, division of these being also followed by contraction of the pupil, though to a less extent than takes place after division of the sympathetic cord in the neck. Irritation of the superior cervical ganglion gives rise to the greatest dilatation of the pupil; so also when the same is extirpated the contraction of the pupil is very great.

A number of researches have recently been made, in regard to this subject, by Budge* and Waller. When the stimulus of the magneto-electric apparatus is applied to any part of the sympathetic cord in the neck, dilatation of the pupil takes place; the part of the nerve nearer the chest being, however, less irritable than that higher up. The superior cervical ganglion is not only more susceptible of the stimulus than any other part of the nerve, but the effect produced upon the pupil also lasts longer. The dilatation of the pupil may be produced by the application of the galvanic stimulus to any part of the sympathetic, from the inferior cervical ganglion to the ophthalmic ganglion. Irritation of the sympathetic below the inferior cervical ganglion, however, has no effect upon the pupil. As regards the origin of the fibres in the sympathetic which influence the pupil, they might be supposed to proceed from three sources: — 1st. They might be regarded as prolonged upwards from the thoracic portion of the main cord, the inferior cervical ganglion being an organ interposed to prevent the transmission of stimuli. Against this view, however, there is the circumstance that the fibres still pass through three ganglia before they reach the eye, the superior cervical, Gasserian, and ophthalmic. 2nd. They might be supposed to arise in the inferior cervical ganglion, or to be derived from the spinal cord through the medium of the rami communicantes. If they arise in the ganglion, the section of the sympathetic cord below this, or of the branches which are connected with the ganglion, ought not to give rise to any contraction of the pupil, this depending, according to Budge, upon the separation of the nerve-fibres from their centre. In a dog which had been put under the influence of chloroform, the inferior cervical ganglion was sought, and the main cord of the sympathetic below the ganglion, as well as all the branches in communication with the latter, were divided one by one. Of all these, only one was found which acted on the pupil. Division of this branch sometimes gave rise to as decided contraction of the pupil as division of the sympathetic cord in the neck. In order to ascertain whether the branch in question has its origin in the spinal cord, the following experiment was made. A rabbit was put under the influence of ether, and the sympathetic of the left side divided in the neck; the spinal column was then opened and the spinal cord cut across in the region of the third dorsal vertebra, and galvanic stimulus applied to the upper cut extremity of the cord; straightway the pupil of the right side dilated, while that of the left side, on which the sympathetic had been cut, did not vary in the slightest. From further experiments it was found that stimulus applied to the spinal cord below the sixth dorsal vertebra has no action on the pupil; above this point, however, and as high up as the fifth cervical vertebra, dilatation was observed on application of stimulus; the portion of the spinal cord which has most influence on the pupil being that in the region of the first three thoracic vertebræ.

As regards the particular fibres in the sympathetic on which its sensory and motor endowments depend, Volkmann* believes that none of the fine fibres, described by him as sympathetic fibres, are possessed of sensory properties in their normal condition. In support of this view, he states, 1st. That the number of these fibres is greatest in parts which are least sentient, as is the case more or less with all the organs of vegetative life, and especially with the pia and dura mater, and arachnoid, with the periosteum and with the blood-vessels. The circumstance that these parts are so very seldom, and some of them never, the seat of impressions which are transmitted to the sensorium, must, Volkmann observes, raise a suspicion that the very rich network of nerve-fibres which occurs in them are not possessed of sensory properties, and the results derived from experiments, as

* See Budge, in Vierordt's Archiv. für physiologische Heilkunde, 1852, Ergänzungs Heft.

* Loc. cit. p. 601.

well as from surgical operations, would seem to show that such is the case. The coats of the blood-vessels he considers to be destitute of sensibility, inasmuch as he found that the operation of fixing the hæma-dynamometer into them gave rise to no distinct sign of pain. 2nd. As regards the fibres which take their origin from the ganglia, it seems in a high degree probable that they at least cannot convey impressions from the organs which they supply to the sensorium. In order to communicate such impressions they must transfer them to fibres which do not terminate in the ganglia, but are directly or indirectly connected with the sensorium, and are, in short, true sensory fibres. Such a transference in the normal condition does not, however, appear to take place. 3rd. It is not at all probable that fibres, which in animals that have been beheaded, or are under the influence of strychnine, show so little connection with the spinal cord that stimulus applied to them cannot excite any reflex movements in the voluntary muscles, should be in a condition to communicate impressions through the spinal cord to the sensorium. 4th. Division of the cerebro-spinal nerves which supply the integument is followed by loss of sensibility in that part, although the sympathetic fibres passing to the same have been left uninjured. In the frog, a great number of fibres are sent from the sympathetic to the cerebro-spinal nerves, and are along with these distributed in considerable quantity to the integument: if now the nerves in the leg of the frog be divided above the point at which the fibres of the sympathetic join them, so as in this way to leave the continuity of the latter uninjured, the limb is notwithstanding deprived of sensibility; the power of exciting reflex action in the muscles of the limb by stimulus applied to the integument being also at the same time destroyed. Division of the fifth nerve, in like manner, is attended by loss of sensibility in all the parts of the face supplied by this nerve; and no reflex action can be excited by stimulus applied to the eye, tongue, &c., although these parts derive fibres from the sympathetic, which are not divided in the operation. Although in the normal condition the fibres in question are not capable of communicating impressions to the sensorium, they may, however, according to Volkmann, do so in diseased states. In this way the severe pain which is sometimes felt in organs supplied by the sympathetic, does not depend so much on cerebro-spinal nerve-fibres as on an altered condition of the ganglionic fibres themselves. The number of cerebro-spinal fibres distributed to such parts is too small to explain it. Severe pain is frequently felt in bones when diseased, although, according to Volkmann, these probably receive none but sympathetic filaments. The circumstance already mentioned, that in experimenting on the sensibility of the ganglia, it has been found that these are frequently incapable of transmitting impressions until by frequent irritation they have been brought into a kind of inflammatory condition, also indicates the same thing.

All the fibres which are sent from the cerebro-spinal system to the sympathetic, through the medium of the communicating branches, are probably derived, according to Volkmann, from the posterior roots of the spinal nerves alone, and are not therefore possessed of motor properties. They hold the relation of centripetal or afferent fibres to the ganglia of the sympathetic. The motor properties of the sympathetic are therefore considered by him to be due entirely to the fibres which arise in the different ganglia. In regard to those movements which, as already stated, are excited in organs supplied with sympathetic nerves, by irritation of the central masses of the nervous system, Volkmann holds that the stimuli to contraction in these cases are not transmitted directly to the organs in which the contractions are manifested, but are first conveyed by the fibres in the rami communicantes to the ganglia of the sympathetic, where transference to the proper sympathetic fibres takes place.

Thus, then, according to Volkmann, the motor properties of the sympathetic are entirely due to the proper ganglionic fibres. The painful sensations which are sometimes felt in parts supplied by the sympathetic are due, not so much to fibres of cerebro-spinal origin as to an altered condition of the ganglionic fibres, while the fibres which are sent to the sympathetic by the cerebro-spinal system act as afferent or centripetal fibres to the different ganglionic centres, and by means of which a connection is established between the sympathetic and cerebro-spinal systems.

According to Valentin, again, both the motor and sensory properties of the sympathetic are due entirely to cerebro-spinal fibres.

It is generally admitted that the sympathetic receives fibres from the anterior as well as from the posterior roots of the cerebro-spinal nerves. The number of these fibres must, moreover, be very considerable, especially in the higher animals; it would seem probable, therefore, that the motor, and especially the sensory properties of the sympathetic are in part due to these fibres. The experiments of Budge and Waller show, almost beyond a doubt, that, in the case of the iris at least, the motor fibres which pass to it through the medium of the sympathetic are derived from the spinal cord. The circumstance, however, that the organs supplied by the sympathetic cannot be influenced by the will, and in the normal condition are removed beyond the sphere of sensation, would seem to indicate that the conducting power of these fibres must be modified by the different ganglia through which they pass in some such way as Volkmann supposes.

Are the ganglia to be regarded as centres of reflex action? By Valentin*, Longet†, and others, they are denied this property.

* Op. cit. p. 697., as quoted by Longet.
† Op. cit. p. 578.

Prochaska* seems to have attributed such properties to the ganglia, inasmuch as he explains the contraction of the heart by supposing that the impressions which are made upon the inner surface of the organ are transmitted to the ganglia by means of sensory nerves, and are there transferred to motor nerve-fibres. Grainger †, in like manner, holds that the ganglia are centres of reflex action, and moreover that each ganglion possesses a distinct so-called excito-motory system of nerves. From what has been already stated, it will be observed that Volkmann also holds the view that, in the ganglia, transference of impression from one fibre to another takes place. From his earlier experiments ‡, however, he was led to conclude that such was not the case. He found, on applying a stimulus to the surface of the intestines in a newly-killed frog, that a contraction ensued which was not confined to the part which had been stimulated, but extended for a considerable distance on either side. After destroying the spinal cord, and again applying the stimulus, he now found that the contraction produced was merely local, confining itself to the part irritated. The extended contraction first produced he believed to be due to reflex action, while the limited contraction in the second experiment he regarded as a mere stimulus movement. From the circumstance, moreover, that the former took place while the spinal cord yet remained, and the latter after it was destroyed, he concluded that it was thereby proved,—1st, that the spinal cord is the centre in which the act of reflexion takes place in the movements of the intestine; and, 2nd, that the ganglia are destitute of such power. Longet § also states that it is only while the spinal cord remains that contractions extending over large portions of the intestine can be excited by local application of stimuli, the contraction so produced limiting itself, after the spinal cord is destroyed, to the point irritated. As was shown by Henle, however, there can be no doubt that movements may be excited by application of stimulus to the surface of the intestine after the spinal cord is destroyed, which are as extended as those excited in the same way while it remains. The contractions produced by local stimuli are so similar both before and after the removal of the spinal cord as to leave no doubt that it can have no share therein. The only question is, whether the difference in character between the extended contractions and those which are limited to the point irritated are due to reflex action, or not. By Valentin and others, the extended contraction is explained in the same way as they endeavour to explain that of the heart, by supposing a particular arrangement of the muscular fibres, by means of which the contraction of one bundle acts as a stimulus to the neighbouring bundles, exciting them successively to contraction. How far this is the case it is difficult to determine; it seems, however, that the relation of the one bundle of muscular fibres to the neighbouring bundles in the intestine is not so different from what it is in the ordinary muscles as to explain the limited contractions which take place in the latter, and the extended contraction of the former, upon the application of local stimuli. The opinion of Henle*, that they are of a reflex nature, the centres of reflexion being the grey matter of the sympathetic ganglia, seems, therefore, to be the more probable. Kürschner also adopts the view that the ganglia are to be regarded as centres of reflex action. On repeating Müller's experiment of irritating the solar ganglion with potash, he observed that the movements thereby produced in the intestines did not commence at a single point, but in several different coils of the intestine at one and the same time. This may, he says, be explained in either of two ways: the stimulus had either affected directly all the motor filaments, by which these different parts of the intestine are supplied, or only a few of them; and from these few a transference took place, in the ganglion, to the others. The latter he believes to be the true explanation; for he found it is quite the same, as regards the extent of the movements, whether the irritant is strongly or slightly applied, and whether a finely-pointed rod of potash or a broad surface of the same is employed.

The contractions which are excited in the heart by application of local stimuli would seem to indicate more clearly that the ganglia are reflex centres. When a heart has just ceased pulsating application of a stimulus gives rise to a contraction affecting the entire organ, the contraction, too, taking place in the same rhythmical manner in which it takes place during life. After some time, the stimulus, when again applied, gives rise to a contraction which does not affect the entire organ, but only the particular auricle or ventricle to which it is applied, and after some time farther the same stimulus gives rise merely to local contractions. The former two seem to be, as Volkmann regards them, movements of reflex action, while the last is a mere stimulus movement. The circumstance that stimulus applied to the ventricles in such a heart gives rise to contractions which commence in the auricles, and therefore at a point distant from that to which the irritation has been applied, seems explicable only on the supposition that the impression thereby produced is conveyed to a nervous centre, and here transferred to fibres proceeding to the part in which the contraction commences.

The following experiment of Volkmann would also appear to favour the view in question. He destroyed the spinal cord in a newly beheaded frog, and satisfied himself

† Observations on the Structure and Functions of the Spinal Cord.

‡ Müller's Archiv. 1838, Einl. Theil. p. 15., &c.

§ Op. cit. p. 577.

* Froriep's Neue Notizen, band xii. p. 247., as quoted by Kürschner.

that no reflex action could be produced in the voluntary muscles. The heart was then laid bare, and during an interval of 101 minutes its pulsations were counted at fourteen different times. Five minutes after destruction of the central organs they numbered 72 per minute; thirty minutes afterwards they were 48 per minute. After this they were found to average between 45 and 51 per minute. He then crushed with the blow of a hammer one of the hind feet; and now, during the 104th minute after the spinal cord had been destroyed, counted 70 pulsations. Thus, then, two hours after the operation of destroying the spinal cord, we have a sudden increase of 20 beats in the minute, which admits of hardly any other explanation than that given by Volkmann, that it was due to the stimulus applied to the foot being reflected to the nerves of the heart through the ganglia of the sympathetic.

Influence of the sympathetic on the vegetative processes. — According to some, these processes go on independently of any influence exercised by the nervous system, while others maintain that the two are more or less intimately connected. Of the latter some believe that the sympathetic is the only part of the nervous system by which such influence is exercised, while others hold that it exercises no influence in this respect which is not also exercised by the cerebro-spinal system.

There can be no doubt that in the plant the processes of nutrition take place without the co-operation of any nervous influence; and in the same way in the embryo of all animals they go on for some time before any trace of nervous tissue has appeared. In the animal after birth, however, they appear to be more or less influenced by the nervous system. This is rendered probable by several circumstances, such as the effects of various powerful mental emotions and of morbid states of the nervous system upon digestion, on the secretion of the saliva, tears, &c.; the effects of the same upon the heart and capillary vessels. This is also shown by the changes which take place in the nutrition of parts, when the nerves by which they are supplied have been divided, or after lesions of the brain or spinal cord. Thus, as shown by Magendie, section of the fifth nerve is very quickly followed by distension of the blood-vessels and inflammation of the conjunctiva, sclerotic, and other parts of the eye, which may terminate, in the course of two or three weeks, in complete disorganisation of the eyeball. It has also been found that section of the nerves of a broken limb prevents the due formation of callus. The experiments of Drs. Sharpey and Baly on the salamander also prove that parts are reproduced much more slowly and less perfectly when the spinal cord has been destroyed to a certain extent than under opposite circumstances. When wounds are inflicted upon both limbs of an animal, and the nerves of the one limb are divided while those of the other limb are left entire, it has been found that while a lively inflammation and normal suppuration take place in the wound of the limb the nerves of which have been left entire, the wound in the limb whose nerves have been cut scarcely inflames at all, and only a thin unhealthy discharge is formed. Lesions of the spinal cord have also been observed to be followed sometimes by mortifications of the paralysed limbs, and this with such rapidity as would seem to indicate that they stand to one another in the relation of cause and effect. The tendency to sloughing observed in typhus and other diseases attended with great depression of the functions of the nervous system would also seem to indicate connection between the nutritive processes and the nervous system.

It has been already noticed that branches of the sympathetic pass along with the arteries in considerable numbers; some of them being apparently distributed to their coats, while others accompany them into the substance of the different glandular organs. It has also been stated that sympathetic fibres have been observed to join the cerebro-spinal nerves, and to run pherically with them to the different organs of animal life. From this distribution of the sympathetic, it has been held that it is in a peculiar manner connected with the nutritive processes. That it does exert an influence over the nutritive processes is seen from the effects which follow division of its branches. In addition to contraction of the pupil section of the sympathetic in the neck has also been observed to be followed by a disturbed state of the circulation in the eyeball, giving rise to swelling and inflammation of the cornea, a shrinking of the eyeball, and at the same time to an increase in the lachrymal secretion. In some of the experiments of Dr. John Reid, the injected state of the conjunctiva took place in the course of a few minutes after the operation. In a dog, in which he had divided the common trunk of the vagus and sympathetic as high up as possible, Valentin * observed that the secretions of the eye were very much increased, remaining so even after the lapse of several months. The same effects were also observed by him after extirpation of the superior cervical ganglion in the same animal. Dupuy found, on removing the superior cervical ganglion of both sides in the horse, that besides the effects above described the operation was followed by an anasarcous condition of the limbs and an eruption on the whole cutaneous surface.

Schiff† found, when the two upper thoracic ganglia in the dog or rabbit were removed, that the animal did not survive the operation for more than thirty-four hours; the heart, in the meantime, pulsated very quickly and forcibly. On examination after death, the blood-vessels of the pericardium were observed to be distended with blood,

* Op. cit. p. 423., as quoted by Longet.

† De vi motoriâ basios encephali, p. 37., as quoted by Valentin.

while a partly fluid, partly solid exudation surrounded the heart, forming in some parts adhesions between it and the pericardium.

From the experiments of Krimer it appears that division of the renal nerves gives rise to changes in the constitution of the urine. According to his observations this fluid, after the nerves have been divided, contains albumen as well as the red colouring matter of the blood, these increasing in the same proportion as the normal ingredients diminish in quantity. Similar results were also obtained by Brachet* in dividing these nerves. He cut the renal artery and with it the nerves leading to the kidney, and then connected the two extremities of the cut vessel by means of a canula so as to keep up the flow of blood. The fluid which passed off by the urethra contained fibrin and albumen as well as the red colouring matter or hæmatine. Analogous experiments were also performed by Müller and Peipers.† A ligature was applied around the renal vessels of the dog and sheep so tightly as to destroy the nerves, and again relaxed in order to allow the circulation to be re-established. Only in one case did they observe the secretion of urine continue in the kidney, the nerves of which had been destroyed, and in this case it contained blood as also hippuric acid. The kidney itself was more or less injected, and rapidly became disorganised.

As regards the influence of the sympathetic on the circulation, it has been already stated, that division of the sympathetic in the neck is followed very rapidly by distension of the vessels of the conjunctiva. From experiments lately made by Bernard, it also appears that in the rabbit the vessels of the ear on the same side in like manner become immediately distended with blood, so that the ear appears quite red, while at the same time its temperature, as well as that of the whole side of the face, rises so considerably, that the difference between it and that of the opposite side is distinctly appreciable to the touch. This experiment I have repeated several times. In a rabbit to which ether had been given, the temperature of the two ears rose to about 95° F., the vessels at the same time being much distended. The sympathetic was then divided about the middle of the neck: shortly thereafter the temperature of the ear on the side on which the nerve was not divided, sunk to 85°, and its vessels became much less distended. The temperature of the ear on the side on which the nerve had been divided, still continued as high as 95°, its vessels also remained distended, and were felt pulsating forcibly. On examining the two ears an hour or so afterwards the temperature of that upon the side on which the nerve had been divided, was still felt to be distinctly warmer than the other: its vessels were also still distended, and pulsating forcibly. How long the effects produced upon the temperature and blood-vessels continue I have not been able to ascertain: they are certainly not so permanent as the contraction of the pupil. While this remains contracted for weeks, or even months, no difference in the condition of the two ears can be distinguished a week or so after the nerve has been divided.*

* Op. cit. p. 326.

† De Nervorum in Secretiones Actione, p. 26.

* The elevation of temperature, according to Bernard, begins immediately after the nerve is divided, and is so quickly developed that in a few minutes, in certain circumstances, the difference in temperature of the two sides of the head may rise to 4° or 5° centigrade. This difference of temperature is perfectly appreciable to the hand, but is better determined by introducing a small thermometer into the nostril or ear of the animal. Removal of the superior cervical ganglion is followed by the same effects as section of the sympathetic cord, only these effects are always more rapid, more intense, and more durable. After section of the sympathetic cord in rabbits the phenomena of excess of sensibility and calorification are scarcely observable beyond five to eighteen days, while in dogs they may continue for six weeks or two months. After ablation of the ganglia in these animals the persistance of the phenomena may be regarded as indefinite: in a dog in which the superior cervical ganglion of the left side had been removed all the phenomena of excess of sensibility and calorification due to that operation were very intense a year and a half after the extirpation of the ganglion, when the animal was sacrificed for other purposes. The temperature of the side of the head on which the operation has been performed is nearly the same as that of the central parts of the body, such as the abdomen, thorax, or rectum; sometimes, however, it is higher, being 40°, while the temperature of the internal parts is 38° to 39°.

The increase of temperature is also attended by an increase in the activity of the circulation, as is very distinctly seen in the ear of the rabbit. But in the following days, or even on the day after the operation, the vascular turgescence diminishes considerably, or disappears, while the heat of the face continues to be very well developed. It is found, by passing the bulb of a small thermometer into incisions properly made, that the elevation of temperature observed on the superficial parts of the head extends to the deeper parts as well, and even into the cavity of the cranium and substance of the brain. This is better observed after extirpation of the superior cervical ganglion. The blood itself, which returns from parts so heated, also possesses a higher temperature. The side of the head on which the temperature has been so raised, presents also a greater resistance to the effects of heat and cold, when the animal is placed in a stove where the ambient heat is greater than that of the body; while the sound side becomes warmer, the other does not. When placed in a colder medium than its own body, the whole side loses temperature more rapidly than the other. There is also a sort of exaltation of vitality on the side on which the operation has been performed, the involuntary movements continuing longer on this side than in other parts of the body.

When the cephalic extremity of the cut sympathetic nerve in a dog is galvanised, not only does the pupil become larger, but all the other phenomena which followed division of the nerve disappear, and the opposite take place; the pupil becomes larger than that of the opposite side; the eyeball projects; the vascularisation disappears; and the temperature sinks below normal. When the galvanisation is stopped, then the phenomena caused by section of the nerve reappear.

By Walter and Brown Sequard the elevation of temperature is attributed to an increased afflux of

The experiments of Walther on the frog would also indicate that the circulation is more or less influenced by the sympathetic.* When the fibres which are sent by the sympathetic to the nerves of the lumbar plexus were divided, he found, on examining the circulation in the web of the foot, that, although at first undisturbed, it very soon afterwards increased in rapidity. The capillaries appeared to be dilated, and contained fewer blood corpuscles than corresponded to their calibre; the increase in their diameter equalled from one sixth to one eighth of the calibre of the vessel. After a time the rapidity of the circulation again diminished, and in some parts it became stagnant. Bidder †, on the other hand, could not in his experiments satisfy himself that any dilatation of the capillary vessels took place. Walther, however, has performed the experiment so frequently, and so uniformly with the same result, that he regards the dilatation of the capillary vessels as constant.

There are, moreover, certain experiments made by Valentin which show that the branches of the sympathetic which are distributed to the walls of the blood-vessels, exercise an influence over their contractions. Thus, when stimulus was applied to the thoracic portion of the sympathetic in the horse, he observed that the thoracic aorta and thoracic duct diminished in calibre to a much greater extent than could be attributed to the mere action of the atmospheric air. In a newly killed young rabbit, in which the part of the vena cava next the heart, as well as the right auricle were pulsating, he found on applying the wires of the magneto-electric apparatus to the right ventricles, that all contraction in the vessel immediately ceased.

Whatever influence the nervous system exercises over the processes of nutrition, it would seem that the sympathetic cannot be regarded as the only nerve concerned : the cerebro-spinal system also appears to share therein. In addition to what has been already stated, p. 470., there are also other facts which favour such a view. Thus Magendie found that, where the spinal cord was divided in the region of the neck, a disorganisation of the eyeball followed, similar to that which ensues upon division of the fifth nerve. Schiff* has observed that when the crus cerebri or optic thalamus in the rabbit was cut across, the secretions of the intestinal canal become altered; the excrements are slimy and mingled with blood ; the digestion is interfered with, the animal, towards the end of the first week, losing all appetite for food. After death the mucous membrane of the stomach and bronchi was found to be more or less injected with blood, the former also being softened. Similar appearances were also observed in the upper half of the small intestine. That, moreover, the influence exercised by the sympathetic over these processes does not differ from that exercised by the cerebro-spinal system, is indicated by the circumstance that several glandular organs, such as the mammary and salivary glands, derive their nerves chiefly from cerebro-spinal nerves.

From the experiments of Schiff and others it would appear, however, that the ganglionic system of nerves is more intimately connected with these processes than the strictly cerebro-spinal nerves are. Thus, Schiff found, in regard to the fifth nerve, that when it was divided between the brain and Gasserian ganglion, the destruction of the textures of the eyeball follow more slowly then when it is divided between the ganglion and the eye. In the frog, also, when the lumbar plexus was divided, the animal continued for two or three months without any disturbance being observed in the nutrition of the limb ; but when several of the lumbar ganglia were removed, dropsical effusion into the abdominal cavity, and inflammation of the peritoneum, ending in the death of the animal, ensued in the course of two weeks.† Axmann ‡, as quoted by Valentin, divided at their roots the nerves which supply the posterior extremity in the frog, but in no instance observed that the operation was followed by any disturbance in the nutritive processes: wounds of the soft textures as well as of the bones healed as rapidly

blood due to paralysis of the blood vessels. Bernard, on the other hand, believes that the phenomena are not due to the effects of paralysis of the blood vessels, but are active; they are of the same nature as the vascular turgescence which arises in a secreting organ when it passes from a state of repose to an active discharge of function, and resemble the afflux of blood, and increased sensibility around a recent wound or foreign body in the living textures; phenomena which are not due to mere paralysis of the arteries.

The sympathetic is the only nerve section of which is followed by an exaltation of temperature. Section of the fifth nerve Bernard found to be followed by diminution of temperature on the corresponding side of the head. When the facial nerve was divided at its exit from the cranium, an elevation of temperature took place on the paralysed side; this was increased when the sympathetics on the same side were also divided. If the facial was alone divided then, after a few days, the temperature returned to an equality on both sides of the face. The calorification produced by section of the facial nerve Bernard attributes to the division of sympathetic fibres which join the nerve during its course through the temporal bone. He also found that when the anterior or posterior roots of the spinal nerves going to form the sacral plexus were divided, the temperature was not increased but diminished. See Monthly Journal of Med. Science, March, 1854. Original paper in Gazette Médicale, Janvier, 1854.

Budge finds that removal of the portion of the spinal cord termed by him the ciliospinal region, is attended by an increase of temperature on the corresponding side of the head in the same manner as when the sympathetic is divided in the neck.

as in the sound leg. When he divided the trunk of the lumbar nerves below the spinal ganglia the skin became gradually pale, its pigment cells diminishing to mere points; the structures softened; the liver and kidney no longer secreted; while dropsical effusions, containing the elements of the bile and uric acid, at the same time took place. The blood corpuscles also gradually disappeared. The vessels of the spinal cord and of its membranes became very much distended with blood. When the lower portion of the sympathetic cord on either side was removed, the blood-vessels of the hind leg and pelvic organs became highly congested; the contractility of the muscular tissue in the legs and in the pelvic organs disappeared. Blood was extravasated into the bladder and rectum, secretion of urine ceased, and dropsical effusions took place. The circumstance that section of sensory nerves is followed by derangement in the nutritive processes much more quickly than similar lesions of motor nerves is also explained by Volkmann as due to the fact of the former containing a comparatively larger number of fine or sympathetic fibres.

TEGUMENTARY ORGANS. In endeavouring to deal with so large a subject as the tegumentary organs of animals, within the limits of an article like the present, it appeared advisable not to attempt to enter into minutiæ of detail (which indeed fall more properly within the province of those who treat of the special classes), but so far as possible to regard these organs as a system in the sense of Bichât — as a sort of zoological class — whose members, the tegumentary organs of particular animals, are but special modifications of one general plan. In reflecting how this might best be done, however, I was met at the outset by certain difficulties and perplexities whose solution appears to me to be essential to any philosophical treatment of the subject, and to the consideration of which I, therefore, propose to devote the following *Preliminary Section.*

§ 1. My first difficulty was to find an answer to the question,—What constitutes a tegumentary organ as distinguished from any other?

The most obvious definition of an *integument* or *tegumentary organ* is, of course, — that which forms the external covering of any animal — *viscus*, on the other hand, being that which is contained. More strictly, it may be said that the integument constitutes that free surface of an animal which is external to the edges of the oral and anal apertures, or where the former alone exists, to *its* edge. Now these definitions are perfectly sufficient so far as surface is concerned; but suppose we make a section perpendicular to the surface, where does integument cease, and where does viscus begin? So far as I am aware, no elucidation of this point has hitherto been undertaken, and yet, for want of it, the greatest confusion prevails in the nomenclature of those organs which constitute the outer wall of the animal frame.

Intimately connected with this question, and indeed forming a part of it, is a second. In man and the higher animals, there is an universally recognised distinction of the integument into two portions,—the *epidermis* and the *derma;* and these terms have been extended to all animals. But, if we inquire what constitutes an epidermis, and what a derma, no definite answer is to be met with. It may be said that the derma is vascular, while the epidermis is nonvascular; or that the epidermis is a simple cellular horny structure, while the derma is complex and fibrous; but these characters, applicable enough among the higher animals, fail completely with the lower.

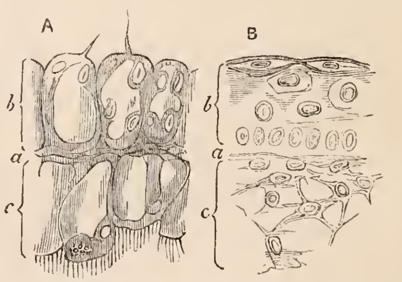
Thus, in the majority of the Invertebrata, the derma cannot be said to be vascular, while, on the other hand, the epidermis, or its representative, assumes the structure of fibrous tissue, bone, cartilage, dentine, and enamel, — acquires, in fact, the utmost complexity, and, instead of possessing a horny nature, contains chitin, cellulose or calcareous salts.

Following Mr. Bowman, — who, of course, when he wrote his well-known article on "Mucous Membrane," in this Cyclopædia, could not contemplate the new questions to which the progress of ten years would give rise,—many regard that which is external to a "basement membrane" as epidermic, that which is internal to it, as dermic structure. This test, however, fails us where we most want it; for among the lower animals, and in some integumentary organs among the higher, membranes identical in structure, or rather in structurelessness, with "basement" membranes, may be met with, forming the surface of what are assuredly epidermic organs.

I believe that here, as elsewhere, the only ultimate appeal lies to development, both as it occurs in the embryo and as it goes on in the adult. What, in fact, is the first process which takes place in the embryo, when the germinal disc is once formed? It is a separation into two layers, by the setting up within the outer portion of the primitive germ of a process of growth independent of that in the inner portion. Where these two areæ or planes of growth, as they might be called, meet, the germ readily separates into two portions, the outer of which is the so-called *serous layer*, the primordial tegumentary system; while the inner is the *mucous layer*, the primordial viscus. Of course each of these, while *actually* integument and intestine, represents *potentially* a great deal more,—the former, for instance, in the higher animals becoming eventually differentiated into the proper tegumentary system and a great part of the nervous, the muscular, and the vascular systems; but what I wish to direct attention to at this moment, is the fact, that this first differentiation into integument and viscus proceeds from the setting up of two independent lines, or rather planes of growth, in the germinal membranes.

In the Hydra and Hydroid Polypes generally, we have the essence of this embryonic state as a persistent condition. If, in fact, the body or almost any organ of one of these animals be examined, it will be found (*see* Memoir on the Structure of the Medusæ, Phil. Trans. 1849) to be composed of two distinct membranes, an inner and an outer (*fig.* 303. A). The junction between the two is distinctly marked by a clear line, which would elsewhere be called a basement membrane (*a*). External and internal to this, there is a layer of young tissue, consisting of a homogeneous periplast with minute imbedded endoplasts ("nuclei"). As we proceed towards the free surface, we find that a process of vacuolation and cellulation takes place in the periplast, until the coarsely cellular appearance with which every one is acquainted is produced.

Fig. 303.



A, hydra; *b*, outer membrane; *c*, inner membrane.

B, young mammal; *b*, epidermis; *c*, derma.

In the Hydra, then, we have the whole thickness of the body divided into two portions by a line, on each side of which, inwards and outwards, there is an increasing histological metamorphosis or differentiation. There is a median *plane of no differentiation*, as it might be termed, external and internal to which, is a zone of *indifferent tissue*, while, still more remote again, is a zone of *metamorphosed tissue*. The absolute structure of the two layers thus produced is very similar *, so much so, that, as is well known, either may perform for a time the function of the other. The distinction between the integument and the mucous membrane in a morphological point of view, however, is as strongly marked as in the most complex animal. The integument, in fact, grows from within outwards—it is endogenous, its youngest portions being internal: the mucous membrane, on the other hand, grows from without inwards — its youngest portion is external, and it is, therefore, exogenous.

We have here, I believe, the fundamental, and the only essential distinction, between true *integumentary* or "*epidermic*" structures and all others. *An integumentary or epidermic organ forms or has formed a part of the external surface, and grows endogenously; its youngest portion and plane of no differentiation being directed inwards.*

If, for instance, we compare the young skin of a mammal with the body of the Hydra, we shall find precisely the same planes and zones.

Fig. 303. B, represents a perpendicular section of the integuments of a fœtal lamb $3\frac{1}{4}$ inches long. (A) marks the position of the line of no differentiation separating the epidermis from the derma; on the outer side of that line lie the close-set endoplasts of the deepest layer (*rete*) of the epidermis, which are disposed somewhat perpendicularly to the surface. On the inner side are the less approximated endoplasts of the outer youngest layer of the derma, more or less parallel to the surface. From *a* to *b*, lies the epidermic area of metamorphosis, the indifferent tissue becoming gradually converted into flattened horny cells. From *a* to *c*, on the other hand, is the dermic area of metamorphosis, the indifferent tissue gradually changing into connective tissue.

It will be observed here, that as the whole serous layer of the germ corresponds in structure with the epidermis only, of the fully formed animal, so the whole integument of the Hydra corresponds with what is usually considered as only a portion of the integument—the *epidermis*—of the mammal. The derma, or true skin of the latter, would not come at all under our present definition of integument, since it has all the morphological characters of the mucous layer of the Hydra, or of the germ; *i. e.* its youngest layer is external, its growth is exogenous, and the metamorphosis of its tissue takes place from within outwards.

In fact, in all animals higher than the Hydroid Polypes (possessing therefore a visceral cavity) we find a complication of structure, corresponding with that which is produced in the germ, when the "*membrana intermedia*" divides into its parietal and intestinal laminæ. Compared with the Hydroid Polypes, the higher forms are double animals, and a section of their bodies is, morphologically speaking, like a section of two Hydræ, one contained within the other. Both the intestinal parietes, and those of the body, present the same distinction into a central *plane of no differentiation*, from which growth and metamorphosis proceed inward and outward on the two respective surfaces, as that observed in the parietes of the Hydra.

The formation of this so-called membrana intermedia, in fact, appears to result from a repetition of the process which gave rise to the two primary layers of the germ. The previously central *plane of no differentiation* is replaced by two others, from which growth and metamorphosis proceed in the same way. The result is, of course, the division of the germ into three layers — a central and two superficial (inner and outer) planes of metamorphosed tissue — and two planes, whence growth and metamorphosis proceed.

It results from all this, that, among the higher animals, the true homologue of the integument of the Hydra is the epidermic layer alone. But it would be exceedingly inconvenient to change the accepted meaning of "Integument" on this ground; and, therefore, I shall, throughout the present article, consider as integument — *the outermost plane of indifferent tissue in the animal body, with its external and internal areæ of metamorphosis collectively; these being simply the expressions of two processes of growth in opposite directions, and their line of contact.*

It must not be supposed that this phraseology involves any hypothetical views: the fact that any integumentary organ consists of these three portions will be found to be either distinctly stated or implied by all writers, and is indeed obvious enough on inspection. But though the facts be old enough, this expression of them is unfortunately so new, that I know of no existing terminology by which it can be properly enunciated. The term "Epidermis," for instance, at present, though it denotes the important character of the direction of growth to which I refer, implies even more strongly the simple cellular structure of an organ; so that to speak of "Epidermic" bony or fibrous tissue would sound almost contradictory. Again, all these distinctions, which have been shown to exist between the two elements of the integument, equally hold good with regard to the mucous membranes. Now we have a term "Epithelium" for the epidermic element of the latter; but there is, as far as I know, none for the element which corresponds with the derma. Nor have we any word for the boundary line between the endogenous and exogenous areæ of growth — the term "basement membrane" expressing only an accidental character of the tissue immediately on one or the other sides of that line.

Although with great reluctance, then, I feel compelled to propose two or three new terms, which may have general application, not only to the integumentary organs, but to all other

* Though not, as it is commonly said, identical.

membranes which possess free surfaces and definite directions of growth and metamorphosis.

The boundary line — passing through indifferent tissue — between any two such opposite areæ of growth and metamorphosis, I term the *Protomorphic line*. The whole external (free) area of metamorphosis I call the *Ecderon;* the entire internal (deep) area of metamorphosis, the *Enderon.*

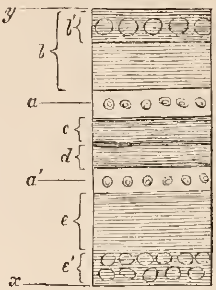
It will be observed that these definitions rest wholly upon the *mode of growth*, and leave altogether out of consideration the *structure* of the resulting tissue. In fact, as I have already said, an extensive study of the integumentary organs convinces one at once that mere structure affords no base for homology; the ecderon, for instance, presenting every variety from the structurelessness of a homogeneous membrane, as in the Tæniadæ, to the complex combination of the so-called enamel, dentine and bone, in the scales of Placoid Fishes.

It is, I venture to think, no small evidence in favour of the importance of these considerations that they enable us to carry still further the doctrine of the identity of structure of plants and animals sketched by Caspar Wolff, and developed in our own times by Schwann. If we make a transverse section of the growing limb of a vertebrate animal, leaving out of consideration, for the moment, the vessels, nerves, and muscles, we observe from the surface inwards, 1st, the ecderonic area of metamorphosis; 2nd, the integumentary protomorphic line; 3rd, the enderonic area of metamorphosis; 4th, the periosteal area of metamorphosis; 5th, the protomorphic line, formed by the indifferent tissue between periosteum and bone; 6th, the osteal area of metamorphosis, within which lies, 7th, the cartilage resulting from the metamorphosis of the tissue of the primitive axis of the limb.

Now, if we compare this with the growing shoot of a young exogenous plant, we meet with exactly the same series from without inwards. There is, 1st, the epidermis, which commonly becomes replaced by a cork or peridermal layer, just as the primary epidermis over a nail is thrust aside by the subjacent and subsequently-formed horny matter; or, as the horny "epidermis" of a Skate is pushed aside and replaced by the calcareous placoid spine. Beneath this lies, 2nd, a protomorphic (or *cambial*) line, from which metamorphosis into periderma goes on outwards, while inwards it passes into, 3rd, the metamorphosed tissue of the mesophlœum. Next to this comes, 4th, the metamorphic area of the endophlœum or liber; within which is, 5th, the protomorphic line of the cambium, which becomes metamorphosed on its inner surface into, 6th, the wood; within which lies, 7th, the pith, the result of the metamorphosis of the primitive axis of the shoot.

I have endeavoured to render these relations obvious by the diagram (*fig.* 304.), which may be taken for a section from centre to surface of a fœtal limb, or of an exogenous branch. *a*, outer protomorphic line between epidermis or periderma and mesophlœnm in the plant;

Fig. 304.



between ecderon and enderon in the animal; *a'*, inner protomorphic line between liber and wood of plant, between bone and periosteum of animal; *b*, *b'*, cork and epidermic layers of plant; cellular epidermis and scale of animal, fish, *e.g.*; *c*, mesophlœum, enderon (derma); *d*, liber, periosteum; *e*, *e'*, wood and pith, bone and cartilage; *x*, axis; *y*, surface.

The consideration of vegetable structures will aid us even further in understanding the manner in which the different varieties of integumentary organs, with which we shall meet, are formed. For it is well known that the outer covering of a plant may ultimately be constituted in one of three ways. 1. The original cellular ecderon may persist unchanged. 2. The "epiderm" persisting, a laminated, but otherwise structureless "*cuticula*," may be developed upon its outer surface, attaining sometimes a very considerable thickness. 3. The original epidermis is cast off, its place being taken by the development of a new layer of different, usually suberous constitution, beneath it, which then goes on growing endogenously, and constitutes the permanent integumentary surface. Now, we find a precise parallel for all these conditions in animals. In the soft integument of most Mollusca and Vertebrata the first condition obtains, the general surface of the integument being constituted by the cellular "epidermis."

In the Annulosa, on the other hand, the integument has certainly, in many cases, and I think probably in the great majority, the character of a vegetable cuticle, consisting as it does of layers developed from the outer surface of the cellular ecderon. In this way also I believe that all molluscan shells are formed.

Lastly, the fish-scale produced altogether beneath the cellular ecderon or epidermis, but growing endogenously after the manner of a true ecderonic structure, appears to be precisely analogous to the corky periderma of the plant; and as the latter, though it is not the original epidermis, takes its place and grows in the same way, so in the fish the scale, which is assuredly not a calcification of the cellular ecderon, yet represents it both in position and in mode of growth.

§ 2. *Morphology of the integuments.*— In the embryonic state of all animals, and in the adult condition of many of the lower forms, the integument, constituted as above defined, forms a continuous investment over the surface of the body without any important processes or irregularities. Such is the case in many of the Worms, Polypes, and lower Mollusca. From such simple forms of integument as these the most rudimentary kinds of appendages or tegumentary organs are produced in one of two ways,—either the outer portion of the ecderon is thickened, and as a spine or as a plate projects beyond the common surface—*e. g.* cells of Hydroid and Polyzoic Polypes ; or the whole integument is developed into a spine-like or plate-shaped process, as in the so-called "bracts" of the Diphydæ, and in all the spines, hairs, and scales of the Insecta, Crustacea, and Arachnida.

The shells and plates of Mollusca and Articulata belong principally to the former division, being simple laminated thickenings of the outer portion of the ecderon. In the Vertebrata the integument but rarely possesses appendages of so simple a nature. Simple plates of this kind, however, coat the surface of the beaver's tail, in which animal, according to Heusinger, "the epidermis is divided by a great number of clefts into hexagonal portions 4 lines long, whose whole edges adhere to the cutis. They usually consist of a couple of superimposed laminæ identical in structure with the rest of the epidermis" (*l. c.* p. 168.). The polygonal horny plates of the Chelonia are of the same nature. The scales on the under surface of the tail of the rat and other rodents, and on the tarsi of birds, are similarly constituted; but here one edge is thrown up, and we have a transition to the scales of the Pangolin,—to those of Ophidia and Sauria,—and to the nails, claws, hoofs, and hollow horns of Mammals, and the horny sheaths of the beak of Birds, all of which are constructed on essentially the same plan, being diverticula of the whole integument, the outer layer of whose ecderon has undergone horny metamorphosis.

Among these the nails, horns, and hoofs of mammalia present certain complexities of arrangement which entitle them to particular notice.

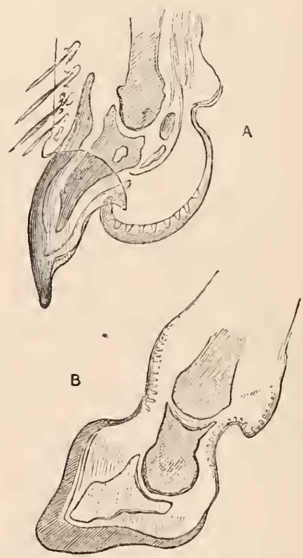
Nails are flattened horny plates developed from the upper surface of the phalangeal integument only; they are free at their distal extremities, but laterally and at their proximal ends they are enclosed within raised ridges of the whole integuments, the *nail walls.* The enderon beneath them in the space which is called the "bed of the nail" is raised into parallel longitudinal ridges or laminæ, which fit into corresponding depressions of the under surface of the ecderon.

Claws are nails which embrace a larger portion of the phalanx, being developed, not merely from its upper surface, but also from its extremity, and extending far round on its sides. In the dog and cat (*fig.* 305. A) the bed of the claw is laminated as in man, but presents no papillæ (Gurlt), and a bony plate extends from the last phalanx into the posterior fold of the nail.

The transition from the claw to the *hoof* is readily understood if we suppose the terminal portion of the former to be blunt and cylindrical, instead of pointed and conical (*fig.* 305.). The elephant and rhinoceros do in fact afford an actual passage from the nail to the hoof, inasmuch as their very flat nails are continuous at their edges with the solid horny covering of the sole (Heusinger).

The solipede hoof has been described in the article SOLIPEDIA; we need therefore only remark here that the *wall* corresponds with the nail in man, and may, by maceration, be separated from the sole and frog, which are developed from the termination and posterior surface of the phalanx. The ridge or "bourrelet" at the upper margin of the wall answers to the posterior nail-wall, and, as in the nail, the horny upper layer of the "epidermis" is continued on to the hoof from it. The structure of the bed of the hoof differs in its different parts. That portion which corresponds with the sole and frog merely presents papillæ, which fit into depressions of the horny ecderon; that which corresponds with the wall is produced into lamellæ like those of the bed of the nail, so that the deep surface of the wall is laminated. In addition, however, long papillæ extend from the "bourrelet" through the superficial portion of the wall, so that, on section, it presents a superficial series of canals, around which the horny matter is disposed in concentric layers.

Fig. 305.



A. Section of the foot in a kitten. B. In a fœtal lamb.

Each half of the hoof of a ruminant (*fig.* 305. B), or of the pig, corresponds in general structure with the entire hoof of a solipede, except that the frog is rudimentary. The horny ecderon presents both tubuli and laminæ.

The excrescences on the inner surface of the leg of the horse are identical with the sole of the foot in structure — consisting of a horny mass penetrated by long papillæ.

The hollow *horns* of the Ruminantia are, to all intents and purposes, *Claws*. The superficial cellular ecderon (epidermis) is continued upon them, and, when this is removed, we come to a laminated fibrous horny mass, which is formed and increased by apposition from the subjacent process of the enderon, supported by its bony axis — a process of the frontal bone. The enderon has neither villi nor lamellæ, presenting only small irregular ridges (Gurlt).

The *horn* of the rhinoceros is commonly said to be constituted by a mass of hairs which have coalesced. However, it consists of an aggregation of tubes, round which the horny matter is arranged in concentric laminæ, as in the horny excrescence of the horse's leg; and as there is no evidence of its having ever been enclosed within a sac, it is more probable that it belongs to the series of the claws and nails.

Glands, hairs, and feathers. — The *Hairs* and *Spines* of mammals, the *Feathers* of birds, and the *Integumentary Glands* agree in one essential point, that their development is preceded by that of an involution of the ecderon, within which they are formed, and by which the former are, at first, entirely enclosed.

At an early period, the rudiments of the hairs, and those of the cutaneous glands of a fœtal mammal, are indistinguishable. They alike consist of solid processes of the ecderon, consisting of a homogeneous matrix, in which lie closely-set endoplasts, bounded internally by a clear, narrow, transparent "basement membrane," which at once separates them from, and connects them with, the enderon.* Externally these processes are continuous with the rete mucosum of the ecderon. In the fœtal lamb, in which I have carefully traced the development of these processes, they increase in size without change of structure, until, in the ordinary hairs, they have attained a length of $\frac{1}{150}$ inch; for the vibrissæ, that of $\frac{1}{60}$ inch. Having reached this length, it is seen that an accumulation of the indifferent tissue of the enderon has taken place around their cœcal ends, which gradually become pushed in, so that, from being rounded, they appear truncated in section, and present a bulb with a hemispherical involution, the rudiment of the papilla. In the ordinary hair no special accumulation of indifferent tissue takes place around the body of the involution; but in the vibrissæ, which are ultimately to possess a thick outer capsule, its foundation appears in this form, and a capillary loop may be seen penetrating the rudimentary papilla.

In the furthest advanced vibrissæ the tissue of the axis of the sac was converted into horny cells, the rudiment of the "fenestrated" or of the inner, horny rootsheath. Over the papilla the rudiment of the hair shaft was indicated by a conical process, horny at its apex and marked by radiating lines. Finally, on each side of the neck of the sac there was a bulging process, the centre of which was occupied by a mass of fatty-looking granules, the future sebaceous glands of the hair.

Hairs are not normally susceptible of indefinite growth, but have, like the teeth, a fixed form to attain. This form is always that of a more or less elongated spindle, inasmuch as the hairs are sharp at their points, becoming broader and thicker in the middle, and diminishing again to their proximal ends. When fully formed, and ready to fall out, in fact, this end of the hair is either pointed, or more or less ragged and brush-like.

As soon as the finishing process of any hair begins the foundation of a new one is laid by the development of a diverticulum of the outer rootsheath towards its base, in which a young hair is developed, in the manner already described, and gradually pushes out the old one.

The varieties of form and appearance presented by the hairs of animals (for which see the works of Hensinger, Eble, Busk, and Quekett, cited at the end of this article) are produced; 1st, by the relative proportions of the medullary and cortical substances, and the arrangement of the former with respect to the latter. Thus the peculiar appearance of Rodent hairs is due to the disposition of the medullary substance. 2nd, by the development of the cuticular layer, whence arise the whorled scales of bat's hair — the imbricated plates of seal's hair, &c.; 3rd, by the shape of the shaft, which may be cylindrical, as in ordinary hair of the head in man; or evenly flattened, as in the short curly hairs; or narrow and cylindrical below, and wide and flattened above, as in the hairs of the deer tribe. The spines of certain mammals, such as *Hystrix* and *Erinaceus*, present some interesting peculiarities of form; offering, as they do, a sort of transition between hairs and feathers.*

The porcupine's "quill," as it is called, is a cylindrical tube which gradually diminishes to a point above and below. At its apex the cavity of the quill is simply conical, but lower down its section becomes polygonal, and, the angles of the polygon being prolonged, resembles a four-rayed star. Still further towards the root of the quill, each ray of the star divides into two secondary rays, and then the secondary rays subdivide into two tertiary rays; so that eventually the cavity of the spine is a complicated star with four and twenty branches. Below its middle, the quill diminishes in diameter, and at the same time the complexity of its internal cavity likewise dis-

* The further development of the *glands* will be most conveniently considered, together with their histological structure, below.

* See Bröcker (Reichert's Bericht, 1849), from whom the account in the text is taken, though the main points have been independently verified.

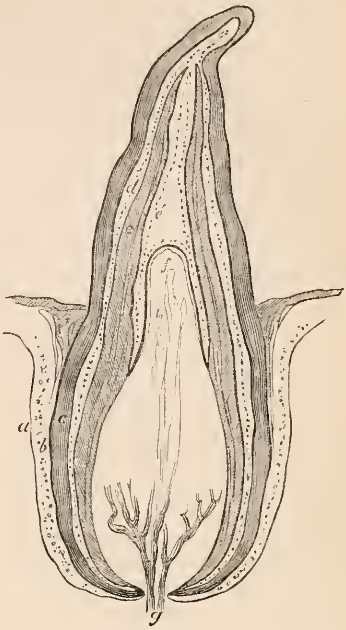
appears, the tertiary rays disappearing first, and then the secondary, &c., until at last the cavity is circular as at the apex. The boundary of the quill cavity is immediately formed by medullary substance; but the cortical substance follows to a certain extent the contour of the inner cavity, so that in a transverse section of the middle of the quill the cortical substance presents the same general outline as the medullary, though its processes and insections are less marked.

In the adult condition, the central cavity is filled by an irregular horny mass, which Reichert and Bröcker regard as the dried-up pulp, but which is probably, as in the feather (*vide infra*), simply the last horny product of the pulp, filling up the space which the latter once occupied; for it is certain that every portion of the porcupine quill has, like every portion of a feather, at one time constituted a cap over the corresponding portion of its pulp. The pulp, in fact, commences like that of a feather, as a smooth conical process upon which the apex of the quill is moulded. As it grows, however, the pulp assumes an angular form, and then, as that of a feather would do, becomes produced into lamellæ. By the constant production of new elements at the surface of these lamellæ and their cornification, the "quill" is produced, and retains internally the impression of the mould on which it was formed. Apart from the arrangement of the lamellæ, the principal difference from a feather which the "quill" presents, is simply that it does not, as it is formed, split up along the lines of the lamellæ of the pulp.

In its main features, the process of development of *feathers* is identical with that of hairs. A solid diverticulum of the ecderon is first formed, within which the primary change consists in the metamorphosis of certain median cells into a cone composed of horny plates. There is thus formed, as in the hair, an outer rootsheath, resembling and continuous with the *rete mucosum*, an inner rootsheath, and a central papilla, the so-called matrix of the feather (*fig.* 306.).

The horny rootsheath (*fig.* 306. *c*) attains a very considerable thickness, and instead of stopping short of the mouth of the sac, as in the hair, its outer end is for a considerable time pushed forwards by its basal growth *pari passu* with that of the feather; so that it eventually projects for a considerable distance beyond the surface. Finally, it opens and allows of the passage of the feather, which grows through it, the horny layer ultimately forming a true rootsheath around the quill. Like the rootsheath of the hair, this structure consists of two layers, an outer (*c*), denser and harder, and an inner (*d*), softer and more flexible. The latter from being marked by the projecting barbs of the young feather has been called the *striated* sheath. Both layers, however, have the same essential structure, being composed of rounded or polygonal horny plates, whose endoplasts are often distinctly retained even in the outer layers. The histological metamorphosis of the feather will be described below, but the manner in which it acquires its ultimate complex general figure requires particular attention. Referring for further de-

Fig. 306.



Sectional view of feather in its sac: Fowl.
e, barb; *f*, pulp; *g*, venal.

tails to the article AVES, I may state here, that every feather consists of the following parts:— *the quill* continuous with the *shaft*, or central axis of the feather, which supports the horizontally expanded *vane*, consisting of numerous long, narrow, flattened laminæ; the *barbs* or primary rays, pointed at their extremities and arranged with their edges upwards and downwards more or less perpendicularly on the shaft. Arranged in a similar manner on the barbs, are the *barbules*, which therefore are disposed more or less parallel to the shaft; from the sides of these, lastly, project short, toothed, curved, interlocking *processes*.

All parts of the feather are solid, except the quill, which is hollow and occupied only by a dry shrivelled mass, the *pith*, in its upper part, while below, during life, it receives the pulp. Superiorly, on the under side, where the quill joins the shaft, there is a small aperture, which communicates with the interior, with a short canal in the shaft, and with a groove which runs along its under surface.

It may be well to remember that the apex of a barbule resembles in structure one of its own processes; that of a barb, one of its barbules; that of the shaft, one of its barbs.

The development of this complicated organ from its *matrix* or *pulp* takes place very simply, by a sort of exaggeration of the combination of hair development with that of the nails, which has already been described as occurring in the spines of the porcupine.

On the surface of the feather-pulp a series of ridges are developed, running pretty nearly parallel with one another from an antero-posterior groove upon the upper surface, which marks the position of the future shaft, to a line parallel with that groove upon the under surface or the process, which is called the *raphe*. These ridges, therefore, bound as many grooves which branch off from the medio-dorsal groove, becoming gradually shallower, to the raphe. These secondary grooves, as they might be termed, however, are not themselves simple; their walls, the ridges, being again produced into short parallel laminæ, and therefore giving rise to tertiary grooves, branching off from the secondary ones. Now, the whole surface of the matrix being covered by an ecderonic layer in process of conversion into the cortical and medullary substances of the feather, the primary groove becomes filled by the end of the shaft; the secondary grooves by the terminal barbs, the tertiary grooves by their barbules, while the processes appear to be outgrowths from these. Were all this conical horny cap to remain entire, the result would be a very complex sort of porcupine's quill; instead of this, however, it breaks up along the line of each ridge, and so we have a feather.

The extremity of the feather being thus constituted, how is its remaining length developed? According to Reichert, the whole pulp elongates, and as fast as a portion of the feather is completed, the corresponding segment of the pulp dries up, constituting for the vane what has been called the *inner striated membrane* (*e′*). However, I believe that this is not the case, the inner striated membrane being, like the outer, a mass of cornified cells detached from the surface of the pulp, just as we shall see the pith of the shaft to be, though this has been also declared by Reichert to be dried-up pulp. I believe that the growth of the feather, on the other hand, resembles that of the hairs and nails; viz. the extremity as it is finished, is pushed up by the growth of the base, the pulp only supplying materials from its surface; and I account for the inner striated membrane by supposing that a comparatively imperfect development of horny cell membranes takes place from that surface of the pulp which would otherwise be left bare, when the terminal cone or plume of the feather is pushed away. When the development of the shaft has gone on in this manner for a longer or shorter time, according to the length of the feather, a change takes place. The primary groove, which has gradually widened with the width of the shaft (to the exclusion of the secondary grooves, which gradually shorten and ultimately disappear) becoming shallower, extends all round the pulp, and the formation of medullary feather substance ceases, that of cortical substance alone remaining. Thus is the hollow quill formed, and its edges, not quite closing above, leave the minute umbilical aperture by which the inner striated membrane is continued into the "pith" of the quill. This pith is produced by the throwing off of successive transverse horny partitions from the apex of the pulp, as the quill is pushed beyond it; thus protecting itself from the air admitted by the umbilical aperture, and which is visible, occupying the chambers thus formed (*fig.* 316. G).

A full description of the various forms of feathers is given in the article AVES in a former portion of this work, to which the reader is referred.

There can be no question as to the relations of the integumentary organs hitherto described to the primary constituents of the integuments, but it is different with regard to those calcified tegumentary appendages, the *scales* of Fishes, and the so-called "*dermal*" *calcified plates* of Reptilia and Mammalia. One point is quite certain with regard to these appendages, that they are not, like the calcified shells of the mollusca, the representatives of the outer portion of the originally cellular epidermis (are not therefore comparable to the "cuticula" of a plant), inasmuch as the latter may always, in their young state, be traced over them. It is for this reason, I imagine, that they are at present ordinarily called "dermal" organs. A truly dermal or enderonic organ, however, ought, if it continues to grow, to retain the same characters as the enderon of which it forms a part. It ought, therefore, to have its protomorphic surface external and to grow exogenously. Now, no scale or plate of any fish, so far as I am aware, does this; on the other hand, it holds good of all, whether Placoid, Ganoid, Cycloid or Ctenoid*, that they commence by the occurrence of a calcfiic deposit immediately beneath the cellular ecderon, and that they increase by continual addition to the inner surface of this primary deposit. There are two ways in which we may conceive that these scales and plates are produced. Either they are a gradual calcification of the whole enderon from without inwards (which is the view taken by Leydig, of the scales of Polypterus), in which case the only tissue of the enderon capable of increase (that of the protomorphic line) being arrested by the calcareous deposit, the whole enderon at these parts must cease to grow, which would appear to be contrary to fact; or the scale corresponds with the cork-layer of the vegetable integument, and like it, though developed beneath the ordinary cellular epidermis, is still a truly ecderonic structure.

A great deal might be said for both these views; and if in this place, I assume the latter to be more correct, it is because I think we must be guided by the homology of the scales with certain other organs, where these relations are more definitely expressed. It may be taken as certain, I think, that the scales, plates, and spines of all fishes are homologous organs; nor as less so that the tegumentary spines of the Plagiostomes are homologous with their

* And I believe it will be found to be equally true of the "dermal" bones of reptiles and mammals.

teeth, and thence with the teeth of all vertebrata. Again, it appears to me indubitable that the teeth and the hairs are homologous organs; they are therefore either both enderonic or both ecderonic. Taking for granted the validity of a basement membrane as a mark of the boundary between ecderon and enderon, I elsewhere* arrived at the conclusion that the teeth are enderonic organs, and that therefore the hairs must follow them. Now, however, that a "basement membrane" turns out to be no test at all, there seems no reason why we should not be guided entirely by the direction of growth, and consider both hairs and teeth as ecderonic organs; the former being a development of the cellular ecderon, and corresponding with the ordinary horny epidermis; the latter, a development of a deep layer of the ecderon beneath this. It appears to me that we can do no other than admit this view for the teeth; but if this be the case, we may apply it to the scales of fish (and the "dermal plates" of reptiles?) also; as there are no difficulties about the latter which are not also presented by the teeth.

There appear, in fact, to be but few objections of any importance to the assumption of the ecderonic nature of fish scales, the principal ones being the continuation of the tissue of the ecderon over the upper surface of the scales; the apparent passage of the bony structure into the laminæ of the connective tissue of the enderon below, and the vascularity of the latter.

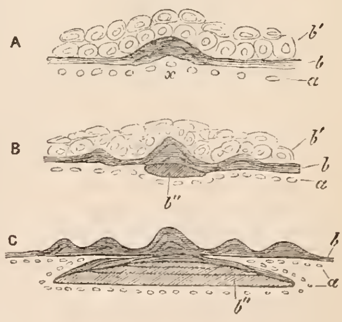
The continuity of the enderon over the scales will be seen below to be more apparent than real. I have not been able entirely to satisfy myself, as to the exact relations of the parts, in the case of the eel, but in the other fishes which I have examined the surface of the scale is very partially covered by the enderon, being in its centre, at any rate, in contact with the cellular ecderon.

The vascularity of the scale never extends to its most superficial layers, and may be explained in the same way as that of the test of an Ascidian, which however is unquestionably an ecderonic structure. The passage of its deep layers directly into the connective bundles of the enderon, which Leydig has observed in Polypterus (and which I will not say does not occur elsewhere, though I have not observed it), would appear to me only to indicate that this scale, and perhaps others, are composed of two portions, a superficial ecderonic part extending as far as the most superficial vascular canals, and a deep portion beneath these belonging to the enderon.

However, all these points can only be decided by a much more extensive series of investigations, principally directed to the ascertainment of the position of the protomorphic line and of the direction of growth of the constituents of every scale, than I have hitherto had time or opportunity to carry out; and as the attention of other observers does not appear to have been directed to these particular points, the question must for the present remain undecided.

Professor Williamson in his valuable and philosophical contributions to our knowledge of this subject (Phil. Trans. 1849-1852) laid the foundation for a comprehension of the mode of development of fish-scales, by pointing out that Agassiz's views, though essentially true, yet require a certain modification. For though a fish-scale does really grow by the apposition of layers to its deep surface, as Agassiz asserted, yet it is not included in a sac of the epidermis (if by that term we are to understand the ordinary cellular ecderon); and it is also true that its deeper portions grow by their superficial surface. Professor Williamson points out, in fact, that every fish-scale consists of at least two portions, a superficial homogeneous, or at most canaliculated, laminated layer, the *ganoin* (so called enamel or horny layer of authors), and a deeper, also laminated, frequently fibrous or osseous portion commonly traversed by Haversian canals. Now these two portions have a certain independence in their mode of growth, at any rate after their first formation, as may be easily understood by the accompanying diagram (*fig.* 307.), which represents a series of imaginary sections of scales from their first growth onwards; *a*, is the protomorphic plane; *b*, *b''*, the deep ecderon; *b'*, the superficial cellular ecderon, and the line *x*, the centre of the scales from which development commenced.

Fig. 307.



Suppose A to be the youngest scale, constituted merely by a thickening and calcification of the deep ecderon, which in B has added several layers by apposition to its inner surface, all of which retain the ganoin structure except the deepest, which becomes fibrous in its texture, and forms the commencement of the "Lepidine" layers of the scale;—these layers, however, being as much a part of the ecderon as the former. In C the scale widening, the edges of its "Lepidine" layer do not remain in contact with the ganoin layer; but it will be obvious that the re-entering angle thus formed by the protomorphic line between the two, is only, as it were, a fold of the deep surface. If the two layers go on increasing

* On the Structure and Development of the Teeth, Quarterly Journal of Micros. Science, 1852.

in this way, however, the ultimate effect will be that, although growing in reality by its deep surface as before, the "Lepidine" layer of the scale will appear to grow by its superficial surface, and that addition of layers to the upper surface of the scale observed by Professor Williamson, will take place. If the explanation here proposed, however, be correct, this will form no objection to, but a confirmation of, Agassiz' views.

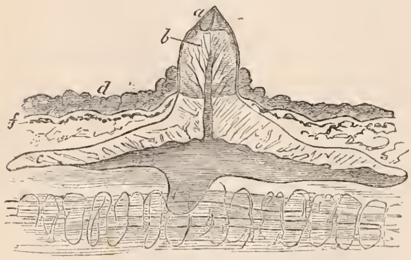
It will be well, however, with this clue to turn from the theory to the facts of scale development.

All that I have observed leads me to confirm Professor Williamson's conclusion, that there is no real line of demarcation to be drawn between placoid, ganoid, ctenoid, and cycloid scales; all these forms passing into one another. Indeed, I conceive that the only method thoroughly to comprehend the cycloid and ctenoid scales is to examine, in the first place, the so-called placoid and ganoid forms.

Hermann Mayer and Leydig have shown (and the fact is readily verifiable) that the scales and spines of the Plagiostome fishes are formed by the gradual deposit of calcareous matter in processes of the integument, which are at first coated by the ordinary cellular ecderon. These diverticula, in fact, originally resemble other papillæ of the skin, and like them, are bounded by a structureless protomorphic layer, marking the boundary between the cellular ecderon and the enderon.

When the formation of the placoid scale commences, however, instead of the successive division and multiplication of the endoplasts and the cellulation of the periplast of the ecderon, which before went on, a deposit of calcareous matter takes place at the boundary-line, and the structureless band remains as structureless or "basement" membrane, investing the future spine. The deposit increases until the enderonic pulp occupies but a very small space, or even completely disappears, and the spine projects as a cylindrical or conical tubercle. When it has attained its full length, the deposit does not cease; new calcareous matter is continually added to its inner extremity, but rather in the direction of breadth than of length, so that, eventually, an irregular broad plate is formed with the spine projecting from its outer surface (*fig.* 308.).

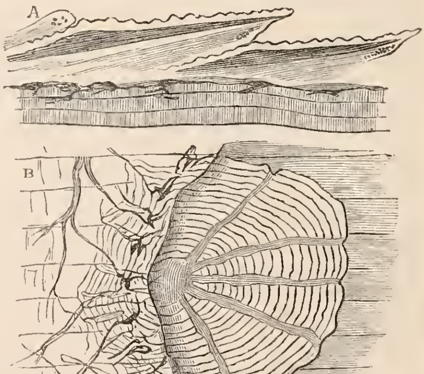
Fig. 308.



It is particularly to be remarked, however, that the projecting body of the spine being once formed, the calcareous additions which give origin to its base (*c*) gradually cease to be in exact apposition with the original protomorphic zone; and in proportion as the base of the spine extends, have we a wider and wider interval, occupied by the tissue of the enderon, between its upper surface and the under surface of the ecderon (*f*). Examining it in the perfect state, then, it would appear that the spine is included in a sac of the enderon; and this appearance is very much strengthened if dilute hydrochloric acid be added, by which the enamel layer (*a*) is dissolved out, and the structureless membrane enclosing the spine rendered distinct; while its continuity with that structureless layer which bounds the enderon is at once obvious. From its development, however, it is clear that this is a simple appearance, and that the apparent sac results from the projection inwards of the extremity of this truly ecderonic structure. In fact, inasmuch as the base of the spine grows like its shaft by continual addition to its inner surface, while its apex is unquestionably an ecderonic structure, this base might be considered to be enveloped in an involution of the protomorphic plane of the ecderon (*fig.* 307. c).

Now suppose such plates as these to have acquired their maximum in width and minimum in height; furthermore, imagine them to be so closely set in the skin that the posterior edge of one over-rides the anterior edge of the one next behind it, and we have the exact arrangement of the scales in the cycloid and ctenoid fish (*fig.* 309.).*

Fig. 309.



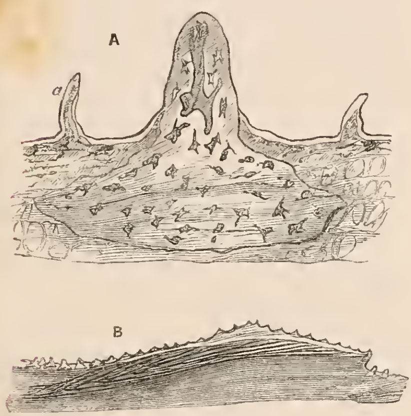
Scale of the Roach (*Leuciscus.*)
A, section; B, surface.

* The flexible cycloid scale of the eel presents an exact parallel to the tooth-like placoid scale of the skate, except that it is flat instead of conical, and that, in the adult state, the scale appears to be completely included in the enderon, and is wholly covered by the cellular ecderon. I believe this appearance of inclusion in a complete sac to proceed simply from the smallness of the original point of contact of the scale with the cellular ecderon, and the rudimentary state in which the whole organ remains.

A careful study of the scales of that remarkable animal the Sturgeon, which exhibits in this, as in so many other characters, its intermediate position between Teleostian and Plagiostome fishes, appears to me to throw still further light upon the difficulties of scale development.

The scales of the sturgeon are large, slightly convex, rhomboidal plates, set obliquely in the skin, so that, while the posterior two-thirds of their surface are bare and hard, the anterior third becomes gradually softer from the prolongation of the integument over it. The posterior surface continues hard up to its sharp edge, but it is supported below by a soft thick layer of integument, which passes on to the anterior soft coat of the scale behind, and thus masks the real overlapping of this scale by the posterior edge of that which precedes it (*fig.* 310. B).

Fig. 310.



Scale of Sturgeon.

A, one of the detached tubercles highly magnified; B, the entire scale.

The surface of the scale is shining and glassy. It is marked by a median ridge, whence it shelves upon each side, and by an elegant sculpturing produced by raised, hard ridges of the same nature, which radiate from the margins centrally, for about a fourth of the semi-diameter of the scale. In the region within this zone, the ridges gradually lose their regularity, the radiating lines anastomosing with one another and forming an elegant polygonal network. The soft surface of the integument of the anterior portion of the scale, is raised into many minute papillæ (*fig.*310. A, *a*), which may be followed for some distance on to the hard portion. Furthermore, it exhibits scattered round spots, with projecting centres of the same appearance as the ridges, and like them feeling hard to the touch.

If a section of the scale be made (*fig.* 310. B), its under surface will be found to have a concavity corresponding with the convexity of the upper. If the section has passed through one of the ridges, it is seen that the osseous tissue of the scale is of two kinds; a superficial homogeneous-looking, dense, comparatively thin layer, and a deep, thick, laminated portion. If traced from the centre of the scale to its anterior circumference the superficial layer loses its continuity, breaking up into conical bodies, which are the sections of the detached calcareous spots mentioned above; the deep layer thins out, its laminæ gradually becoming fewer, and leaving a soft membranous space between their upper surface and the under surface of these spots. In the centre of the scale again, a series of rounded apertures are seen in a tangential section, the sections of canals which radiate through the scale and become more numerous and wider towards its margin. They are connected below with vertical canals passing through the laminated layer, and anteriorly they pass into the wide membranous space above referred to. There is no histological difference of any importance in the structure of these two layers; each is composed of true bone with radiated corpuscles; the upper being more dense and homogeneous, the lower less dense and laminated.

If a section be made through several of the ridges of the upper surface, it will be seen that they are entirely composed of the hard homogeneous osseous tissue. On their sides, however, and in the valleys between them, more or less of soft integument remains, whose pigment masses give the valleys a dotted appearance. On the other hand, a section of one of the detached tubercles shows, except in its consisting of osseous tissue only, that it is identical with a single spine of the Skate (*fig.* 310. A). It appears to me, therefore, that there can be no doubt that the ganoid, overlapping scale of the sturgeon commences by an isolated placoid spine; that other spines are developed around this, and their bases uniting, constitute a placoid scale, between whose elevations little valleys, bridged over by the soft integument, remain; that to the base of such a plate as this, continual additions of osseous laminæ are made, the radiating Haversian canals being left between the first laminæ and the superficial plate; and finally that, extending in size, the anterior face of this complex scale becomes over-ridden by the preceding one. Complicated as it may appear, it is obvious that all this structure results from the continued endogenous growth and union of the primary ecderonic calcareous deposits, which constitute, as it were, so many centres of ossification for the large scale. The final structure, however, is (if we leave out of consideration its histological character), to all intents and purposes, that of a cycloid scale; and its mode of growth is identical with that of the large cycloid scale described by Prof. Williamson.

The increase of the scale is concentric; addition being made to its posterior, as well as to its anterior edge and surface; the only difference being, that in the latter case the development of the upper layer is less rapid than that of the lower, while in the former they are coincident; that soft membranous separation therefore, which exists between the two layers anteriorly, is far less developed posteriorly; and the soft continuation of the scale which is flat anteriorly, is inflected posteriorly; the process of addition being otherwise the same. Suppose, now, that each detached calcareous centre of ossification as it is added to the posterior margin of the scale, instead of being flattened, were produced into a spine as in the Rays, then it is perfectly clear that instead of a cycloid scale, the result would be a serrated ctenoid scale. And this appears to be exactly what takes place in the scales of the perch, according to Prof. Williamson's description.

From all this, I think, we arrive at Prof. Williamson's conclusion, that fish-scales are essentially tegumentary teeth; that like the latter organs, they result not from the calcification of the cellular ecderon covering those folds of the integument, upon which they are developed and which correspond with the dental pulp, but by a calcareous deposit taking place beneath this, in what represents a deep layer of the ecderon; finally that it is, for the present, an open question whether the deep layers of all scales are produced by a continuation of this process, or whether in some cases a deep truly enderonic structure may be added to this superficial ecderonic constituent to constitute the perfect scale. A process of the latter kind would, at any rate, find its parallel in the eventual union of the teeth of many fishes with their jaws, and in that of the plates of the chelonia with the vertebral elements.

§ 3. *Histology of the tegumentary organs.* — Having thus arrived at a general idea of the mode in which the various forms of integumentary organs are produced from the primary morphological constituents of every integument, we have now to consider their minute histological elements and the mode in which these proceed from the indifferent tissue of which all organs are primarily composed.

The tegumentary tissues, like all others, are produced by the metamorphosis of the periplast of the protomorphic or indifferent tissue from which they take their origin, the endoplasts, to all appearance, taking but little share in the metamorphic processes. The chemical metamorphosis of the periplast may be either into horny, chitinous, calcareous, or cellulose matter; in form it may become fibrous, laminated, vacuolated, bony, prismatic, &c.

As a general rule, the endoplasts tend to disappear, *pari passu*, with the metamorphosis in form and composition of the periplast; but the differences presented by different tissues in this respect have given rise to the establishment of a distinction between what is called the process of *conversion* and that of *excretion*. For instance, in the development of a hair or of a nail, the elements of the protomorphic layer evidently pass, as such, into the perfect substance of these organs; the periplast simply becoming horny, and the endoplasts remaining for a long while, or even always, visible in the cornified tissue. This is therefore a process of "*conversion*" of the protomorphic tissue. On the other hand, the chitinous coat of the lower Annulosa and the shells of the lamellibranchiate and gasteropod Mollusks arise in a totally different manner. The elements of the protomorphic layer do not pass into them entire, but they are formed, like the cuticula of a plant, or like the dentine and enamel of the teeth, by the successive outgrowth of layers of the outer portion of the periplast. No endoplasts, therefore, are ever found in them, and there is no *conversion* of the protomorphic tissue, but a process of *excretion*.*

At first sight this distinction would appear to be very decided, and likely to afford a good ground for the formation of definite subdivisions of the integumentary organs into classes. Unfortunately, it is often difficult in practice to assure oneself in what way a given tegumentary organ has been formed. While the presence of endoplasts in a metamorphosed tissue is good evidence of its having been developed by conversion, their absence is no proof that the tissue has been developed by excretion; inasmuch as it may simply be due to their very early disappearance. In fact, if any one affirm that the shell of a Unio or of a Crustacean, notwithstanding the impossibility of detecting endoplasts in its youngest laminæ, is in reality formed by the successive apposition of entire layers of the protomorphic tissue, in which the endoplasts disappear so early that they cannot be detected, it would be very difficult absolutely to disprove the assertion, though we might ask for evidence of its truth. Disbelieving in the doctrine of the special vital activity of the endoplasts, I confess the question does not seem to me to be of much importance, and I have only enlarged upon the subject because great weight has by high authorities been laid upon these distinctions. It appears to me that the processes of conversion and of excretion grade one into the other, and that no real subdivisions can be based upon the occurrence of either to the exclusion of the other. I will, however, take care to indicate what appear to me to be clear instances of each. I shall now proceed to consider the histological structure of the integuments of animals in the following order: — 1. Hydroid and Actinoid Polypes and Beroidæ. 2. Annulosa, including the Worms and Echinoderms. 3. Mollusca, including the Ascidians and Polyzoa. 4. Vertebrata.

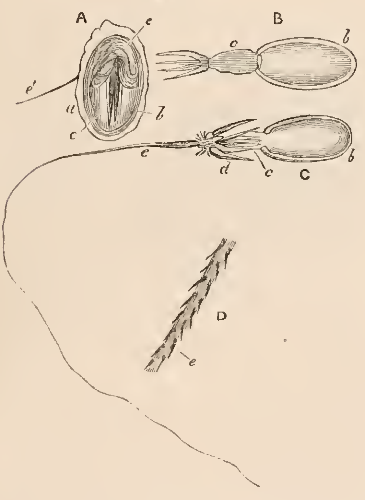
1. *Hydroid and Actinoid polypes.*—In these animals the integument consists either of a simple cellular and vacuolated ecderon, or the outer layer of this is developed into a structureless coat, which may become thickened by repeated additions, and thus attain considerable dimensions. In the common

* Using the word in the sense of "growth out," not in the common perverted signification of fluid transudation and hardening.

Campanularia, for instance, the outer wall of the bud from which a polype is to arise consists, at first, of a mass of indifferent tissue. As development proceeds, the outer portion of the mass is converted into a structureless membrane, which becomes detached from the body of the polype through its whole extent, and constitutes the future *cell*, the subjacent ecderon taking on the ordinary cellular structure. On the pedicle the same process goes on to a less extent, the structureless layer becoming separated only at intervals, so that the pedicle acquires a ringed appearance.

An integument of one or other of these descriptions is to be met with in all the Sertularian and Actinoid Polypes, and is obviously, in these cases, the result of a process of excretion. In the *Medusæ* and *Beroidæ*, on the other hand, where the integument is thick and gelatinous, the ecderonic tissue is converted, as a whole, into what closely resembles rudimentary connective tissue, in which elastic elements and muscular fibres are developed. The presence of peculiar organs, called the "*Thread or Urticating cells*," constitutes an extremely characteristic feature in the integument of these creatures. These

Fig. 311.



(*fig.* 311.) are composed of a delicate membranous sac (*a*), enclosing a much thicker one (*b*), which is open at one extremity, the aperture being stopped by the end of a more or less irregular short stiff sheath (*c*), sometimes giving attachment to several distinct rays or spines (*d*), applied together, which is fixed to the edges of the aperture, and occupies the axis of the inner sac. To the extremity of this sheath a long, frequently toothed filament is attached (*e*), and lies coiled up round the central sheath, and in close contact with the walls of the sac. The latter are very elastic, and seem to be tensely stretched by the contained fluid during life; for, on pressure, the sac suddenly bursts, and its contents are evacuated so rapidly as hardly to allow of the process being traced. I believe, however, that the long filament is pushed out by the side or through the axis of the central sheath, remaining still firmly attached to the latter, so that the result is the appearance exhibited in the accompanying figure (*c*), where the sac is seen empty, the long serrated filament being attached to the sheath, which, everted and with its spines spread out, is itself fixed to the margins of the aperture. The violent protrusions of these minute serrated filaments, aided, perhaps, by some aridity of the liquid of the sac, is in the larger kinds, such as those which exist in Physalia, exceedingly irritating to the human skin, and usually proves fatal to the minute creatures on which the Hydrozoic and Anthozoic polypes prey.

Integument of the Annulosa.—The integument of the lower Annulose tribes, of young forms and of the more delicate parts of a great majority of the higher Annulosa, consists of a thin structureless chitinous membrane developed from the subjacent cellular ecderon, in a manner essentially similar to what has been described in the Polypes.

Leydig has particularly described this form of integument in Entomostracous Crustaceans, (Branchipus and Argulus) in insect larvæ, (Corethra), and among the Annelids in Piscicola, Nephelis, Hæmopis, Sanguisuga, Clepsine and Lumbricus, where the integument consists of two portions—a deep cellular layer and a superficial layer, which is either absolutely structureless, or is fibrillated; being in no case formed by the coalescence of the subjacent cells, but by excretion from them.

A similar structureless excreted integument is found also in Planariæ, Nemertidæ, in many Cestoidia, Nematoidea and Trematoda, and, according to the late researches of Leydig, on Synapta, in the Echinoderms also. Where the integument is not very thin, and consists of several layers of chitinous matter, the added laminæ commonly take on a fibrous structure. The Nematoid worms present particularly good examples of this complication. Thus, for instance, the integument of Mermis albicans, which has lately been examined with much care by Dr. Meissner, consists of three layers, the middle of which is double. The outermost of these layers is either structureless or presents a distinction into transverse hexagonal plates, each of which occupies $\frac{1}{6}$ of the circumference of the animal. At the head and tail, small polygonal plate-like markings replace these, and such small plates could be detected, making up the large ones. Dr. Meissner calls them "cells," but expressly states that he never detected any nucleus in them, and it seems more probable that they are produced by modifications of the original external structureless layer, similar to those which, as will be seen, occur in the Crustacea and Mollusca.

The middle substance of this integument is composed of two layers of fibres one above the other. The fibres are parallel in the same layer, but those of the two layers cross one another at right angles, so that they form two sets of opposite spirals. The fibres are sharply contoured, dense, and brittle, and those of each layer are divided into six sets, corresponding with the six sections of the body. At the sutures the fibres of each bend back upon themselves, and run in a parallel course to the opposite suture.

The deep layer is the thickest; it appears longitudinally striated on section, and may be split into lamellæ of any thickness; otherwise it is perfectly structureless.

In the Nemertidæ, according to the researches of Quatrefages, the integument has essentially the same structure, consisting of a superficial structureless ciliated lamina, with deeper vacuolated and fibrillated layers. In the other Turbellaria the vacuolated structure is predominant.

This fibrous chitinous integument is still better developed in the Insecta.

According to Mayer (*l. c.*) the chitinous integument of Lucanus cervus is composed of glassy rods with sharply defined dark, parallel edges, which by their mutual apposition and anastomosis, and probably by the interposition of a connecting mass, form thin layers. The rods in each layer are parallel, but those of different layers cross one another at angles of from 45° to 90°; so that a horizontal section presents a sort of elegant cross-hatching, the lines of which are about 0·008 mm. apart. The outer surface of this laminated mass is invested by a transparent homogeneous substance containing pigment, and above this by a layer of epidermic "cells" (0·005 to 0·01 mm. in diameter), with nuclei and nucleoli, their edges being separated by an intermediate substance. Internally, there is also a layer of epidermic "cells" which are polygonal from mutual pressure. They are without nuclei, but possess a short spine, arising from the centre of the cell, and ending by a sharp point. Quekett (*l. c.*) describes a similar structure, consisting of striated laminæ, in the integument of Dynastes Hercules.

The integument thus described closely resembles that of the larger Crustacea (*vide infra*), and I should have placed it with them, except for the very distinct statement of Mr. Newport with regard to the development of the integument in Melöe. According to Mr. Newport's researches, the integument of the young Melöe is at first composed of polygonal nucleated cells, the largest of which is about $\frac{1}{2000}$ of an inch in diameter. As the animal grows, the nuclei divide and subdivide by a process of fission, and the integument becomes composed of several layers. After awhile, the deeper of these undergo a fibrous metamorphosis, and constitute a fibro-cellular structure, which gives attachment internally to the muscles, while the external layers continue to grow, and to be reproduced as distinct cells.

If this were the mode of development which obtained in all Insecta we must consider their chitinous integument to be produced by conversion of the previously existing cells of the ecderon. However, Leydig's statements are equally decided, that the integument of Corethra presents no appearance of cellular origin, and the question may, therefore, for the present, probably be considered undecided.

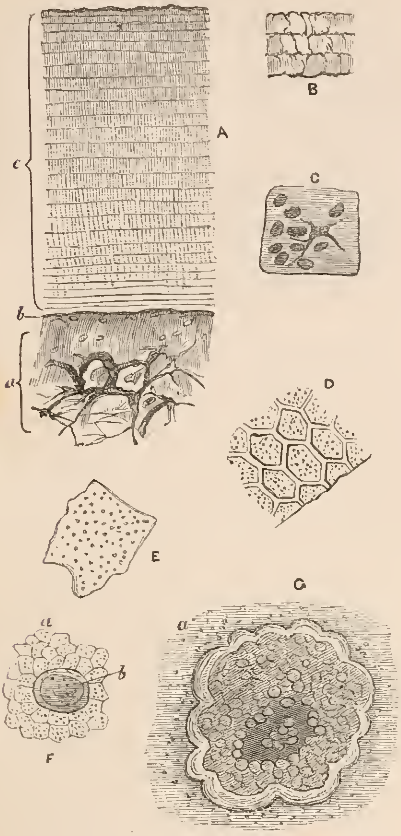
The calcified integument of the Crustacea presents the same general structure as that of the other Annulosa, consisting of superposed chitinous, more or less fibrous lamellæ, the outer of which are infiltrated with a calcareous deposit. In the small transparent Crustacea, as we have already seen, the integument is composed of structureless layers, developed by excretion on the surface of the ecderon, and even in the largest forms, the minute hairs, &c., present precisely the same appearance; but in the thick integument of the Decapoda, certain layers of the shell have been described, not without considerable show of reason, as possessing a cellular organisation (Carpenter).

I have carefully examined the shell of the common crab in relation to this point, and the following are the results of my investigation.

It appeared to me in the first place, that, without seeking for a moulting crab, the structure of the integument in its uncalcified state might be readily ascertained by examining the soft membrane connecting the articulations of the limbs, which, as is well known, is continuous on either hand with the calcareous integument, and passes into it. In a section of this soft layer (*fig.* 312. A), I found from within, outward, 1. The enderon (*a*) composed of connective tissue, excavated by vascular channels, and containing numerous aggregations of pink and yellow pigment, frequently disposed in a stellate form, or even forming anastomosing net-works along the rudimentary elastic fibres of the tissue. 2. The surface of this (*b*) was constituted by a protomorphic layer, consisting of a homogeneous substance containing endoplasts (C), which sometimes adhered to the enderon, sometimes to the hard integument, when the latter was detached. 3. Superficial to this, was the chitinous layer of the integument (*c*) composed of a number of laminæ of great delicacy, and not more than $\frac{1}{3000}$ of an inch apart. The deep laminæ were much softer than the superficial, and the outermost lamina of all was hardest, and of a brownish colour, constituting the structureless epidermis of Carpenter and Lavalle.

In section, the deep laminæ (B) presented only an indication of perpendicular fibrillation; but this became more marked superficially, the outer part of the section appearing closely striated. The deep laminæ, when stripped off, presented no definite structure, but they readily fell into plaits; while the superficial laminæ appeared dotted over. I sought in vain for any appearance of endoplasts in the deep layer, where, however, had they existed, they must have been readily detected; and I therefore conclude, that the chitinous lamellæ are formed from the subjacent ecderon, by a process of excretion. It should be remarked, however, that a minute polygonal areolation is observable at times upon the most superficial "epidermic" layer. I do not know from what cause this

Fig. 312.



A to E, from the crab; F, G, from the shrimp.

proceeds, but the areolæ are certainly not cells.

Such is the structure of the soft inter-articular integument, in which I could find no calcareous matter. If it be traced into the hard calcified shell, the only alteration observable is, that a dark calcareous deposit takes place, the earthy matter being infiltrated, as it were, through the laminæ. The deposit affects, however, only the middle layers, the extreme outermost being left as the "horny epiderm;" while a variable number of the inner laminæ remain as a more or less thick, soft coating upon the inner surface. These soft layers may be stripped off as a parchment-like membrane, with the muscles, and their relations to the enderon are then readily examined. They are here as structureless as where they constitute the deep layer of the inter-articular membranes.

The structure of the calcified layer has been carefully described by Dr. Carpenter, who showed, that in the crab and lobster they are traversed by tubules identical with those of dentine, and pointed out the error of Lavalle in regarding these as fibres. There can, I think, be no doubt, that in the crab and lobster, Dr. Carpenter's doctrine is correct; but I am equally of opinion, that for other crustacea, such as the shrimp, M. Lavalle is right. I believe, in fact, that the tubular structure is produced by the horizontal lamination giving way, as the calcareous matter is deposited, to perpendicular fibrillation of the chitinous matrix, and that, eventually, the uncalcified fibrils disappear, and leave tubules in their place. That at least appears to be a natural conclusion from the fact, that the perpendicular fibrillation of the soft tissue becomes more and more marked externally; and thus, by decalcifying the calcified shell, we obtain horizontal separable laminæ composed of short perpendicular fibres.

The colouring matter has always appeared to me to be generally diffused through the upper layer, and not to be confined to what Dr. Carpenter describes as the "cellular layer." The latter is a very thin stratum, made up of only a few of the superficial laminæ, which I have found to be most readily observable by detaching with a sharp knife a very thin scale from the upper surface of the crab shell. It is composed, exactly as Dr. Carpenter has figured it, of regularly polygonal, often six-sided areæ, frequently presenting a darker radiating patch in the centre, and, at first sight, irresistibly suggesting a true cellular structure.

I believe, however, that it is in reality nothing of the kind, but that, like similar appearances in the molluscan shell, this is simply the result of the concretionary manner in which the calcareous matter is deposited. We have seen, in fact, that there are no such appearances in the deep uncalcified layers, nor in the thin layers which invest the minute transparent appendages—considerations which appear to me to be in themselves decisive against the cellular nature of these bodies. In addition, decalcification brings to light no endoplasts in the "cells," but in their place we observe clear polygonal spaces in the membrane (*fig.* 312. D) which present the same dots (section of tubules) as those which exist in the simply laminated portion of the integument (*fig.* 312. E). Finally, if the decalcified scale include a sufficient number of layers, it is easy, by altering the focus of the microscope, to trace the areolation inwards, until it becomes gradually fainter, and disappears, passing into the ordinary dotted laminæ.

I believe, then, that the "cellular" layer, results from a peculiar additional deposit of calcareous matter in the uppermost layers of the shell; and this view is strikingly confirmed by what may be observed in the shrimp. The integument in this crustacean (*e. g.* the carapace) has exactly the same general structure as that of the crab, consisting of hard upper and soft deep layers, which are dotted and striated, and not tubular. The former owe their hardness to a generally diffused, transparent, calcareous deposit, which allows the previous dotted structure of the laminæ to be perfectly obvious. In some parts and in the superficial layers, this deposit is structureless and homogeneous (*fig.* 312. G, *a*), but in other parts the youngest layer presents very delicate polygonal meshes, whose areæ were about $\frac{1}{1000}$ in. in diameter (*fig.* 312. F, *a*). Decalcification completely destroys this appearance; so that I imagine it to be caused merely by the mode in which the primary deposit in the membrane takes place, the areolæ becoming almost immediately fused together by further deposit.

Through these homogeneous hardened outer layers thus constituted, there are dispersed more opaque spots (*fig.* 312. F, G, *b*), more or less rounded in their outline, and varying in diameter from $\frac{1}{500}$ in. or less, to ten times that size. The smallest of these bodies have exactly the appearance of cells (*fig.* 312. F, *b*), consisting of a dark centre, with a circular more transparent wall, and every variety of form may be observed between these and large masses, such as that figured (*fig.* 312. G, *b*), with a lobulated laminated circumference, and an irregular centre, composed of small masses like dentine globules. In the former the dots of the original tissue may be still seen; but in the latter they are not traceable and seem to be obliterated. If dilute hydrochloric acid be added while the object is still under the microscope, however, these bodies are gradually dissolved out with effervescence, and the structure of the place they occupied is found to be identical with that of the other portions of the integument. They are, therefore, nothing but concretions of calcareous matter, whose deposit has taken place in a peculiar form, quite independently of the primary structure of the part; this form being, in the smaller concretions, most deceptively cell-like. It appears to me that this case, in which the assumption of structure without cell development may be so plainly demonstrated, has a most important application, not only to the mode of formation of Crustacean and Molluscan shells (*vide infra*), but to the development of the teeth, strongly confirming, I think, the view which I have taken of that process.

Integument of the Mollusca.—The soft surface of the body of the Mollusca in general is constituted by an ordinary, commonly ciliated, cellular ecderon, which needs no special description. The hard or soft shells which so many of them possess, arise in two modes; the calcareous and horny integumentary appendages being, I believe, invariably produced by *excretion*, while the Ascidian test, which contains cellulose, is formed by *conversion*. It will be advisable to treat of the structure and histological development of these two forms separately; and, first, of the

Excretionary integument of the Mollusca.—This is to be met with in its simplest form in the Polyzoa, in which the integument (ectocyst of Allman) is formed by a structureless membrane containing imbedded calcareous or silicious particles.*

An admirable example of the calcareous integument formed by *excretion* is to be found in the shell of Unio and Anodon. The outer surface of the shell in these Lamellibranchs is, as is well known, covered by a brownish or greenish irregular membranous substance, the so called "epidermis" of the shell. This substance, however, by no means constitutes a single membrane; on the other hand, the surface of the shell is marked by an immense number of closely set, more or less parallel, concentric lines, some of which appear to be formed by rugæ of the "epiderm," while others are the free edges of epidermic laminæ cropping out under those of older date. Viewing this surface of the shell by transmitted light with a low power, a number of polygonal closely-set areæ come into view on depressing the focus through the thickness of the epiderm.

The inner surface of the shell has, for the greater part of its extent, a pearly or nacreous lustre; but along the gape of the shell, at a distance of from less than one line, to as much as two or three lines, from the free edge, the nacreous appearance ceases, and we find, instead, a brownish hue similar to that of the epiderm, and becoming gradually more intense till the very margin is constituted by a flexible brown membrane continuous and identical with the epiderm on the exterior. If the surface of the flexible zone be examined as before, its outermost portion appears quite homogeneous; as we pass gradually inwards, however, dots appear in it, and the hard portion of the brown zone presents polygonal areæ, precisely resembling those under the epiderm on the outer surface. Where the nacreous appearance commences, these areæ disappear, becoming obscured by an opaque white substance, which is marked by elevations and depressions, corresponding with, though less prominent than, the principal ones upon the external surface.

If, now, a section perpendicular to the surface and to the concentric lines be taken, and viewed in the same way by reflected light, the cause of the various appearances which have been described will become obvious.

It will be seen that the thick middle of the shell is composed of three substances; of a very thin external brown layer, the "epidermis," and of two other layers more or less equal in thickness; an external, composed of minute polygonal prisms or columns set perpendicularly to the surface, and an internal, which looks structureless, with a fracture like loaf sugar. The outer prismatic layer preserves its thickness as far as the "brown zone" above described, and then gradually thins out into the flexible marginal membrane. The inner nacreous layer, on the contrary, gradually thins out, and ceases at the commencement of the brown zone. The ends of the prisms are, therefore, bare in the brown

* I am indebted to Mr. Busk, whose extensive researches on these animals are well known, for the information on which this statement is based.

zone, whence the polygonal areolation observed in it; while its colour arises partly from the brown epidermis shining through, partly from a slight tinge of the same kind which runs through the prismatic substance, and renders it distinguishable, even to the naked eye, from the intensely white nacreous layer.

Thin vertical sections of these shells present the following appearances under a high magnifying power. The external edge is constituted by a delicate brown band, the "epidermis," in which no structure of any kind can be detected. Within this is the prismatic layer, a dense transparent substance marked by strong parallel lines which run perpendicularly to the surface and either extend completely through the layer, or terminate by joining some other within it. In the former case, the spaces which they enclose appear like the sections of prisms (of $\frac{1}{200}$ of an inch, more or less, in diameter): in the latter, they resemble longer or shorter cones whose bases are turned outwards. A number of such short cones are usually interposed between those ends of the prisms which are in contact with the epidermis.

Internally, or at the line of contact of the prismatic with the nacreous layer, the lines either remain parallel or converge.

The prisms are readily broken away from one another, and in this case, or in a sufficiently thin section of the whole layer, they are seen to be traversed by very closely set parallel transverse lines about $\frac{1}{10000}$ in. apart. Each prism, however, does not possess a set of striæ peculiar to itself; on the other hand, the parallel lines stretch without interruption through the whole length of the prismatic layer, as if the prisms were not there. A horizontal section of the prismatic layer presents, as has been said, a coarse polygonal reticulation corresponding with the lines of contact of the prisms. The substance of the latter appears granular, but without any other structure in fully formed portions (*fig.* 313. A).

When a section of the prismatic substance is acted upon by dilute acid, the calcareous matter is extracted, and a membranous framework is left, presenting all the structural characteristics of the original tissue, except that the prisms are now hollow, and from their transverse striations have been well compared by Dr. Carpenter to the scalariform ducts of plants. This membranous residuum readily tears up into laminæ, each of which corresponds, usually, to a number of the fine horizontal striæ.

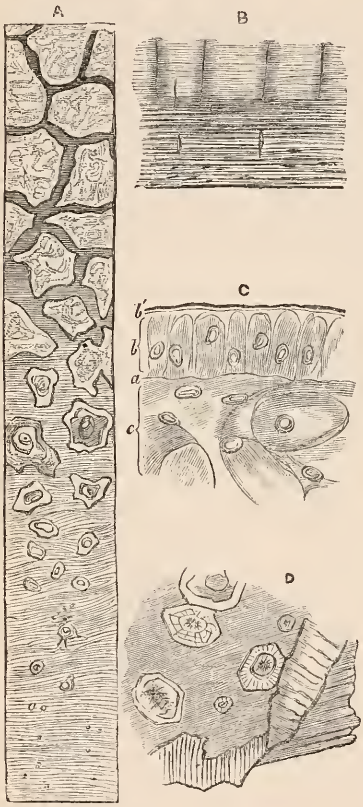
The white nacreous substance — *membraneous shell substance* of Dr. Carpenter—which constitutes the interior of the shell, presents, in a vertical section, a horizontally striated appearance identical with that of the prismatic layer, and when macerated in acid it breaks up into corresponding laminæ. In fact, if we leave out the vertical markings which give rise to the appearance of prisms in the latter, the two structures are identical. This point appears to me to have been overlooked and to have given rise to the impression that there is a much greater histological difference between the prismatic and membranous substances, than really exists. The examination of the line of junction of the two substances (*fig.* 313. B), however will at once show their fundamental identity. The ends of some of the prisms will be seen in fact to project beyond the others into the membranous substance; but it will be observed that the horizontal lines of the latter pass without interruption through the prisms, and therefore that the laminæ of the two structures are identical.

If we reduce these facts to their simplest expression, it will result that these shells are *composed throughout of superficial thin membranous laminæ, the outermost of which remains as epidermis, while the inner receive a deposit of calcareous salts.* Next comes the question, however, how are the structural differences between the prismatic and membranous layers produced.

Dr. Carpenter, in his well-known Essay, propounded the doctrine that both varieties of shell structure are the result of the development and coalescence of cells supplied by the mantle of the mollusk; these cells remaining permanently distinguishable and coalescing in rows, in the prismatic structure, but bursting and becoming confused into a homogeneous tissue, in the membranous substance. Nor, indeed, would it have been very easy in 1848 to arrive at any other conclusion than this, to which so great a number of appearances at first sight tend. Enabled, however, by Dr. Carpenter's great kindness and liberality to form my own judgment from his beautiful preparations, and having also worked over the fresh shells for myself, I have come to very different conclusions. I will not say that occasionally cells may not be enclosed in shell, but I believe I am in a position to show that, as a rule, shell-growth is not a case of *conversion*, but one of *excretion*, cells not being in any way directly concerned in the matter.

We may consider, first, the growth of the shell as a whole; and, secondly, that of its three constituents. Inasmuch as we know, that the shell of the young Unio or Anodon was once as thin as, or thinner than, the "epidermis" of the adult shell, and smaller than the smallest area, bounded by a concentric line on its outer surface; further, since we know that no addition is made to the outer surface of the shell directly; it is clear that the shell must grow in size by addition to its margin; in thickness, by addition to its under surface. Furthermore, since the extreme margin of any shell is constituted by the horny "epiderm," internal to which is the gradually thickening layer of prismatic substance, constituting the brown zone, within which again is the white nacreous area, formed by the superposition of membranous layers over the fully-formed thick prismatic substance; from all this, it appears to be equally certain that any given spot of the mantle of a young bivalve must give origin, directly or indirectly, first, to "epiderm;" secondly, to prismatic substance; and, thirdly, to nacreous substance; so that, on examining the free edge of a growing shell, we ought, since the "epiderm" is structureless and transparent, to be able to observe the gradual formation of the prismatic substance upon its under surface. This is, in fact, the case. *Fig.* 313, A, represents such a free edge of the shell of Anodon, *a* being the direction of the flexible zone; *b*, that of the perfect prismatic substance.

Fig. 313.



A to C, Unio; D, Helix.

Dr. Carpenter describes the appearances here figured in the following terms (*l. c.* p. 8.):

"Although the prismatic cellular structure has not yet been actually observed in process of formation, yet certain appearances, which are occasionally met with in the marginal portions of its newest layers, throw great light upon its mode of growth, and indicate its strong resemblance to cartilage in this respect; for in these situations we find the cells neither in contact with each other, nor polygonal in form, but separated by a greater or less amount of intercellular substance, and presenting a rounded, instead of an angular form (*fig.* 314. C). Upon looking still nearer the margin, the cells are seen to be yet smaller and more separated by intercellular substance, and not unfrequently we lose all trace of distinct cells, the intercellular substance presenting itself alone, but containing cytoblasts scattered through it. This appearance has been noticed by myself in *Pinna* and *Unio*, and by Mr. Bowerbank in *Ostrea;* so that I have no doubt that it is general in this situation. We may, I think, conclude from it that the cells of the prismatic cellular substance are developed, like those of cartilage, in the midst of an intercellular substance, which at first separates them from each other, that as they grow and draw into themselves the carbonate of lime poured out from the subjacent surface, they approach each other more and more nearly; and that, as they attain their full development, their sides press against each other, so that the cells acquire a polygonal form, and the intercellular substance disappears."

I have given Dr. Carpenter's statement at length, because it appears to me to express very distinctly the interpretation which one is at once tempted to put upon the appearance, but which I must reject for the following reasons:—In the first place, if we examine that portion (*a*) of the margin beyond the smallest granules (*cytoblasts*, Carpenter), it is seen to be either absolutely structureless or obscurely striated, not a trace of a cell or endoplast being anywhere visible. Secondly, if any dilute acid be added under the microscope, the apparent nuclei and cells vanish with effervescence, and leave behind them clear empty spaces, of exactly the same shape and size as they themselves had. Thirdly, the supposed cells have a peculiar concentrically or radially-striated structure, resembling sections of urinary calculi on a small scale, and still more the corresponding bodies in the integument of the shrimp (*suprà.*) For these reasons I think it must be granted that the appearances in question, however cell-like, are, in reality, not the expression of the development of a cellular structure at all, but merely that of the mode in which the deposit of calcareous matter takes place in the membranous basis of the shell. In fact, I believe that the calcareous matter appears first in small and distinct globules (the "cytoblasts"), and that more or less concentric deposits take place round these, the result of which is, that the membranous basis is more and more displaced, and that the deposited masses eventually come almost into contact. The regularity of the ultimate prismatic structure results from that of the distances of the granules primarily deposited, and the even rate of addition to each subsequently.

There appears to me to be but one interpretation to be placed upon these facts; viz. that cells as such do not enter into the formation of the shell of the Naiades at all, but that it is constituted by the successive excretion of membranous laminæ from the surface of the epidermis of the mantle.* The outer laminæ retain their membranous nature, only becoming so far altered as to assume the horny aspect of the so called "epidermis;" in the next laminæ, which are added to the inner surface of the young shell, calcareous matter is deposited in granules, additions to which are made in such a manner as to constitute the cellæform concretions, and ultimately, the process going on in the same way in successive layers, the prisms; in the innermost laminæ, finally, the calcareous deposit results in an even, homogeneous, folded or striated layer. By scraping with a sharp knife the inner surface of the shell of Anodon, freshly detached from the mantle, I have obtained a distinct tough membranous layer, scattered through which were a vast number of close-set irregular granules of calcareous matter. A similar structureless layer without the granules constitutes the outermost surface of the ecderon of the mantle (*fig.* 313. c, *b'*) and may occasionally be detached as such. Such a layer consisting of the thickened outer portion of the periplast of the ecderon of the mantle is by no means an anomalous structure, as we have a formation of exactly the same kind in the "cuticle" of plants, and in the chitinous lining of the intestine in Insects; and I believe that the shells of mollusks in general consist simply of a multitude of thin layers successively thrown off, super-imposed and coherent, all the peculiarities of their structure arising from subsequent modifications, which are altogether independent of cells. This view is in perfect agreement with all that is known of the nature of the shells of larval Gasteropods and Acephala, which are invariably either of an absolutely structureless, thin, transparent, membranous character, or at most present a delicate striation. It may be added that not the slightest trace of a cellular structure is to be met with in the pellucid shells of the Heteropoda and Pteropoda. So much for the two primary forms of shell structure, the membranous and the prismatic. A most interesting variety of the former is the *nacreous* (mother-of-pearl) lining which is presented by many shells, both of Acephala and Cephalophora. The pearly iridescence proceeds, as Dr. Carpenter has well shown, from the folding of the membranous layer into close plaits, and not, as has been supposed, from the alternate cropping out of calcareous and membranous layers. Dr. Carpenter proved this by decalcifying with acid a layer of nacre from *Haliotis splendens*. The iridescence remained; but if the plaits of the layer were pulled out by stretching it with needles, the iridescence disappeared.

Another variety of structure usually, but not alone found in the membranous shell substance, is the *tubular*. "All the different forms of membranous shell structure are occasionally traversed by tubes which seem to commence from the inner surface of the shell, and to be distributed to its several layers. These tubes vary in size from about the $\frac{1}{20000}$ to the $\frac{1}{2000}$ of an inch, but their general diameter in the shells in which they most abound is about $\frac{1}{4500}$ of an inch. The direction and distribution of these tubes are extremely various in different shells; in general, when they exist in considerable numbers, they form a network which spreads itself out in each layer nearly parallel to its surface, so that a large part of it comes into focus at the same time in a section which passes in the plane of the lamina. From this network some branches proceed towards the nearer side of the section as if to join the network of another layer, whilst others dip downwards, as if for a similar purpose" (Carpenter, *l. c.* p. 14.). In other instances the tubes run obliquely through all the layers. The former structure was found by Dr. Carpenter in the outer yellow layer of *Anomia ephippium*; the outer layer of *Lima scabra* and in *Chama*, the latter in *Arca*, *Pectunculus*, and *Trigonia*. In the latter case, the tubules are not continuous, but are seen under a high power to be formed by rows of isolated vacuities, one for each lamina; corresponding, I imagine, with the appearance, "as if they had arisen from the coalescence of lineally arranged cells," pointed out by Mr. Bowerbank and Dr. Carpenter. Having already given what are, I believe, sufficient reasons for denying the existence of cells of any kind in molluscan shells, I need hardly add that I cannot think this to be the true explanation of the mode of development of these tubules. In fact, I consider that the tubular shell structure is identical with that of dentine, and has precisely the same origin; its tubuli arising not from cells, but like the canaliculi of bone, by a process of vacuolation in the calcified tissue. I regard the structure and mode of development of the Molluscan like that of the Annulose shell, in fact, as evidence of the strongest and most unmistakable kind in favour of the views with regard to the formation of dentine which I ventured to put forth in my essay "On the Development of the Teeth." Tooth and shell completely represent one another, structure for structure; Nasmyth's membrane is the homologue of the "epidermis," the enamel that of the prismatic structure, the dentine, that of the membranous structure; and all three are produced without the intervention of cells by the differentiation of primarily structureless laminæ. The existence of tubuli in the prismatic substance is not mentioned by Dr. Carpenter, but I have noticed them very distinctly in one of the sections of Pinna from his cabinet.

Finally in Rudistes and the sessile Cirrhopods, Dr. Carpenter has pointed out the existence of a peculiar *cancellated* structure "like that of Pinna on a large scale" only that the segments of the prisms are hollow instead of solid. These hollow prisms are

* This is, after all, only a return to the opinion of Poli, whose observations on shell structure are remarkably accurate, and should never be overlooked. See his Testacea utriusque Siciliæ. Pars prima "in qua de Testarum natura atque affectionibus disputatur."

covered externally and internally by a structureless layer.

To complete this view of the different varieties of shell structure, it may now be interesting to consider the mode in which they are combined in the shells of the various classes of the Mollusca. In the *Brachiopoda*, the calcareous shell is composed entirely of membranous laminæ, which are superimposed at a very acute angle with the surface of the shell, and are further remarkable for being thrown into sharp folds $\frac{1}{2000}$ to $\frac{1}{700}$ of an inch apart, perpendicular to their planes. In the great majority of the recent species again, all the layers of the shell but the outermost are perforated by canals ·0006 to ·0024 of an inch in diameter, each of which contains a cœcal process of the mantle, corresponding with those processes which we have seen into the cellulose tunic of the Ascidians; the shells of *Lingula* and *Orbicula* are composed of horny laminæ perforated by oblique tubuli like those of dentine (Carpenter, *l. c.*). The shells of those families of Lamellibranchs, in which the lobes of the mantle are more or less united, are similarly composed almost entirely of laminated membranous shell substance, *e. g. Mytilus, Modiolus, Tridacne, Isocardia, Conchaceæ, Nymphaceæ.*

The tubular structure is met with in the *Arcaceæ*, in *Lithodomus*, in *Cardium*, and has generally a marked relation with the costations or sculpturing of the outer surface; the membranous and prismatic structures are combined in the *Myaceæ* and *Solenaceæ*, and in those genera which have the lobes of the mantle disunited, as *Ostrea, Unio, Pinna.*

In the Gasteropoda the shell substance is invariably membranous, but the laminæ of which the shell is composed, usually three in number, are marked by parallel lines into rhomboidal bodies, which are described by Dr. Gray as crystals, by Messrs. Bowerbank and Carpenter as elongated, mutually adherent cells. I believe that neither of these expressions is exactly correct, but that these bodies have the same origin as the prisms of the lamellibranchiate shell; a conviction in which I am strengthened by finding concentrically laminated bodies, like those of the Lamellibranchiates, upon the inner surface of the shell of *Helix* (*fig.* 313. D).

In *Patella* the middle layer is composed of perpendicular prisms, like those of Pinna. *Chiton* resembles it in this respect, but the outer layer is here composed of fibres parallel to the surface, and is pierced by short canals. In *Haliotis*, calcified plaited laminæ alternate with structureless horny layers, in immediate contact with which, says Dr. Carpenter, "is a thin layer of large cells of a very peculiar aspect." Dr. Carpenter considers that the plaited laminæ are cellular in this shell also.

Among the external shells of the Cephalopoda that of *Nautilus* has an external "cellular" layer as in Mya, and an internal nacreous layer like that of Haliotis.

The shells of all Lamellibranchiata, Brachiopoda, and of the majority of Gasteropod Cephalophora are external, being from their very origin never included in any involution of the mantle. It is different, however, with certain Cephalopoda and pulmonate Cephalophora, in which the shell commences its development as an internal organ covered over by the outermost layer of the mantle, and may either remain so enclosed during life (*e.g.* Sepia, Limax), or ultimately become naked as in Spirula and Clausilia. Although, however, these shells are truly internal (a distinction which, as I have endeavoured to show, carries with it some important conclusions),* yet the careful observations upon their development in Sepia by Kölliker, and in Clausilia by Gegenbaur, appear to furnish abundant evidence that they are still truly ecderonic structures, and that they bear the same relation to ordinary shell as a nail bears to a horny epidermis among the higher animals. We know, in fact, that the nail, though to all intents and purposes mere cornified epidermis, is at first an internal structure, being covered over by the outer layers of the fœtal epiderm. A nail remaining so covered would correspond with the shell of Limax or Sepia, while an ordinary nail represents that of Clausilia. Gegenbaur, in fact, has shown that the shell of the latter mollusk commences at first like that of Limax by the deposition of a layer of calcareous particles in the midst of the cellular ecderon of the mantle beneath its outer layer of cells. The shell of Limax goes no further than this stage, while in Clausilia (and probably in Helix, &c.) it gradually increases by addition to its under surface, and finally bursts through the cellular investment which takes no share in its formation. It is the same with Sepia. Here the internal shell, or sepiostaire, is composed of two layers, a dorsal and a ventral; the former, according to Kölliker, is a thin membrane composed of slightly wavy, parallel, somewhat dark fibrils 0·001–2″ broad, which frequently appear to be composed of still more delicate fibrillæ. So far as this membrane corresponds with the ventral layer, it is covered on both surfaces by a thin structureless lamina of carbonate of lime, which has a pearly aspect on the ventral surface where it is not covered by the ventral layer; while it is granular on the dorsal surface, and on the ventral, where it is covered by the proper ventral layer, presents ridges to which the plates of the latter are attached. The thick ventral layer of the sepiostaire is composed of lamellæ set at a very oblique angle to the dorsal layer, and united together by close-set partitions at right angles to their surface. Acted upon by acid, this portion of the shell leaves behind it a membranous skeleton of exactly the same form, but presenting no further structure.

Young embryos present merely a fibrous rudiment of the dorsal layer. The ventral

* See Memoir on the Morphology of the Cephalous Mollusca, Phil. Trans. 1852.

layer is formed by the successive deposit of calcareous laminæ inwards. When the first lamina has been formed, a deposition of small cylindrical bodies takes place upon its inner surface. These increase, widen and become ramified at their extremities, forming ramified columns. A second calcareous lamina is now formed, connecting their ramified extremities, upon whose under surface the like process takes place, and this is repeated until the ventral layer has attained its full thickness. The ramified columns are regularly transversely striated; with the age of the shell additions are continually made to their lateral dimensions until they coalesce and constitute the septa of the perfect shell, upon which the striæ remain visible.

Kölliker was unable to find any cellular structure in the columns or laminæ themselves, but describes a layer of nucleated cells under the shell, which he regards as the agents in its secretion. Some researches recently made by H. Müller (Gegenbaur, Kölliker and H. Müller, *l. c.*) corroborate this view. He finds the shell of the Loligidæ invested by an excessively vascular membrane, which is almost wholly covered by a layer of epithelial cells towards the shell. On the dorsal surface they are for the most part rounded ; on the abdominal surface, and particularly towards the anterior point, they form narrow cylinders which attain a length of as much as 0·07‴. They appear to give rise to the structureless layers of the shell. The lateral styles of the Octopods present similar relations.

The structure thus described, though apparently so widely different from that of ordinary mollusks, does not really differ very widely from the cancellated shell structure of Rudistes, &c., or still better of Pleurorhynchus as described by Dr. Carpenter. If we leave out the sides of the hollow prisms in the latter shell in fact, it will correspond exactly with one lamella of the ventral layer of the sepiostaire.

For a comparison of the shells of Spirula and Belemnites with those of Sepia and of Gasteropods, I must refer to Dr. Carpenter's Memoir so often cited.

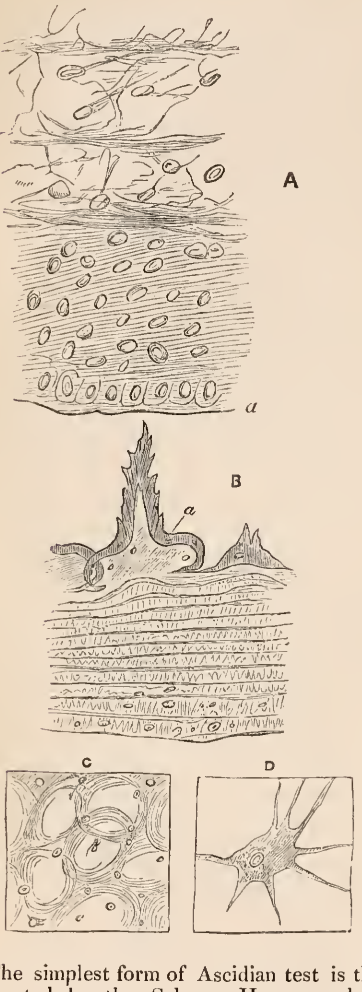
2. *Conversionary integument of the Mollusca containing cellulose.* — This form of integument has hitherto been found in the Ascidians alone, in which the existence of cellulose was first detected by Schmidt in 1845. Schmidt's discovery was confirmed, the fact of the existence of cellulose in all the genera of Ascidians determined, and the chief morphological characters of their test set forth in the memoirs by Löwig and Kölliker " Sur les Enveloppes des Tuniciers," which appeared in 1846, since when further investigations have been made by Schacht and by myself. I must refer the reader to these papers for an account of the various opinions which have been entertained with regard to the structure of the Ascidian test, as I can only lay before him what are in my belief the facts of the case.

The test of the Ascidians is never composed of pure cellulose, but consists of an animal membranous matrix, to which the cellulose has the same relation as the calcareous salts have to the membranous basis of bone or of shell. The cellulose is, in fact, diffused through the membranous matrix, thoroughly impregnating it.

This membranous nitrogenous matrix in which the cellulose is deposited, presents great diversities of structure in the genera of Ascidians, representing, in fact, almost every known tissue. Thus in one genus we have a test resembling cartilage ; in another, like bone ; in a third, like connective tissue. It may either be without vessels or traversed by branched and ramified vascular processes of the body. It is in all cases, however, a product of the metamorphosis of the ecderon of the outer tunic or mantle and, complicated as its structure may be, corresponds morphologically with the shell of other mollusks, or with the epidermis of the higher animals. In fact, if a section be made through the outer tunic and test of an Ascidian, as in *fig.* 314. A, taking care not to disturb the natural relations of the parts, we observe at the line of contact between the outer tunic and the test (*a*) an arrangement of the parts very closely resembling what exists at the junction of the derma with the rete Malpighii in the human skin. The outer tunic, like the former, is constituted by bundles of rudimentary connective tissue which run inwards to form sheaths around the muscles, leaving between them spaces, the sinuses of the blood vascular system, while externally they fuse together into a homogeneous substance containing endoplasts, which is thrown into processes and passes insensibly outwards into a layer of similar substance, with very close-set endoplasts almost perpendicular to its surface, which forms the commencement of the proper test. Externally to this rete Malpighii, the deposit of cellulose commences; the tissue undergoing at the same time a fibrous metamorphosis. The line *a* is therefore a protomorphic line, and the test is the product of the growth and *conversion*, by deposit of cellulose within its elements, of a true ecderon.

The separation of the ecderon (or test) from the enderon (outer tunic) takes place with great readiness in some Ascidians, as Phallusia, &c.; while in others, such as Boltenia, many Cynthiæ, Salpæ, &c., it can be effected with considerable difficulty, or not at all, and this difference has even been raised to the rank of a zoological distinction, the Ascidians having been in consequence divided into Monochitonida and Dichitonida. I believe, however, that in all those Ascidians whose test is unprovided with vessels, it is, normally, closely adherent to the outer tunic, and I am inclined to think that this is equally true even of those forms, such as the Phallusiæ, in which in preserved specimens the test and outer tunic are so commonly found detached from one another. Here, however, as the test is provided with an abundant vascular supply proceeding from one point of the body, it may normally become separated elsewhere. Careful examination of fresh specimens can alone decide this point.

Fig. 314.



The simplest form of Ascidian test is that presented by the Salpæ. Here, we have merely a gradual growth of the periplast and a deposit of cellulose within it, the endoplasts either remaining as such or becoming surrounded by cell walls. The resulting tissue, in fact, is identical with cartilage, if we suppose cellulose to have taken the place of chondrin.

In the Pyrosomata, the test has a structure which, on the one hand, resembles bone, on the other some forms of fibro-cartilage. The endoplasts, in fact, have become surrounded by cell walls, which are produced into long, frequently anastomosing processes (*fig.* 314. D); these retain their animal composition, while all the immediate tissue is strongly impregnated with cellulose. This is the fundamental structure of the test in the Phallusiæ and Clavelinæ also; but here an additional complication results from the development in the substance of the test of a series of rounded cavities, which gradually enlarge until they almost come into contact, and give rise to a spongy texture. The intervening septa at the same time frequently become obscurely fibrous (*fig.* 314. *c*). Now these "vacuolæ," whose origin and nature appear to me to show their identity with the "cancelli" of bone developed from cartilage, have been described by Löwig and Kölliker, and by Schacht as cells; and the latter has even stated that they possess a nitrogenous lining membrane. This is, however, a mistake, arising from the imperfect operation of the reagents by which the cellulose is detected; it is simply less abundant close to the cavities of the vacuolæ, but may with care be demonstrated to exist up to their very edges.

Botryllus, Synöicum, Syntethys, Boltenia, and the Cynthiæ, present a new series of appearances: here the periplast of the ecderon is metamorphosed into fibres, which, however, are not composed of pure cellulose, but of a nitrogenous substance impregnated therewith. In Synöicum the test is soft, and presents very much the structure of some forms of rudimentary connective tissue. We find, in fact, a more or less distinctly fibrillated basis with scattered endoplasts; some of these are invested by round granulous nitrogenous cell-walls, while in others the cells are spindle-shaped and prolonged at each end into fibres (representing thus the elastic element of ordinary connective tissue), or they may be stellate. Botryllus, Syntethys, and Boltenia, present a similar structure, varying, however, in the extent to which the nitrogenous cell-walls on the one hand, and the periplast impregnated with cellulose on the other, have undergone development. Thus the periplast is broken up into very obvious fibres in Botryllus, while in Boltenia the fibrillation is pale and indistinct. On the other hand, I have nowhere met with so great a development of the nitrogenous cell-wall as in Synöicum.

In Boltenia a more or less distinct lamination makes its appearance in the test, and this peculiarity, as well as the fibrous structure altogether, attains its maximum in the Cynthiæ. In Cynthia papillata, for instance, the middle substance of the test is composed of numerous, very obvious laminæ, which consist of fibres directed alternately parallel with, and perpendicular to, the surface of the test (314. B.) At first sight, they appear as Löwig and Kölliker have described them, to be decussating sets of longitudinal and radiating; but on a careful examination of their sections I invariably found that the apparently radiating fibres bend round as they approach the apparently longitudinal set, and in fact pass into the latter. The longitudinal bands are, however, no thicker at one end of a section than at the other, so that the transverse fibrils cannot be merely given off from them. A transverse section, again, exhibits the same appearances as a longitudinal one; so that I think the fibres must in reality have a more or less regularly circular arrangement around the centre of the spaces occupied by the radiating bands, the apparently longitudinally fibrous bands arising merely from the decussation of these circular fibres. Great numbers of granular corpuscles (endoplasts ?) are scattered through the midst of the "transversely fibrous" spaces. In Cynthia pomaria, Löwig and Kölliker describe peculiar "cells" in the inner layer of the test, consisting of such corpuscles surrounded by a thick circularly fibrous wall, and the existence of these bodies appears to be additional confirmation of the view I have taken as to the mode in which the fibres in Cynthia papillata are disposed. If in the latter, the fibres were disposed more closely around particular corpuscles, the test would, in fact, break up into just such circularly fibrous cells.

I have hitherto described only the structure of the middle, most characteristic portion of the Ascidian test; it is next necessary to notice the inner and outer surfaces; the former of which is ordinarily said to be covered by a cellular epithelium, the latter by a more or less structureless horny epidermic layer.

The so-called epithelium is, I believe, in all cases merely the innermost unmetamorphosed layer of the ecderon, corresponding with the rete Malpighii of the "epidermis" of higher animals. As the Ascidian integument is ordinarily examined (*i. e.* in spirit specimens), it is in the condition of the macerated integument of one of the higher animals, and just as the "epidermis" of the latter may or may not, if stripped off, bring away with it the deepest layers of the *rete*, so the Ascidian test, when detached from the outer tissue, may or may not retain the corresponding structure.

The horny so-called "epidermis," on the other hand, is a structure well worthy of attention, as a similar element is, as we have already seen, to be met with in the widely different integuments of other Mollusca. In all Ascidians I have found the outermost surface to be formed by a structureless homogeneous layer, which contains less cellulose than the subjacent tissue, and often has a brownish horny aspect. In many Salpæ, Phallusiæ, and Cynthiæ, this outer layer constitutes merely a tough wrinkled investment. In others (Synöicum, Boltenia) it is prolonged with the subjacent layer into spines and processes, but without being much thickened. In other Bolteniæ again, and in various Cynthiæ, it is greatly thickened, and almost by itself constitutes large spines or even tesselated plates. In Cynthia papillata (*fig.* 314. B), the whole outer surface of the test is covered with spines (*a*), whose bases expand into polygonal plates, which strongly resemble the spines of the Rajidæ, to which reference will be made below. The brown substance here appears to have invaded the subjacent tissue, leaving spaces for the pre-existing endoplasts, so as to give rise to a structure precisely resembling the bone of the Plagiostomes, while to complete the resemblance, the pointed extremity of the spine is marked by lines which pass from its central cavity, parallel with one another, to the surface. I am not sure that there are tubes, but otherwise the appearance is exactly that presented by the pseudo-dentine of the integumentary spines of the skate.

It would appear, according to Milne Edwards, and the late observations of Krohn, that the rudiment of the mantle exists in the ovum of Phallusia before the cleavage of the yolk commences, as a structureless pellucid coat, containing solitary or aggregated greenish cells; and it would seem as if the outer structureless layer with which we are at present concerned, arose from this coat, while the main thickness of the mantle is the product of the metamorphosis of the subsequently developed ecderon.

From all that has been said, I think it results that the Ascidian test is formed from the ecderon of the animal by a process of conversion which consists in the deposit, through its periplast, of cellulose, and a coincident morphological change which may result in the production of a tissue essentially resembling either cartilage, bone, connective tissue, or even dentine; and that, therefore, an attentive study of the integument in this class alone is sufficient evidence that mere structure is no proof of the ecderonic or enderonic nature of any given organ.

Integument of the Vertebrata. — In these animals there are two classes of integumentary organs, differing in structure, chemical composition, and mode of development. These are, 1st, the *horny* and *glandular* tegumentary organs produced by the *conversion* of the cellular ecderon; and 2nd, the *calcified* tegumentary organs which appear very frequently to be developed by a process of *excretion*.

1. *Conversionary horny organs.*—If a section be made of the integument of any mammal, it will be seen to be composed, leaving out of view its various appendages, of two principal portions, the enderon or derm, and the ecderon or epidermis. The latter, separated by a more or less distinct transparent line from the former, is internally composed of a homogeneous soft substance, in which are dispersed numerous oval or rounded endoplasts, set more or less perpendicularly to the surface of the enderon. Further outwards, they gradually become more distant and a cavity is developed round each, so that the ecderon becomes distinctly cellular. Still more externally the cellular periplast becomes changed in composition, being converted into a denser horny substance, and the change usually takes place so suddenly that the horny external portion (epidermis) is sharply marked off optically, and can be readily separated mechanically and chemically, from the internal unaltered soft portion, the *rete Malpighii.* The cell cavities at the same time become flattened, and by degrees almost obliterated, apparently by the pressure of the subjacent growing tissue; but the endoplasts remain, and may always be detected if the horny layers are

distended and rendered transparent, by the action of acids or alkalies. The horny stratum of the epidermis is therefore the result of the *conversion* of the walls or periplast of a whole layer of the cells of the ecderon into horn.

The hard structures of nails, hoofs, and horns (*i. e.* horny sheath of the horns of Ruminants) are developed in exactly the same manner; nor am I aware that any tissue enters into these organs, which is not entirely produced by the horny conversion of a cellular ecderon. The hoof of a fœtal lamb was entirely composed of such horny cells.

Structure of hairs, spines, and feathers. — In these tegumentary organs, we have to consider, first, their own proper structure, and, secondly, that of the sacs in which they are at first wholly, and always partially, enclosed.

The *shaft* of a hair is composed of three distinct structures, an external, the *cuticle;* a middle, the *cortex;* and an internal, the *medulla.*

Fig. 315.

Hair, Man.

A, B, D, E, F, from the nose; C, from the head.

The *cuticle* (*fig.* 315. C, D, E) on that portion of the shaft which lies within the hair sac, consists of two layers, while only the inner of them remains in the protruded portion. Viewed in section, as when a hair is observed in its totality, the cuticular layers form a thin double margin to the shaft, the outer (*b*) having the appearance of minute rhomboidal cells, joined end to end; the inner (*a*) seeming to be composed of close-set fibres arranged parallel to one another, and obliquely to the axis of the hair. If, however, the focus of the microscope be adjusted to the surface of the hair, or if the cuticular layer be detached from the shaft, these rhomboidal cells and parallel striæ are found to be the expression of irregular transparent structureless plates, overlapping one another, and closely united into tough membranes, to which their projecting edges give a striated appearance. No trace of endoplasts is visible in the older of these plates, and the matter of which they are composed is singularly unchangeable, remaining untouched on the addition of strong sulphuric acid, or of caustic potash, which completely dissolve the inner substance of the base of the shaft, and leave the cuticle in the form of a transparent, colourless, double membrane. In man, the outer layer of the cuticle ceases at the level of the sebaceous glands; and the edges of the plates of the inner layer lie very closely appressed to the shaft; in many of the lower animals, however, the plates are at a greater angle to the axis of the hair, and their projecting edges give rise to the most elegant sculpturings of its surface.

The *cuticle* proceeds from the horny metamorphosis of the two outermost layers of the pulp of the hair. The lowest portion of the bulb of a hair, if viewed in section, presents a sharply defined edge (*fig.* 315., C), which may occasionally be raised up by reagents as a distinct structureless membrane; but is normally perfectly continuous with the subjacent transparent homogeneous periplast of the pulp, in which lie the ordinary rounded or oval vesicular endoplasts of young indifferent tissue. Tracing the margin of the hair upwards, we find, next, that the two most superficial series of these endoplasts (D, *a*, *b*) are distinguished from the rest, by being free from that deposit of pigment granules which surrounds the endoplasts of the proper shaft substance; and these two series are more or less distinctly contained in cavities or cells. The outer series is disposed more parallel, the inner more perpendicular to the surface. Still higher, (E) the cavities of the outer series are larger, and their party walls straight and sharply defined, while the endoplasts, which were at first plainly visible, disappear. In the inner series, both cavities and endoplasts disappear, and the periplast seems to split up into thin parallel horny plates (E), whose edges become more and more strongly marked. Such are the steps in the development of the cuticular layers which may be observed in short thick human hairs, such as those of the nostril. In those of the head, however, and in the hairs of the body of the calf, I have been unable to trace the cuticle into anything but a structureless layer, wrinkled externally, which passed into the superficial structureless layer of the deepest part of the bulb (C). I formerly thought that this indicated an important difference, but it is readily accounted for, if we suppose the process of development to be the same in each case, the endoplasts only disappearing very early in the latter.

The main substance of the rest of the shaft of all hairs, and its entirety in some, is composed of the *cortical tissue.* This is a horny hard substance, clear and homogeneous in white hairs, but filled with pigment granules, and moreover having its own special coloration in coloured hairs, which may be broken up mechanically, or by the action of strong alkalies and acids, into long, pale, sometimes striated fibres, which may or may not present remains of elongated endoplasts. Besides the latter and the pigment granules, a multitude of striæ and dots are visible in the cortical substance, which are produced by canals and cavities containing air.

The cortical substance results from the metamorphosis of the corresponding portion of the hair bulb. The primarily rounded vesicular endoplasts (*fig.* 315. A), become greatly elongated and spindle-shaped, without ever, so far as I have been able to observe, becoming surrounded by a distinct cell cavity or wall (*fig.* 315, B). At the same time pigment granules arise in the periplast; it acquires a fibrous appearance, becomes horny, and splits up more and more readily into plates and fibres in the direction of its length. As it attains its perfect structure, rounded and elongated vacuolæ, which there is no reason whatever to suppose result from confluent cell cavities, arise in it and become filled with air. In fact, the perfect cortical substance is a sort of rudimentary horny dentine.

Lastly, the *medullary substance* — which attains a considerable development in the short thick hairs of man, and in those of the body of many mammals, but is frequently absent, as in the hair of the head of man, and according to Brücke (Reichert's "Bericht," 1849) in the bristles of the pig, the whiskers of the dog, seal, walrus and the long hairs of Myrmecophaga jubata—consists of a horny matter like that of the cortex and continuous with it, excavated into polygonal cavities, which frequently contain air bubbles and pigment granules. The cavities communicate, and the air may be driven from one into the other.* In the fully formed hair, they contain no remains of endoplasts. The medullary substance, like the cortical, proceeds from the metamorphosis of the indifferent tissue of the pulp, but the process, instead of being one of vacuolation and fibrillation, is essentially one of cellulation. The endoplasts, instead of elongating, remain rounded. Cavities are developed round them, whose partition walls become thick and granular. The cavities then gradually enlarging eventually open into one another, and the endoplasts disappear. The whole structure and mode of development of this tissue, in fact, show its complete identity with the "pith" of feathers, as we shall see more fully below.

The *hair sac* is an involution of the whole integument, and as such is composed of an enderonic and of an ecderonic portion. The former, which is continuous with the subcutaneous tissues, when well developed, consists externally of a network of fine elastic fibres, within which is a layer of homogeneous tissue containing endoplasts which are more or less elongated transversely, and which form the superficial layer of the enderon. Within this is a structureless layer, the commencement of the ecderon, enclosed by which are the representatives of the cellular ecderon, the so-

Fig. 316.

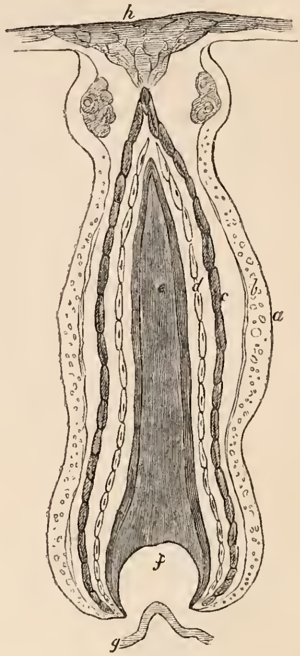


Diagram illustrative of the position of the different layers of the hair sac in a young hair.

a, *b*, outer rootsheath; *c*, fenestrated rootsheath; *d*, imperforate rootsheath.

called *rootsheaths*. These are commonly described as two, the *outer* (*a*) and the *inner* (*c*, *d*); the latter again being composed of two structures, an external, the *fenestrated inner rootsheath* of Henle, and an internal, which I described in 1845, and which may be called the *imperforate inner rootsheath*. The *outer rootsheath*, like the others, is thicker above than below, thinning out where it joins the bulb at the bottom of the sac. It consists entirely of tissue resembling that of the rete mucosum, and needs no particular description.

The *fenestrated, inner rootsheath* lies in immediate contact with the outer rootsheath. It is composed of more or less rounded or polygonal flat plates, with faintly marked boundaries, united by their narrow ends, and leaving spaces between their sides (*fig.* 315. F). It is very tough and resistant, both to mechanical and chemical action, and no endoplasts can be seen in its elements. The *imperforate rootsheath* (*a*) is composed of flat thin flexible plates not unlike those of the preceding layer; but they present no intervals, their boundaries are strongly marked, and in the centre of each there is a peculiar, elongated, often more or less dumb-bell-shaped endo-

* Griffith, Lond. Med. Gazette, 1848.

plast. In the human hair sac there are usually only one or two laminæ in this layer, but in Rodents there are said to be many.

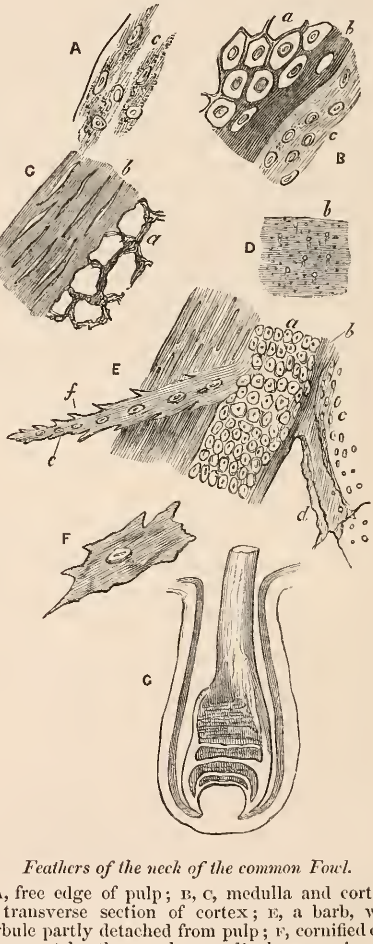
If we examine a hair sac above the level of the bulb, it will be clear that these inner rootsheaths are not generated from the contiguous surface of the external rootsheath, as would at first seem probable. No transitional forms, in fact, are visible in the direction of the transverse diameter of the sac. Traced towards the base of the sac, however, it is obvious that opposite the lower portion of the bulb the inner layers of the outer rootsheath become metamorphosed into horny cells; and that of these cells, the inner are converted into the imperforate layer, while the outer undergo a more complete cornification, and lose all trace of their primitive endoplasts. The clefts which ultimately exist between these cornified plates are not present in the young state, but are the results of a secondary vacuolation. They have nothing to do with the disappearance of the endoplasts; for traces of the latter may be observed in the *centre* of horny plates, at whose *edges* the clefts are commencing (*fig.* 315. F). It would appear, therefore, that the rootsheaths grow like the shaft of the hair itself, not by addition to their surface, but by growth of their deep-seated inner ends.

Such is the composition of the growing hair; but the completely formed hair (see § 2. *Morphology*) presents very great differences in the minute structure of its inner termination. In the first place, the shaft runs out into an irregularly conical mass, like a worn-out painter's brush. It consists, at its extremity, entirely of cortical substance, and the cornification runs in irregular lines into the indifferent tissue, which occupies the bottom of the hair sac and represents both pulp and outer rootsheath. The inner rootsheaths terminate above this point, in an irregularly horny layer, which unites with, and is in a manner reflected into, the cuticle of the shaft, which ceases above its brush-like expansion. Finally, the outer rootsheath in the immediate neighbourhood of the inner, is metamorphosed into large horny cells, like those of the cellular ecderon. The development of these from the indifferent tissue of the outer rootsheath, may be very clearly traced. The periplast first becomes enlarged and marked off into definite granular areæ around each endoplast, and the limits of each area are metamorphosed into clear horny walls. The cavity which these inclose enlarges, and the endoplast, with its surrounding granular matter, remains attached to one wall, and then eventually disappears, while the cavities enlarge, and their walls thicken into clear horny "cells," which may eventually be detached from one another.

The whole process of the completion of the root of a hair, then, is simply a return of the diverticulum of the ecderon, — the metamorphosis of whose elements, so long as the hair was in course of formation, was guided and determined into distinct forms along certain fixed lines, — to its general tendency to undergo the ordinary cellular metamorphosis over its whole surface. With this return to its primitive tendencies, the increase of the hair of course ceases, and sooner or later it is pushed out and falls away.

The spines of the Porcupine, of the Hedgehog, and of the Echidna*, present in their histological, as in their morphological relations, an interesting approximation to feathers. Externally, they are coated by a cuticle, while the principal mass of their walls consists, at the ends, of a fibrous horny substance; in the middle, there is added to this a medullary substance composed of polyhedral horny cells.

Fig. 317.



Feathers of the neck of the common Fowl.

A, free edge of pulp; B, C, medulla and cortex; D, transverse section of cortex; E, a barb, with barbule partly detached from pulp; F, cornified cell, from rootsheath; G, horny diaphragms in the quill.

The section of the *shaft* of a fully-formed feather presents exactly these constituents except the cuticle; the centre is occupied by *medullary substance* (*fig.* 317. B, *a*), composed

* See Bröcker (Reichert, Bericht. Müll. Archiv. 1849).

of a coarsely granular horny substance excavated by polygonal cavities of about $\frac{1}{1000}$ inch in diameter, frequently if not invariably containing air, which adds to the dark hue (by transmitted light) arising from the granular opacity of the horny matter. At its edges, this tissue passes into the *cortical substance*, which, in a transverse section (*fig.* 317. D) appears as a clear, homogeneous or slightly granular mass, dotted over by minute apertures, about $\frac{1}{10000}$ in. in diameter, and $\frac{1}{3000}$ in. apart. In a longitudinal section, on the other hand (*fig.* 317. C, *b*), the general mass appears obscurely striated in a longitudinal direction; and in the place of the circular apertures, we see elongated fissures, somewhat narrowed at each extremity, whose transverse sections constituted these apertures. The pointed ends of the fissures were continued by a line which could frequently be traced into some other fissure above or below, so that I conceive the fissures are in reality more or less complete canals.

The *quill* of the feather is entirely composed of cortical substance; the *barbs* have the same structure as the shaft; the *barbules* present both cortical and medullary substances in a rudimentary condition. Each barbule in fact (*fig.* 317. E, *e*) exhibits along its axis a series of oval cavities, the remains of cells like those of the medulla, while its lateral portions are composed of striated horny matter like that of the cortex, and are produced into the curved and hooked lateral *processes* (*f*).

The polygonal cells of the medullary substance are produced from the indifferent tissue of the pulp in exactly the same manner as those of an ordinary horny, cellular ecderon from that of the *rete mucosum*: that is to say, the periplast increases, and becomes marked out into polygonal areæ; it then acquires a horny consistence, and a stronger and stronger definition along the lines of demarcation, until polygonal "cells" (as in *fig.* 317. B, *a*) are formed. The walls of the latter now thicken and become granular; the endoplasts disappear, and at length nothing is left but the honey-combed perfect medullary substance. The mode of formation of the *cortical substance* is the inverse of this. On examining the line of junction (*fig.* 317. B) of the pulp (*c*) with recently formed cortical substance (*b*), it is observable that the endoplasts do not become surrounded by cell cavities, but that the periplast acquires a granular, longitudinally fibrous, appearance; while the endoplasts, though they are occasionally visible in the striated mass, soon completely disappear.* The elongated cavities or tubuli do not at first exist in the cortex, but are the result of a secondary vacuolation, and so far as I have been able to observe, have no relation with the pre-existing endoplasts. In fact, these canals, like those in the hair-shaft, the clefts in the fenestrated rootsheath, and the canaliculi of bone, must be regarded as the results of a secondary vacuolation. The feather sac resembles that of the hair in all essential points of structure, except that the relations of the layers of the inner rootsheath are different. As in the hair, two layers may be distinguished in the inner rootsheath, an outer, strong, dark, horny membrane corresponding with the fenestrated membrane, and an inner delicate flexible layer, corresponding with the inner horny rootsheath. The former has a structure intermediate between that of the two layers of the inner rootsheath in the hair, consisting of irregular polygonal plates, which retain the remains of their endoplasts (*fig.* 317. F), as in the inner layer of the horny rootsheath, and do not become separated by fissures; while they resemble the plates of the outer horny rootsheath in their thickness, complete cornification and striated appearance.

The inner layer of the horny rootsheath is a delicate, often granular membrane, which closely invests the outer surface of the feather, and from presenting a cast of its elevations and depressions, has been called the outer "striated membrane" of the feather sac (*suprà*, § 2.) It is a sheet of horny matter, in which traces of closely-set endoplasts are discoverable. The inner (*fig.* 317. E, *d*) "striated membrane" is a membrane having a similar structure, possessing similar relations to the inner surface of the feather, and which is continuous with the so-called "pith" in the quill of a fully formed feather. The mode of development of these rootsheaths is identical with that of those in the hair, and therefore requires no further elucidation here.

Tegumentary glands. — The other conversionary productions of the ecderon which we have to consider, are the glandular appendages, which are always diverticula of the cellular ecderon inwards.* Under this head I include only those small glandular organs which, so far as we know, have no reference to any other functions than that of cutaneous transpiration or fatty secretion, referring to the articles on special divisions of the animal kingdom for an account of those organs, such as the "water vessels" of Echinoderms and Trematoda, the nidamental glands of Mollusks, the genital glands of Vertebrata and Insecta, which might strictly be regarded as productions of the integument.

Tegumentary glands in this limited sense are somewhat rare among the Invertebrata. They have, however, been observed in the Annelids, where they consist of delicate tubes, terminating internally by a blind extremity containing a single nucleated cell. Such glands exist on the ventral surface of the head and foot discs in Piscicola, and are scattered all over the body in Clepsine and Nephelis. Similar glands are found opening upon the ventral surface of Argulus foliaceus.

* Compare Schwann, Untersuchungen, &c.

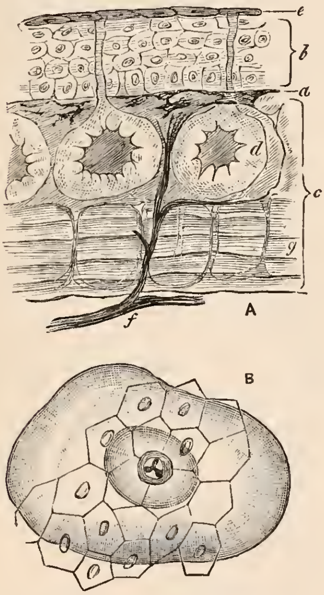
* Unless, indeed, these simple "mucous cells," described by Clark and Leydig in Fishes, and which are merely modified cells of the cellular ecderon, should be regarded as glands.

Simple cœcal glands are scattered over the whole surface of the body of the Procession Caterpillars, opening at the points of the hairs; on the sides of the body in Myriapods, on the joints of the legs in Beetles and Bugs.

In Mollusca a peculiar, probably glandular, canal exists in the foot of certain Lamellibranchs, and glandular cœca have been observed in the lower surface of the foot in Paludina. A ciliated canal runs in the foot of Pulmonata, and receives glands on each side. The existence of cutaneous glands in the Cephalopods appears doubtful—at least, H. Müller could only find them as shell glands in the expanded arms of Argonauta.

Among the Vertebrata, Fishes, Ophidia, Chelonia and Birds, appear to possess no proper cutaneous glands*; in Sauria they attain a very slight and local, but in Batrachia and Mammalia, an immense development. In the frog, the whole surface

Fig. 318.



The cutaneous glands of the Frog. A, section; B, superficial view.

of the ecderon is beset with minute trifid apertures, so disposed between three epidermic cells, as to present a singular resemblance to the stomata of plants (*fig.* 318. B). These lead directly into spherical sacs (*fig.* 318. A. *d.*), which are lined by a continuation of the cellular ecderon, and lie in the superficial part of the enderon above its stratified layer (*fig.* 318. A. *g.*) (*vide infra*). Nerves (*f*) and vessels penetrate the latter to reach the superficial layer of the enderon, and ramify among these close-set glandular sacs. The sacs usually contain only a clear fluid*; they are contractile, and may be made to expel their contents by irritation of the nerves distributed to them.†

In Mammals, we meet with two kinds of cutaneous glands, sebaceous and sudoriparous. The former are almost invariably developed in connection with the hair sacs, consisting in fact of diverticula of the Malpighian layer of the cellular ecderon of the upper portion of these sacs, whence their position is always superficial. The innermost cells of the solid process become filled with fat—break down, and pour their contents into the hair sac itself, by whose aperture they make their exit. Sometimes, as in the hairs of the head in man and in the pig's bristles, the sebaceous glands are very small and simple, while in other localities they throw out processes, and assume the appearance of complex racemose glands, disposed like rosettes around the hair-sac, from which they are developed.

Sudoriparous glands.—These glands, like those just described, are, as Gurlt pointed out, simple, elongated processes of the deep layer of the ecderon, differing from the sebaceous glands chiefly in producing a clear fluid, instead of a fatty secretion. As Kölliker has shown, however, no line of demarcation is to be drawn on this ground, the secretion of the axillary sudoriparous glands in man being an essentially sebaceous substance. The sudoriparous glands are cylindrical cœcal tubes varying, in man, from $\frac{1}{100}$ to $\frac{1}{500}$ of an inch in diameter, whose walls are either thick or thin. In the former case they consist of a simple ecderonic cellular coat, contained within a prolonged sheath, formed by the uppermost layer of the enderon, and, like it, composed of a homogeneous or indistinctly fibrillated periplast, with imbedded endoplasts. Outside this, or rather forming part of it, is a layer of longitudinally-disposed smooth muscles, and the whole is coated, like the deep surface of the rest of the enderon, by a more or less distinct layer of connective tissue. In the thin-coated glands the muscular layer is absent, but the cellular ecderonic coat is frequently so thick that they possess no cavity at all. The thick-walled glands are met with in man in the axilla, scrotum, anal region, &c.; while those of the rest of the body are almost entirely of the thin-walled description. The glands terminate superiorly in undulating canals, which reach the surface of the enderon, and are continued to that of the ecderon by oblique channels excavated in its substance between its cells. Inferiorly, they form close coils, which lie in the subcutaneous

* Dr. Clark, in his excellent account of the skin of the eel (Trans. Mic. Soc. 1849), describes cutaneous glands in that animal. The so-called "glands" of the lateral line, however, have since been shown by Leydig to have a very different structure; and I confess I have not been able to convince myself of the existence of the other glands described by Dr. Clark. I can find nothing like them, except the strong perpendicular semi-elastic bands, which traverse and unite the bundles of connective tissue in this as in other fishes.

* Stated by Bergmann and Leuckart to have an irritating property in Triton.

† Ascherson: Haut-drüsen d. Frösche, Müller's Archiv, 1841. Czermak: Haut-nerven d. Frösche. Ibid. 1849.

areolar tissue, and receive twigs from the vessels in their neighbourhood.

In the other Mammalia, the general structure of the sudoriparous glands is as in man. In the sheep, according to Gurlt, they present the same coiled arrangement, while in the ox and dog they are straight and simple. In the ox they have rounded, dilated extremities, and are everywhere similar in shape and size. On the hairy parts of the body of the dog, they are small simple cœca, which are very difficult to discover; while on the ball of the foot of this animal they are very large and resemble those of man. Very large sudoriparous glands have likewise been observed upon the horse's prepuce.

Scales of fishes. — In the Ganoid fishes *Accipenser* and *Polypterus* the substance of the scales is composed of ordinary bone whose superficial layer is only denser than the rest, and exhibits a local developement of fine branching tubuli; but in other fishes, two, if not three, distinct layers are usually distinguishable in the scales.

In many Plagiostomes, for instance, the placoid scales have the same composition as the teeth, consisting of a superficial layer of nearly structureless dense "enamel," or as Prof. Williamson more conveniently terms it, "Ganoin," while the deeper substance is composed of a tissue in every respect similar to dentine, whose innermost portion in some cases passes into true bone, — an addition which might be compared to that of the cement in the teeth. Leydig, indeed, has shown that the resemblances between the scales and the teeth of Placoid fish extend even to their mode of developement. If the pulp contained in the central cavity of the spine-like scale of a *Raia clavata* be pulled out, globular calcareous masses of $\frac{1}{1000}$ of an inch and upwards in diameter, and either solitary or adhering together in masses, will be found to be attached to its surface. "These globules are exactly analogous to the dentine globules described by Czermak, which in human teeth afford the formative material for the matrix of the dentine. What, however, appeared to me especially worthy of notice was the circumstance, that the most distinct and beautifully branched canals, having exactly the same appearance as those in the substance of the spine, were already visible in these isolated calcareous bodies, and on carefully examining the fine processes of the canals, no doubt could exist that they were only interspaces or gaps. On carefully adjusting the focus, in fact, it was obvious that one of these large calcareous globules is itself only an agglomeration of many smaller globules, and it could be observed that the gaps left between the latter became the fine processes of the tubules. From these facts, I believe that the correct mode of conceiving the growth of the substance of the spine is, to suppose that the calcareous matter is excreted from the vessels of the pulp, and then in all probability combined with organic matter, runs into smaller masses; these unite together into larger ones, and become applied to the inner surface of the central cavity, coalescing, and thus adding to the thickness of the spine. Between the calcareous globules, however, canalicular gaps or tubules remain, which form a connected network and communicate with those branched cavities which already exist in the spine.

The scales of the Sharks and the dermal spines of the Rays, then, (and I would draw particular attention to this result,) are perfectly identical in structure with the teeth, even to the absence of nerves in the pulp, and must be united in the same structural group. I have already (On the Skin of Freshwater Fishes, Zeitschrift für Wiss. Zool. B. iii. H. 4.) pointed out the close affinity between the scales of a number of osseous fishes and their teeth: and scales likewise present globules of calcareous matter, which become fused together to form the homogeneous substance of the scale. A process, corresponding with that which occurs at the surface of the pulp in the teeth and cutaneous spines, here takes place from the surface of the sac of the scale (Schuppentasche). The scales of osseous fishes, the spines of the Rays, and the scales of the Sharks, therefore, all belong to the series of dental structures, which in no respect interferes with the entrance of true bony tissue (like the "cement" in the higher animals) into their composition, as we find to be the case in the scales of the Ganoids (Müller), and in the truly bony semicanals which are attached to the scales of the lateral lines of many fishes." *

For the details of the various modes in which Ganoin, true osseous tissue, and those varieties of tubular, more or less dentine-like tissues, to which Prof. Williamson has given the names of "Lepidine and Kosmine," are combined together in the scales of Ganoid and Placoid fish, I must refer to that gentleman's memoirs, already so often cited.

In the Ctenoid and Cycloid fishes there is a superficial "Ganoin" layer, composed of numerous thin structureless calcified laminæ, which are frequently thrown into folds, papillæ or spines. The deeper substance of the scale is composed of a series of layers of a membranous substance, each layer being composed of parallel fibres which take a different direction from those of the superficial and subsequent layers, so that the fibres of alternate layers cross diagonally. No endoplasts or cells are ever distinguishable among the fibres. In the deepest part of the scale these layers are entirely membranous; but in passing towards the surface, minute lenticular masses of calcareous matter make their appearance in the membranous substance. As Prof. Williamson justly states, these lenticular bodies are not developed between the membranous fibres and lamellæ, but in them: "they commence as a small calcareous atom, and in-

* Leydig: Rochen und Haie, 1852.

crease in size by the external addition of new concentric laminæ; the direction of the latter not being parallel with, or having any reference to, that of the laminæ of fibrous membrane with which they so amalgamate; thus they are not depositions from, but growths in the membrane; which growths, as they increase in size, retain their primitive tendency to assume a lenticular form." Following the layers of the scale outwards, these isolated calcareous deposits not only enlarge, but ultimately become fused together, forming at length either a continuous calcareous mass in each layer, or presenting fissures which in some cases traverse the original lenticular calcareous deposits, in others are interstitial to them. I think one cannot but be struck with the complete analogy between the structure and mode of developement here described and those which I have previously shown to obtain in the calcified tegumentary organs of the Mollusca and Crustacea. The ganoin layer corresponds very closely with the "epidermis" of the shell or test; the middle laminated calcified substance is formed by the fusion of concentrically laminated concretions deposited in a membranous matrix in the Fish, the Mollusk, and the Crustacean alike; while the deep uncalcified layers of the scale are represented by the "horny" laminæ which have escaped calcification in Haliotis or Unio, and still more closely by the fibrillated uncalcified layers of the Crustacean test.

Structure of the enderon. — The enderon of the Invertebrata is usually entirely composed of rudimentary connective tissue or of mere indifferent tissue, consisting, in the latter case, simply of a matrix with imbedded endoplasts, while in the former it is produced into plates and bands, never exhibiting, however, the peculiar bundles and elastic fibres which are met with in fully formed connective tissue.

In Paludina, according to Leydig, the pigment masses, which lie on the surface of the ecderon, are connected by "clear large cells, with a small parietal nucleus." From their occurrence, wherever in the higher animals connective tissue is found, Leydig calls them "Binde-substanz-zellen"—"Connective tissue cells;" but, as he himself points out, they frequently contain carbonate of lime, and their relation is rather, like that of the similar cells in Piscicola, to fat.

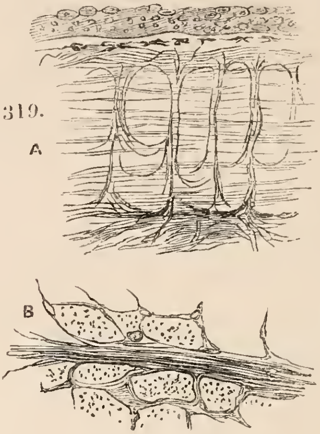
A wonderful complication of structure is attained by the skin of the Cephalopoda. According to H. Müller *, who has recently made some careful investigations on this subject, there lie beneath the cellular ecderon in these animals: 1st, a fibrous layer, usually colourless, but occasionally white and glittering. 2nd, the layer with the chromatophora (*vide inf.*). 3rd, beneath these a peculiar layer, which gives rise to the colours produced by interference, the metallic lustre, and intense whiteness of many localities. It consists frequently of regular plates, which evidently proceed from nucleated cells. 4th, deeper still lie the larger bundles of connective tissue, the muscles and the vessels.

In the Vertebrata, the superficial layer of the enderon is similarly composed of indifferent tissue, and of rudimentary connective tissue; the former passing gradually into the latter, as

Fig. 319.

A

B



Enderon of the Skate.

we trace it inwards, developing its elastic element to a greater or less extent, and acquiring a more or less distinctly fascicular arrangement of its collagenous element. In the higher Vertebrata, these bundles are usually disposed as an irregularly felted mass; but in Fishes and Batrachia, they form regularly superimposed horizontal strata, tied together by perpendicular columns, which penetrate the interspaces of the bundles, and spread out into the irregular connective tissue on the deep and superficial surfaces of the stratified mass (*fig.* 319. A). On the addition of acetic acid, it is seen that the boundaries of the strata are formed by irregular bands of elastic tissue, in which the remains of the primitive endoplasts may be seen (as in fibro-cartilage), whose strongest fibres are horizontal, though they send out others irregularly in all directions. The perpendicular columns are likewise composed of bundles of pale elastic fibres (*fig.* 319. B), and if the intersection of the horizontal with the vertical divisions be carefully examined, it is seen that the former are, as it were, given off by the latter, which thus gradually break up and thin out, terminating above and below in the elastic fibres of the unstratified superficial and deep layers. A horizontal section of this portion of the enderon presents a very peculiar appearance, the transparent vertical columns looking like radiating spaces, as which they were, in fact, at first described.

Pigment of the enderon. — The enderon presents scattered masses of pigment, sometimes contained in cells and sometimes free, in many Invertebrata (Annelids, Trematoda, Echinoderms, Crustacea, Mollusca). In other Invertebrata and in the higher Vertebrata, the pigment is confined to the ecderon. In Fishes and Reptiles, however, a well-marked layer of pigment lies at the surface of the enderon in the form of scattered granules

* Bericht, &c. Zeitschrift für Wiss. Zoologie. 1853.

and of irregular more or less stellate masses which are not enclosed in cells. The silvery lustre of the skin of fishes is due to minute rods which constitute a layer at this surface, and should probably be regarded as a peculiar form of pigment granules.

In the Cephalopoda and some Gasteropoda among the Invertebrata, the integument undergoes during life the most extraordinary variations of colour, becoming overspread with successive clouds of the most vivid hues. These are produced by the contraction and expansion of peculiar sacs — the *chromatophora*—containing masses of pigment granules. According to H. Müller, (whose observations I have recently had the opportunity of repeating,) these are sacs attached to whose walls are contractile fibre cells arranged radially, and frequently anastomosing with those of other cells. They do not always contain pigment, but frequently present a distinct nucleus. Several layers of these chromatophora of different colours are frequently disposed, one over the other, in a given portion of the skin, and produce by their different states of contraction, relatively to one another, successive changes in the colour of the spot.

Among the Vertebrata the Chamæleon, as is well known, presents similar phenomena.

Papillæ of the enderon. — The enderon is frequently produced into conical or cylindrical processes, which either merely contain a vascular loop, or are supplied, in addition, with special nerves. In the Invertebrata, we find, in the processes of the mantle into the shell of the Brachiopoda described by Dr. Carpenter, organs which, I have no doubt, must be regarded, like the corresponding processes in the Ascidians, as vascular papillæ. Among the Articulata like processes extend, in the Crustacea, through the whole thickness of the integument to its surface, giving rise to the colourless spots observable on the shell of the crab, for instance. I imagine, however, that these spots were usually occupied by a hair when the shell was thin. In the Mollusca, the marginal processes of the mantle of the Lamellibranchs and Gasteropods, the papillæ of Onchidium, &c. and those of Tremoctopus (H. Müller) are very probably both vascular and nervous papillæ like those of fishes.

Among the Vertebrata, fishes present large projecting papillæ, particularly about the region of the lips and operculum, which are both vascular and nervous. Simple papillæ (nervous?) are scattered over the surface of the body in Plagiostomes and some Ganoid fishes.

I am not aware that papillæ have hitherto been observed on the integument of Birds and Reptiles. In most Mammals, they are very small, if they exist at all, upon the general surface of the body, attaining a considerable size only in such organs as the ball of the foot (Cat, Dog), or on the muzzle. The Cetacea, however, appear to make a remarkable exception to this rule; it is stated (Heusinger, Breschet, and Roussel de Vauzème) that the very thick integument of these animals is traversed by vascular and nervous papillæ, four or five lines long, which extend as far as the outer horizontal horny layer of the ecderon, so that a horizontal section of the ecderon is like that of a horse's hoof. In man, again, the papillæ are, as is well known, so abundant as to have given rise to the term *pars papillaris*, for the superficial layer of the ecderon. The structure of those which appear to possess special nervous functions will be considered below.

Sensory appendages of the enderon. — Very little is known of the ultimate distribution of the nerves to the integument in the Invertebrata, but we are indebted to Leydig for showing that in certain Crustacea, Insecta, and Mollusca, it is very similar to what occurs in the vertebrate classes. Thus in *Argulus foliaceus* the peripheral nerves become pale, and divide, and at the point of division there is a 'nucleus' as in the embryonic fibres of the frog. In *Artemia salina*, *Branchipus stagnalis*, and in the Heteropod Mollusk *Carinaria*, the termination of the tegumentary nerves is essentially similar. The larva of the Dipterous insect *Corethra*, presents even peculiar sensory appendages, in the delicate plumed hairs which beset the sides of the body. These are articulated in the ordinary way, and have an internal ligament, a sort of spring, attached to their base, which is enlarged and receives the enlarged and cellæform termination of a nervous twig. It will be obvious that this arrangement is peculiarly fitted for communicating the slightest vibration to the nerves.

In the Vertebrata (fishes, reptiles, man), the ordinary mode of termination of the integumentary nerves is in one or two plexuses, whence the fine terminal branches proceed, and end by dividing into minute branches indistinguishable from the imperfect elastic fibrils of the enderonic tissue. Loops have also been observed, but it is impossible to say whether, in any case, these are real terminations or not. Gerber and Kölliker have also described "nerve coils" in animals, and in the conjunctiva and lips of man.

The simplest form of sensory appendage in the Vertebrata is presented by the large papillæ of fishes, into which a bundle of nerve fibres enters, some of which terminate in the papillæ, while others, whose looped bands may be readily distinguished, probably pass out again.

In certain fresh-water fishes (Barbus, Leuciscus), Leydig has described papillæ of this kind, which have a cup-shaped depression at their extremities, lodging a globular mass of what he describes as modified epithelium.

Special modifications of the tissue of the papillæ for sensory purposes in the fingers, tongue, lips, &c. of man have lately been discovered by Meissner and Wagner, and described by them, under the denomination of the *Corpuscula tactûs*. Kölliker, who doubts their special relation to the tactile function, on the other hand, prefers to call these bodies, *axile corpuscles*. They are simply ovoid masses of imperfect connective tissue occupying the centre of the papillæ, and further distinguished by having their endoplasts and imperfect elastic

Fig. 320.

A papilla with its Corpusculum tactûs surrounded by three vascular papillæ.

fibrils arranged transversely to the axis of the papilla, so that they appear to be made up of transverse superimposed laminæ (*fig.* 320.). One or two dark-contoured nerve tubules come up through the base of the papilla, and running along one side of the corpuscles, thin out and terminate, without, so far as I have been able to see, entering its substance. In fact, these nerve tubules are, as Kölliker pointed out, accompanied by a delicate neurilemma, and the axile corpuscle itself appears to me to be nothing more than the enlarged end of this neurilemma.

In Birds, a large proportion of the tegumentary nerves terminate in bodies which are, on the one hand, related to these axile corpuscles, and on the other to the well-known Pacinian bodies (*fig.* 322). They are, in fact, usually described under the latter name; but their small size and superficial position, the paucity of their concentric lamellæ, and the transverse striation of the solid central axis, ally them closely with the corpuscula tactus. They are found in the skin around the sacs of the feathers, in the beak, and in the interosseus spaces of the fore-arm and leg.

A special article (Pacinian Bodies) has already been devoted to the organs of this kind which are met with in Mammalia, and it need only be added here, that late researches have shown that the Pacinian bodies of mammals, like those of birds, are solid masses of rudimentary connective tissue; the appearance of capsules and of a central cavity, arising merely from the arrangement of the elastic element and the extreme transparency of the collagenous substance.* They are in fact nothing but thickened portions of the neurilemma, and the nerve which they enclose either passes through them, or more usually terminates, more or less abruptly, in the central solid axis.

In the article on the Pacinian Bodies reference is made to the peculiar organs described by Savi in the Torpedines. These Savian bodies, in fact, are little more than Pacinian bodies converted into sacs by the development of a cavity between their central and peripheral portions. Now Leydig has discovered that these Savian bodies do not stand alone, but that they form a part of a great series of peculiar integumentary sensory organs, which are most characteristically, if not solely, developed in the class of Fishes — the so-called *mucous canals* and *follicles*. It has long been noticed, in fact, that in osseous fishes one series of the scales along the sides of the body differ in their structure from the rest, giving rise to what is called the *lateral line;* and that a canal runs beneath these scales from the tail to the head on each side; that then becoming connected with its fellow by a transverse branch over the occiput, each canal passes forward on the sides of the head, dividing into two principal branches, one of which following the course of the suborbital bones terminates at the end of the snout, while the other passes down on to the lower jaw. Similar organs, but having a more complicated arrangement, are known to exist in the cartilaginous fishes; but it is commonly supposed that these canals and follicles secrete the mucus with which the skins of fishes are lubricated. However, in a very beautiful series of researches, Leydig has shown that the mucus is furnished by the cellular ecderon, and that the so-called mucous canals and follicles are sensory organs. The limits of this article will not permit me to enter into any of the details of structure of these organs, but they may all be described generally as sacs or canals lined by a cellular investment, like that of the skin upon which they open, and filled with a more or less gelatinous substance. If the organ be a sac, a single protuberant knob, if a canal, a series of them project into the cavity. Each knob is covered by a coat consisting of tiers of much-elongated cylindrical cells. Its substance consists of more or less gelatinous connective tissue, and it receives a nerve (a branch of the fifth or of the vagus), whose fibres divide and become lost in its tissue. In the osseous fishes this nerve usually perforates the peculiarly modified scale of the lateral line, which supports and encloses the canal at these points. In the cartilaginous fishes, the canals have sometimes special fibro-cartilaginous coats; or if sacculi, a number of them may be contained in a common cartilaginous investment, as in the Chimæra. Leydig insists with great justice on the identity of the structure of these organs with that of the semicircular canals of the ear.

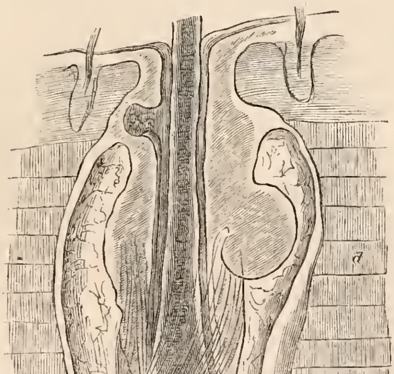
The connection of these sacs and canals with the corpuscula tactus and Pacinian bodies

* This fact was ascertained and stated independently and contemporaneously in 1853, by Leydig and myself. See Quarterly Journal of Micr. Science, No. V., and Siebold and Kölliker's Zeitschrift, B. v. Heft 1.

appears to me to be clear; for the knob which projects into the cavity of the mucous canal is homologous with the central "nucleus" of the Savian body, and this with the solid axis of the Pacinian body, and with the corpusculum tactûs, so that the "tactile" sac of the Chimæra, *e. g.*, may be said to be a tactile corpuscle which is connected with the surface of the integument.

No organ at all resembling these has certainly been met with, above the class of Fishes, in either Reptilia or Birds, but in Mammalia there are structures which must, I think, be placed in the same category. About the lips and nose of almost all mammals in fact, there are certain long, strong hairs, the vibrissæ or "whiskers" (*fig.* 321.). These in their general structure resemble ordinary hairs, but the sac of each, instead of lying free in the enderon, is enclosed in a second thick sac, composed of firm, dense, connective tissue, which attains at times an almost cartilaginous hardness. A looser areolated tissue connects this with the outer surface of the proper hair sac, and supports an abundant vascular network proceeding from vessels which enter at the deep end of the sac. Furthermore, a very considerable nerve pierces one side of the "sclerotic" coat near this end, and passes to the surface of the proper hair sac, upon which it spreads out and forms a nervous expansion, its fibrils dividing and subdividing, and so terminating.

Fig. 321.



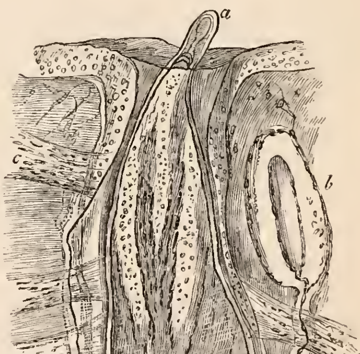
Vibrissa from the snout of the Mouse.
a, "sclerotic" sac; *b*, hair-sac; *c*, nerve-trunk; *d*, muscular fibres.

Considering the different habits of life of the mammal and the fish, I think one cannot but be struck with the similarity of plan between their vibrissæ and the "tactile" canals. The sensory impression is conveyed to the gelatinous contents of the canals in the fish by the vibration of the dense medium in which it lives; while in the mammal the impulse is communicated by the contact of some external object with a long elastic hair lever; but the final arrangement for the receipt and appreciation of the impressions is essentially the same in each case, nor indeed does it differ from that which is met with in the highest organs of sense.

Muscles of the enderon.—In the Invertebrata the great majority of the muscles are, as is well known, inserted into the integument, but those which are attached to the chromatophora of mollusks and to the spines of annelids and other worms, might be regarded as belonging more especially to the integumentary system.

In Fishes and Reptiles the superficial layer of striped muscles of the body is always more or less connected with the integument; but hitherto no unstriped fibres appear to have been detected in it. In Birds, however, the unstriped muscles attain a very great development, forming a thick layer whose bundles (*c*) run between and are attached to the sacs of the feathers (*fig.* 322.).

Fig. 322.



Pacinian body (*b*) and feather-sac (*a*) from the base of the mandible of a pigeon. *c*, muscles of the feather sacs.

In the majority of Mammals there is a special tegumentary striped muscle, which attains an enormous development in the hedgehog, while a mere rudiment of it remains in man, as the platysma myöides. Here, however, the striped "*peaucier*" muscle is replaced by the unstriped bundles which, as Kölliker has shown, run from the upper layer of the enderon to the bases of the hair sacs, and effect the various movements of which the hairs are capable.

Calcareous deposits in the enderon.—Deposits of this kind are very frequent in the Invertebrata. In the Pulmonate and some Gasteropod Mollusks, for instance, globular masses of carbonate of lime are scattered through the enderon, and would almost seem to take the place of fat. In nudibranchiate mollusks, such as the Doridæ, spicula of like nature are met with, and these sometimes unite into true internal shells, as in the genus Villiersia. The greater part of the skeleton of the Actinoid polypes, and the whole of that of the Echinoderms, is composed of calcareous networks of this kind, and globular masses of calcareous matter are scattered through the enderon of the Tæniadæ, though the clear spherical bodies observed in these worms are by no means always of this nature. Whether these enderonic calcareous deposits ever take place in the Vertebrata appears to me to be, as I have said above, an open question, only to be decided by a very careful examination of the mode of growth of their so-called "dermal" bones.

(*T. H. Huxley.*)

RUMINANTIA (Lat. *ruminare*, to chew the cud), Eng. *Ruminants*; Fr. *Ruminans*; Ger. *Wiederkäuende Thiere*, — a well defined order of mammalian quadrupeds, presenting the following essential characters: Upper jaw in nearly all cases destitute of incisor teeth, their place being supplied by a callous pad, while the lower jaw has six incisives; canines inconstant; molars usually six on each side of both jaws, with flattened crowns surmounted by two double and irregularly crescentic folds of enamel. Stomach compound and divided into four cavities, so as to provide for the ruminating act. Cœcum large. Placenta generally in the form of cotyledons. Feet ungulate and bisulcate.

This order forms two natural divisions, comprising the Hornless ruminants (akeratophora, Col. H. Smith) which are few in number, and the Horned ruminants (keratophora) which are very numerous. The English naturalist Ray, who was the first to propose a classification based on philosophical principle, enumerated only fifteen species. Pallas subsequently divided the entire family into six genera, and the Baron Cuvier into eight or nine; but the number of subdivisions held to constitute *genera* by later authorities has been very greatly extended. To serve our present purpose we shall retain only the Linnean and two other genera, which may be conveniently arranged under the five following heads or sub-orders: —

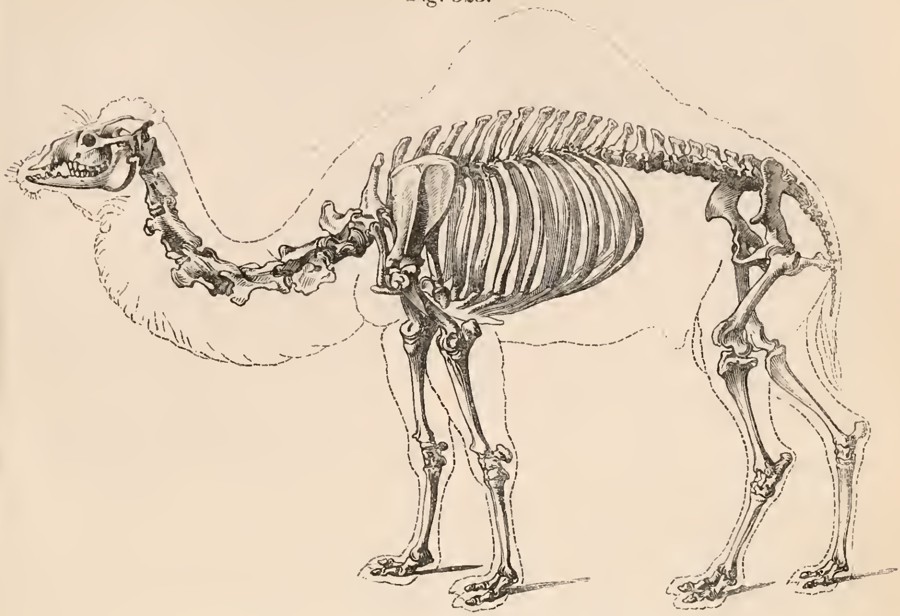
I. Camelidæ -	Camelus -	*Linn.*
	Auchenia -	*Illiger.*
II. Cervidæ -	Moschus -	*Linn.*
	Cervus -	*Linn.*
	Camelopardalis -	*Linn.*
III. Antilopidæ -	Antilope -	*Linn.*
	Catoblepas -	*Smith.*
IV. Œgosceridæ -	Capra -	*Linn.*
	Ovis -	*Linn.*
V. Bovidæ -	Bovis -	*Linn.*

The Camelidæ differ in many important particulars from the horned ruminants, and exhibit an approximation to the Pachydermata. The dental formula is peculiar; thus in the genus Camelus there are,—

$$i.\ \frac{1-1}{3-3};\quad c.\ \frac{1-1}{1-1};\quad p.m.\ \frac{2-2}{1-1};\quad m.\ \frac{3-3}{3-3} = 30$$

and in this respect the Auchenias, or Llamas, disagree only in the number of molars, which is usually fourteen. The distinguishing features of this family depend principally upon the beautiful provision of water-cells in the walls of the paunch or first cavity of the stomach, the absence of horns and the sub-bisulcate feet, which are "callous beneath, and

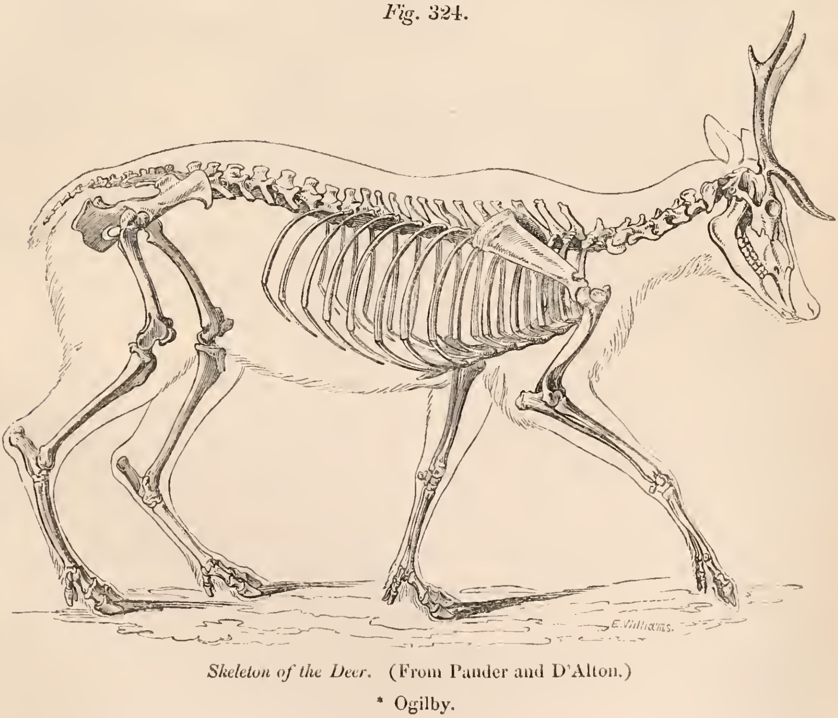
Fig. 323.



Skeleton of the Camel. (From Pander and D'Alton.)

have the toes distinct at the tip from the sole."* The uterine and fœtal membranes are unprovided with the ordinary ruminant or cotyledonoid form of placenta. Professor Owen has demonstrated another remarkable character arising out of the non-development

Fig. 324.



Skeleton of the Deer. (From Pander and D'Alton.)

* Ogilby.

of foramina for the passage of the vertebral arteries through the transverse processes of the lower six cervical vertebræ. This anatomical arrangement occurs in no other existing tribe of mammifers, but in an aberrant form of fossil pachyderm (*Macrauchenia*), Dr. Owen has detected the same anomaly, and has thus established an additional connecting link between the Pachydermata and Ruminantia.

In the classification of the Cervidæ given above we have included two genera not usually considered as forming a part of this family. One of the principal characters of the Cervidæ proper consists in the presence of deciduous horns or antlers: the genus Moschus, however, like the Camelidæ, is hornless; and the genus Camelopardalis is provided with persistent horns which are at all times clothed with a hairy integument. The dental formula of the Cervidæ and all other horned ruminants is usually as follows, —

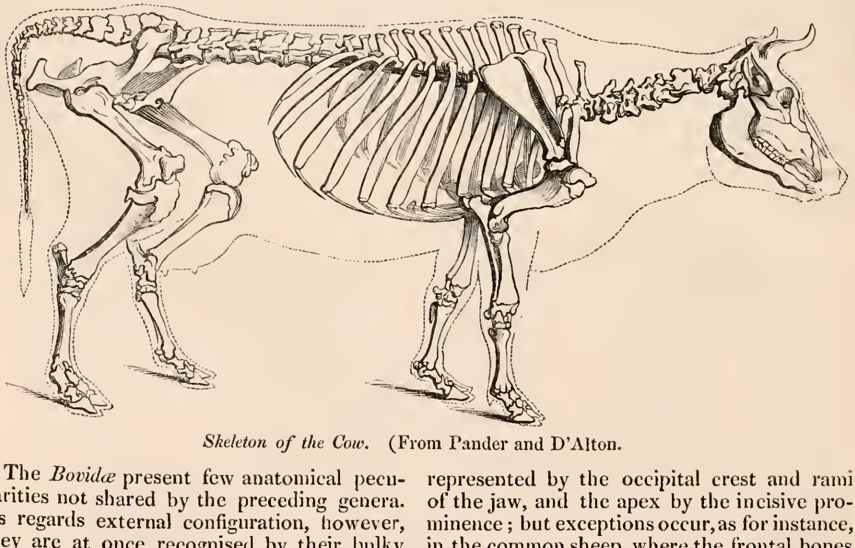
$$i. \frac{0\ \ 0}{3\ \ 3};\ c. \frac{0\ \ 0}{1\ \ 1};\ p.m. \frac{3\ \ 3}{3\ \ 3};\ m. \frac{3\ \ 3}{3\ \ 3} = 32.$$

The Musk-deer tribe have in addition two long and conspicuous canines in the upper jaw, projecting in the males below the mouth. (*fig.* 330.). The male Kijang or Muntjak (*Cervus muntjac*, Zimmerman) has likewise two prominent canines in the upper jaw (*a, fig.* 331.). In the Giraffe there is a complicated glandular and pouch-like structure in the neighbourhood of the ileo-colic valve.*

The Antelopidæ include the greater number of the Cavicornua or hollow-horned division of ruminants in which the bony axis of the horn is solid, persistent, and destitute of cavities or pores. They have, for the most part, a slender figure adapted for rapid progression, and, like the Stags, are further distinguished by the possession of infraorbital glandular sinuses.

Under the term Œgosceridæ (*Œgosceros*, Pallas) we have brought together the closely allied genera *Capra and Ovis.* The Goats are characterised chiefly by their long horns, which are directed upward and backward, are more or less angular in front, rounded behind, and generally marked by transverse bars or ridges. The chin is clothed with a long beard. The Sheep which have no beard differ mainly in having the horns directed at first backward, and subsequently bent spirally forward. Between the toes at the anterior aspect of the feet is situated a special glandular sebaceous sac; this structure is also found in other ruminants, — the Rein-deer, for instance. Neither the Sheep nor Goats exhibit the lachrymal sinuses so characteristic of the majority of the Antelopes and Stags.

Fig. 325.



Skeleton of the Cow. (From Pander and D'Alton.

The *Bovidæ* present few anatomical peculiarities not shared by the preceding genera. As regards external configuration, however, they are at once recognised by their bulky massive size, the broad muzzle, and powerful limbs (*fig.* 325.). The horns are directed laterally, with an inclination upward more or less curved. In their habits and in the structure of the skin, some of the species, the Buffaloes, for example, approach the pachydermatous type.

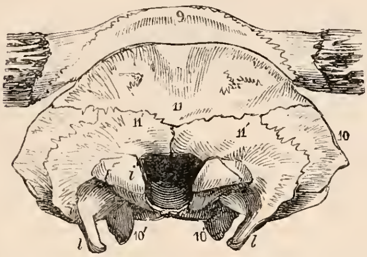
Osteology. — The general form of the skull in ruminants, when viewed laterally, is that of an isosceles triangle, the base of which is represented by the occipital crest and rami of the jaw, and the apex by the incisive prominence; but exceptions occur, as for instance, in the common sheep, where the frontal bones are so much arched as to produce a somewhat oval figure, and in the camel, where, owing to the abrupt termination of the nasal and sudden depression of the intermaxillary bones, an obliquely quadrilateral form is the result (*fig.* 334). The forehead is usually straight and elevated, the orbits are placed wide apart, and the muzzle, except in Bovidæ,

* See "*Glands of Intestine*" in this Article.

is attenuated and compressed. Throughout the whole order there prevails considerable disparity as respects the cranium and face; the bones of the latter occupy fully two-thirds of the entire length of the skull, and the area of the face on section is nearly double that of the cranium.

Bones of the cranium. — Eight bones enter into the composition of the adult cranium; viz, an occipital, a parietal, two frontal, a sphenoidal, an ethmoidal, and two temporal; and, in addition to these, some species are provided with two ossa triquetra or interparietals.

Fig. 326

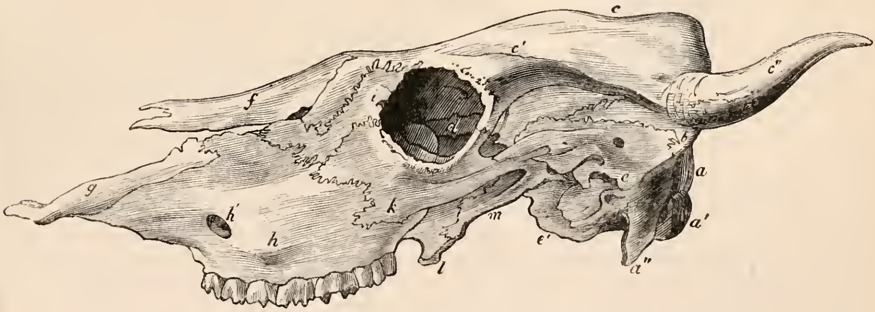


Skull of the Ox viewed from behind. (From a specimen in Lond. Coll. Surg. Museum.)

The *occipital* bone (11, *fig.* 326.), as in most of the mammalia, is originally divided into four, one superior, one inferior, and two lateral pieces (11′, *fig.* 326.). These become early consolidated, and in the calf at the time of birth they are firmly united together and to the parietal and interparietal bones lying immediately in front. The occipital crest is prominent in the Llamas, and still more fully developed in the true Camels. In Bovidæ the crest corresponding to the occipital is formed by the junction of the parietal and frontal bones, the superior occipital remaining flat. In ruminants generally, the paramastoid processes (*l fig.* 326.) are much elongated, falciform, and curved inwards, and between these and the occipital condyles (*i*) a very deep fossa intervenes. In Camelidæ, at the angle formed by the union of the petrous portion of the temporal with the lateral and superior occipitals there is a large opening on either side. In this family the anterior condyloid foramina are of moderate capacity, but in Cervidæ they are of great size and sometimes four in number, in which case two remain small. In Œgosceridæ and Bovidæ they are also large and occasionally double.

The *parietal* (9*) is single, and with a few trifling variations, is articulated to the cranial bones in the usual manner. The lambdoidal or parieto-occipital suture lies considerably in front of the crest, except in Bovidæ, where it lies below, and is separated from the frontal suture by the intercalated and narrow wedge-shaped parietal bone. The Œgosceridæ have the parietal in the form of a flattened band, encircling the cranium and extending between the orbitar wings of the sphenoid on either side (*b*, *fig.* 335.). It is broader in the goats than in the sheep. In Bovidæ the parietal does not extend so far forward (*b. fig.* 327.). In the Giraffe the lateral processes of the parietal are narrowed

Fig. 327.



Skull of the Ox, viewed laterally. (From Spix.)

to a mere point, but the body of the bone which reaches from between the horns as far back as the occipital crest has a longitudinal diameter of fully six inches. The coronal or fronto-parietal suture in this species and a few other genera is situated in a line with the osseous protuberances which support the horns. It is most frequently placed behind; in the Gazelles, however, it appears in front.

The *frontal* bones (8) are of large size and great breadth; this latter feature being more especially manifest in the Camels, the Sheep, and certain bovine species. In the Camelidæ they extend backward between the anterior divisions of the parietal bone, and in front they are articulated to the lachrymals by a transverse suture, which is less extended in the Llamas than in the true Camels. In the Llamas and in the genus Moschus a small part of the frontal is connected to the superior maxillary. There are several supra-orbital or frontal foramina (*c*) with rounded orifices, which in the Camels are placed near the middle line and at the centre of the forehead. In the Llamas these openings are placed rather farther back and united by a longitudinal groove. The frontals are ele-

* The numerals here refer to all the subjoined figures of crania with the exception of *figs.* 327. and 335.

vated posteriorly in Bovidæ (*c*, *fig*. 327.) and prolonged toward the occipital crest, in the formation of which they apparently contribute,—a circumstance giving rise to the peculiar physiognomy characteristic of the group. The osseous protuberances supporting the horns, of which we shall speak more particularly when describing the latter in detail, take their origin in most cases from the frontal bones. In the Giraffe the slight eminences analogous to the osseous cores are partly formed by the parietal bone, the coronal suture passing directly through the centre from side to side (*fig*. 328.) ; the an-

Fig. 328.

Front view of the skull of a Giraffe. (From a specimen in Lond. Coll. Surg. Museum.)

terior or central eminence, situated immediately behind the nasals, and in part formed by them, differs in no respect, save as regards its position, from the other two, the elevation in all instances being produced by the expansion of the cranial sinuses beneath. There is a single large supra-orbital canal, having its superior outlet midway between the upper border of the orbit and the central frontal eminence (*fig*. 328.). In Cervidæ generally, the canal opens at the upper surface by a longitudinal furrow (*fig*. 329.), but this is more particularly marked in Bovidæ (*fig*. 333.). In regard to the cranial sutures in Cervidæ, M. F. Cuvier observes that "all those portions, such as the second half of the frontal, the greater part of the coronal, and the occipital or lambdoidal, which surround the base of the core, exhibit an excessive multiplication of interlineations, because the weight of the horns and the shocks to which the parts are exposed require that the bones should be firmly connected" (*fig*. 329).*

The *sphenoid* (12) articulates, except in Bovidæ, with all the cranial bones ; but its orbitar wing, which is largely developed, is concealed in great measure within the cerebral cavity, and covered by the lateral expansions of the frontal bones. In the Camelidæ the pterygoid processes of the sphenoid are directed vertically downwards and terminate in two laminæ, the external one being longer and larger than the internal : the latter process only makes its appearance very low down, and is so closely applied to the external lamina, as to leave scarcely any trace of a pterygoid fossa ; neither is there any space between it and the wing of the palatine bone. In this family the spheno-orbitar fissures and the spheno-palatine foramina are of great size. The optic canals are only separated from the former by a thin osseous partition, and the openings for the passage of the third branch of the fifth pair of nerves are rounded and placed far back. The Cervidæ have the posterior division of the sphenoid developed into an extremely attenuated and short temporal wing, which, nevertheless, is articulated to the parietal, the lateral processes reaching very far forward. The orbitar wing of the sphenoid in the same family separates into two divisions, one extending upwards and backwards, and also uniting with the parietal, the other being prolonged horizontally forward, between the frontal and palatine bones, and terminating anteriorly at the border of an opening which corresponds to the spheno-palatine foramen. In the Giraffe the temporal wing of the sphenoid is short and connected by a well-marked suture to the T-shaped process of the narrow lateral expansion of the parietal ; it approaches very closely, but is not united to the orbitar plate of the frontal as has been conjectured. In the work last alluded to in the foot-note it is stated that the frontal and sphenoid bones are united at an early period, rendering it difficult to make out their limits. In the cranium of a Giraffe about two years old, and at present in our possession, the sutures involved in the union of the above-mentioned osseous segments, fortunately yet remain distinct, and in this individual the orbitar wings of the sphenoid do not divide into two laminæ, as seen in the Stags, but at the floor of each orbit they form a broad, short, and triangular fan-shaped plate, the centre of which is pierced by the hole for the passage of the optic nerve. The spheno-orbitar apertures are round and of enormous size in the Giraffe : in the Stags the spheno-palatine foramina are also large ; and this is more especially the case in Camelopardalis, where they lie concealed behind the molar prominences. In the genus Moschus the anterior sphenoid is largely developed, and its wings form the greater part of the posterior wall of the orbits. The body of

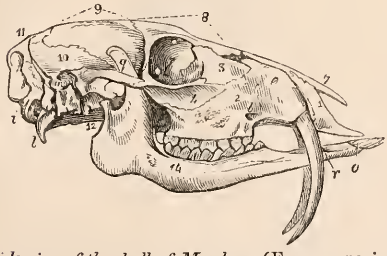
* Cuvier, Leçons d'Anat. Comp., 2de edit. tom. ii. p. 366.

Fig. 329.

Front view of the skull of the Deer. (From Lond. Coll. Surg. Museum.)

this portion of the bone is compressed, and, in consequence of a central space left unossified (*fig.* 330.), we are enabled to look into

Fig. 330.



Side view of the skull of Moschus. (From a specimen in Lond. Coll. Surg. Museum.)

the orbit of the opposite side; a peculiarity not confined to the animals under consideration, being more marked in certain of the Rodentia and in birds. In Bovidæ the temporal wing of the sphenoid, which is of comparatively large size and much curved backward, does not reach the parietal bone as in the other ruminants; and it is further distinguished by a sharp pointed ridge developed from its anterior margin, which in the preceding genera is only feebly indicated, though tolerably prominent in the Giraffe. The anterior wing extends horizontally forward and is convex on its orbitar surface (*d*, *fig.* 327.). Part of the body of the posterior sphenoid forms, in conjunction with the anterior third of the basi-occipital, two projecting elevations, which are separated from each other by a deep groove: these also appear in the Goats, where they are less marked. In both families the spheno-palatine and the spheno-orbitar foramina are capacious; but in Œgosceridæ the latter openings are somewhat compressed. The *os ethmoides* has the same relations as usual, its cells being greatly developed in the Giraffe.

The *temporal* bone (10), as in other mammalia, consists of three segments. In Camelidæ the zygomatic arches form, in conjunction with the sunken temples and strongly pointed occipito-parietal crests, a striking feature, which imparts to the cranium of this family a carnivorous type of structure. This morphological peculiarity is chiefly noticeable in the Camels properly so called; and in them the glenoid cavity is very deep, being supported in front and behind by prominent apophyses, the posterior of which is united at its base to the tympanic bulla (*fig.* 334.). The latter is much compressed, and also firmly connected above to the paramastoid apophyses of the occipital, leaving a conspicuous cavity between. In the Llamas, at the root of the zygomatic apophysis, there is a large round foramen immediately above the external meatus. In Cervidæ and Antelopidæ the post-glenoid apophysis is feebly developed, and the base of the zygoma is flattened and prolonged backwards toward the occipital crest; the squamous portion is rather extensive and the tympanic bulla of large size. Similar arrangements obtain in the Giraffe, but the zygomatic apophyses are more curved than in the Stags. The base of the zygomatic process in many of the Antelopidæ is pierced by an oval opening, which is situated midway between the external auditory meatus and the glenoid facet; and from it there sometimes proceeds a fissure, which takes an upward direction, to join the parieto-temporal or squamous suture.* This foramen occurs in the Muntjack deer (*fig.* 331.), and, as we have before stated, in the

Fig. 331.

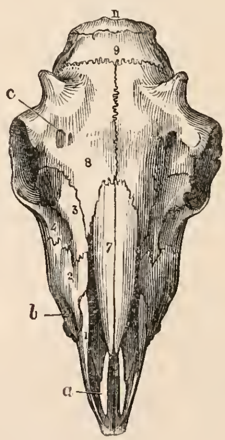
Cranium of the Muntjack. (From Lond. Coll. Surg. Museum.)

Llamas also. In Œgosceridæ the squamous portion of the temporal is comparatively small (*e*, *fig.* 335.), and the tympanic bulla, which is moderately large and somewhat flattened, terminates by a sharp styloid process anteriorly. The post-glenoid apophysis is represented by a very narrow ridge of bone, leaving only a slit-like cavity between it and the meatus. In Bovidæ the temporals (*e*, *fig.* 327.) are partially hid by the overhanging frontals: they develope short and strong zygomatic apophyses; their bullæ (*e′*, *fig.* 327.) are much narrowed, and their styloid processes are divided at the tip into several needle-shaped points.

Bones of the face. — These are more numerous than those of the cranium, and we shall only notice the more important of them in detail.

The *nasals* (7), which vary much in size, are long in the true Camels, a little spread out at the base and deeply notched in front, forming together three salient points: in the Llamas we find them very short and broad posteriorly. In Cervidæ generally, the nasals are much extended lengthwise and bifurcate anteriorly (*fig.* 329.): in the Muntjack (*C. Muntjac*) and in the Giraffe they are particularly wide apart at the upper or posterior border (*fig.* 331.); and in the latter species they exhibit a gradual but marked rising towards the central eminence of the frontals (*fig.* 328.). The naso-frontal suture in the genus Moschus is much denticulated. The nasals are very short in the Eland or Canna (*A. oreas*, Pallas), and in the Moose-deer (*C. alces*, Linn.) In Œgosceridæ and Bovidæ the bones of the nose are moderately long, and slightly convex above in the former (*f*, *fig.* 335.); in the latter family and in the Goats they are divided in front (*f*, *fig.* 327.); but in the Sheep they form together a single V-shaped process (7, *fig.* 332.).

Fig. 332.



Skull of the Sheep, front view. (From Lond. Coll. Surg. Museum.)

The *intermaxillaries* (1) are usually much prolonged, but they do not develope incisive teeth except in the Camelidæ, and a few other species. In the Camels properly so called, and in the aberrant cervine genus Moschus, the outer rami of these bones incline at the superior part almost vertically upwards (*fig.* 334.); but in the Llamas they maintain throughout an oblique direction as obtains in ruminants generally. In both genera they are compressed laterally, and brought round in front, so as to resemble in some measure the beak of a bird; the incisive foramina are remarkably

* F. Cuvier.

small. In Œgosceridæ (*g*, *fig.* 335.) and Cervidæ, for the most part, the ascending rami incline at a very oblique angle, and in Camelopardalis they exhibit a slight concavity at the upper margin. In this last named genus the intermaxillary bones are very long and extremely

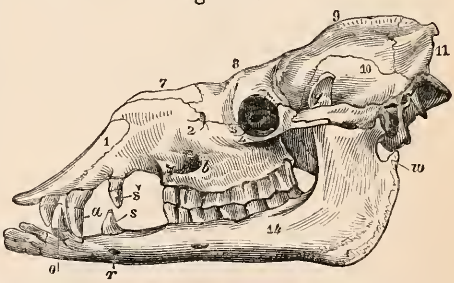
Fig. 333.

Front view of the skull of an Ox, with the right horny sheath detached from the core. (From Lond. Coll. Surg. Museum.)

attenuated at the tip (*fig.* 328.); in Bovidæ, on the other hand, they are of diminished length (*g*, *fig.* 327.), straight, of great thickness and broad in front, giving to the muzzle an aspect characteristic of the group (1, *fig.* 333.). The incisive openings are elongated, capacious, and widely separated in the Giraffe (*fig.* 328.), they are still more so in the Stags (*fig.* 329.) and Antelopes (*fig.* 342.); and in Œgosceridæ and Bovidæ they form enormous clefts, especially in the latter (*fig.* 333.). Several genera have a small free space between the converging points of the intermaxillaries; and this is particularly noticeable in the Giraffe (*fig.* 328). The bones in question are of great length in the Eland or Cape Elk, and in the Moose-deer.

The *maxillaries* (2) usually carry six molars and premolars on either side; exceptions, however, occur in the Camelidæ where one of the premolars is absent, and in this family, as also in the aberrant genus Moschus and in the male *Cervus Muntjac*, canines are developed (*a*, *fig.* 331.). In all ruminants they send processes of greater or less extent to the inner and under part of the orbit, in the situation where these bones lie partly concealed by the jugular or malar bone. As regards the bones themselves there are few other peculiarities worthy of notice; but we may remark, in passing, that in the Giraffe the maxillaries project more than two inches beyond the tips of the nasals. The suborbital foramina (*b*) are placed in the Camelidæ a little before the orbits and above the alveolar ridge, at a point corresponding with the line of juxta-position of the middle and third premolars (*fig.* 334.). In the Giraffe and in other Cervidæ the infra-orbital aperture is seen further forward, on a level with the first premolar: in Œgosceridæ it is on a line with the second (*h*, *fig.* 335.). The Bovidæ have a long suborbital canal opening above the first premolar (*h'*, *fig.* 327.), as in the Stags and Giraffe.

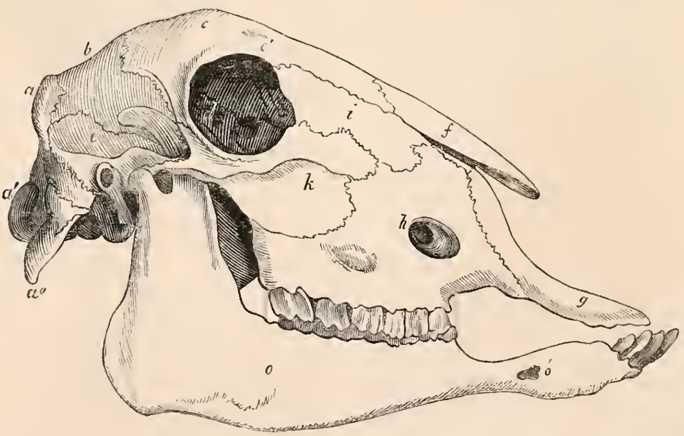
Fig. 334.



Lateral view of the skull of the Camel. (From a specimen in Lond. Coll. Surg. Museum.)

The *lachrymals* (3) are directed forward, and occupy a considerable extent of the cheek; at their point of union with the frontal, nasal, and intermaxillary bones there is usually left a vacant space more or less patent. This space in the true Camels is stated to be of large dimensions; but, out of four *crania* we have examined in reference to this particular, in one only was this opening distinctly visible; in the others the extension of the periosteum, which closes the cavity in front, had ossified, leaving only a few small foramina, irregularly disposed. In the Llama the opening is significant and communicates with numerous sinuses. In regard to the true lachrymal passage in Camelidæ this is represented externally by a single foramen placed directly behind the orbitar ring; but there is in the Camels a second hole which is quite distinct, being connected with the spheno-palatine canal at about half an inch from its orbitar orifice. In Moschus the lachrymal bone is large; it does not articulate with the nasal, and there is no facial cavity: the foramen is close to and within the orbital ring (*fig.* 330.). In Camelopardalis the bone is moderately large and is separated from the nasal in front by an interspace (*fig.* 328.), which, in the single specimen we have dissected, is of a triangular form, and measures an inch and a half in length, and five-eighths of an inch in breadth. According to the experience of Professor Owen this vacant space is invariably present, though not always equally conspicuous. At the orbital ring, midway between the frontal and maxillary lines of articulation, there juts out a small tuberosity, which is bounded on either side by a shallow groove; and from this point the bone is carried downwards and backwards to form, in conjunction with the molar protuberance of the maxillary and the inner border of the malar bone, a shelf-like floor to the anterior half of the orbit. In the specimen just mentioned there exists but one lachrymal foramen, which is of large size, infundibuliform, and situated nearly an inch distant from the anterior border of the orbital ring. In the Stags the lachrymals are hollowed out on the cheek for the reception of the special suborbital glandular apparatus, and they are of large size, but do not touch the nasals, being separated from them by a very extended membranous interspace (*fig.* 329.). In the orbit these bones exhibit relations similar to those indicated in the Giraffe; but there are two foramina, one placed on each side of the lachrymal tuberosity, beneath which they intercommunicate. The possession of "tear-pits," or suborbital sinuses, is not shared by all the Antelopidæ, and in those species in which they do occur the degree of depression in the lachrymal bone is very variable, being in some comparatively shallow, in others well marked: the same observation applies to the open space situated immediately above. Respecting the absence, prevalence, or coexistence of these morphological peculiarities we may, according to M. F. Cuvier, divide this family into three groups: in the first are to be reckoned those which have both a lachrymal depression and a facial interspace, such as is seen in the Gazelle (*A. dorcas*, Pallas), the Stein-boc (*A. tragulus*, Licht.), and the Grys-boc (*A. melanotis*, Licht.); in the second, those possessing the "tearpit," but having no vacant space such as occurs in the genus *Catoblepas*, the Koba (*A. koba*, Ogilby), the Cambing-outan (*A. Sumatrensis*, Desm.), the Chickara (*A. quadricornis*, De Blainv.), the Caama (*A. caama*, Cuv.), and the Bubale (*A. bubalis*, Pallas); in the third, those having the interspace, but no depression, such as takes place in the Reh-boc (*A. capreolus*, Licht.), the Chamois (*A. rupicapra*, Pallas), the Canna (*A. oreas*, P.), and the Nil-ghau (*A. picta*, P.). The Œgosceridæ have the lachrymals very large and of great length, this being especially the case in the Sheep, where they articulate with the bones of the nose (*i. fig.* 335.). The Goats have usually a small open space on the cheek, both of the above genera being provided with a small tubercle at the anterior margin of the orbit. The foramina are placed within the ring and are remarkably large in the Sheep. The lachrymals in Bovidæ are of still greater size, and very conspicuous (*fig.* 327.); they develope prominent antorbital

Fig. 335.



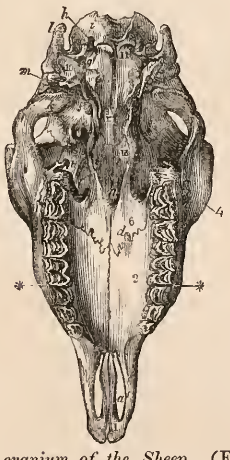
Skull of the Sheep, viewed laterally. (From Cuvier.)

tubercles and have the connecting sutures on the face marked by deeply toothed interlineations. There is no membranous interspace, and the foramen, which is funnel-shaped, is situated at the margin of the orbital ring immediately behind the tubercle.

The *malar* or *jugular* bones (4) do not offer any very striking peculiarities. They are bulky and strong in the Camelidæ, and of great breadth below the orbit: in the Llamas they advance further forward upon the cheek than in the true Camels, and the zygomatic apophyses are very short. In Moschus the post-orbitar apophysis is of considerable size—that of the zygoma somewhat narrower (*fig.* 330.). In Antelopidæ and Cervidæ generally, the malars are slender, and have short zygomatic apophyses: this latter feature is especially noticeable in the Giraffe. They are broad and of great thickness in Œgosceridæ (*fig.* 335.), in which family and in Bovidæ they are much prolonged upon the cheek, in the latter being a little bifurcate anteriorly at the maxillary line of suture (*fig.* 327.).

The *palatines* (6) are largely developed. In Camelidæ, where the roof of the mouth is very long, the palatal laminæ have a great longitudinal diameter; in the Llamas the transverse suture extends to a level with the anterior border of the first true molar; the central palatal cleft, which is angular, reaches the front margin of the middle or second true molar, while the lateral notches proceed as far only as the anterior border of the last molar. In Cervidæ the palatals occupy a large square space at the inner and lower part of the orbit, but this is not the case in the Giraffe, where this part of the bone is rather smaller and lies partly concealed by the shelf-like process of the lachrymal and the molar prominence of the maxillary bone. The lateral fissures at the guttural margin of the palate are very wide in this family and extend deeper into the roof of the mouth than does the mesial cleft. These three clefts are placed in the Giraffe nearly on the same level, the central fissure having a semicircular outline. In the Muntjack deer the two lateral notches are much in advance of the mesial cleft. The guttural portion of the combined palatines in Œgosceridæ is of great breadth, and the fissures, which are not very deeply notched, are all very nearly on the same level (*n*, *fig.* 336.): the orbitar or

Fig. 336.



Base of the cranium of the Sheep. (From Lond. Coll. Surg. Museum.)

ascending plates are large and square, but deficient at the upper part, where there intervenes a space or hole analogous to the spheno-palatine foramen. This opening is particularly capacious in the Sheep. In Bovidæ the palatines occupy about a fourth part of the oral roof: the ascending or suborbitar portions, which are of enormous bulk, are almost entirely hid by the lateral overlapping of the posterior border and supra-molar prominences of the upper jaw; the palatal notches are very deep, especially the two lateral, which are remarkably broad and somewhat in advance of the mesial.

The *vomer* and *ossa spongiosa seu turbinata*, in consonance with the general extension of the facial bones in ruminants, are chiefly particularised for their longitudinal development. In the orbits the wings of the vomer are represented by very small laminæ, which appear at the upper border of the opening corresponding to the spheno-palatine foramen. In certain of the Stags the azygos portion descends between the pterygoid apophyses of the sphenoid to a level with the palate, dividing the mesial fissure in two and contributing to form in this region a backward expansion of the oral roof. The spongy bones will be referred to when describing the organ of smell.

The *inferior maxilla* or jaw-bone proper is of great length; in which respect it follows the course of the bones of the upper jaw. Between the canine and first premolar of either side there is in the typical ruminant, an extended interval, at which part the body is constricted; and immediately in front of the mental foramen (*r*, *fig.* 337.) it again ex-

Fig. 337.

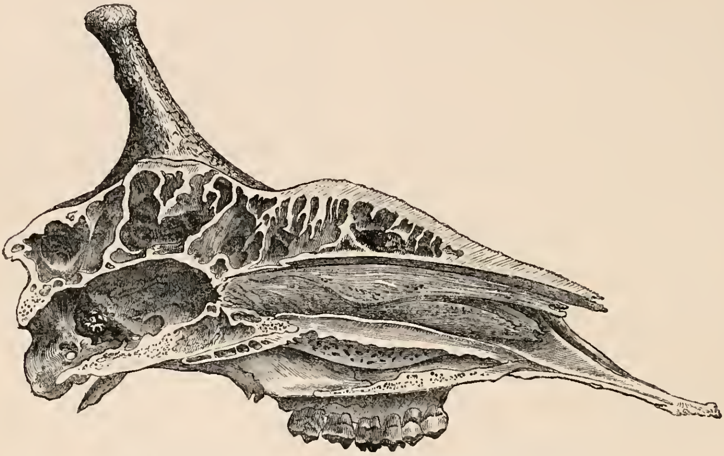
Jaw-bone of the Sheep. (From Lond. Coll. Surg. Museum.)

pands toward the alveolar margin to give support to the teeth. The angle of the jaw is prominent and rounded posteriorly; in this situation also it is comparatively thin and broad, as in Solipeda. The coronoid processes of the rami (*g*, *fig.* 337.) are particularly long curved backward, and a little hooked at the summit. The glenoid apophysis is short, and the facet flat and slightly concave, to admit of free lateral motion on the wide convex articular surface of the temporal zygoma. The sigmoid notch is shallow. In the Camel there is an additional process at the parotid border (*w*, *fig.* 334.), analogous to the similar but more marked apophysis in Carnivora.

Cranial peculiarities. — Under this head we proceed to notice certain arrangements requiring further attention, and in the first place the remarkable sinuses which exist in the skull of the Giraffe. Though these be nothing more than an extension of the ordinary frontal, ethmoidal and sphenoidal cells, yet their significance is not the less apparent or important when considered in a physiological or teleological point of view.

It has been considered necessary to preserve the cranium of the Giraffe at present in our possession entire; consequently, we are unable to offer any account of these sinuses from personal examination, which is the less to be regretted, as Prof. Owen has placed

Fig. 338.



Sectional view of the cranium of the Giraffe. (From Owen.)

on record the following description of this structure*; "The part of the skull to which the elastic ligament is attached is raised considerably above the roof of the cranial cavity by the extension backwards of large sinuses, or air-cells, as far as the *occiput.* The sinuses commence above the middle of the nasal cavity, and increase in depth and width to beneath the base of the horns, where their vertical extent equals that of the cerebral cavity itself. The exterior table of the skull, thus widely separated from the vitreous table, is supported by stout bony partitions, extended chiefly in the transverse direction, and with an oblique and wavy course. Two of the most remarkable of these bony walls are placed at the front and back part of the base of the horns, intercepting a large sinus immediately over the middle of the cranial cavity, and from a third and larger one behind. The sphenoidal sinuses are of a large size."

Slight differences in the development of the cranium are found in Giraffes inhabiting respectively the more northern or southern regions of Africa, these peculiarities having especial relation to the position and approximation of the horns. In the Abyssinian specimen (about two years old) dissected by us, several particulars were noted, a few of which are here selected †: —

	Inches
Length of cranium - - - - - -	19
Breadth between orbits - - - - -	8¾
Incisive angle to central eminence - -	11½
Length of horns - - - - - -	5½
Distance between horns at the base - -	0½
Depth of orbit - - - - - -	3
Diameter of orbital ring - - - - -	2½
Breadth of occipital condyles - - -	3⅞
Vertical depth of each condyle - - -	2½
Length of lower jaw - - - - -	15½

In this list will be remarked the extreme elongation of the bones of the face, as shown by the distance of the incisive angle from the central prominence—the great depth of the orbits—the narrow space between the bases of the horns — the length of the jaw—and more particularly the extended vertical diameter of the condyloid facets of the occipital bone. The elongation of these articular surfaces in the direction indicated, permits of the head being drawn into a line with the neck, and Prof. Owen states, from observing this action in the living animal, that he has seen it stretched backward beyond this line.

Horns. — In the Giraffe we have a unique example of solid persistent horns, completely invested with a hairy integument. They are placed on two bony elevations, having a position analogous, in some respects, to that of the osseous cores of the Stags; but, being separated from them by a synchondrosis, they are to be regarded as independent developments or "epiphyses" and not "apophysial" outgrowths (*fig.* 328.). As has been already observed, the protuberances are formed in part by the parietal and frontal bones, the

* Memoir on the Anatomy of the Nubian Giraffe, Zool. Trans. vol. ii. p. 235.

† Dr. Cobbold, On the Anatomy of the Giraffe, Annals of Nat. Hist. for June, 1854.

coronal suture passing transversely across the centre of each osseous expansion, from side to side. The bones are easily detached by maceration (at least in the younger animal), and when withdrawn, there is brought into view an intervening sheath-like periosteum, which can also be separated from the concavity at the base of the horn. This cup-shaped hollow, owing to the columnar disposition of the osseous laminæ, and the very numerous perforations for the passage of nutrient vessels, presents the appearance of a sieve, depressed into a conical form. Both in the Cape and Nubian varieties a sexual difference obtains in reference to the extent to which the horns are developed. In the male adults they are larger and more closely approximated at the base than in the females, and, according to Prof. Owen's observations on the horns of the Cape Giraffe, "their expanded bases meet in the middle line of the skull, so that they would entirely conceal the coronal suture even if it were not early obliterated in this sex."* The basal portions of the horns in the females are widely separated. In our specimen (a Nubian male). the internal and lower margins of the horns remain, severally, half an inch apart, and the interfrontal suture is still distinct throughout its entire length. In regard to the asserted existence of a third horn surmounting the anterior central protuberance, an examination of the cranium, above alluded to, only serves to confirm the extended observations and conclusions of Prof. Owen on this subject. We have shown that this elevation is due to an enlargement of the subjacent frontal sinuses, and in this respect it resembles the posterior horn-shaped apophyses. It must be remarked, however, that although, in our example, there is no superimposed osseous deposit, there is, nevertheless, a cartilaginoid thickening of the periosteum in that situation; this, we can readily believe, might constitute a nucleus favourable to the formation of an epiphysis similar in all respects to the true horns lately described. We have not had an opportunity of inspecting the crania in the museum of the Royal College of Surgeons, London, but, through the kindness of Dr. Ball, have examined the skeleton of a male Giraffe which died (during sexual excitement) at the Dublin Zoological Society's Gardens, and which is now preserved in Dr. Harrison's Anatomical Museum. In this individual the central cranial eminence is not smooth as in our specimen; on the contrary, it is particularly rough, owing to the deposition of osseous nodules, which bear a marked resemblance to the irregular bony laminæ prolonged from the attenuated margins of the bases of the true horns. If these rough prominences could be shown to be separable by maceration, we might with good reason infer the rudimentary existence of a third horn; if, on the other hand, they are merely exostoses or outgrowths (and to this opinion we incline), we think their deceptive aspect offers, in some measure, an explanation of the incorrect description of this structure recorded by Cuvier, and the inaccurate figure given by Rüppell.*

* Memoir, *loc. cit.*

The deciduous branching horns of the deer present two well-marked morphological types, — one group possessing rounded antlers, and the other having them more or less flattened and palmated. Of the former, characteristic examples are seen in the horns of the Roebuck (*C. capreolus*) and Red Deer (*C. elaphus*), — and of the latter, in the Elk (*C. alces*) and Fallow Deer (*C. damas*). The remarkable periodical development of these cranial outgrowths is most interesting in a physiological point of view, and both types of structure exhibit the same general law of increase. The male calf of the Red Deer at the sixth month differs from the female of the same age, in having two small elevations or "bossets," which represent the first indication of horns. These processes acquire, in the second year, the form of simple unbranched stems or "dags" (*a*, *fig.* 339.), at which date the deer

Fig. 339.

Development of the horns in the Red Deer. (From Cuvier.)

is designated a "brocket" by the English, and by the French a "daguet." The dagger-like horn being shed, its place is occupied in the third year by another, carrying usually one, but sometimes two, and even three branches or "tynes" (*b*, *c*); in this condition he is called a "spayard." The horn of the fourth year assumes a more complex aspect (*d*, *e*), and the summit or "crown" of the stem begins to spread and divide; at this stage he is styled a "staggard." At the fifth year there are five or six branches, and at this period he is termed a "stag." At and after the sixth and seventh years the number of "tynes" is very variable, and the growth of the horn being now perfected, the individual is technically denominated a "hart" (*f*). The palmated horns of the Fallow Deer exhibit similar gradations of development. At the second year the "buck-fawn" or

* Atlas zu der Reise in Nordlichen Afrika, von Edouard Rüppell, Pl. 9. Since the above was written Prof. Quekett has politely afforded us an opportunity of inspecting the *crania* in the Hunterian Collection. The osseous nodules noticed in the Dublin specimen not only exist in one of these crania, but they could be partly raised from the subjacent bone by the easy insertion of the finger-nail under the margin.

"pricket" puts forth a simple "dag" or cylindrical shaft (*a*, *fig*. 340.), which is slightly bent forward. In the third year the branching commences, and he is said to be a "sorel" (*b*). The antlers in the fourth year grow more numerous, and the stem is bifid at the summit (*c*); at this period the Fallow Deer is

Fig. 340.

Development of the horns in the Fallow Deer. (From Cuvier.)

entitled a "sore" by sportsmen. After this date the upper part of the brain or shaft becomes more palmated, and irregular serrations or "snags" are produced at the margin (*d*); the animal is now a "buck of the first head," and, as age advances, the snags enlarge, and take on, more or less, the appearance of true antlers. In the Rein Deer the horns undergo a similar metamorphosis; they are of great size in both sexes, but are somewhat less branched and slender in the female; the brow-antlers are much prolonged forward over the forehead.

The nature of the anatomical change which takes place in the adult individual during the periodical renewal of the antlers, is characterised by, and contemporaneous with, the following phenomena; — a strong determination of blood to the head takes place at the spring of the year, and the vessels surrounding the frontal apophyses enlarge. This increased vascular action results in the secretion of a fibro-cartilaginous matrix, manifesting itself externally by a budding, commencing at the summit of the "core," at the spot where the horns of the previous season had separated. In the early condition the horn is soft and yielding, and it is protected only by a highly vascular periosteum and delicate integument, the cuticular portion of the latter being represented by numerous fine hairs, closely arranged. From this circumstance the skin is here termed the "velvet." As development goes on, a progressive consolidation is effected, — the ossification proceeds from the centre to the circumference and a medullary cavity is ultimately produced. While this is taking place a corresponding change is observed at the surface. The periosteal veins acquire an enormous size and by their presence occasion the formation of grooves on the subjacent bone. At the same time osseous tubercles, of ivory hardness, appear at the base of the stem; these coalesce by degrees and enclose within their folds the great superficial vascular trunks, which are thus rendered impervious. The supply of nutriment being cut off, the first stage of exuviation is accomplished by the consequent shrivelling up and decay of the periosteal and integumentary envelopes. The full growth of the horns is now consummated, and the animals, being aware of their strength, endeavour to complete the desquammation by rubbing them against any hard substances which may lie in their path; this action is technically termed "burnishing." After the rutting season the horns are shed, to be again renewed in the ensuing spring.

The disposition of the horns is invariably symmetrical in a state of health, but the antlers are sometimes disproportionate on either side and their growth incomplete from deteriorating circumstances. A remarkable sympathy exists between the generative organs and the horns, and any imperfection in the one induces a corresponding change in the other. In consequence of this reciprocal influence, the development of the horn may be arrested and the periodical shedding prevented by castration. An illustration of this is to be seen in the cranium of a Fallow Deer preserved in the College of Surgeons' Museum, London. The horns of ruminants are seldom more than two in number, but exceptions occur in the case of the extinct Bramatherium and gigantic Sivatherium (*fig*. 341.) found in the tertiary deposits of Northern

Fig. 341.

Front view of the cranium of the Sivatherium. (From a model in the Lond. Coll. Surg. Museum.)

India. Living instances of more than a single pair are seen in the Four-horned Goat and Many-horned Sheep; also in the Jungliburka Antelope (*A. subquadricornutus*) where the anterior pair are rudimentary, and in the Chousingha (*A. quadricornis*), several species of which have been described by authors (*fig*. 342.).

The structure of the horn in Cavicornua is exceedingly simple. The frontal "apophyses" or "cores," instead of branching, form cylindrical shafts, more or less solid, the surface being protected by the ordinary periosteum, and by an extension of true skin, the cuticular portion of which is developed into a dense horny sheath (*fig*. 333.). If a transverse section be carried through the base of the "core," a number of cavities will be exposed, which are continuations of the frontal sinuses. These spaces do not exist in certain of the antelopes, as for example in the Gazelle (*A. dorcas*) and the Sasin (*A. cervicapra*). The horns exhibit a great variety of curvature and outline, and in those of the Cabrit or Prong-horn Antelope (*A. furcifer*), we have an approach toward the cervine type. The prong is situated about half way up, and may be considered as analogous to the brow-antler; immediately below it the root is rough, scabrous, and nodulated, being covered also by a hairy integument (*fig.* 343.).

Fig. 343.

Horns of the Cabrit. (From a specimen in Lond. Coll. Surg. Museum.)

In the Buffaloes the horns acquire a prodigious size, and the cuticular sheath forms, in some instances, a thick envelope over the entire forhead.

Vertebral column and bones of the trunk. — Considerable disparity prevails in the length of different portions of the spine, depending upon the comparative elongation of the individual bones, and not upon their number. The following table, selected from Cuvier, illustrates the trifling deviations in a numerical point of view, — the seven cervicals being added and indicated in the totals: —

	D.	L.	S.	C.	TOTALS.
Camel - -	12	7	4	17	47
Vicugna -	12	7	5	12	43
Moschus -	13	6	3	14	43
Red Deer -	13	6	4	16	46
Giraffe - -	14	5	4	18	48
Gazelle - -	13	6	4	14	44
Chousingha -	13	5	4	14	43
Goat - -	13	6	4	12	42
Sheep - -	13	6	4	16	46
Ox - -	13	6	5	18	49

In Camelidæ the bodies of the vertebræ of the neck are much lengthened (*fig.* 323.), but it is in the Giraffe (*fig.* 345.) that we see the most remarkable conformity to the cervical type in this respect. The spinous processes of this division of the column are lessened in all mammiferous animals in proportion to the length of the cervix, and therefore we find them in the above mentioned ruminants almost entirely effaced (except in the seventh vertebræ) to admit of free motion backward. This action is further facilitated in the Camels and in the Giraffe by the ball and socket-like conformation of the articular ends of each vertebral body, as pointed out by Profs. De Blainville and Owen. The anterior extremity of the "centrum" is convex (*fig.* 344.), and the posterior concave, but there is no intervertebral synovial apparatus as seen in reptiles. The transverse processes in the short-necked typical ruminants are compressed, and form double "apophyses" on either side. The anterior or inferior pair are directed forward, and the posterior or superior project laterally, their common expanded base being pierced for the passage of the vertebral artery. In the latter particular, a similar arrangement obtains in the Giraffe, but the openings are placed nearer the spinal canal, because the transverse processes are feebly developed, as in all other long-necked ruminants. The Camels and Llamas do not exhibit the perforation in question. In them, the vertebral arteries enter the posterior opening of the great neural canal, external to the dura-matral sheath, and in this position they are partly lodged in a groove at the base of the superior lamina. At the anterior part of the bone this channel becomes arched over for a short space, and converted into a distinct passage

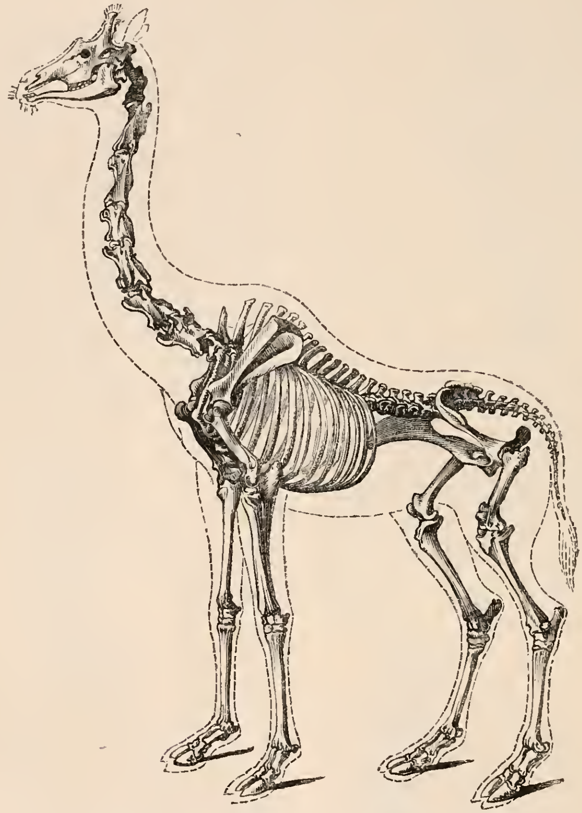
Fig. 344.

Section of the cervical vertebræ of the Camel. (From Coll. Surg. Museum.)

(*fig.* 344.). The *atlas* in the Camels is not thus modified. In all other ruminants, including the Giraffe, an opening exists in this bone, which is placed at the fore part of the superior ring. The odontoid process of the *axis* or *dentata* is well marked and prominent in the short-necked ruminantia, but the Giraffe and Camels have it very small and incorporated with the articular end of the body; in them, also, very slight traces of transverse "apophyses" are detectable.

The *dorsal* vertebræ are distinguished for the great length and development of their spinous processes. The latter have an extraordinary elevation in the Giraffe, for the attachment of the powerful *legamentum nuchæ*, which is broadest at this point (*fig.* 345.). The spinous "apophyses" are large in the Bovidæ, and still more bulky in Camelidæ. The transverse processes of the *lumbar* vertebræ in the first-named family are extremely prominent, and have a straight lateral direction. In the swift-bounding Stags and Antelopes they are shorter, and a little curved forward. In Camelidæ they are largely developed, slightly bent downward, and abrupt at their extremities, the last pair being comparatively short and narrow. The *sacrum* consists of three, four, or five pieces consolidated together, to the anterior of which the *ossa ilea* are articulated. The spinous processes form a single continuous crest. The *caudal* vertebræ vary in number, and, in the foregoing table, eighteen are assigned to this region in the Giraffe. Prof. Owen has counted as many as twenty in the Nubian variety. The Llamas, Stags, Goats, and certain of the Antelopes have the tail short, with a proportionate diminution of bony segments; this appendage is of considerable length in the true Camels, the Gnus, the Oxen, and some of the Sheep.

Fig. 345.



Skeleton of the Giraffe. (From Pander and D'Alton.)

The *ribs* vary chiefly in respect of their size. The Giraffe has seven directly united to the sternum, and an equal number unattached. Eight are true and five false in the Stag, and the same division occurs in the Ox. They are strong in the true Camels and in the Giraffe, being particularly broad toward the sternal ends. The same peculiarity holds good with most of the bovine species. In the Camel seven pairs are connected to the sternum, the anterior ones being straight and short; five remain unsupported. The ribs are very narrow in the Bison, and particularly slender in the Antelopes and Deer. The *sternum* is flattened in ruminants, its first bone being rounded in front, and somewhat attenuated. This is especially the case in the Giraffe, where the breadth increases towards the posterior border, at which point it is extremely thick. It is more or less curved in the Camel and Giraffe, particularly in the latter. We have observed in the skeleton of an Arabian Camel, preserved in the Edinburgh College of Surgeons' Museum, that the second bone of the sternum is of very great bulk, while the first is small and flat anteriorly.

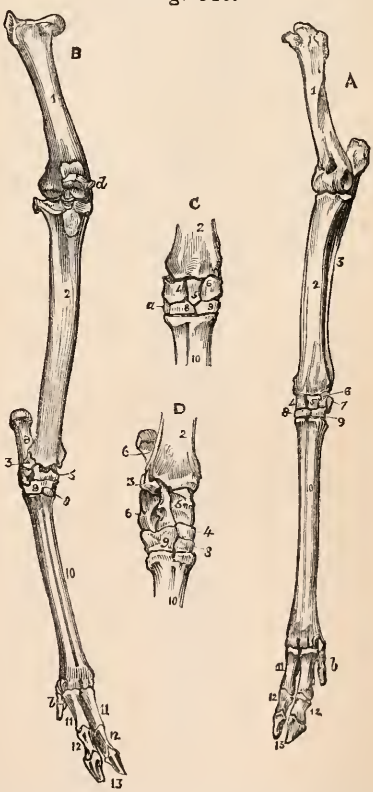
The *pelvic bones* are broad and strong in the Camels and bovine tribes, and comparatively slight in the Antelopes and Deer. In the Giraffe and in the Camelidæ the crest of the ileum is rounded, the neck long, and the upper surface of the bone concave. The ileum is extremely prominent and large in the Ox and Buffalo, and in respect of the neck, acquires an almost vertical position; the prominence of the ischium is placed on a higher level than the cotyloid cavity. In ruminants generally, the posterior angle of the ischium presents the appearance of a tripod. The ischiatic notch is deep. In Œgosceridæ, Cervidæ, and Antelopidæ, there is a depression immediately in front of the cotyloid cavity for the insertion of the tendon of the straight muscle of the thigh. In Moschus, according to M. F. Cuvier, the sacro-ischiatic ligament and connecting aponeuroses ossify, in consequence of which there is formed in this region a shield-like osseous plate extending from the crest of the ileum to the ischial tuberosity.*

Bones of the anterior extremity. — There are no traces of a *clavicle* in this order. The *scapula* is long, and has the form of an isosceles triangle, the base of which is represented by the spinal border, and the apical angle by the glenoid facet. In Camelidæ the spine of the bone is prolonged downwards over the neck, forming, in this respect, an approach to the pachydermatous type. The acromion apophysis is likewise developed in Bovidæ; but it can scarcely be said to exist in other ruminants. In every division of the family we find the neck of the scapula much elongated, and the extreme manifestation of this peculiarity in the Giraffe, together with a nearly vertical direction of the bone, produces the remarkable elevation of the shoulder, characteristic of that animal. The coracoid process exists only in a very rudimentary condition, or is altogether absent. The relative disproportion between the supra and infra-spinal spaces is very striking; usually the former consists only of a narrow plate of bone, but its development in the Camel is more cogent. In Bovidæ the root of the spine is blended and continuous at its acromial end with the anterior scapular border.

The *humerus*, according to its thickness and bulk, affords a very fair criterion of the comparative activity and strength of the different species. In Camelidæ and Bovidæ this bone is very massive, and the tuberosities are of great size, the lesser prominence being more elevated than the greater in the first of these two tribes, and hollowed out in front by a capacious channel. The linea aspera stands out boldly, and the external and internal condyles are drawn back, as it were, to deepen the olecranon cavity. The trochlear grooves and ridges are also well marked. The foramen for the passage of the nutritious artery is generally situated at the commencement of the lower third of the bone; but a slight variation is occasionally observed. Thus, in regard to its position in the Giraffe, Professor Owen states that the "medullary artery enters the bone at its inner side about the junction of the upper and middle third," while it is added, that in the skeleton preserved in the Museum of Comparative Anatomy at Paris, the vessel enters the *left* humerus at the point of union of the middle and lower third.* We have found a similar disposition to occur in our example. The foramen enters at the posterior and inner surface of the right humerus, and is situated very near the centre of the shaft; but in the bone of the left side it is placed further down, as in the Parisian specimen: the opening is likewise rather smaller.

The *bones of the forearm* (*fig.* 346., A. 2, 3) are

Fig. 346.



Bones of the fore and hind limbs of the Deer. (From Lond. Coll. Surg. Museum.)

* For details, see Art. "Pelvis."

* Memoir, *loc. cit.*

intimately united, and, being connected to the humerus by a simple hinge joint, are always retained in a state of pronation — as the surface corresponding to the palm of the hand is always directed backwards; to increase the steadiness and strength of the limb, the upper end of the ulna is very thick, and in the upright position of the animal the articular angle of the olecranon is firmly locked between the brachial condyles. There is a deep groove indicating the radio-ulnar line of union, at the upper part of which is a vacant space, and another is sometimes present near the distal end. In certain individuals the ulna is represented by two distinct pieces, the central part of the shaft having disappeared. In all cases the olecranon is extremely prominent, and the bone is relatively much longer than the radius. There is no vacant interval between the bones in the Camel, which together acquire an extraordinary length. The radius and ulna in the Javanese musk are nearly of equal bulk, and the line of attachment is very distinct throughout. In a specimen preserved in the Edinburgh College of Surgeons' Museum, the bones of the right side are anchylosed only at the middle of the shaft.

All ruminants possess six *carpal bones* (A. *fig.* 346.), and some have seven, which are disposed in two rows. In the upper may be recognised the *os scaphoides* (4), *os lunare* (5), *os cuneiforme* (6), and *os pisiforme* (7); in the lower the *os trapezoides* (8) and *os magnum* (9), and in the Giraffe and Camel the *os unciforme* (C, *a*.).

The *metacarpals* are represented by a central *cannon* bone (10), and in the Deer-tribe and Antelopes by two additional rudimentary splint-like pieces, which are separated from the lower and back part of the former by the intercalation of four *ossa sessamoidea*.

Fig. 347.

ection of the cannon bone. (From Lond. Coll. Surg. Museum.)

The large central shaft or cannon is in reality composed of two metacarpals, as can be readily demonstrated by making a longitudinal section, such as is displayed in the annexed woodcut (*fig.* 347.). In this view the duplicity of the shaft is shown by the thin lamina of compact osseous tissue (*d*), traversing the hollow cylinder from end to end; and its duality is further evinced by the bifid character of the distal extremity (*a*, *b*), as well as by a deep median furrow at the posterior surface. The two splint bones are homologous with the metacarpals of the index and little fingers in the human subject. They are not present in all ruminants; but in the Deer they attain a considerable size, and support two small digits. In some cervine species these styliform metacarpals are seen attached at both extremities of the cannon bone. In the genus Moschus they are as long as the shank, forming thus a transition towards the four-toed pachydermata.

Six *phalanges* enter into the composition of the cloven foot, the two upper being the longest, and having a position analogous to the pastern bone of Solipeda; the superior articular surfaces are deeply grooved for the reception of corresponding ridges (*fig.* 347. *c*, *c*), surmounting the trochlear facets of the cannon bone. The second pair are short, the distal end presenting an extended convex plane for the hinge movement of the ultimate phalanx. A sasamoid bone is sometimes seen behind this joint. The last pair are more or less triangular, and their combined plantar surfaces form a semicircular disc, resembling that of the coffin bone of the Horse. In those genera which have supernumerary digits, the rudimentary phalanges do not, under ordinary circumstances, reach the ground; and though invested with a hoof-like covering, they can but slightly aid in supporting the weight of the body. In the Rein-deer, however, as Sir Charles Bell observes * "these bones are strong and deep, and the toe, by projecting backward, extends the foot horizontally, thus giving the animal a broader base to stand on, and adapting it to the snows of Lapland, on the principle of the snow-shoe." The same observation applies, though in a more limited sense, to those species where the lateral toes are less conspicuously developed, in which case the elasticity and firmness of the spring will be heightened when bounding through weedy thickets and on grassy moors.

Bones of the posterior extremity. — The hind and fore limbs are not of equal length, and if the actual extent of the individual bones be added together, the balance will be found in favor of the posterior limb. This is evident at a glance in the genus Moschus, and in the Giraffe there is no exception to this rule. In order to make our position clear, the following relative admeasurements are deciphered from personal examination: —

* Bridgewater Treatise, "On the Hand," p. 93.

	Fore limb.	Hind limb.
Dromedary - - - -	62 inches	65 inches
Javanese Musk - -	7½ "	11 "
Red Deer - - - - -	31 "	38 "
Rein Deer - - - - -	32 "	39½ "
Fallow Deer - - - -	27 "	34 "
Irish Elk - - - - -	51 "	60 "
Goat - - - - -	19 "	24½ "
Ox - - - - - - -	38 "	48 "

It will be remarked that the proportionate difference, as here indicated, is much less in the Arabian camel than in the more typical ruminants.

The *femur* (*fig*. 346. B. 1) resembles for the most part that of other mammifera, being characterised by a rather short shaft and neck, and having the head placed nearly in a line with the longitudinal axis. The great trochanter is prominent, and forms the highest point when the limb is placed in an upright position. The inter-trochanteric fossa is capacious. The bone presents at the inferior end an extended articular surface, and bulges at the forepart, where it is deeply grooved for the patella and tendon of the quadratus muscle. Behind the external condyle is a hollow, and its rough outer margin is continuous with the faintly indicated linea aspera. In the Giraffe the distal extremity of the thigh-bone attains a prodigious development. The nutritious artery enters at the anterior aspect of the cylinder a little below the cervix, as in other keratopherous ruminants; we have also observed the arterial foramen of the left side to be about half an inch lower than on the right, an arrangement analogous to the deviation noticed in connection with the humerus of this species.

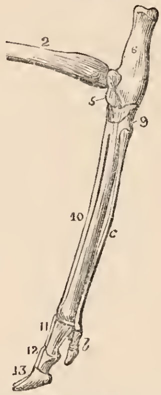
The *patella* (*d*) is comparatively small and compressed laterally; it is sharp in front, and the applied surface exhibits two well marked facets.

The *tibia* (2) is the longest bone of the hind leg, and is chiefly remarkable for the prominence of its spine, which projects from the upper fourth of the shaft and presents a sharp ridge directed outwards. A long styliform *fibula* is stated to exist in Moschus, which is united to the external border of the tibia. In the Javanese Musk preserved in the Edinburgh College of Surgeons Museum, there is no appearance of this bone. Slight traces of the fibula, however, are met with in other cervine genera, in the form of small osseous nodules jutting from the head of the tibia, and in some of the Deer tribe there is likewise to be noticed a small bone constituting the external maleolus (*fig*. 346, D A. 3). This supplementary piece is, in all probability, the representative of the lower end of the fibula, and it is articulated by three distinct facets to the tibia, os calcis, and the astragalus.

The bones of the tarsus, properly so considered, are five in number, viz.,—*os calcis*, (2) and *os astragulus* (5), two *ossa cuneiformes* (8), and a single mass (9) resulting from the union of the *os scaphoides* and *os cuboides*. In the Giraffe and in certain Antelopes and Deer the two cuneiforms are conjoined. The bone of the heel is in all much elongated. In Camelidæ the scaphoids and cuboids (D 4 and 9) are disconnected.

In conformity with the disposition of the metacarpal bones in the anterior limbs, the *metatarsals* form a single cannon bone posteriorly (10). More evident traces of original duplicity are observable in the latter, than in the corresponding cylinder of the fore-limb, owing to the presence of a furrow in front in addition to the one placed behind; the latter groove being moreover particularly deep. In Cervidæ and Antelopidæ, splint-bones homologous with the metatarsals of the second and little toes of the human subject are occasionally present, to support two supernumerary digits as obtains in the fore-leg; but these spurious phalanges are sometimes seen without the styliform appendages. In Moschus the rudimentary metatarsals acquire a much greater significance, extending upward nearly as far as the tarsus (*c*, *fig*. 348.). We have already alluded to a similar peculiarity in the metacarpus of this aberrant genus. The disposition of the true digital phalanges and their accompanying ossa sessamoidea simulates in every respect that displayed in the construction of the cloven foot of the anterior extremity.

Fig. 348.



Bones of the hind limb of Moschus. (From Lond. Coll. Surg. Museum.)

Myology.—The muscles of ruminants exhibit few peculiarities apart from those of quadrupeds generally. They present arrangements very similar to those seen in Solipeda, and in the article devoted to the consideration of that group, numerous comparisons have been instituted in reference to the more important myological deviations found in this order. Selecting principally the Ox and Sheep as types, we have to offer, in regard to this great system of motary organs, the following particulars :—

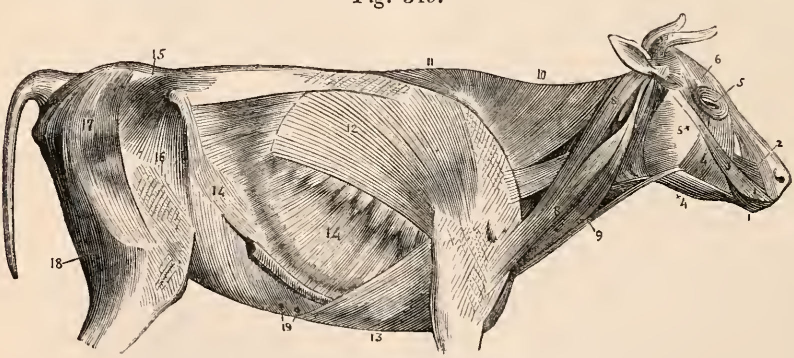
Panniculus carnosus.—Traces of this superficial muscular investment exist over the whole surface of the trunk, but in certain localities the fibres are more cogent, and form separate bundles, so as to assume more or less the character of distinct muscles. Eight or ten such bundles may be remarked in different species. In the first place we have a broad band extending from the fore-part of the neck, and spreading toward the lips and forehead; this constitutes the *musculus cutaneous faciei.* Again, it is very strongly marked at the neck, especially in the Sheep; here it is denominated the *m. cutan. colli.* In other domestic animals of the non-ruminant kind, such as the Dog, Cat, and Pig, this second division of the fleshy envelope is still more striking. Over the shoulder of the Ox there is a third layer of thickened fasiculi (*m. cutan. humeri*); and lastly, we find a highly developed mass, taking its origin from the fascia lata of the thigh immediately above the patella, and proceeding forward, the fibres radiate toward the scapula in front and the abdomen below; this is the *m. cutan. maximus seu abdominis.* The insertion of the panniculus is directly into the skin, which everywhere covers it, and "on this texture it can alone act, seeing it is completely isolated from the deeper seated parts, by an universal layer of fascia, which thus enables it to slide more freely upon them. When in action, the fibres throw the skin into folds that form right angles to their general course; the chief points from which they act being the angle of the jaw, the scapula, the patella, and the pubis." * The principal function appears to be that of serving as an instrument of defence. By its action animals have the power of jerking and shaking the skin, thus removing irritating matters, — also of erecting bristles and spines as instanced by the defensive armature of the Hedgehog, — and in aiding the process of lactation, as obtains in the Marsupiatæ. Were it not for the constant and involuntary action of the muscle, the torture (to which many animals, particularly cattle, are subjected, from the stings and bites of flies and other insects), would become intolerable, and consequently we find in those creatures which are most exposed to their injurious attacks a preponderating development of this structure.

In the same category as the above cutaneous muscles may be associated the *musculus preputialis seu umbilicus*, the superficial *orbicularis palpebrarum*, and certain of the complicated set of organs which act upon the concha and scutum of the external ear. Of the latter, sixteen pairs have been described as common to the Ox, and nearly as many have been indicated in the Sheep. In both genera they surround the ear on all sides, and offer similar characters in respect of relative size and position. By their reciprocal action the auricular appendage is turned in every direction, as well as rotated upon its own axis; it is likewise expanded and contracted by such of them as proceed from one part of the concha to another. The orbicular muscle of the eyelid (5, *fig.* 349.) is thick and fleshy, and its action is aided above and below by thin strata of fibres coming from the panniculus; these are independent of the ordinary elevators and depressors of the lid.

Muscles of the head and trunk. — Referring to the accompanying figures for a general outline of the superficial and deep muscular layers included in the above division, we propose to treat in detail of such muscles as acquire a particular interest in respect of their position or importance in a physiological point of view.

In the clavicle-bearing mammals the *trapezius* consists of two parts, — an anterior or clavicular portion, and a posterior or scapular division; but in ruminants and other quadrupeds which are unprovided with these bones, the posterior section is alone represented by the trapezius properly so called (10, 11, *fig.* 349). On this account it is comparatively small and restricted in its superior attachments, the fore-part being narrow and connected to the elastic ligament of the neck and the dorsal portion, which is somewhat shorter and thicker, becoming attached to the spinous

Fig. 349.

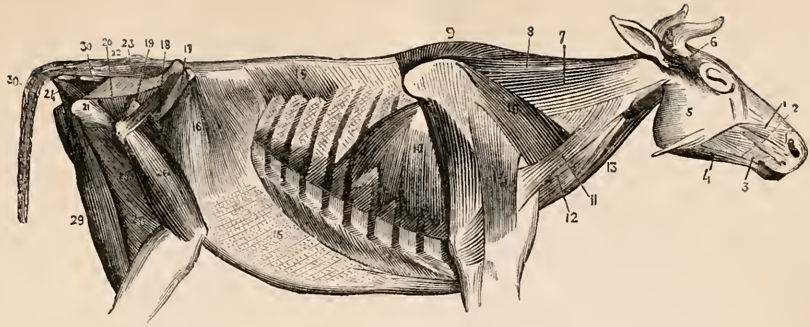


View of the superficial muscles of the trunk in the Ox. (From Gurlt.)

1, orbicularis oris; 2, levator labii superioris; 3, zygomaticus; 4, depressor palp. inferioris; 4 *, risorius santorini; 5, orbic. palpebrarum; 5 *, masseter; 6, corrugator superciliorum; 7, depressor auriculæ; 8, 8, 8, deltoides; 9, sterno-maxillaris; 10, 11, trapezius; 12, latissimus dorsi; 13, pectoralis major; 14, obliquus externus; 15, glutæus maximus; 16, tensor fasciæ latæ; 17, 18, biceps femoris.

* Mercer, On the Structure and Uses of the *Panniculus carnosus*, Med. Gazette, 1840—41, p. 346.

Fig. 350.



View o the deep muscles of the trunk in the Ox. (From Gurlt.)

levat. lab. super.; 2, pyramidalis nasi; 3, buccinator; 4, depressor lab. infer.; 5, masseter; 6, temporalis; 7, splenius capitis; 8, levat. ang. scap.; 9, rhomboideus; 10, serratus major; 11, caput secundum deltoidei; 12, scalenus anterior; 13, caput secund. sterno-maxillaris; 14, abductor brachii superior; 15, serrat. post. inferior; 16, obliquus internus; 17, iliacus internus; 18, gluteus medius; 19, glut. minimus; 20, glut. maximus; 21, pyriformis; 22, levat. caudæ brevis; 23, lev. caud. longus; 24, coccygeus; 25, rectus femoris; 26, vastus externus; 27, adductor magnus; 28, semitendinosus; 29, adduct. tibiæ longus; 30, intertransversales caudæ.

processes of the anterior six or eight dorsal vertebræ. In the Camel it originates from the posterior half of the cervical ligament and the spinous apophyses proper to the first half of the thorax. It is more limited in the Giraffe, where, according to the investigations of Prof. Owen, "it consists of two pretty distinct portions; one arises from the transverse processes of the fifth and sixth cervical vertebræ; its fleshy part is thick and strong, but expands as it passes downwards and backwards, and finally is lost in a strong fascia overspreading the large shoulder joint. The second portion is thin and broad; it arises from the ligamentum nuchæ, and is inserted into the fascia covering the scapula."*

That part corresponding to the clavicular or anterior division of the trapezius in the human subject is widely separated from the muscle just described, and is associated with the *cleido-mastoideus* and *deltoides* so as to form a tripartite mass, for which Cuvier proposed the name of *masto-humeralis*. It is the *levator humeri proprius* of Stubbs, the *communis capitis, pectoris et brachii* of some, and the *deltoides* of others (8,8,8, *fig*.349). In the Sheep and in the Ox it consists principally of two portions with an intervening smaller muscular bundle situated at the centre of the neck, and connecting the clavicular portion of the trapezius to the tendon of the cleido-mastoidens. The superior or more superficial belly becomes implanted into the humerus, while the inferior or deeper division is inserted into the sternum. At their upper attachments the duplicity is very apparent, the broad muscular part being united to the ligamentum nuchæ, and the rounded tendon being fixed to the mastoid apophysis.

After removing the trapezius, our attention is at once directed to a large broad muscle, which in the human subject is represented by the *splenius capitis* and *splen. cervicis*. In the Ox and most other ruminants, the cranial division is alone present; but in the Sheep, according to the researches of Meckel, there are two portions — an anterior or cranial, which is narrow and insignificant, and a posterior of large size, taking its origin by two bundles from the third and fourth cervical vertebræ, to be attached to the transverse process of the atlas. In the Camels both may be said to be absent, but there is a small muscular slip, proceeding from the tendon of the *digastricus* to be inserted into the occiput, which Meckel thinks may constitute a rudimentary form of the splenius capitis.

Beneath the splenius, and often incorporated with it, lies the *trachelo-mastoideus*, which is feebly developed in ruminants and solipeds, but is of large size in the marsupials and edentate mammals. The great *complexus* and *digastricus colli* muscles are united into a single mass, as in the Horse, and in these animals this compound muscle arises by nine or ten fleshy and tendinous slips — intersected by aponeurotic prolongations — from the third cervical to the second or third dorsal vertebræ inclusive. In the Camel there are only seven bundles of origin, and a single long aponeurotic septum, and in the Sheep all traces of the latter are absent.

The *transversalis cervicis* is closely adherent to the trachelo-mastoideus. Separated from the former, there is in some ruminants a muscle, which — corresponding with that portion of the sacro-lumbalis in man, called the cervicalis descendens—stretches from between the transverse apophyses of several of the lower cervical vertebræ to the oblique and transverse processes of certain of the dorsal segments. Meckel alludes to this peculiarity in the Horse.

The *scaleni* muscles, three in number on either side, are very long and powerfully developed in the Camel and Giraffe, presenting in the latter, according to Prof. Owen, four distinct masses, which take their origin "from

* Memoir, *l. c.*

the fourth, fifth, sixth, and seventh cervical vertebræ, and are inserted into the manubrium sterni and first rib." In the Sheep the fleshy bundles are very small; they also arise from the lowermost four cervical vertebræ; but in the Camel they are connected to all the bones of the neck, except the dentata, the posterior scalenus being particularly short, and only attached to the last.

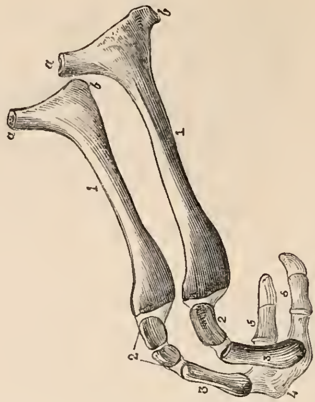
The *longus colli* and *recti* have a similar disposition to those of Man. The former is divided into a superficial and deep portion, the latter division extending as far back as the third vertebræ of the thorax. In the Camel this muscle exhibits an increase of development proportionate with the elongated neck, its posterior attachment commencing at the body of the fourth dorsal segment. The *rectus capitis anticus*, *major* and *minor*, are comparatively insignificant in all ruminants and solipeds.

The muscular arrangements at the fore-part of the neck present many points of interest; for example, — the sterno-cleido-mastoideus of anthropotomists is represented in the majority of mammifers by two distinct muscles. The first of these, the *sterno-mastoideus* or *maxillaris*, is a slender fleshy band which divides near the middle and fore-part of the neck into two portions, one being inserted a little in front of the angle of the lower jaw, and the other becoming attached to the mastoid process. In the Sheep the anterior tendon extends as far forward as the zygomatic arch, and immediately behind the jaw the muscle is united to the deltoides, beneath which it is also connected to the *rectus capitis anticus major* by an intervening tendon. In the Camels this muscle is fleshy throughout its entire extent, and at the lower part is joined to its fellow of the opposite side; superiorly, its tendons are fixed — one to the mastoid process, and another to the maxilla over the region of the submaxillary gland. The characters and position of this muscle are precisely similar in the Giraffe. The situation of the cleido-mastoideus has been already indicated in the description of the tripartite deltoides.

Hyoid apparatus. — Before noticing the muscles connected with the os hyoides it is necessary to direct attention to its osseous framework.

The hyoid bone is made up of a congeries of ossicles more or less consolidated, having relation to totally different parts of the skeleton, but here associated together for the threefold purpose of supporting the tongue and larynx, and affording a *point d'appui* for the muscles destined to act upon these organs. In the ruminant, as in Solipeda, nine distinct elements may be recognised, arranged in four pairs, the ninth piece being represented by the body or *basi-hyal* bone. Fig. 351. indicates the relation of these parts in the sheep. Commencing from above, the first pair—the styloid bones — or *stylo-hyals* (1, 1) are seen to have an enormous longitudinal development, being also somewhat hammer-shaped and compressed laterally, to favour muscular attachment. Their peculiar figure is due to the

Fig. 351.



Hyoid bones of the Sheep. (From Lond. Coll. Surg. Museum.)

presence of two apophyses at the temporal extremity (*a a*, *b b*) and it is by the superior process that the bony chain is connected with the cranium. In the Horse these bones are proportionally longer, but they are shorter in the Camelidæ than in the typical ruminants. In Man the styloid processes of the temporal are homologous with the stylo-hyals. The second pair or *epi-hyals* (2, 2) are intercalated between the first and third series of ossicles, and complete a right angle, formed by the relatively horizontal and vertical position of those bones; they have an insignificant appearance in most of the genera, but attain in the Camels a considerable size. More than two nodules are sometimes present. The epi-hyals are most conspicuous in the carnivorous mammifers, but in the human subject are merely represented by two long ligamentous bands, which in a few instances have been found ossified. The third pair or *cerato-hyals* (3, 3) have a nearly vertical position when the head is raised, and they constitute with the epi-hyals, the lesser cornua which in Man are feebly indicated, being recognised only by two small pisiform nodules moveably articulated to the body of the hyoid, and forming, as in the present instance, a right angle with the greater cornua. In the typical ruminants these elements are larger than the *epi-hyals*, but in the Dromedary, according to Duvernoy, this character is reversed. The body of the hyoid or *basi-hyal* (4), of a triangular form, is placed below the cerato-hyals and anterior to the greater cornua, the four ossicles of which they together consist, being articulated to the extremities of its lateral apophyses on either side. There is generally a slight bulging at the anterior and middle part, indicative of the tendency to antero-posterior elongation, which feature becomes very manifest in other vertebrata, and more particularly in birds; it is to this point that an additional element — the true lingual bone or *glosso-hyal* — is connected, in many of the avian and piscine families, traces of it also appearing in Solipeda and other quadrupeds; it is remarkably large in the Bear. In Camelidæ the basi-hyal presents no anterior protuberance. The fourth pair or *thyro-hyals* — hypo-branchials of fishes and amphibia—(5, 5) represent the greater cornua of the anthropotomist, but in certain mammifers, as in the family under consideration, their extent of development is subordinate to that of the lesser horns. In birds, on the other hand, the length of the thyro-hyals is extreme, the lesser cornua being either rudimentary, or altogether absent.*

The muscles proper to the hyoid chain of bones present many interesting modifications. The *sterno-hyoids* and *sterno-thyroids* (which in Man and mammifera generally, remain distinct throughout their entire extent), are united below in the majority of ruminants, their common band of origin dividing near the middle of the neck, the larger division being connected to the hyoid bone. Meckel states that the sterno-hyoid is entirely absent in the Camel, and Duvernoy remarks the same peculiarity in the Sheep; but Gurlt figures the upper part of it in the latter animal and in the Ox. A muscle analogous to the *omo-hyoid* presents a remarkable difference of origin, relatively, in the typical ruminants, the Camel and the Giraffe. In the Sheep it originates, according to Meckel, in the form of a muscular band of considerable dimensions, which is given off by the rectus capitis anticus major, and leaves that muscle at a point corresponding to the third cervical vertebra to be inserted into the hyoid immediately behind the attachment of the thyro-hyoid muscle. Its relation in the Giraffe will be reverted to presently. In the Camel the disposition of this structure is extremely complicated. From the researches of Meckel we learn that it arises from the anterior division of the transverse process of the fourth cervical vertebra, and is confounded near its commencement with the lowermost bundle of the straight anterior muscle of the head; it subsequently divides into three portions, the first becoming inserted into the lower lip, the second going to the posterior cornua of the hyoid, and the third attaching itself to the lower jaw, upon which it acts as a powerful depressor. Professor Goodsir has remarked to us that an anomaly analogous to this latter distribution is sometimes seen in the human subject. The *stylo-hyoid*, which is absent in certain Carnivora, its place being supplied by a narrow muscle termed the *ceratoido-lateralis*, is present in the Ruminantia, where the latter muscle appears as a prolongation of the stylo-hyoid rather than as a distinct muscle. The first of these two muscles — regarding them as such — proceeds by a long tendon from the posterior and inferior apophysis of the styloid bone, to be attached below to the base of the thyroid cornua; the *ceratoido-lateralis* also descends obliquely from the lesser horn to the greater. In both the above-named families and in the Pachydermata there is likewise a special muscle termed the *masto-styloid;* it is short and triangular, and, arising from the mastoid process of the temporal bone, becomes inserted into the inferior apophysis of the hammer-shaped extremity of the stylo-hyal element or styloid bone, immediately above the origin of the tendon of the stylo-hyoid muscle. The *mylo-hyoid* is distinctly double, the anterior bundle having an extended longitudinal development, while the posterior division is short, and has its fibres directed transversely outward. The *genio-hyoids* of either side are incorporated at the middle line.

In the foregoing description of the muscles connected with the hyoid apparatus we have intentionally omitted those of the Giraffe, preferring, on account of the peculiar interest which the muscular arrangements of this animal present, to treat of them separately. We quote at length, therefore, from the accurate researches of Professor Owen.* "The *mylo-hyoideus* is a thick and strong muscle, it arises from the whole of the internal surface of the lower jaw, and is inserted principally into the *raphe*, or longitudinal commissure, dividing it from its fellow of the opposite side. It adheres firmly to the *genio-hyoideus:* this arises by a well marked tendon from the posterior rugous surface of the symphysis menti, and has the usual insertion. The *genio-glossus* arises by a tendon close to the inner side of the tendon of the *genio-hyoideus;* its fleshy belly has a considerable antero-posterior extent, and diminishes to a very thin edge at its anterior margin. The digastricus has the usual origin, and is inserted, broad and thick, into the under side of the lower jaw. The *stylo-hyoid* is external to the *digastricus*, and is remarkable for the slenderness and length of its carneous part. The most interesting modifications in the muscles of the *os hyoides* were found in those which retract that bone. The muscle which, as in some other ruminants, combines the offices of the *sterno-thyroideus* and *sterno-hyoideus*, arises in the Giraffe by a single long and slender carneous portion from the anterior extremity of the *sternum;* this single fleshy origin is nine inches long, and terminates in a single round tendon, which is six inches long; the tendon then divides into two, and each division soon becomes fleshy, and so continues for about sixteen inches; then each division again becomes tendinous for the extent of two inches, and ultimately carneous again, when it is inserted into the side of the thyroid cartilage, and is thence continued in the form of a *fascia* into the *os hyoides*. We have in this alternation of a contractile with a non-contractile tissue a striking example of the use of tendon in limiting the length of the carneous or contractile part of a muscle to the extent of motion required to be produced in the part to which the muscle is attached. Had the sterno-thyroideus been continued fleshy as usual from its origin through the

* See art. Tongue.

* Memoir, *l. c.* p. 232.

whole length of the neck to its insertion, it is obvious that a great proportion of the muscular fibres would have been useless; for as these have the power of shortening themselves by their contractility only one-third of their own length, if they had been continued from end to end in the *sterno-thyroidei*, they would have been able to draw the *larynx* and *os hyoides* one-third of the way down the neck; such displacement, however, is neither required nor indeed compatible with the mechanical connections of the parts; but, by the intervention of long and slender tendons, the quantity of the contractile fibre is duly apportioned to the extent of motion required for the *larynx* and *os hyoides*. The muscle analogous to the *omo-hyoideus* of other animals, is adjusted to its office by a different and more simple modification; instead of having a remote origin from the shoulder-blade, its fixed point of attachment is brought forward to the nearest bone (the third cervical *vertebra*) from which it could act upon the *os hyoides* with due power and extent of contraction. Its insertion is by a small round tendon."

The muscles of the back and tail present few deviations worthy of remark. The *spinalis* and *longissimus dorsi* exhibit the same attachments as in Solipeda. The *sacro-lumbalis* is proportionately strong in ruminants. The *semispinalis colli*, according to the observations of Meckel, is very largely developed in the Camel, originating from the spinous apophyses as well as from the transverse processes of the five or six anterior dorsal vertebræ. These additional points of origin, while they afford a greater leverage power, constitute at the same time an important peculiarity in this long-necked animal.

The *diaphragm*, which is present in all mammifera, exhibits three openings for the passage of the aorta, œsophagus, and inferior vena cava. A very remarkable feature exists in connection with this muscle in the Camelidæ. It consists in the presence of a small bone situated near the margin of the central tendon. Meckel states that Dr. Jœger was the first to direct attention to this anomaly in the Dromedary and in the Vicugna*, the observation being subsequently confirmed by Dr. Leuckart and himself. In the two-humped or Bactrian Camel its presence was overlooked by the original discoverer, but afterwards ascertained by Meckel to occur in this species also. The bone offers slight variations according to the age of the individual; it is thin and rather more than two inches long in the adult Camel; in the Vicugna it is but feebly developed. Its solidity is not acquired until a late period, for, in a Dromedary about two years old, the cartilaginous matrix only was discernible. In conclusion it may be said that this osseous formation is apparently designed to give support to the diaphragm, which is of great bulk in these animals.

* Syst. der vergleich. Anat. (Fr. edit., tom. vi. p. 212.)

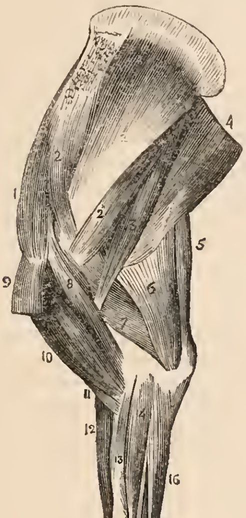
Muscles of the shoulder and fore-limb.—The *trapezius* has already been considered. The *levator anguli scapulæ* (8, *fig.* 350.) varies little from the ordinary mammiferous type. The *rhomboideus* (9) is usually represented by two muscles, *r. minor* and *r. major;* the former, sometimes called the *superior*, arises in the Sheep from the ligamentum nuchæ as far forward as the second vertebra of the neck, and the latter, or *rhomboideus inferior*, proceeds from the spines of the first two or three dorsal vertebræ, the fibres of both converging to be inserted into the upper border of the scapula. In the Horse the muscle is single, and extends forward to the occiput, but is only connected superiorly to the cervical ligament. It is very feebly developed in the Camel, passing only from the spines of the two anterior dorsal vertebræ to the posterior angle of the scapula. In certain Pachydermata and in the Cetacea its appearance is still more insignificant, but it is particularly large in the carnivorous mammals and in the Ornithorhynchus. In the Giraffe it is inserted, like the largely developed serratus major, into the cartilage surrounding the base of the scapula; and in reference to the use of this structure Prof. Owen observes that "as the fore-part of the trunk is, as it were, slung upon the two great *serrati* muscles which principally support the weight of the remarkably deep chest of the Giraffe, the interposition of the elastic cartilages between the upper attachments of the muscles and the capitals of the bony columns of the two fore-legs, must be attended with the same advantage as is obtained by slinging the body of a coach upon elastic springs." * The *serratus magnus* or *major* (10, 10) is exceedingly strong in this order. In quadrupeds generally, it differs from the human subject in presenting a cervical attachment in addition to its costal connection. In the Sheep it has no less than thirteen bundles of origin, eight of which come off from a corresponding number of the superior ribs, the remaining five proceeding from the transverse apophyses of the third to the last cervical vertebra inclusive. In other ruminants there is a slight numerical variation in regard to the fleshy digitations, but their general disposition is the same, being in all cases subsequently united and implanted into the base of the scapula, there forming, in conjunction with the trapezius, a sling-like support to the anterior extremity. The *serratus minor* has an arrangement in mammifera similar to that of its anologue, the lesser pectoral of the human subject; but in the latter it is inserted into the coracoid apophysis of the scapula, while in the former it is usually connected to the humerus. In many carnivorous, edentate, and marsupial families this muscle is entirely wanting.

The *latissimus dorsi* (12, *fig.* 349.) is somewhat feebly developed in ruminants, but its attachments are similar to those in Man. The *pectoralis major* (13, *fig.* 349) is proportionately

* Memoir, *l. c.*

greater, and divided into two,—a small fleshy bundle proceeding from the anterior extremity of the sternum to the lower part of the humerus, and a larger mass coming off from the whole length of the sternum posterior to the former, its fibres passing obliquely forward to be inserted into the external tuberosity of the same bone. There is an additional muscular slip in the Sheep and Horse, by the action of which the crossing of the fore-legs is produced; this is denominated by hippotomists the *ambibrachialis communis*. Cuvier remarks the same muscle in Cetacea. Corresponding to the scapular division of the deltoid in the human subject, there is, in ruminants and solipeds, a muscle called the *abductor longus brachii* or *abd. brach. superior* (14, *fig.* 350.); it generally exhibits two points of

Fig. 352.



Superficial layer of muscles of the fore limb of the Ox. (From Gurlt.)

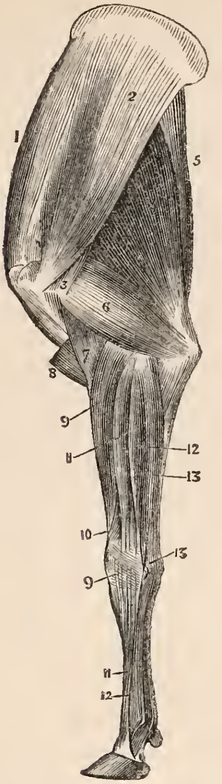
1. supra-spinatus; 2, infra-spinatus; 3, abductor brevis; 4, anconeus longus; 5, exten. cubiti longus; 6, ancon. externus; 7, brachialis internus; 8, deltoides; 9, 9, exten. carpi radialis; 10, abductor pollicis; 11, 11, extensor digit. longior; 12, 12, exten. digit. brevior; 13, 13, flexor carpi ulnaris externus.

attachment above, one at the spine of the scapula, and the other from the infra-spinous fossa. On their passage down, the fibres coalesce, and become inserted by a common tendon into the linea aspera of the humerus. The external scapular muscles, viz., the *supra-spinatus* (1, *fig.* 352.) and *infra-spinatus* (2), are powerfully marked in this order; the former is implanted by a double tendon of insertion into the anterior and internal tuberosities of the humerus, the latter being connected below to the external tuberosity. The round muscles have the same attachments as in man, but the *teres major* or *t. externus* (3, *fig.* 353.) is in Ruminantia and Solipeda smaller than the *teres minor* or *t. internus* (2, *fig.* 353). The *sub-scapularis* (2, 2 *fig.* 353.) is of large size, and subdivided.

The *coraco-brachialis* (8, *fig.* 353.) is always present, although there be no indication of a coracoid apophysis; the greater part of the muscle lies deep, and is connected to the inner border of the upper half of the humerus, the remainder lying more superficially, and continuing as far as the internal condyle into which it is implanted. The *biceps brachii coraco-radialis* or *flexor cubiti longus* (10, *fig.* 353.) has a similar disposition to its analogue in Man; but in Carnivora and Solipeda, where the coracoid process is absent, it exhibits but one head. In the Bear, according to Cuvier, the absent division is represented by a muscular slip passing off from the coraco-brachialis. Meckel states that in the Camel and Dromedary the apparently single tendon of origin arises from the margin of the glenoid cavity as usual, but it is very thick, and can easily be separated into two portions, which are united only by cellular tissue. These, as they pass over the head of the humerus, swell out and enclose between them a sesamoid body consisting of fibro-cartilage; the external of the tendons is the larger, and also subdivides, giving off a strong tendinous cord which becomes incorporated with the antibrachial aponeurosis. The *brachialis internus*, or *flexor cubiti longus* (7, *fig.* 352. and 11, *fig.* 353.), is comparatively weak. In the typical ruminant it rises from the posterior and external part of the neck of the humerus, but in the Camel it commences lower down from the middle third of the bone, its tendon of insertion in all cases being anterior to that of the long flexor. The divisions of the *triceps extensor cubiti* are described under different names by hippotomists, but this disposition is similar to that of Man. The *extensor cubiti longus* (5, *fig.* 353.) is the *extensor magnus* of Bourgelat; the *extensor brevis* is the *extensor medius* of the same author, and the *anconeous longus* of Gurlt; the *brachialis externus* is the *extensor brevis* of the former and the *anconeus externus* of the latter. There is also another muscle termed by Gurlt the *anconeus internus* (7, *fig.* 353.).

The Ruminantia and Solipeda are generally described as possessing neither *supinators* nor *pronators*, but the above-named author figures in the Ox a small muscular bundle, which he calls the *pronator teres* (13, *fig.* 353.); and moreover Meckel points out the rudiments of this muscle in the Camel, remarking at the same time that its function is no longer that of a pronator but of a flexor. The *extensor carpi radialis* (9, *fig.* 352.) is single in the Camelidæ, as in the Horse, rising from the external condyle and inferior fourth of the hu-

Fig. 353.



Deep layer of muscles of the fore-limb of the Ox, viewed from within. (From Gurlt.)

1, supra-spinatus; 2, 2, subscapularis; 2*, teres minor; 3, teres major; 4, latissimus dorsi; 5, extensor cub. longus; 6, anconeus longus; 7, ancon. internus; 8, coraco-brachialis; 9, pectoralis major; 10, biceps brachii; 11, brachialis internus; 12, extens. carpi radialis; 13, pronator teres; 14, flexor carpi radialis; 15, flexor digit. sublimis; 16, flex. carpi ulnaris internus.

merus to be inserted into the base of the cannon bone at the fore-part. Antagonistic to this, is the *flexor carpi radialis* (14, *fig.* 352.), the tendon of which is connected to the base of the cannon bone behind. The tendons of the *extensores digitorum longior* (11) and *brevior* (12, *fig.* 352.) separate in front of the foot, the divisions of the former being inserted into the base of the ultimate bones of the toes, and those of the latter into the distal extremities of the penultimate phalanges. A muscle corresponding to the *abductor pollicis* (10) is present, notwithstanding the absence of the thumb, and becomes attached to the inner aspect of the inferior end of the cannon bone. The *flexores carpi ulnaris externus* (13) and *internus* (16, *fig.* 352.) are both inserted into the pisiform bone. The tendons of the *flexor digitorum sublimis* (15, *fig.* 352.) and of the *flex. digit. profundus perforans* remain distinct, the latter piercing the former as usual, to be implanted into the base of the distal phalanges of either toe.

Muscles of the haunch and hind-limb.—The *gluteus maximus* (15, *fig.* 349.), which is but feebly manifested in all quadrupeds, owing to the horizontal position of the body, has an insignificant development in ruminants. It rises from the crest of the ilium and sacral fascia, receiving in its passage down a strong tendon from the *tensor fasciæ latæ* (16, *fig.* 349.); the tendon proper to the glutæus becomes inserted below the trochanter, while that of the tensor is continued on in front of the tibia, performing in some measure the office of a flexor. The *biceps femoris* or *vastus longus* of Bourgelat (17, 18, *fig.* 349.), is a muscle of striking proportions in this order and in solipeds. It originates by two distinct heads, one of which proceeds from the tail and sacro-sciatic fascia, and the other comes off from the tuberosity of the ischium; the fibres of both proceed downward, and are inserted, the former chiefly into the head of the tibia, and the latter into the general aponeurotic covering of the leg. In consequence of the posterior border of the front division overlapping the ischiatic portion, there results a well marked groove or raphé, forming a characteristic feature externally on the skin as when the muscle is in action; this is better seen in the Horse. The arrangements of the *iliacus internus* (17, *fig.* 350.), *glutæus medius* (18), and *minimus* (19), and *pyriformis*, are similar to those in Man, differing mainly in proportion, the last named being particularly small; the same observation applies more or less to the *obturator externus* and *internus*, the *gemelli*, *quadratus femoris*, *vasti* and *adductores*, the two groups of muscles comprehended under the latter titles being chiefly interesting on account of their great size and strength.

Having already extended our myological descriptions beyond the prescribed limits, we conclude this part of our subject by observing that the muscles of the hind leg resemble those of Solipeda so closely as scarcely to demand a separate notice, while those acting upon the digits have the same general disposition as in the fore limb.

Integumentary System. — Under this head we proceed to indicate very briefly certain peculiarities of the hair, and more particularly the elastic cushion of the sole of the foot, and the remarkable protuberances situated on the back of the Camel.

While the growth and condition of the cuticular layer of the skin in the different classes of ruminants is of the highest importance in an economic point of view, it is not the less certain that the phases of development through which the integumentary covering passes — its varied aspect and periodicity of renewal, together with the causes which induce such changes — are matters of high interest to the physiologist.

In no group of mammiferous quadrupeds have we a more striking example of the adaptation of structure to the exigences of the creature than obtains in the remarkable dorsal ump, and in the cushion-like sole-pad of the Dromedary.

The hump consists essentially of adipose matter, developed in the subcutaneous areolar substance, its secreting cells having undergone an extraordinary local increase. To support such a mass, the connecting tissue exhibits a corresponding augmentation, the fibres assuming the character of ligamentous bands, which are firmly united below to the capitals of the bony columns of the dorsal vertebræ. In reference to the function of this growth travellers have ascertained beyond all controversy that it serves as a store-house of nourishment, affording to the animal, in conjunction with the stomachal water-cells, a provision against the inanition which long journeys would otherwise entail. In accord with this statement, it has been observed that the hump of the Dromedary becomes attenuated and reduced under circumstances of impoverishment, while, on the contrary, it is marked by rapid increase and ultimate plumpness when the supply of food is abundant.

The general character of the dermal envelope in Camelidæ deserves little comment; the hair is coarse and shaggy in the typical species, and of a soft woolly texture in the Auchenias, where it is also very long. At certain points it acquires in the Camel a rigid bristle-like character, this being especially manifest at the under part of the feet, near the margin. In this spot, however, the hairs are scanty, and they are entirely absent for a small space, over the so-called knees, and at the under and fore-part of the chest, where from constant pressure during the recumbent posture of the body, the cuticle acquires a horny consistency. These callosities are not present in the Llama.

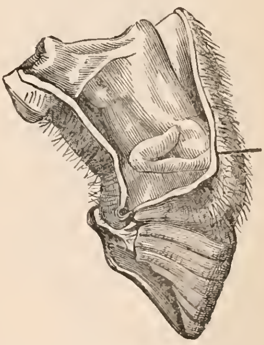
One of the most interesting anatomical features, forming a distinction between the two cameline genera, consists in the degree of organisation of the foot-pad and corneous investment of the toes. In the Camels, properly so called, the digits are more or less completely imbedded in the broad elastic cushion which extends for a considerable distance laterally on either side of the foot, binding and fixing the phalanges immoveably together; while at the same time it is particularly worthy of remark, that the hoofs are merely represented by two rudimentary nails situated on the dorsal surface of the tip of each toe. In the Llamas the sole-pad is double and narrow, each division being limited to one side of the cloven foot, while the nails, instead of being weak, are very powerfully developed, and strongly curved. In consequence, therefore, of the easy separation of the toes, combined with the modifications of the pad and hoof here referred to, it is at once evident that such a condition of the foot is peculiarly adapted to an animal whose life is destined to be spent, unlike that of his more highly valued congener, on the rugged slopes and precipices of a mountainous district.

In the solid-horned Ruminantia very important changes coexist with the shedding of the antlers. These organs occupied our attention when describing the anatomical relations and development of the horns; but, as some physiologists are disposed to regard them as part of the dermo-skeleton, we take this opportunity of reverting to the subject. If such a view as the one here mentioned be not supported by the mode of growth, it acquires nevertheless an appearance of consistency when we bear in mind that the annual shedding of the horns takes place contemporaneously with that of the hair. By others, this simultaneous loss of structure is regarded as a mere coincidence, affording no proof, they say, of the integumentary character of the cranial outgrowths, but rather indicating a special provision, for the explanation of which we are to look to another source. This argument is followed up by assuming that, were it not for the change alluded to, the young Deer would sustain injury from the *bucks*, which, at the period of the full evolution of the antlers, exhibit a destructive and relentless ferocity. After the loss of the offensive weapons, it is well known that their disposition acquires a milder habit. In furtherance of this view of the question we are likewise reminded that it is necessary to associate the persistency of the horns of the Giraffe with the equally well ascertained fact, that in this aberrant cervine genus, there is, as in Cervidæ proper, a periodical desquammation of the cuticle not affecting the hairy covering of the cranial epiphyses, and involving no subsequent alteration in the animal's psychical character, which, under ordinary influences, is proverbially gentle, and always the same.

In a former part of this article, reference has been made to the epidermic nature of the corneous investment of the bony cores in *cavicornua*, and the extension of it found prolonged over the frontal region in the Buffaloes, a tribe exhibiting an approach to the Pachydermata in many respects, and more especially in the organisation of the hide, which has a leathery consistence, and is scantily provided with stiff bristly hair.

In conclusion we may remark that the cloven condition of the hoof in the typical ruminant is evidently designed to impart lightness and elasticity to the spring; and, in order

Fig. 354.



Foot of the Sheep.

to give full effect to such an arrangement, many species are provided with a special glandular sebaceous follicle between the toes, whose office is to furnish a lubricating secretion, calculated to prevent injury from friction of the digits one against the other. *Fig.* 354. represents the position and dimensions of this organ in the Sheep. According to Sir Charles Bell there is yet another intention in this cloven form, viz., that of aiding the voluntary elevation of the foot when it has sunk deeply into soft ground. "We may observe," he says, "how much more easily the Cow withdraws her foot from the yielding margin of a river, than the Horse. The round and concave form of the Horse's foot is attended with a vacuum or suction as it is withdrawn; while the split and conical shaped hoof expands in sinking, and is easily extricated."*

Digestive System. — *Buccal Cavity.* — The lining mucous membrane of the oral cavity is very rough, being covered throughout with very prominent papillæ. At the roof of the mouth they have a flattened form, and are arranged in parallel rows, producing a series of ridges or bars, the margins of which are denticulated and directed backward. They are very conspicuous in the Camel, and in the Giraffe we have counted from fourteen to eighteen rows; the papillæ of the anterior ridges, however, lose much of their linear arrangement. Respecting the use of this peculiar grooved structure, Mr. John Zaglas appears to have offered a satisfactory solu- ion. Speaking of the action of the tongue during deglutition, he says, "I may here hazard the opinion, that the transverse rugæ on the palate of Man and the lower animals are intended, to a certain extent, for the support of the tongue in the act of elongating itself backwards. The varieties which they exhibit coincide with what would appear to be required in the relations of the tongue and oral cavity. In Man, in whom the alveolar process is perpendicular, they are slightly developed, and situated far forward. In the lower animals, in which the alveolar process is small or oblique, the rugæ are situated farther back, and are more fully marked, particularly in those which swallow bulky and comparatively rough morsels, as in the ruminants and solipeds."† The oral roof of the Giraffe is marked by an extensive deposit of leaden-coloured pigment, stretching from the alveolar margin to the centre of the palate; small isolated patches also occurring still farther back. A callous thickening of the gum occupies the place and supersedes the function of the non-developed intermaxillary incisives. The buccal papillæ attain their greatest size in the region of the cheek opposite the true molars. In this position they take on the character of horny spines, very like those seen in the œsophagus of the Turtle. They have either the form of simple elongated cones, or are aggregated together, and blended so as to present two, three, or even four points. This complicated disposition is well shown in the accompanying figure (*fig.* 355.) from the Camel; in

Fig. 355.

Buccal papillæ of the Bactrian Camel. (From F. Müller and Wedl.)

the Giraffe the longest spines, which are fully half an inch in length, give off secondary processes, thus resembling very closely the fungiform papillæ of the human tongue after the epithelial layer has been removed. Professor Owen is of opinion that the principal function of these organs consists in adjusting the bolus during mastication.

Teeth. — Consistent with the compound character of the ruminant stomach, a parallel complexity obtains in the structure of the teeth, at least, in those concerned in triturating the food.

In those families which have *incisives* in the lower jaw only, *these* exhibit simple trenchant crowns, which slant horizontally forward; and being opposed only by the hardened gum of the upper jaw, the function they perform during the act of feeding is rather that of breaking or tearing, than cutting. The action is accompanied by a swinging movement of the head forward, the powerful muscles inserted into the occiput along with the elastic ligamentum nuchæ, rendering such a motion almost effortless. In Œgosceridæ, Bovidæ, and Cervidæ generally, where the incisors form a broad line at the expanded tip of the lower jaw, the extent of their grasp is considerably increased by the prominent position of the *canines* on either side. These latter partake of the function ascribed to the former, and their aspect is so similar that many anatomists have been led into error respecting their true nature. In the Giraffe the canines present divided crowns, and are not placed so far in front; nevertheless, they are closely applied to the outer incisors, the whole series together forming a semicircle.

The characters of the *molar* teeth chiefly demand consideration in this place. These, though presenting every variety and modification of contour in the different families, manifest at the same time a certain uniformity of type throughout the entire order. A sin-

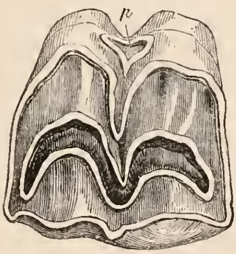
* Bridgewater Treatise, p. 92.

† Goodsir's Annals of Anatomy and Physiology, Part II. p. 122.

gle example will illustrate the points most deserving of attention.

The true molar tooth of the permanent series has a quadrilateral form, its outer and inner lateral surfaces being bounded by margins more or less convoluted. The crown in the young state presents four elevated cusps, which, by subsequent attrition, disappear. The ground surface, thus flattened, is marked in the centre by double crescent-shaped ridges of enamel, so disposed as to present, along with the central mass of *dentine* and external crust of *cementum*, alternate layers of hardened tissue, having different degrees of density. By such an arrangement it consequently follows that the enamel being the least affected by trituration, remains somewhat above the level of the other dental substances,—a condition highly favourable for the due performance of mastication, and one resulting in all cases from the vertical folding of the original formative capsule. The upper molars of certain individuals present an accessory island-shaped portion of enamel at the internal border, by which the extent of grinding surface becomes enlarged. This additional facet only makes its appearance in a tooth which has been employed for some time, as it depends upon the wearing down of a columnar fold which is developed at the side between the lobes, and which does not extend so high up as the summit of the crown in the unworn tooth; it is well seen in the Ox and Deer (*p*, *fig.* 356.)

Fig. 356.



Molar tooth of the Deer.
(From Owen's "Odontography.")

Tongue. — The lingual organ undergoes certain modifications, in accordance with the habits and kind of aliment on which the ruminant subsists. These peculiarities do not involve any material departure from the type of structure invariably found in other mammifers ; on the contrary, the muscular elements and their relations to surrounding parts remain nearly the same. The deviations of which we have to speak principally refer therefore, to the form of the organ and its epidermal covering. In Ruminantia, more than in almost any other order, the tongue is specially designed to fulfil the offices of prehension as well as deglutition, and it necessarily follows that the several portions of the machine destined to carry out such complicated functions, exhibit a corresponding complexity of development. Those regions, arbitrarily denominated by the anthropotomist the *root*, *body*, and *tip*, acquire great significance in this group of animals, being morphologically indicated on the dorsal aspect of the organ ; and they not only manifest a structural distinctiveness, but the functions over which they preside subserve different purposes. The anterior moiety is employed in collecting, and perhaps in some measure ascertaining the nature of the food ; the second aids in adjusting and preparing the morsel, but is more particularly concerned in thrusting the bolus backward into the œsophageal cavity ; while the third circumscribes and regulates the movements of the organ in its entirety, acting from the *point d'appui* of the hyoid bone (Zaglas).

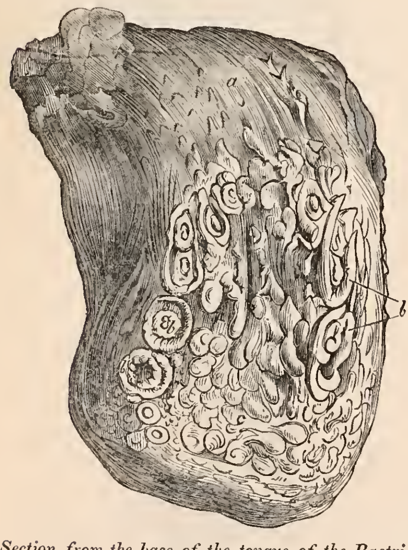
The surface of the tongue is armed with forms of papillæ similar to those of Man and other mammalia. Two kinds, namely, the simple *filiform* and *fungiform*, are conspicuous and very numerous on the dorsal aspect of the elongated prehensile portion in front, and two other varieties — the *conical* and *circumvallate* — occupy the dorsum towards the root, leaving the inter-molar region comparatively free. Of those papillæ at the fore part, the simple filiform are curved back-

Fig. 357.

Tongue of the Giraffe. (From Owen.)

ward, and are by far the most abundant of all these structures; they are very closely set together at the tip, and have a horny epidermal covering, approaching in this respect the rasp-like retroverted spines on the tongue of Carnivora. The *fungiform* or spherical gustatory papillæ are sparsely scattered here and there, but somewhat closely aggregated at the lingual margins. In the Giraffe, notwithstanding the deposition of a dark purple pigment which distinguishes the anterior half of the tongue, the last named papillæ present a very striking appearance, resembling so many small highly polished beads of a deep black colour. They are well shown in the annexed woodcut (*fig.* 357.). The conical papillæ situated behind and towards the root, may be grouped under the same category as the retroverted filiform spines seen in front; but as they proceed in the direction of the pharynx their conoidal character becomes obliterated, and they assume a more or less flattened oval or rounded form. The *papillæ circumvallatæ*, though not occurring in great numbers, are largely developed, and in the Camel exhibit a very complicated structure (Meckel); the middle projecting portion, instead of being smooth and single, is split up, as it were, into numerous finely serrated secondary filaments, leaving a small central depression unoccupied, while the elevated circumferential margin outside the circular fossa shows at the same time a tendency to subdivision (*b*, *b*, *fig.* 358). In the Giraffe

Fig. 358.



Section from the base of the tongue of the Bactrian Camel. (From F. Müller and Wedl.)

and Deer they offer a faint indication of the central dimple, but their character otherwise accords with the appearances usually presented.

The *muscles* of the tongue, as already hinted, display few marked deviations from the ordinary mammiferous type; nevertheless, the comparative glossologist recognises in these slight differences, points fraught with peculiar anatomical and physiological interest. To enunciate this speciality fully in all its bearings would demand more time and space than has been placed at our disposal, and it is not without regret that we are compelled to limit the exposition of so captivating a subject to the few following remarks, gathered in great measure from the monograph of Mr. Zaglas and the observations of Professor Owen on the tongue of the Giraffe. Fortunately, we have had an opportunity of confirming the previously recorded particulars concerning the lingual organisation of this remarkable animal, and in regard to the myological arrangements of the tongue in other ruminants, the writings of Cuvier, Blandin, and others, furnish some important details.*

The *styloglossus* rises from the lowermost extremity of the styloid bone, and extends along the under surface of the tongue as far as the tip, being separated only from the muscle of the opposite side by the interposed *genio-glossi*. It is powerfully developed in the Giraffe, and is confined in its position by strongly marked bands of muscular fibre directed outwards from the superior border of the genio-glossus (where that muscle dips into the medullary substance), to the marginal expansion of the lingual fascia investing the dorsum. This muscle is of small dimensions in the Camel. The *hyo-glossus* is a compound structure, its several portions differing only from those in man by being more distinct and widely separated; the division recognised as the *cerato-glossus* by the human anatomist is usually described as the *stylo-glossus minor* in the lower animals. The *genio-glossus* varies considerably in size, and is unconnected with any part of the hyoid apparatus (Blandin); ordinarily, the laminæ of each muscle are easily parted in consequence of the looseness of the interposed areolar substance as far as the mesial line, where the fibres begin to dovetail into one another. In Man the fasiculi are short and comparatively thick, but in the Deer and Camel the two muscles are thin and united anteriorly. These applied muscular laminæ are very strong, and have a great longitudinal extension in the Giraffe; posteriorly they admit of easy separation, but in front the fibres are intermixed, attenuated, and with difficulty isolated. In connection with this part of the subject it may be remarked that the researches of Mr. Zaglas have shown the septum (*linea albescens* of Caldani) or cartilago-lingualis to have no real existence in the Sheep, Deer, Calf, or Camel; and we may add that our own examinations prove that this structure is likewise absent in the Giraffe. The value of this observation is enhanced when we bear in mind, that in other mammals — the Carnivora more especially — this

* Blandin, Thèse Inaug. sur la Structure de la Langue de Bœuf; also, Mémoire, &c., Archiv. Gén., tom. i. 1823.

septal fibro-cartilaginous aponeurosis (which we take to be the homologue of the true lingual bone), is strongly indicated.

Much confusion has arisen in regard to the muscles constituting the cortex of the tongue. The general term lingualis has been applied to numerous muscular bundles situated on the dorsum immediately beneath the lingual fascia. According to Gerdy they may be arranged in four groups * ; of these the most superficial layer appears to be quite distinct from the rest, and on this account it has been separately described as an independent muscle by Bauer and Zaglas, the latter aptly designating it the *noto-glossus*. This superficial muscular mass spreads over the whole upper surface of the tongue; it apparently exists in all mammifera, being more highly developed in some than in others; it is feebly indicated in the Camel. Without accepting the following inference, we may remark that Dr. Mercer, in his "Anatomical Observations on the analogous Structure of the Lingualis and Panniculus Carnosus," endeavours to show that one of the principal offices of the lingualis is to erect the rasp-like papillæ; and it is evident that he only attributed this function to that portion of the muscle, since denominated the *noto-glossus*, for, he adds, "the first" layer of the lingualis, "which is the most conspicuous, can alone act on the surface of the tongue and its papillæ."† The fibres of the *lingualis*, properly so called, take their origin from the lingual margins near the root, and pass transversely or obliquely inwards to a point a little beyond the middle line; in the short-tongued quadrupeds and in Man the bundles reach as far forward as the tip, but in the ruminants their extension is comparatively limited. Respecting the disposition of the associated muscular filaments, collectively termed the *transversus*, considerable difference obtains in regard to what may be called the fibres of insertion. In the ruminant type, where no lingual septum is present, the fibres decussate with those of the opposite side, extending therefore beyond the mesial plane, while on the other hand, in Man and animals having a well-marked *linea albescens* — such as is seen in Carnivora — the fibres do not pass beyond the middle line, but are intimately united to the septum (Zaglas). The *perpendicularis externus* offers nothing remarkable, and the *glosso-palatinus* and *glosso-pharyngeus* have no existence in this order.

The distribution of the *vessels* and *nerves* of the tongue have the same general arrangement as in other Mammalia; but in consequence of the greater longitudinal development of the organ they exhibit a corresponding augmentation. Prof. Owen remarks a disparity of calibre affecting the lingual arteries of the Giraffe, that of the left side being paramount and anastamosing freely with the vessel of the right side as far as the commencement of the prehensile portion — judging from the lithographed representation appended to that distinguished anatomist's "Memoir." Our own specimen exhibits this peculiarity in a still more striking degree, the left vessel being — as compared with the right — a mere arterial twig. We have not found this vascular anomaly in the Cervidæ proper, neither is it present in other allied genera. The lingual *veins* in Camelopardalis are particularly broad and somewhat plexiform, and the nerves, in the retracted condition of the tongue, are beautifully tortuous.

The *salivary glands* are chiefly noticeable on account of their large dimensions and elongated excretory passages. The orifices of the Whartonian ducts, are visible at the anterior part of the mouth beneath the tongue, and in the Giraffe are protected by two small membranous valvular folds fringed with papillæ. The tonsils are bulky, and in the Camel communicate with the oral cavity by numerous canals, the apertures of which are surrounded by slight prominences of the mucous membrane. In Camelopardalis, the amygdala assume a higher type of structure, and open by a short common duct capable of admitting the tip of the little finger. There is yet another peculiarity in the faucial region of this aberrant cervine genus, arising out of the presence of a rudimentary uvula, which on close inspection we find to be made up of three minute papillæ, intimately conjoined at their bases.

The *œsophagus*, in accordance with its functional activity in this family, is thick and fleshy. It is surrounded by two distinct layers of muscular tissue — an outer and inner: the fibres of the former being transversely circular, those of the latter obliquely longitudinal. They have a deeper colour than obtains in the non-voluntary muscles, but do not exhibit any transverse striæ; in some particulars, however, microscopic investigation has shown them to resemble very closely the voluntary type (Owen).*

The ruminant *stomach* affords a striking illustration of the *special* evolution of a complex mechanism from the *general* or more simple type of structure, and to the mind of the unprejudiced truth-seeker it irresistibly indicates evidence of design; this train of reasoning is not weakened by the fact that two, if not three, of its divisions are essentially dilatations of the lower extremity of the œsophagus.

The first compartment or *Paunch* (*b, fig.* 359.) — otherwise called the *Rumen*, *Ingluvies*, or *Panse* — occupies a considerable proportion of the abdominal cavity. It is the largest of the four stomachs, and its general form is that of a square with rounded angles. Externally there are two well-

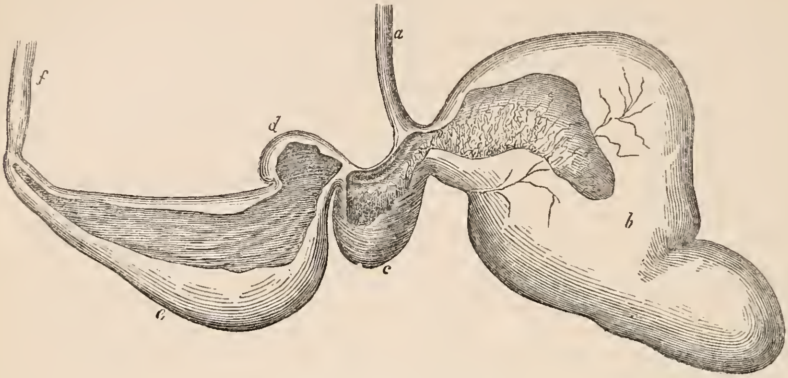
† Anatomical Observations, &c. Edinburgh, 1841.

* The sharks, which possess the power of ejecting their stomachal contents, have the muscular fibres of this viscus marked by transverse striæ. We have seen this in *Lamna cornubica*.

marked constrictions, corresponding to folds of the lining mucous membrane; and thus subdivided, the viscus resembles, as it were, an enormously distended coil of intestine bent into the figure of an italic *S*. In the typical species the internal surface is densely beset

Fig. 359.

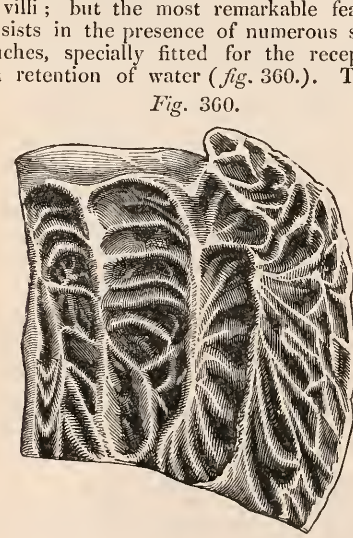


Composite stomach of the Sheep.

with villi; these give to the membrane a peculiarly rough aspect, and at different portions of the cavity their form is curiously modified. Usually they are remarkably prominent, pedunculated, more or less club-shaped and compressed; or they may be tapering and pyriform. In some localities their size is insignificant, and they almost disappear at the margins of the salient folds. In the Giraffe we find their dimensions strikingly uniform at one spot, while, in another region great irregularity in this respect is observable; the same remark holds good in other horned species, where the deviations from this type are too slight to merit a separate notice.

The organisation of the paunch in the Camelidæ differs very materially from that of the ordinary ruminant. Instead of presenting a rough internal surface, crowded with villosities, the mucous membrane is conspicuously smooth and entirely destitute of villi; but the most remarkable feature consists in the presence of numerous small pouches, specially fitted for the reception and retention of water (*fig.* 360.). These

Fig. 360.



Water-cells in the paunch of the Camel.

sacs, which may be looked upon as so many diverticula developed from the walls of the cavity, are arranged in two distinct groups — one on the right side and the other on the left; the former being by far the larger, and in the adult Dromedary measuring about one foot and a half in length, and six inches in breadth (Meckel). The cells of each batch are disposed in parallel rows, separated from one another by strong muscular bundles, given off from a single large band of fibres which commences at the cardiac extremity of the rumen, and proceeds in a longitudinal direction, dividing the entire cavity into two compartments. The muscular fasiculi are arranged transversely, and give off secondary bundles at tolerably regular intervals, so that the rounded orifices of each sacculus are guarded by powerful square-shaped muscular sphincters. Some of the cells are more complicated than others, being subdivided into numerous loculi by folds of the lining membrane. The largest of the reservoirs in the adult Dromedary, when dilated, have a depth and width of about three inches. In the Llamas the structure of this apparatus, though more feebly indicated, is very similar to that of the Camels, properly so called.

The second stomachal viscus (*c*, *fig.* 359),— otherwise called the *reticulum bonnet*, or *water-bag* — has a globular outline, — is of much smaller dimensions than the paunch, and forms a sort of cul-de-sac between it and the third cavity. It originates in common with the rumen, and like that organ may be regarded as a kind of hernial dilatation of the lower end of the œsophagus. By some it has been looked upon as a mere appendage to the former, being continuous with it at the upper and anterior part, and separated only by a projecting membranous fold, precisely similar to those met with in the first cavity. In the typical species it is distinguished internally by the presence of a multitude of acute-angled polygonal cells, and from this circumstance has been vulgarly denominated the *honey-comb-bag*. The cells are particularly shallow in the Rein-deer and Giraffe, being circumscribed by very narrow laminæ, scarcely elevated above the level of the mucous surface. The lining membrane is further characterised in the horned ruminants by a cuticular covering developing a great number of minute and sharply pointed conical papillæ, which occupy every part of the cavity, but are most prominently marked along the ridges of the laminæ, imparting to these folds a denticulated aspect. In the Camels and Llamas the honeycomb-cells acquire a form and capacity strictly analogous to the water-cells of the paunch; but there are some slight modifications of structure, apparently conformable with the more temporary or immediate purposes which they subserve. The apertures of the cells of the rumen — destined to retain water for a lengthened period — are narrow and guarded by productions of the lining membrane, while those of the reticulum, constantly parting with their aqueous contents during the ordinary act of rumination, are more patent, and not covered in by special membranous folds; moreover, in the distended condition of the cells, the external surface of the paunch is marked by a corresponding number of vesicular bulgings, but in the reticulum the walls remain smooth and do not exhibit any very evident traces of the contained water-cells; their internal subdivisions are likewise more numerous and complicated than in the rumen. Another distinction — already alluded to — between the typical and akeratophorous species, obtains in the absence of an internal cuticular epidermis in the bonnet of the Camelidæ. In all ruminants at the anterior border of the second stomach is situated a short demi-canal, constituting the remains of that portion of the œsophagus not involved in the great gastric dilatations, two of which we have now described. This elongated channel — very well shown in the accompanying woodcut, *fig.* 359., — forms a bond of communication between the gullet and the three first digestive cavities, and it is provided with an extension of the muscular tunics of the œsophagus, modified to suit its twofold office, to which we shall again have occasion to refer when speaking of the ruminating function in detail.

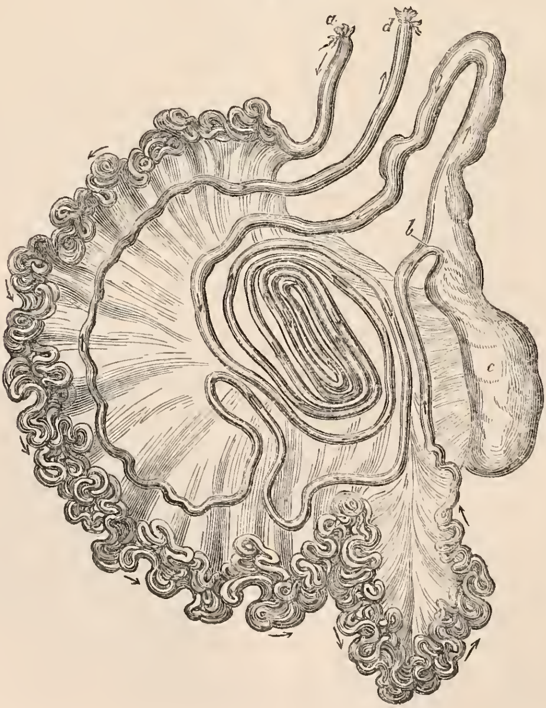
The third stomach (*d*, *fig.* 359.), commonly called the *Psalterium*, *Manyplies*, *Omasus* or *Feuillet*, intervenes between the water-bag and the fourth or true digestive cavity, communicating with the former by a constricted orifice and with the latter by a very wide opening. It is the smallest of the stomachal viscera, subglobular in form, and smooth externally; but the extent of its absorbing surface bears no relation to the diminished bulk of the organ, seeing that it is enormously increased by a remarkable folding of the internal lining membrane, the duplicatures of which resemble the leaves of a book, — hence the names above indicated. The laminæ are longitudinally disposed, and in the empty condition of the viscus are closely applied against each other. In breadth they exhibit proportionate differences, so that we find an alternating assemblage of laminæ presenting three several degrees of development; one, a very narrow fold, another, very broad, and a third of intermediate width, serially intercalated between the two. Altogether about forty such septa have been counted in the Sheep, and more than double that number in the Ox. The internal surface is beset throughout with small conical, pointed papillæ, similar to the villi of the reticulum, those placed at the free margins of the folds being paramount. In Camelidæ the psalterium is greatly elongated, attenuated at either extremity, and three or four times more bulky than the water-bag; otherwise, its organisation conforms with the peculiarities observable in the horned species.

The fourth stomach (*e*, *fig.* 359.), technically termed the *Reed*, *Abomasus*, or *Caillette*, constitutes the true digestive apparatus, analogous to the simple gastric organ of the non-ruminating vertebrata. It is about one third of the size of the paunch, and smooth externally, has an elongated pyramidal figure, and terminates by a narrow tubular portion at the pyloric extremity, the muscular tunics at this point acquiring a considerably increased thickness. Internally the secreting membrane is distinguished by irregularly disposed longitudinal folds, slightly elevated above the surface and intercommunicating by smaller rugæ of the same nature, having an oblique or transverse direction. There are no papillary eminences like those in the reticulum and manyplies, the lining membrane being soft, highly vascular, and occupied by the follicular openings of true gastric glands as in the human stomach. At the pylorus, in addition to the ordinary narrowing usually found at this part, there exists a special valvular process, developed from the mucous membrane at the commencement of the duodenum; in the Giraffe this protecting fold is situated just within the stomach (Owen). In the akeratophorous Ruminantia the reed is relatively smaller than in the horned species; in other respects it offers no appreciable difference.

The *ruminating function* is characterised by the following phenomena: — The food, on being received into the mouth, undergoes a very partial mastication, and in this crude state is speedily carried down the œsophagus, where, on arriving at the lower part, the lips of the muscular channel, placed at the entrance of the three first stomachs, separate, so as to ensure its passage into the paunch, In like manner, subsequent to the act of drinking, the margins of the œsophageal groove open, and the water is conveyed into the cells of the reticulum. In the Camels a proportion of the fluid passes into the first cavity, there to be retained by the great water-pouches, as a special provision against those contingencies which their mode of existence involves. While the coarse vegetable ingesta are being macerated by the moisture secreted from the walls of the rumen (and probably also from the water taken in by the mouth, some of which may have entered the cavity), portions of the indigestible mass are transmitted into the second stomach for further maceration, and from thence into the demi-canal, to be moulded into the form of pellets, and returned to the mouth by a kind of reversed peristaltic action. The softened bolus, thus brought back into the mouth, is destined to receive a thorough and deliberate remastication, and it is somewhat singular that this part of the process (called "chewing the cud") varies in different species. Professor Owen has the merit of showing that in the Cameline ruminants the bolus is triturated alternately from side to side, whereas, the action of the teeth in the horned Ruminantia, including the Giraffe, is always in *one* direction—it may be from right to left or left to right — occasioned by the rotatory motion of the jaw. The necessary reduction of the aliment having been accomplished, it is again transferred to the stomach in a pulpy semifluid condition; but this time, instead of entering the first or second cavities, it passes directly along the (now closed) œsophageal groove into the manyplies. Here, the superfluous moisture is supposed to be absorbed before it is ultimately transmitted into the fourth stomach, in which organ the true digestive act remains to be fulfilled. The first, second, and third stomachs are incompletely developed in the newly born individual, where no chewing of the cud taking place, the food passing directly into the fourth; in the Calf a peculiar organic acid is secreted by the lining membrane of the reed, which possesses the power of converting the albumen of milk into *curd* and *whey:* this, in the prepared condition, is termed *rennet.*

Concretions are frequently found in the paunch, and occasionally in the reticulum, composed of various substances, such as hair, vegetable tissues, or calcareous matter, having a more or less rounded figure. The balls, so common in the Calf and Cow, result from the licking of their own hides or that of others, — the hair thus collected being rolled into the characteristic shapes by a kind of felting process going on in the stomach; after a time they become coated with a dark earthy deposit of great hardness, the surface acquiring a considerable polish. Sometimes they have the form of compressed spheres, but are more usually barrel-shaped; their size is seldom larger than a cricket-ball. There is a specimen from the Cow in the Edinburgh University Anatomical Museum (presented by Dr. Mc Nab, of Jamaica), measuring eleven inches in length and twenty-nine in circumference. The fibrous concretions in the Camel consist of numerous small pedunculated pellets, strung together in botryoidal masses; at least, such is the form presented by those we have seen from a Dromedary dissected by Professor Goodsir. The formation of the so-called *Bezoar stones* in the stomach of the Chamois takes place in

Fig. 361.



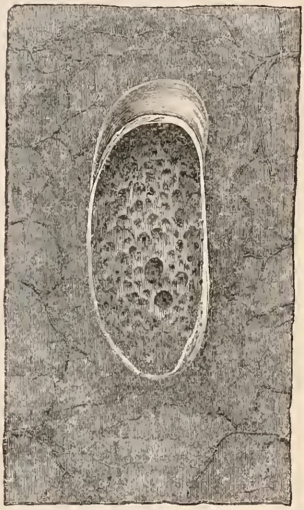
Intestines of the Sheep.

consequence of a partiality for saline matters, which the animal gratifies by licking portions of rock containing saltpetre; in this way, silicious and other earthy particles swallowed at the same time, accumulate and adhere together in the form of calculi.

The *intestinal tube* is remarkable for its length; in other respects its characters are for the most part extremely simple. Taking the Sheep as a type, we observe the descending or duodenal portion (*a*, *fig.* 361.) to be short and straight, but rather thicker than the remainder of the small intestine, which is twisted into a multitude of gyrations until within a short distance of its termination, where the convolutions cease, and the gut ascends in a direct line to join the colon (*b*, *fig.* 361.). The large intestine is scarcely broader than the small throughout the greater part of its extent; nevertheless, it is very much expanded at its commencement, and also a little dilated at the rectum (*d*, *fig.* 361.). The central mass of the colon folds itself into a series of double concentric circumvolutions, which are within one another, but not exactly on the same level, the inner coils being the most prominent; from this peculiar disposition it follows that the fœces are at first directed concentrically inwards and subsequently reversed excentrically outwards. The arrangement of the intestines in the Cameline ruminants differs little from the ordinary type: in the Llama the duodenum is enlarged at its origin, and further characterised by a short oval pouch, placed anterior to the first duplicature of the gut (Cuvier). The elongation of the digestive tube, as compared with the animals' length, from mouth to anus, may be reckoned, according to Meckel, as 12 to 1 in the Camels, Antelopes, and Deer; 22 to 1 in Oxen; and 28 to 1 in Sheep. The proportionate length of the large and small intestine also varies considerably; thus, while of equal length in Camelidæ, the smaller doubles that of the larger in Cervidæ, and is fully five times greater in Œgosceridæ, Antelopidæ, and Bovidæ (Meckel). The entire length of the intestinal canal in one of the Giraffes dissected by Prof. Owen, exceeded 134 feet. The *cæcum* (*e*, *fig.* 361.) is in all species bulky, and, like the colon, smooth and unprovided with lateral bulgings; its blind extremity is more or less obtuse, rounded, or club-shaped.

The *intestinal glands* in Ruminantia generally do not offer any deviation worthy of notice; in the Giraffe, however, we have discovered a curious exception to this rule, arising out of the presence of certain pouch-like folds in connection with the glandulæ agminatæ, and in particular with a very remarkable extension of the last Peyerian patch beyond the ileo-colic opening.* Probably more than one half of the entire series of agminated follicles exhibited this peculiarity, but in consequence of our having retained only some six or eight feet of the gut for minute examination, we are not in a position to state with accuracy either the total number or precise localization of *all* the glands (four of which were found) presenting this anomaly. In the small intestine the fold consists simply of a semilunar valve-like production of the mucous membrane, overlapping the anterior or duodenal end of each patch*, so as to leave a sort of cul-de-sac, the exposed or convex surface partaking of the ordinary villous texture, and the internal wall or concavity becoming follicular; it is conspicuous when distended, and leaves a fossa capable of admitting the tip of the little finger (*fig.* 362.).

Fig. 362.



Peyerian patch from the Giraffe, showing a valvular fold at one end. Natural size. (Original.)

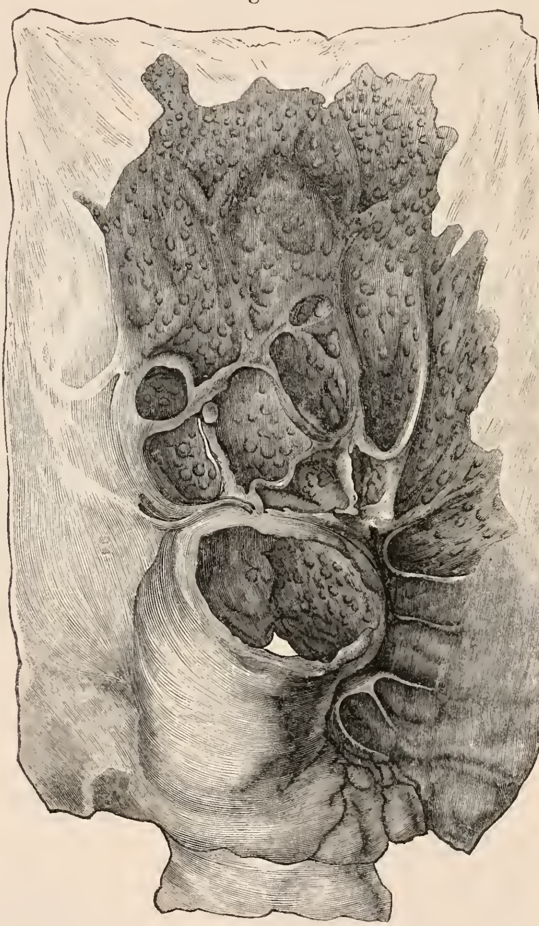
Far more striking and complicated is the pouched structure situated within the cœcal extremity of the colon (*fig.* 363.). Here, we have from fifteen to twenty sacculi combined to form a beautiful network of cells, seven of them resembling in many respects the water reservoirs of the reticulum, and having a depth which varies from three to four lines; the remainder are more or less incomplete, and those farthest from the ileo-colic orifice are mere depressions, the walls of separation being scarcely elevated from the surface. With the exception of two minute fossæ to the left of the valve, and three rather larger below, towards the cœcal extremity of the gut, the entire mucous membrane, both within and without the pouches, is beset with follicles having precisely the same character as those of the last Peyerian patch, of which indeed they are, in reality, a continuation;

* On a remarkable pouched condition of the *Glandulæ Peyerianæ* in the Giraffe. By T. Spencer Cobbold, M.D., Edin. Philosoph. Journal, New Series, vol. iii. 1856.

* Possibly the position here given is incorrect, as the intestine had been divided into sections before the structure was detected, rendering it difficult to decide this point with certainty.

for, not only do the follicles extend to the ileo-colic opening, but the intervening upper lip of the circular valve is likewise glandular. A few of the cavities are subdivided by secondary lamellæ, but generally speaking these are not very prominent. The larger folds, which contain muscular fibres of the non-voluntary kind, are extremely thin, transparent and extensile, so that the amount of secreting tissue is much greater than is at first sight apparent; in one example, to the left of the figure, the orifice of the saccule is much contracted, while the cavity on the other hand is particularly capacious. Altogether, without taking into consideration the laminated foldings, the follicles within the colon cover a space equal to about two square inches. We were unable to determine the length of the other division of the patch proper to the ileum, the intestine having been cut across too near the valve; its longitudinal extension may have been five or six inches; transversely, it occupied nearly the whole calibre of the tube.

Fig. 363.



Sacculated compound gland in connection with the ileo-colic valve of the Giraffe. Natural size. (Original.)

The *liver* is exceedingly simple, of small size, and wedge-shaped; it is thick at the anterior and right borders, and very thin at the lower or posterior margin. The lateral lobes are only indicated by a slight fissure at the entrance of the suspensory ligament, dividing the gland into two unequal halves,— that of the right being paramount and frequently developing a minute lobular appendage posteriorly. In the Giraffe it is elongated, compressed, and slightly cleft, so as to indicate a bilobular tendency: on the under surface there is an elevation corresponding to the lobus spigelii, the outer edge of which is particularly conspicuous. The entire gland in the Edinburgh specimen weighed only five pounds and six ounces, and measured in the long diameter sixteen inches — nine transversely, and but two and a half in thickness. The Camels have the under surface and inferior border characterised by a multitude of polygonal lobules, which are minute and varying in size, but circumscribed by rather deep grooves. This family, in common with the Cervidæ proper, is further distinguished by the absence of a gall-bladder, whereas the hollow-horned Ruminantia invariably possess this structure. In connection with this subject, Prof. Owen has pointed out a most curious anomaly in the aberrant cervine genus Camelopardalis. Out of three individuals anatomised by him, and a single specimen by ourselves, in one instance only has there been found a bile-cyst — a circumstance serving to illustrate a feeble alliance with the Antelopidæ on the one hand, and a near approach to the Cervidæ and Camelidæ on the other. The gall-bladder, discovered by Prof. Owen, occurred in a female Giraffe; it was bifid at the fundus, and exhibited several peculiarities which he has thus described.* "It was at-

Fig. 364.

Double gall-bladder of the Giraffe. (From Owen.)

tached in the usual manner and situation to the under part of the liver, having a covering of peritoneum over three-fourths of its surface. It measured three inches in length, and two inches in diameter. On making a longitudinal incision down one side of this apparently single gall-bladder, it was seen to be divided throughout its length by a middle vertical *septum*. Further dissection of this septum showed that the gall-bladder in fact was double, and that the two reservoirs of equal size were connected together, side by side, by means of a common investment of serous membrane. The lining membrane of each bladder was smooth; they communicated separately with the commencement of a single cystic duct, the terminal orifices admitting freely the blunt end of a common probe, and being protected by a valvular fold."

* Memoir, *l. c.* p. 228.

The hepatic duct attains an enormous size in the Sheep, and in this animal as also in the Ox and Goat, the common *ductus choledicus* enters the duodenum about twelve inches from the pylorus. The opening is a little less than eight inches distant from the stomachal orifice in the Camel, — and in the Llama, Deer, and Antelope, is situated quite close to the valve (Cuvier, Meckel).

The *pancreas* is somewhat bilobed, and, like the liver and spleen, comparatively insignificant. The excretory canal is spacious in the Sheep, and unites with the common duct of the liver about two inches from the duodenal communication; its junction takes place rather closer to the gut in the Camel. These passages are separate in the Ox, and sometimes leave a considerable interspace between their duodenal terminations.

The *spleen* usually presents a flattened oval or rounded figure; in its normal position it is applied against the left side of the paunch, and has about one-sixth of the weight of the liver. In the Llama its form is semilunar, and it is particularly narrow in the Antelopes, Deer, and Giraffe. On making a section through the spleen of the Ox, the malpighian corpuscles are seen to be remarkably large and conspicuous.

Organs of circulation.—The *heart* of the ruminant as in other mammifera, lies parallel with the sternum near the middle line. Its capacity corresponds with the large bulk of the herbivorous quadruped, but the auricles are relatively small as compared with the ventricles; this feature is more noticeable in Cervidæ, and in the Giraffe, where the organ in its entirety is rather more elongated than in the Camels. One of the most striking peculiarities possessed by certain species of this order, in common with many other animals, such as the Hog, Elephant, and Horse, — consists in the presence of one or sometimes two small ossifications situated in the *septum ventriculorum* at the root of the aorta; these so-called "bones of the heart" are flattened, more or less curved or cruciform, and generally speaking they are less strongly developed in the female; in the Giraffe this bone is about two-thirds of an inch in length (Owen). The distribution of the great vessels proceeding from the base of the heart resembles for the most part that of the human subject, but the *aorta*, as in Pachydermata, divides close to its origin into two unequal trunks, the smaller passing forwards and representing the *arteria innominata*, and the larger curving backwards to supply the place of the descending trunk. The ascending vessel gives off the *subclavian* artery much nearer to the heart in Solipeda than in the Ruminants (Meckel). In the Bactrian Camel the subclavian is not quite so far distant as in the Horse, while in the Dromedary this division leaves the *innominata* within two lines from its insertion into the heart (Daubenton). The deviations of the *vertebral* were indicated when describing the characters of the cervical vertebra in the different genera. The thyroid body is supplied by the *inferior thyroideal* only, the *superior* being distributed to the larynx. In the fore-limb, a vascular twig, corresponding to the *interosseous artery*, is present both in the Ruminants and Solipeda; it is very voluminous in the former, and but faintly marked in the latter. The *common carotids* are remarkable for their length in certain individuals; the most interesting peculiarity, however, obtains in the presence of numerous anastomising branches given off by, and tortuously inter-communicating between the internal carotids. It is this plexus which has been long known under the name of *rete mirabile*, being situated within the cavernous sinus on either side of the sella turcica, and occasionally extending backwards to join the vertebral artery. Similar appearances are found in Carnivora, and in Cetacea where they are are not confined to the region of the cranium; many other anomalies of the same kind occur in other families, the most striking being seen in the Sloth, where the *brachials* and *femorals* are split up, as it were, into numerous hair-like capillaries. The *spermatic artery* is exceedingly large in the Bull and twisted into a multitude of convolutions. In regard to the *venous system* of ruminants we have only to remark that, according to Weigel, valves are developed in the *portal vein.**

Organs of respiration. — The structural modifications observable in this system depart so slightly from the ordinary mammiferous type as scarcely to call for a separate notice. The organisation of the *larynx* is simple, its anterior ligaments and ventricles being absent; in many species the thyroid cartilage is comparatively narrow. The tracheal rings are for the most part incomplete, and vary numerically in accordance with the length of the neck. According to Meckel there are fifty in Moschus; sixty in the Stag; seventy in the Chamois, Ox, and Sheep; eighty in the Llama; and upwards of a hundred in the Dromedary. We have counted ninety-two in the Giraffe, where the length of the trachea is between four and five feet; in this genus the epiglottis is short and thick, and the arytenoid cartilages are remarkably large and prominent, as in Ruminantia generally. Occasionally there are three primary bronchial subdivisions; when the trachea is simply bifurcated, the right bronchus is paramount. Most ruminants have the lung of the right side separated into four lobes, and the left into two; in the Camel the right pulmonary organ is double, while the left is single, and exhibits no subdivision. The *thymus gland* is extensively developed in this order and prolonged forward on either side of the trachea.

Nervous system. — The *brain* is elongated, and more or less oval-shaped; it is narrowed anteriorly in the Sheep, and somewhat abrupt in this direction in Cervidæ (*fig.* 365.). Con-

Fig. 365.

Brain of the Giraffe. (From Owen.)

sidered in reference to the bulk of the animal the brain is significantly small in this order, as in Pachydermata and Solipeda. Its weight in the Ox is only one-fourth of the human brain, although the body of the former is six times larger than that of the latter; virtually, therefore, the brain in Man is twenty-four times greater than in the Ox (Monro). The proportionate weight of the cerebrum as compared with the *cerebellum* and *medulla oblongata*, is likewise less considerable in ruminants generally than in the human subject. The cerebral convolutions are numerous and tolerably

* Weigel, de strato musc. tunicæ venarum mediæ, etc., p. 31. Leips. 1823.

symmetrical as in the Horse; the cerebellum is divided into several irregularly disposed lobules of variable size.* The base of the brain is more flattened than in Man. In the Giraffe the cerebrum lies on the same level as the cerebellum, and does not overlap it (*fig.* 365.). The anterior pair of the *corpora quadrigemina* are paramount in most if not in all the species. The *corpora mammilaria* are of considerable size. The lateral ventricles intercommunicate. All the nerves at the base of the cerebrum are conspicuously large, especially the olfactories, which form broad bulbous expansions in front, where they are applied to the cribriform plates of the ethmoid bone. The *spinal chord* and *nerves* are chiefly remarkable for their length in certain genera; in the Giraffe the filaments entering into the composition of the anterior and posterior nervous roots of the chord, are widely separated from one another at their origins.

Organ of vision. — In common with many other quadrupeds, ruminants are provided with an *Harderian gland;* it is situated at the inner angle of the eye, and opens by a single duct behind the so-called *membrana nictitans* or third eyelid. The *glandulæ lacrymales* are lobulated. The eyeballs are placed wide apart, and are particularly prominent in Camelidæ and in the Giraffe, enabling these animals to look straight in a backward direction without turning the head. The pupillary aperture is oblong transversely, as in Cetacea and Solipeda, the latter family having flocculent masses developed from the *uvea* which project into the anterior chamber. The most striking feature of the ruminant eyeball arises from the presence of a *tapetum*, provided with an extremely brilliant metallic lustre, varying in tints of yellow, green, blue, violet, and purple.

Organ of hearing. — The essential part of the auditory apparatus is similar in construction throughout the entire mammiferous series; but the external auricular appendages are largely developed in Ruminantia, and moved by a numerous and complicated set of muscles: these have already been referred to. Internally, a small sessamoid bone is sometimes found in connection with the stapedius muscle of the Ox. In ruminants generally, the *cochlea* scarcely exhibits the same amount of turning as in man, the number of coils being rather less than two and a half; in the Chamois only two whorls are present. Minor differences exist in the form of the semicircular canals; in the Camelidæ and Capreæ their curvature is elliptical, and in Antelopidæ it forms the segment of a spiral; in Solipeda the curve is parabolic. In the first of these families the canals are particularly spacious. The *tympanum* in Bovidæ is irregular in form, and made up of numerous cells; — these are absent in Œgosceridæ, where the cavity is farther distinguished by its capaciousness.

Organ of smell. — The olfactory sense is very highly developed in the present family, but the organic modifications are unimportant, except in so far as they refer to a corresponding structural increase. An interesting and special provision, however, is formed in the Camel for the protection of the schneiderian membrane from the injurious effects of the *tornado*, during which, particles of sand are driven along the deserts with great violence; the nasal aperture instead of being patent, assumes the form of a narrow cleft, and to ensure its temporary closure, a subcutaneous sphincter muscle is placed at the entrance, subject to the control of the animal's will; under ordinary circumstances the nostril is well guarded with stiff bristly hairs. The openings of the cribriform lamellæ of the os ethmoides are particularly large, and the inferior turbinated bones are enormously developed and folded longitudinally into several gyrations. In most species the nasal, maxillary, and other cranial sinuses are very extensive.

Urinary organs. — The only peculiarities worthy of remark under this head have reference to the imperfectly lobulated character of the kidneys in Bovidæ, and the large size of the urinary bladder in ruminants generally, the latter feature being a characteristic of all herbivorous quadrupeds. The glandular bodies situated towards the inner side of the renal organs are more or less oval and elongated.

Reproductive system. — The *male sexual organs* exhibit few departures from the ordinary mammiferous type. The *testes*, as in Solipeda and Man, are enclosed within a scrotum, which is pendulous, and divided by a thin cellular septum. The gland itself is invariably egg-shaped, its longitudinal extension being considerably increased by the projecting *epididymis* above and the *globus major* below. It is more significantly characterised by the presence of a *corpus highmorianum*, which is essentially a production of the *tunica albuginea*, traversing the organ lengthways, and giving off numerous aponeurotic bands, — the latter radiating inwards between the seminal tubes and separating them into lobular bundles. The *tunica vaginalis* is continuous with the abdominal cavity. The *vesiculæ seminales* are largely developed, and exhibit two lateral horns which have a globular form in Œgosceridæ and Cervidæ. These lobes are by some described as *prostatic;* but others regard a narrow glandular layer, lying immediately in front of the above, as the representative of the last-named structure. In the Ram the *vasa deferentia* unite near

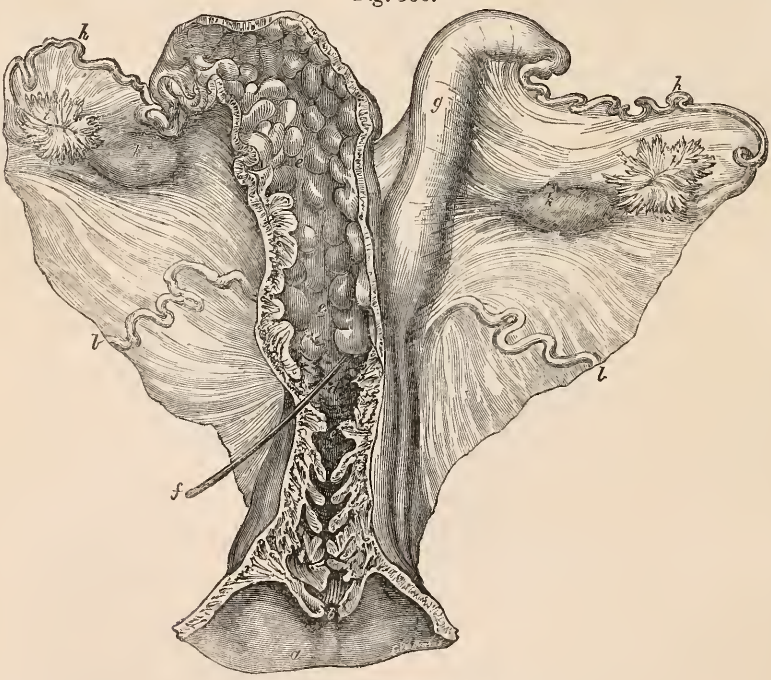
* The design and scope of the present article forbid our entering minutely upon the Comparative Anatomy of the Brain and some other organs of special interest. We cannot, however, quit this part of our subject without referring to the important Memoirs of M. Camille Dareste, in the *Ann. des Sc. Nat.*, on the "Convolutions of the Brain in Mammifera," and more particularly to his third Memoir (No. 2., tom. iii., série iv.). In this paper M. Dareste shows that the complicated arrangements exhibited by these organs in the different ruminant families, may be all reduced to a simple type,—and this typical condition he has beautifully illustrated (in his second Memoir) by a description of the actual appearances found in the brain of the Javanese Musk.

their terminations to form a single common duct. The *glands of Cowper*, placed behind the urethral bulb are rounded and conspicuous. The *penis* is long and usually bent upon itself, in the form of the letter *s* a little anterior to the bulb. In some genera the *glans* is apparently very small in consequence of its attenuation, as in the bull. In all cases the canal of the urethra ends in front by an extremely narrow whip-like process of the *corpus spongiosum*, reminding us of the modifications of this organ in certain mollusks. The *prepuce* is prolonged forward in the form of an elastic sheath, which in the Giraffe is so closely adherent to the bulbous root of the glans, as to be with difficulty separated ; by putting the parts a little on the stretch, we have found the reflection fully two inches posterior to the glans. Preputial follicles abound in the Antelopes and Cervidæ, and in the Musk-deer there is a special glandular pouch communicating with the cavity of the prepuce by a single duct ; it is from this structure that the substance *musk* is derived.

Female organs. — Generally speaking the *ovaria* (*k*, *fig.* 366.) and *fallopian tubes* (*h*) have the same relation to each other as in other mammifera, but differences exist in regard to the connection of these parts with the broad ligaments in the cameline and horned ruminants severally. They have been indicated by Prof. Owen as follows.* — " In the Camel the greater part of the *capsula ovarii* is formed by the expanded fimbriated aperture of the oviduct itself, which is of very large size, and which encloses the ovarium, In Deer, Antelopes, and Cows, the ovarium is lodged in a depression or *sacculus* of the broad ligament, which is more or less deep, and has its apertures more or less contracted in different species. In the Giraffe the *peritoneal sacculus* of the ovary, formed by an expansion of the broad ligament of the uterus, is wide and deep, and encloses almost the whole of the ovary. The fimbriated extremity of each oviduct, or fallopian tube, is expanded upon the outer margin of the ovarian capsule. The inner surface of the pavilion is beset with very numerous and fine oblique *striæ*, and is further increased by narrow folds of *laminæ* converging towards the contracted opening duct. The oviduct forms three or four wavy folds, and is then continued along the walls of the wide *ovarian capsule* to the extremity of the uterine horn, which makes an abrupt curve to meet it."

In all ruminants, as in Solipeda and several other mammalian orders, the cavity of the uterus (*a*, *fig.* 366.) is prolonged superiorly

Fig. 366.



Uterus and its appendages, from the Sheep.

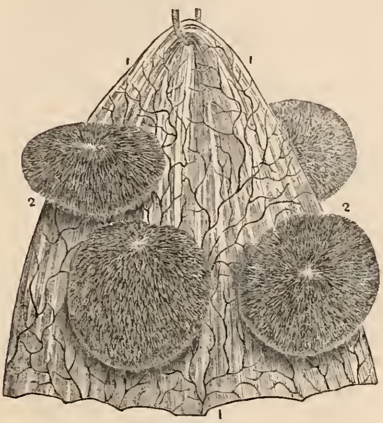
into two horns from the inner surface of which project a number of glandular protuberances (*e*, *e*, *fig.*366.). These processes are highly vascular, and exhibit eminences and follicular depressions for the implantation of the tufted filaments of the *cotyledons* or *placentulæ*. In the Camels, where the ovum is nourished, as in the Mare and Sow, by a villous chorion universally adherent to the uterine walls, these processes are not pre-

* Memoir, *l. c.* p. 241.

sent. In the typical species, numerous transverse and prominent rugæ are developed internally at the lower part of the uterine cavity; they are somewhat irregularly disposed in parallel rows, and are more crowded together towards the *os tincæ*, where they are split up, as it were, into fine longitudinal lamellæ, imparting to the *os*, when viewed from below, a peculiar radiated aspect. This latter feature is very striking in the Camels and in the Giraffe. The vaginal mucous membrane (*a*) is smooth throughout, and contracted inferiorly at the external orifice. In horned Ruminantia the *clitoris* is placed just within the *vulva*, but external to the vaginal outlet in the Camelidæ (Owen). Preputial follicles also occur in the female ruminant as well as Cowperian glands, which are situated near the root of the clitoris.

In the *gravid uterus* of the typical species, the fœtal membranes — consisting of the *chorion* (1, *fig.* 367.), *amnion*, and *allantois* —

Fig. 367.



Portion of the chorion of a Cow, showing the cotyledons. (*From Gurlt.*)

are connected to the walls of the cavity by numerous small *placentulæ* or *cotyledons* (2, *fig.* 367.), which embrace and dove-tail with a corresponding series of processes developed from the uterus. The cotyledons are productions of the chorion, and have an oval or rounded shape, more or less compressed, the exposed surface being usually cup-shaped; after the expulsion of the fœtus these bodies come away with the membranes, and the uterine protuberances diminish considerably in size. In the Sheep and Cow the number of the placentulæ varies from about seventy to a hundred. Like the *chorion*, the *amnion* is highly vascular. The *allantois* exists in the form of a closed sac, and only partially covers the amnion. In the Cameline ruminants the ovum is retained in situ by a universally adherent villous chorion, such as is found in Solipeda and Pachydermata.

The *mammary glands* are situated in the inguinal region between the thighs; the *teats* are four in number, except in Œgosceridæ, where there are only two. Rudimentary nipples are occasionally found in the male on either side of the scrotum; in the Horse they exist on the sheath of the penis.

UTERUS AND ITS APPENDAGES.

—The reproductive organs in woman consist of the Ovaries, Fallopian Tubes or Oviducts, Uterus, Vagina, and Vulva. These are commonly subdivided into the *formative* and *copulative* organs. To the first division belong the ovaries, Fallopian tubes, and uterus; to the second the vulva; while the vagina, on account of its offices in copulation and in labour, may be regarded as common to both.

This division nearly corresponds with another and more artificial arrangement, by which these parts are subdivided into the internal and external generative organs; those being regarded as internal which are protected within the body and concealed from view, while those which can be easily seen are termed external: the line of demarcation being here at the entrance to the vagina.

Of the several organs just enumerated, the uterus has doubtless, on many accounts, prior claim to attention. It is the largest of these parts. It is that which contributes the greatest amount of material to the new organism which it contains and protects. It is that part in which alone a direct connection of attachment subsists between the fruit and the parent. Its functions, so far as they contribute to each individual act of reproduction, are exercised for much longer periods of time than those of any other portion of the generative apparatus. It exerts a powerful reflex influence, especially during pregnancy, upon other parts and organs. The diseases and accidents to which it is liable are more numerous, and are attended by greater danger to life than those which affect any other portions of these structures, whilst its several morbid states, as well as its natural condition, may be ascertained during life with a degree of precision which virtually removes the uterus from the category of internal parts.

But it is only in a practical or obstetric point of view that the uterus can be regarded as the most important of the generative organs. Physiologically considered, it is by no means entitled to the foremost place; for although the presence of the uterus is necessary to the completion of the generative act in its regular course, yet reproduction to a certain extent may be accomplished without it. The uterus is necessary to reproduction, first, as affording the only channel by which the seminal fluid can obtain access to the ovum; and next, as constituting, together with the vagina, the only natural passage for the exit of the fully matured ovum, which requires this contractile organ to effect its expulsion by that passage: such expulsion not being essential to the generative act because the fœtus may be extracted by the Cæsarean section without necessary loss of life either of the parent or offspring, while other parts—the Fallopian tubes for example—may, to a certain extent, perform the offices of a uterus in all that relates to the protection and nutrition of the ovum. Moreover, the entire removal of the uterus may have no other effect upon the individual than that of preventing impregnation and menstruation by the simple abstraction of the parts necessary thereto.

On the other hand, the ovary, though constituting only a small portion of the reproductive organs, is nevertheless that part to which all the rest are subservient. It is the organ which furnishes the generative element essential to the reproductive act. It is that part which, in a great measure, regulates the growth of the body, and determines the distinctive characters of the sex. It is the organ upon the presence of which depends the sexual passion and the process of menstruation; whose congenital deficiency is indicated by the absence externally of all signs of a secondary sexual character; whose artificial removal entirely unsexes the individual, and the decline of whose functional activity, as age advances, is the cause of the generative faculty being lost in the female long before the ordinary term of life has expired, and at

Fig. 368.

Uterus and appendages of an adult virgin, posterior aspect. (*Ad Nat.*)

a, uterus; *bb*, ovary; *cc*, Fallopian tube or oviduct; *dd*, fimbriated extremity or infundibulum of the tube; *ee*, terminal bulb of the duct of Müller; *ff*, portion of broad ligament and blood-vessels; *g*, vaginal portion of cervix uteri; *h*, os uteri externum; *i*, anterior and *l*, posterior wall of vagina; *m*, ligamentum ovarii; *n*, tubo-ovarian ligament.

a much earlier period than that at which the power of procreation ceases in the other sex.

In a physiological sense, therefore, the uterus, as well as every other part of the generative apparatus, must be regarded as an appendage of the ovary; and the title "Uterus and its Appendages" is employed, in accordance with ordinary usage only, as the heading of this Article, in which it is proposed to consider the structure and functions of the entire female generative organs as they exist in Man.*

OVARY.

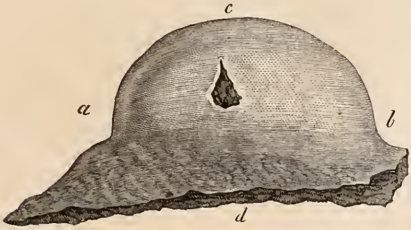
NORMAL ANATOMY.

(SYN. *Ovarium*, *Testis Muliebris*, Lat.; *Ovaja*, Ital.; *Ovaire*, Fr.; *Eierstock*, Germ.; *Eijerstok*, Dutch.)

The ovaries (*fig.* 368. *b*, *b*) constitute two follicular glands appropriated to the formation of the female generative element. They are perfectly closed, resembling in this respect the ductless glands. Each, however, is furnished with its proper excretory duct, (*fig.* 368. *c*, *c*) between which and the gland a temporary connection is established, at certain intervals, during that period of life over which the reproductive faculty extends.

Form. — The ovary is not usually fully developed until some time after the establishment of puberty. It is then of an oval form

Fig. 369.



Ovary of a young adult virgin before the surface has become scarred by repeated discharges of ova. (*Ad Nat.*)

a, distal, and *b*, proximal extremity; *c*, superior, and *d*, inferior border. In the centre is laid open a Graafian follicle from which an ovum had recently escaped by spontaneous rupture.

(*fig.* 368. *b*, and *fig.* 369.), flattened on its sides, and somewhat resembling the testis in figure, but rarely or never, in a state of health, attaining to the full size of that organ.

The following division may be made of its superficies: viz., into two sides, situated anteriorly and posteriorly with regard to the body; two extremities, outer and inner; and two borders, superior and inferior.

Of the two sides, that which is directed anteriorly (*fig.* 370. *e*) is both shorter and less

Fig. 370.

Vertical section of ovary. (*Ad Nat.*)

The posterior surface, *f*, more rounded than the anterior, *e*; at *h* are numerous blood-vessels divided; *gg*, Graafian vesicles; *d*, place of entrance of vessels between the layers of the broad ligament.

convex than the posterior, which is generally rounded and gibbous (*fig.* 370. *f*). In this respect the ovary resembles the uterus, whose posterior surface is always more rounded than the anterior; by attention to this peculiarity the right ovary may be readily distinguished from the left after these organs have been detached from the uterus.

Of the two extremities, the outer or distal (*fig.* 369. and *fig.* 372. *a*) is usually rounded and bulbous, whilst the inner (*figs.* 369. and 372. *b*) becomes gradually attenuated until its outline is merged in the proper ligament (*fig.* 368. *m*) by which the ovary is attached to the uterus. The upper and lower borders also differ from each other. The former (*fig.* 369. *c*) is convex, and forms a segment of a circle, whose diameter is continually diminishing as age advances. The latter is straight or slightly concave, constituting the base of the ovary, or the line by which it is connected to the posterior duplicature of the broad ligament (*figs.* 369. and 370. *d*).

Dimensions and Weight. — The ovary of a healthy adult measures from 1″ to 2″ in length, from 6‴ to 12‴ in depth or perpendicular diameter, and from 3‴ to 6‴ in width or transverse diameter.

These dimensions, which vary considerably in different individuals, exhibit a much wider range when the observations are extended to different epochs of life. The organ is then found to undergo far more remarkable changes in bulk and figure than are observable in the corresponding male organ.

The following table, giving the highest, lowest, and mean dimensions of twelve healthy ovaries, taken indiscriminately from women in various conditions during the period of fertility, will serve to exemplify the first of these variations: —

* For the comparative anatomy, as well as for the general treatment of the subject of generation, the reader is referred to the articles, GENERATION, ORGANS OF; GENERATION; and to those descriptive of the different classes and orders of the animal kingdom throughout this Cyclopædia. The occasional introduction here of illustrations from comparative anatomy and physiology is employed for the purpose of elucidating those questions which cannot be clearly explained by observations made only upon the human subject.

	Longitudinal.	Perpendicular.	Transverse.
Highest	2″	1″ 1‴	6‴
Lowest	1″	6‴	3‴
Mean	1″ 4‴	9‴	4½‴

Another and more accurate method of estimating the bulk of the ovary consists in weighing. The following are the extreme and mean weights of five ovaries taken from healthy adults: viz., greatest weight, 135 grs.; least, 60 grs.; mean (of five examples), 87 grs. On comparison of these results with Krause's estimate of the weight of the testis, which gives the mean weight of the male organ, also in five instances, as 354·4 grs.*, it appears that the ovary, though furnishing the larger portion of the generative element in the act of reproduction, has an average bulk of less than one quarter of that of the corresponding male gland.

Position and Connections.— The ovary is so intimately connected with the uterus, in whose changes of position, both normal and abnormal, it necessarily takes part, that it cannot be said to have any fixed or definite seat. It is most commonly found lying somewhat deeply in the lateral and posterior part of the cavity of the true pelvis, concealed from view by the small intestines, and in part covered by the Fallopian tube of the same side. Relatively to the uterus, the ovary is placed on either side of that organ, at a distance varying from 4‴ to 18‴, and behind and a little below the level of the point of entrance of the Fallopian tubes (*fig.* 368.).

Each ovary is invested by a layer of peritoneum derived from the posterior lamina of the broad ligament, to which the ovary is thus attached by a kind of mesentery.

Besides this indirect connection with the uterus, through the intervention of the broad ligament, the ovary has also another and more direct attachment by the aid of its own proper ligament (*ligamentum ovarii*), which serves to bind it more securely to the uterus. (*Fig.* 368. *m*.)

The ovary is further connected at its outer extremity to the mouth of the Fallopian tube by one of the processes of the pavilion, which serves to keep the organ always in close proximity to its excretory duct (*fig.* 368. *n*).

The distance which intervenes between the ovary and the uterus varies considerably on each side, not only in different individuals, but also in the same subject, where it is very rarely found to be equal; the right ovary, so far as my observations have gone, being farther removed than the left in the proportion of nine out of twelve instances.

During pregnancy, the ovary suffers frequent changes of position. As the uterus expands, it carries the ovary along with it into the abdominal cavity, at the same time the relative situation of these parts is materially altered, the fundus uteri gradually expanding and rising above the former level of the ovaries, whilst the latter appear to be bound down more closely to the side of the uterus, until at term their position is usually found to be below the centre of that organ.

Component Parts. — The ovary is composed of, 1st, protecting parts, or tunics; 2nd, a parenchyma, or stroma, in which are imbedded; 3rd, the proper secreting structures, in the form of closed sacs or vesicles, containing the ova; 4th, vessels and nerves.

1. *The Protecting Parts or Tunics.*—These are two in number, and correspond precisely, both in structure and derivation, with the analogous coverings of the testis.

The peritoneal covering (*fig.* 371. A) constitutes the outermost of these coats, and consists of the layer of peritoneum derived from the posterior lamina of the broad ligament, which serves to connect the ovary with the parts adjacent. Except at its base, the ovary is so closely invested by this peritoneal lamina, that no effort with the scalpel will suffice to detach it from the tunic beneath. This intimate union, however, of the two coats ceases at the base of the ovary, where a white, irregular, and somewhat elevated line is observed on either side, extending in a horizontal direction, and rising higher on the anterior than on the posterior surface of the gland. In its intimate texture, this covering of the ovary differs in no respect from the peritoneum covering the viscera generally.

The tunica albuginea, or *tunica propria*, (*fig.* 371. BB) constitutes the special or proper covering of the ovary. It serves to give form and solidity to the organ, and to protect the ovisacs and ova from injury. This coat has a nearly uniform thickness of ⅓‴, and forms a complete investment for the ovary, except at its lower border, where the fibres are either very thinly scattered and interlaced, or are altogether wanting, leaving a longitudinal space, termed the hilum or vascular fissure, by which the vessels and nerves enter the organ. This space measures 3‴—4‴ in width, and extends along the entire base of the ovary.

The tunica albuginea has been commonly regarded as a more condensed portion of the stroma, or parenchyma, of the ovary; but from this it is readily distinguished, not only by its clear white colour, and dense and almost cartilaginous hardness, but also by its microscopic characters. On account of its extreme toughness, this tunic is not very easily separable into fragments sufficiently minute for microscopic examination. But when small portions have been so obtained, the margins of the fragments exhibit numerous close-lying and irregularly arranged fibres of developed connective tissue, projecting from a dense, structureless matrix interspersed with granules, which serves to connect the fibres together, and to which apparently is due, in a great measure, the peculiar toughness of this membrane, while its remarkable whiteness is

* See art. Testis, Vol. IV. p. 976.

explained by the much smaller number of blood-vessels that it contains, as compared with the general parenchyma of the ovary. The tunica albuginea, therefore, is not merely a more condensed form of the ovarian stroma, but appears to result from a development of tissues which exist in the stroma in an elementary or embryonic form, as well as from a more close conjunction and blending of those tissues.

2. *The Parenchyma or Stroma*, (*fig.* 371. C, and *fig.* 372. *s*) constitutes the proper tissue of the ovary. It lies immediately beneath the tunica albuginea, and fills up the whole of the intermediate space between the ovisacs, to which it acts as a germ bed, protecting the ova from injury, and serving for the conveyance of blood-vessels to the ovisacs. This tissue is sometimes of a pale-pink, but more often of a bright-red colour, from the large number of blood-vessels which it contains, whose arrangement proceeding from within, and radiating outwardly in all directions, gives to this tissue, when viewed by the naked eye or by

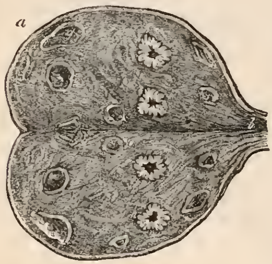
A, peritoneum; B, tunica albuginea; C, stroma; DDDD, Graafian follicles in various stages of growth; EE, outer coat of the follicle (tunic of the ovisac); FF, inner coat of the follicle (ovisac); GGG, epithelial lining (membrana granulosa); HH, ovum and cumulus; I, orifice by which the follicle has discharged an ovum; K, Fallopian tube; L, fimbriæ; M, posterior ala of broad ligament or mesentery of ovary; N, tubo-ovarian ligament; O, ligamentum ovarii.

a common lens, the appearance of being formed into bundles or laminæ.

The microscope, however, serves to resolve this tissue into its true elements. When so examined, the stroma is found to be composed mainly of blood-vessels, to which a great part of its strength and toughness is due, the intermediate spaces being filled up by a fibrous structure not separable into bundles, like ordinary connective tissue, and having no distinct fibrillar arrangement, its chief elements being single white fibres of ordinary connective tissue, numerous fusiform embryonic fibres, and elliptical and round cells or granules, the whole being coherent and strongly united together.

3. *The Graafian Vesicles. Folliculi ovarii, s. Graafiani, s. Ovisacci.*—When the substance of a healthy ovary is divided by a clean incision, if the subject be not too advanced in life, the section will be found to have included several vesicles varying in diameter from 4‴ down to sacculi of microscopic minuteness. These vesicles, familiarly known as the ova of De Graaf, although the credit of antecedent observation is certainly due both to Vesalius * and Fallopius †, are variously distributed through the ovary according to the age of the individual. In infants and young subjects, the ovisacs are found only at the periphery of the organ, where they form a thick rind, the interior of the ovary being occupied only by blood-vessels and stroma. But after puberty the division into a cortical and central part becomes less distinct, the ovisacs becoming buried deeper in the stroma, so that occasionally, in making sections of the part, they are encountered as deep as the base of the organ. They are always, however, most numerous near the surface.

Fig. 372.



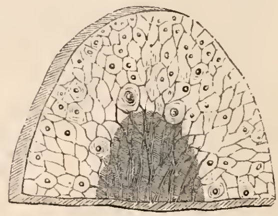
Longitudinal section of adult ovary. (*Ad Nat.*)

a, distal; *b*, proximal end; *s*, stroma; *g*, Graafian follicles of the ordinary size before enlargement; *h*, stellate remains of follicles which have burst and shrunk after discharging their ova.

The number of developed vesicles contained in each ovary, and visible to the naked eye, varies considerably in different subjects. Up to a very recent date it appears to have been assumed that their number was limited. They were usually estimated at 12 to 20 in each ovary; and it was generally supposed that, when these were exhausted by child-bearing and miscarriage, the power of procreation of necessity ceased. More recent and careful observation, however, has shown that the number of vesicles in each ovary amounts in healthy organs to 30, 50, 100, or even 200; whilst in very young subjects their numbers exceed all power of accurate computation.

The vesicles are most easily displayed in the adult ovary by making a perpendicular section through the organ in the direction of its longer axis. In this way the largest number will have been divided by one incision; and such a section, as in *fig.* 372., will often suffice to exhibit 8 to 12 vesicles of different sizes. On submitting the section, however, to the microscope, others of a smaller size, which had previously escaped attention, will be brought into view; and in continuing the incisions in various directions, fresh vesicles will be laid open of various sizes and in different stages of development. If the ovary of an infant be selected for observation, the organ should previously have been hardened by maceration for several days in spirit. A clean section is thus easily obtained by a sharp knife; and if this be examined by a 1-inch object glass, the little spherical ova, coagulated by the action of the spirit, will be readily seen, each one lying in its proper ovisac, by which it is immediately surrounded, and the whole so closely set and so numerous that a single section suffices to display several hundred of them at one view (*fig.* 373.).

Fig. 373.



Section of part of the ovary of an infant, aged 20 *months. The central portion consists of stroma and blood-vessels only. The lighter peripheral part is composed entirely of close-set ovisacs, containing ova of various sizes.* (*Ad Nat.* × 16 *diam.*)

The Graafian follicle, when not subjected to pressure from surrounding parts, or from adjacent vesicles, is spherical or oval in form, (*fig.* 371. DD, and *fig.* 372. *g*) and consists of certain tunics and contents. The number and composition of its coats have been variously described by recent observers; and upon this subject a difference of views would be of comparatively little importance, if upon a right solution of this question did not depend the clear comprehension of those changes which occur in the Graafian follicle during preg-

* De Corporis humani Fabrica, lib. v. cap. xv. p. 459.

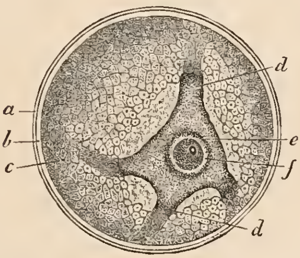
† Obs. Anat., Op. omnia, 1606, vol. i. p. 106.

nancy, and which result in the formation of the body termed the *corpus luteum*.

Without entering upon the question of the number of laminæ into which the walls of a Graafian follicle may be split by skilful manipulation, it will suffice to consider those only as distinct membranes or coats, which exhibit obvious differences of structure and relationship, during the various phases of development and decay which the follicle undergoes from its first formation to its final disappearance. In this view the walls of the Graafian follicle must be regarded as being composed of three membranes; and indeed but for the importance attached to the use of the third or innermost of these, which in any case is hardly more than a thin layer of granules, it would have sufficed if the coats of the vesicles had been enumerated as two only.

The external fibrous or vascular coat (*fig.* 374. *a*, *fig.* 371. E) constitutes the *tunic of the ovisac* of Barry, the *tunica fibrosa*, S. *theca folliculi* of Baer. It forms no portion of the original ovisac, but is a superadded part, derived from the parenchyma of the ovary. This coat closely embraces the ovisac, and partakes

Fig. 374.



Graafian vesicle of the rabbit × 100 (?) *diameters.* (*After Barry.*)

a, outer coat or tunic of the ovisac; *b*, ovisac; *c*, epithelial lining or membrana granulosa, a portion of which has been removed in order to display *dd*, retinacula (here too distinctly marked); *e*, tunica granulosa of Barry immediately surrounding the ovum, consisting of, *f*, zona pellucida, within which is the yelk and germinal vesicle and macula.

in its spherical figure; it carries numerous blood-vessels, which pass from the ovarian stroma to become expanded in a vascular network over its walls (*fig.* 371. D).

Examined by the microscope, this membrane is seen to be highly vascular. It is composed of a fine membrane, containing few fibres, but everywhere abundantly studded with oval nuclei, visible without the aid of acetic acid, and probably, in part at least, due to the presence of so many blood-vessels in its tissue. This coat contains no oil globules. Its chief use appears to be to give increased support and protection to the true ovisac which it surrounds, and to convey blood-vessels from the ovary for its nutrition, and for the supply of the fluids which the ovisac contains.

The second or internal coat, as it is commonly termed, of the Graafian follicle is the ovisac itself. It constitutes at first an independent structure; but receiving afterwards the before mentioned investment from the ovarian parenchyma, the two coats unite to form the Graafian follicle. The ovisac is.

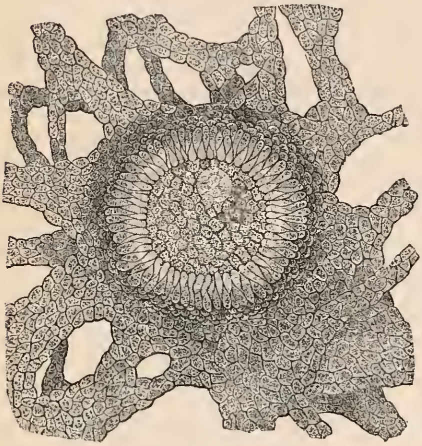
Fig. 375.

Structure of ovisac. (*Ad Nat.* × 350.)

composed of embryonic fibres of connective tissue (*fig.* 375. *a*), of rounded cells or granules, *b*; and of a large proportion of minute oil globules, *c*. The embryonic fibre-cells lie parallel with each other, and together with the granules form the bulk of the tissue in nearly equal proportions. The oil drops are very numerous; and after the preparation has been under examination for some time they are seen to float up to the surface of the drop of water in which it is placed, and to collect upon the under side of the glass disc used for covering it. In addition to these there is found a small quantity of developed fibres of connective tissue, which appear to give firmness to the whole. The Graafian follicle thus composed, contains, in close contact with its inner wall, a stratum of nucleated cells, forming an epithelial lining, termed the *membrana granulosa* (*fig.* 374. *c*, *fig.* 371. G). The cells or granules which give a name to this membrane are so lightly held together that it has been doubted whether the stratum which they form is really entitled to the denomination of a membrane. Nevertheless this structure appears to play an important part in regard to the ovum, which is always found lodged within a portion of it. At the commencement of the formation of the ovisac, according to Dr. Martin Barry, these peculiar elliptical nucleated cells or granules are nearly equally diffused through the fluid which it contains, the ovum lying in their centre. But about the time at which the ovisac unites with its covering or tunic to form the Graafian follicle, these granules are found to have become separated into little groups, leaving interspaces filled by fluid. Further, as this separation advances, the granules arrange themselves in such a manner as to constitute three distinct structures. The principal portion collects upon the inner surface of the ovisac forming the *membrana granulosa* just described (*fig.* 374. *c*). A second portion becomes aggregated upon and around the ovum, taking its form and constituting a special investment for it. This is the *tunica granulosa* of Barry (*fig.* 374. *e*). A third portion collects to form a structure composed of a central mass in which the ovum with its tunica granulosa is imbedded, corresponding with the *cumulus* (*fig.* 371. H, H) of Baer, and of certain cords or flattened bands, from two to four in number, which pass off from the central mass outwards, to become united with the layer of granules lining the follicle. These radiating bands or cords are termed by Barry the *retinacula*, (*fig.* 374. *dd*) from their supposed office in suspending the ovum, and retaining it in its proper situation in the Graafian follicle.

That the *retinacula*, however, are not essential structures is proved by the fact that they are wanting in many of the Mammalia as well as in Man. They have been observed chiefly in the Rodentia and Ruminantia, where their form and number are subject to considerable variation. The subjoined figure exhibits the ovum

Fig. 376.



Ovum of rabbit surrounded by the tunica granulosa and portions of retinacula. (*After Coste.*)

surrounded by the layer of granules which constitutes the *tunica granulosa*, and externally to this the radiating bands or *retinacula*, the whole of those parts, external to the ovum, being composed of nucleated cells.

Besides these structures, the Graafian follicle contains a pellucid albuminous fluid, of a slightly yellowish colour, partially coagulable by heat. In this fluid float numerous granules similar to those of which the parts just described are formed, together with a varying quantity of oil-like globules.

Lastly, in the midst of the granules at an early period, and subsequently in that more definite arrangement of them which constitutes the *tunica granulosa*, is contained the ovum (*fig.* 374. *f*, and *fig.* 376.), a full description of which is given in the article under that title.

4. *Vessels and Nerves.*—The ovary derives its supply of blood chiefly from the ovarian (spermatic), but in part also from the uterine arteries. So free, indeed, is the communication between these vessels, that the organ may be equally well injected from either source. The communication is effected chiefly by means of a branch of the ovarian artery, which passes inwards to inosculate with a terminal branch of the uterine artery, this anastomotic branch being occasionally so large as to constitute the principal source of supply of the ovary. The terminal vessels are conducted to the lower border of the ovary between the folds of the posterior duplicature of the broad ligament, where they lie in parallel lines, and are readily distinguished by their tortuous or spiral form. Having entered the base of the organ, they spread out into those numerous ramifications which penetrate every part of the ovarian stroma, and give to this structure its peculiar fibrous aspect. From their extreme branches the blood is returned by the veins, which pass to the base of the organ, where they are very numerous (*fig.* 370. *h*). They form, near the ovary and between the folds of the broad ligament, a plexus termed the ovarian or pampiniform plexus, (*fig.* 369. *d*) the vessels of which communicate also with the uterine plexus. Valves are found in the ovarian veins only in exceptional cases.

The ovary derives its nerves from the renal and inferior aortic plexuses.* The nerves enter the organ along with the blood-vessels.

Functions of the Ovary.

The ovary is to the female what the testis is to the male—the germ-preparing organ, the part in which is formed the female generative element, and therefore the essential portion of the entire sexual apparatus. To it all other structures may be regarded as accessory or superadded; for in by far the largest proportion of the animal kingdom they are either found in a rudimentary state, or else have no existence. But not only is the ovary the organ in which the formation and evolution of the germ take place; its offices farther extend to the separation and expulsion of the ova, when they have reached such a state of maturity as will render them susceptible of impregnation. This process, commonly termed ovulation, takes place spontaneously, and without the intervention of the male, which is not necessary thereto. All animals possessing an ovary are subject to this law; and Man constitutes no exception to the rule. But the functions of the ovary are exercised only during a certain period of life. The ova, which are formed at or near the time of birth, and sometimes before that event, are not called into activity until the body of the parent is sufficiently developed, to suffer the parturient act without destruction or serious detriment to its own tissues, such as would be incompatible with the continuance of its own life, and such as is witnessed in those lower tribes where the whole of the vital energies of the parent are exhausted by one effort of reproduction, or its tissues are even disrupted by the process which produces its kind. But long before the time arrives at which the generative faculty is capable of being fully exercised, it is probable that many of the ova which were first formed have perished, their place being continually supplied by new formations.† Their numbers, however, are so great that, if only the one thousandth part of those originally contained

* Snow Beck, Phil. Trans. 1846, part ii.

† Barry, Phil. Trans. 1838, part ii. p. 319. Dr. Ritchie, Med. Gaz., vols. xxxiii., xxxiv.

in the ovary remain, and no new ones are superadded, there will still be more than sufficient for all the purposes of reproduction. But as the functional activity of the ovary, so far as relates to the emission of ova in a state fit for impregnation, is restrained on the one side until the arrival of a certain stage of development of the parent, so on the other a period equally arrives, after which this power of producing and emitting ova altogether fails; and it is plain that both these restrictions contribute to one and the same end, the limitation, namely, of the office of reproduction to that period of life in which the vital energies of the producing body, having attained to full perfection, remain still unimpaired, so that the qualities of health and vigour in the parent may be transmitted undiminished to the offspring.

From this it results that the ovary in Man, as well as in the Mammalia generally, has three noticeable periods: the first, of preparation; the second, of activity; and the third, of decay: and these correspond respectively with the periods of infancy and childhood, of youth and prime, and of decline and old age.

The condition of the ovary at each of these epochs will be traced; but the middle period is obviously that to which the chief interest attaches.

During certain portions of this epoch, and in some instances through more or less of its whole extent, the ovary is employed in ripening and emitting ova. In this respect, however, greater variation is perceptible in different species than in any other particular. But in all alike this one circumstance is observable, namely, that the emission of ova is a periodic occurrence.

Now the periods of emission of ova may so occur as to make the times of parturition coincident with the returns of those seasons which are most favourable for the rearing of the young. In such cases the capacity for impregnation may be limited to one period of the year, the ova being ripened and emitted only at that time. The roe affords an interesting example of this. The doubts which have been sometimes entertained as to the precise time at which the roe becomes impregnated have now been settled by the recent very careful researches of Bischoff*, who has proved that this occurs at the end of July and during the month of August, and that it is only then that the ovaries of the female contain ripe ova, and the testes of the male ripe semen. At other times these are not to be found; hence it follows that in this animal impregnation is impossible at all other seasons.

But in many animals the periods of ripening and discharge of the ova recur with much greater frequency; and probably climate, food, domestic care and the like, exercise a certain degree of influence in modifying the returns of these periods.

In the human female the same periodicity is observable; and it is now rendered in the highest degree probable that in her case the times of ripening and generally of the discharge of the ova are coincident with the times of menstruation*, just as it has been proved beyond dispute that in other Mammalia the same process accompanies that more obvious condition of aptitude and desire for sexual intercourse to which the terms œstrus and rut are applied.

* Entwick. des Rehes, 1854.

A periodical maturation, therefore, of ova, accompanied by dehiscence of the ovicapsules and discharge of their contents, may be said to constitute the principal offices of the ovary during the prime of life. But notwithstanding that these processes are periodically performed, the ovary cannot at any time be said to be in a condition of perfect rest, except under circumstances which will be presently noted; for whilst some ovisacs may be observed to be advancing and preparing to emit ova, others may be seen receding or becoming obliterated. The climax, however, of each serial process is the dehiscence or rupture of one or more follicles. Upon this the whole force of the ovary is, as it were, for the time concentrated. This event being terminated, the activity of the ovary passes away as regards that particular follicle. Enough, however, of vital energy remains in the now useless part to suffice for the healing of the wound, and the closing and obliteration of the cavity left after the escape of the ovum. But the blood gradually deserts the walls of the previously congested ovisac, the distended vessels in its neighbourhood shrink and become obliterated, and the action is transferred to another set of follicles, one or more of which pass through a similar order of changes.

Two circumstances, however, arrest for a time this process. The one is the occurrence of utero-gestation, the other the performance of lactation; and although occasional exceptions may be observed, yet so far as this question has been examined, the evidence collected favours the belief, that in pregnant women and in those who suckle, no ova are emitted during the continuance of either of these processes.†

This view also, so far as relates to lactation, receives support from the well-known circumstance that a considerable degree of immunity from impregnation occurs during the continuance of lactation, a circumstance easily explained upon the supposition that at that time usually no ova are matured or emitted.

It will now be necessary to trace in detail the process of ovulation, so far as regards the structures concerned in that process which properly belong to the ovary.

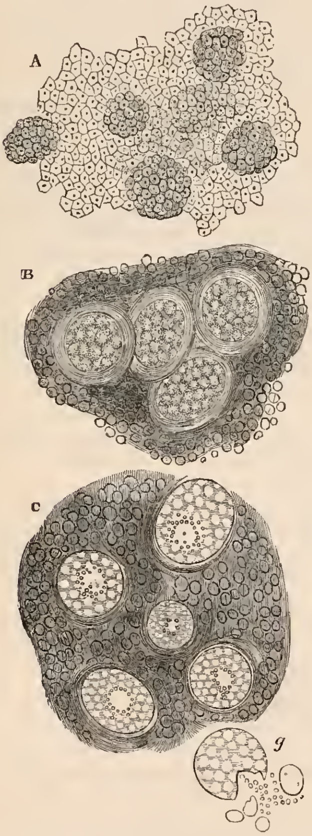
A general account of the Graafian follicle in its mature state having been already given at p. 550., the changes which this important structure undergoes at different periods of its development and decay will now be examined.

* The question of the connection between menstruation and the maturation and discharge of ova from the ovary, is considered under the head "Menstruation" at page 666.

† Négrier, Recherches sur les Ovaires, chap. ii. iii.

First Stage. Origin of the Graafian Follicle.—The time of the first appearance of the follicle within the ovary is subject to considerable variation in the different orders of Mammalia. In all it occurs at a much later period than the first appearance of the seminiferous tubes in the male. Bischoff, who has devoted much attention to the examination of the follicle in its earliest stages of formation, has never been able to discover the least trace of it in the dog and rabbit before birth. This is also the case in most instances in the human embryo, although examples occur of the ovarian follicles being already formed in the new-born

Fig. 377.



Represents the mode of formation of the Graafian follicle. (*After Bischoff.*)

A, portion of ovary of a fœtal dog. The Graafian follicles are seen in the first stage of formation, consisting of little groups of primary cells in the midst of a tissue of similar structure.

B, Portion of ovary of a dog four weeks old; a delicate fibrous coat now surrounds the groups of nucleated cells.

C, Portion of ovary of a pig three weeks old. The follicle is here composed of transparent membrane, the outer surface of which, in the larger ones, is become fibrous. Its inner surface is lined by an epithelium of pale cells (membrana granulosa); within this is the germinal vesicle, surrounded by granules resembling yelk granules. These contents are seen dispersed from a ruptured follicle at *g*.

infant, and in advanced embryos. At first nothing is distinguishable in the ovary except a uniform mass of primary cells and cell nuclei. When the follicle or ovisac is about to form, there may be perceived little round or ovoidal aggregations of primary cells, forming groups which are distributed in considerable numbers through the ovary. These, from the circumstance that the substance of the ovary is likewise composed of similar cells, are scarcely distinguishable from the stroma in the midst of which they arise (*fig.* 377. A).

Now Barry, who also very carefully examined the early formation of the follicle in the rabbit, maintains that within these little groups of cells the germinal vesicle is already contained. Barry represents the germinal vesicle at its first formation as surrounded by minute oil globules, and a collection of granules, forming together little elliptic masses which are distributed through the ovary. A comparison of the descriptions and illustrations of these two observers leaves no doubt that both refer to precisely the same object.

Round these little groups of cells is now perceived a delicate transparent membrane, which is at first apparently destitute of organisation. This is the ovisac in its first stage of formation (*fig.* 377. B, C). The precise mode of its development has given rise to much speculation, which is interesting chiefly with reference to the question whether the ovisac is to be regarded as the vesicle of evolution of the ovum, or whether the ovum, or parts of it at least, are previously formed, and the ovisac is afterwards superadded.

Bischoff explains the formation of the fine homogeneous membrane which is first seen surrounding the little groups of cells by supposing that those which form the peripheral layer become confluent, and that by their junction they constitute this boundary wall, whilst the original cell contents are dispersed.

This membrane soon afterwards becomes lined with a stratum of endogenous cells, which form an epithelium upon its inner surface. A close examination shows further that this cell layer is bounded by a homogeneous tunica propria.

Hence Bischoff concludes that the follicle is, as Henle asserts, a primary secreting follicle, which, like all secreting follicles, is not composed of a primary cell membrane, but results from a confluence of cells. He has never seen in it, when still in the condition of a homogeneous transparent membrane, a cell nucleus, as would be the case in a primary cell. The contents of the vesicle, according to Bischoff, consist of a clear fluid containing cell nuclei and granules; the latter closely resembling the subsequently-formed yelk granules. Somewhat later is observed within these follicle vesicles, which in the meantime have become more developed and numerous, a second transparent spherical vesicle, containing a nucleus which closely resembles, and is considered by Bischoff to be the germinal vesicle. Hence, whilst the observations of Barry, confirmatory of the views of Baer, and supported now by Dr. Allen Thomson*, led the former to conclude that the formation of the ovum commences before the existence of the ovisac, the researches of Bischoff point, on the other hand, to the ovisac itself, as the formative organ of the ovum.

The general appearance of the ovisac, when first formed, is that of a pellucid, and often yellowish vesicle, having an elliptic form, and at first so minute as not to exceed $\frac{1}{50}$—$\frac{1}{100}'''$ in diameter; as, for example, in the ox, the ovary of which animal, according to Barry, would contain in a cubic inch 200,000,000 of such ovisacs.

The ovisac is more or less pellucid, according to its size. In the smaller ones, the walls are so transparent as to admit of the form of their granular contents being seen through them (*fig.* 377. B, C); but as development advances, they become merely translucent. The walls, which are relatively very thick in the small ovisacs, are elastic and distensible, and have an undulating surface, presenting numerous depressions, to which is referable the plaited or folded appearance which the contour of the ovisac assumes under pressure.

The ovisac is sometimes formed in the parietes of an already developed Graafian follicle; but whether originating here, or, as is more commonly the case, in the proper substance of the ovary, it is always at first seen lying perfectly loose in a little cavity, excavated, as it were, in the substance of the surrounding tissues. Subsequently a covering, or tunic, consisting of a rather dense connective tissue, susceptible of becoming highly vascular, and closely connected with the ovarian stroma, is gradually formed upon the outer surface of the ovisac, with which this outer covering now becomes closely united. This is the structure termed by Barry the tunic of the ovisac (*Tunica S. theca folliculi*). And it is by the union of these two that, according to his observations, the Graafian vesicle is formed. At this stage of its development there exist all the elements of the completely-developed follicle, viz., the outer vascular or fibrous coat, the inner softer layer, or proper tunic of the ovisac, and the still more internal epithelial layer of granules representing the membrana granulosa, together with the elements, at least, of the ovum, and the fluid contents of the sac.

These constitute the most important points regarding the development of the Graafian follicle at the time of its first formation in the Mammalia generally. They serve to facilitate greatly the study of the same parts in Man.

With regard to the human follicle, the corresponding stage is most readily observed in the infant, a few months after birth. If at that age a section be made of the ovary, it will be seen to be composed of a parenchyma, which is somewhat lax towards the centre and base, but more dense in the peripheral portion of the organ. The more lax central portion consists of blood-vessels and wavy bundles of connective tissue, the latter being much more distinct in the ovary of the infant than in the adult. The more dense peripheral portion is that in which alone the ova are found. It is made up almost entirely of a mass of minute ovisacs, already containing ova (*fig.* 373.).

These ovisacs, at present in a rudimental condition, are of various dimensions. In the example given, their average diameter was $\frac{1}{500}$—$\frac{1}{1000}''$. But it happens, occasionally, that ovaries of a very early age are found to contain ovisacs or Graafian follicles of comparatively large size. Thus, in a specimen in my possession from a child of seven months, one ovary contains a follicle of rather more than $1'''$ in diameter, whilst the other is almost entirely occupied by five follicles, the largest of which measures $2\frac{1}{2}+1\frac{1}{2}'''$, and the smallest is one quarter of that size. In this case the entire length of the ovary is only $7'''$.

Second Stage. Growth, Maturation, and Preparation for Dehiscence of the Follicle.—When the period approaches, or has already arrived, at which an animal becomes apt for reproduction, and is ready to receive the male, a certain number of follicles progressively increase in size, and become more and more superficially placed. Shortly, the more advanced series occupy the surface of the ovary, and present the appearance of round grains close-set, so as to give to the organ sometimes the appearance of a bunch of grapes (*fig.* 378.). This is more particularly the case in the sow, which affords an excellent example for tracing these changes in the follicle.

Fig. 378.

Portion of ovary of the sow. The Graafian follicles project above the surface of the ovary. Several, riper than the rest, are conspicuous by their size. a, unripe; b, riper follicles; c, stroma.
(*After Pouchet.*)

Each grain, *a*, consists of a vesicle filled with a limpid fluid, albuminous, viscid to the touch, of a slightly yellow colour, and coagulable by heat and alcohol. Their walls, previously diaphanous, now become opaque from the thickening of the *inner* membrane of the vesicle, *i.e.*, of the ovisac itself. From four to six of these vesicles will be found to become simultaneously developed in each ovary (*fig.* 378. *b*, *b*). These are always the most superficial. Their form is generally ovoid. They increase until they attain a diameter of about $\frac{4}{5}''$.

* Page 76. of this vol., Supplement.

The augmentation in bulk of the follicle is, in the first instance, due almost entirely to an increase in its fluid contents. It is probable that this fluid is supplied by the minute capillaries with which the ovisac is furnished, and which, long before the vesicle has attained its full diameter, appear in the form of a rich network upon its inner surface, giving to the latter a bright red colour.

And now a thickening of the walls of the follicle becomes very manifest, accompanied by an exudation of blood which collects in the interior of the sac. The period at which this escape of blood commences is variable. Sometimes it may be seen in follicles of not more than $1\frac{1}{2}'''$ diameter, but more frequently when they have attained a size of about $3'''$.

As this exudation of blood takes place at a period certainly antecedent to the rupture of the follicle, it cannot be traced to vessels lacerated during that process, but must proceed from the congested capillaries just described. It resembles arterial blood, and is rich in globules, which at first remain free and distinct; but when the distension of the follicle has become considerable, the blood coagulates into a dark-red clot.

This pouring-out of blood has been termed the menstruation of the follicle; but beyond the purpose of increasing the distension of the latter, preparatory to its rupture, no use has been assigned to it, except by Pouchet, who maintains that in the sow the ovum lies at the bottom of the follicle, instead of near its upper or free surface; and that as the sanguineous exudation increases, it collects between the inner surface of the ovisac and the membrana granulosa, and so carries upwards the latter, together with the ovum which is lodged upon it. He asserts, further, that in proportion as this exudation increases, the albuminous fluid previously occupying the follicle is absorbed, until the entire cavity becomes filled with blood.

The result of this process is, that the ovum, previously lying at the bottom, is now transported to the upper part of the follicle, immediately beneath the point at which the rupture of the walls is about to take place.

Notwithstanding the minuteness of Pouchet's description, its accuracy, so far at least as concerns the supposed purpose of this exudation of blood, has been called in question. The fact, however, cannot be disputed, that, in many animals, as well as in man, the follicle does contain blood, often in considerable quantity, previous to its rupture. And this is a very important point, because it serves to refute the statement of some who maintain that the presence of blood, or of a clot, within the follicle, affords certain evidence that the rupture of the latter, together probably with the escape of the ovum, has already occurred. Barry also, in his researches upon the rabbit, says, that after certain of the ovisacs have discharged their ova, "some of the larger Graafian vesicles, remaining unbroken, are frequently found to contain a considerable quantity of blood. Such spots, he observes, have been noticed by several observers, who supposed them to indicate the Graafian vesicles from which ova were destined to be expelled.

Thus Barry's prior testimony serves to confirm that of Pouchet and others, to the effect that the blood found within the follicle does not result from its rupture, but that it is there antecedent to that process.

Some other changes which occur in the follicle previous to its rupture may here be noticed. The thickening just spoken of takes place in the inner membrane, or that which constituted originally the ovisac. This thickening is sometimes so considerable as to increase the diameter of the follicular walls to three times their original amount. At the same time, their contour becomes somewhat undulating, and their colour approximates to that of the buffy coat of the blood.

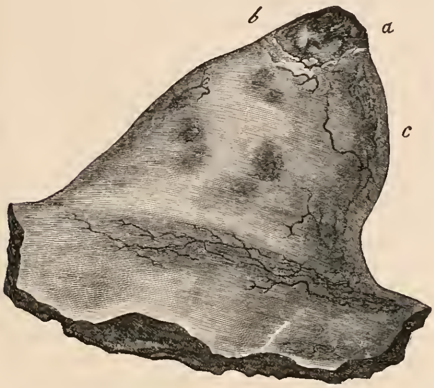
While these changes are going on in the substances and in the contents of the follicle, preparation is being made externally for the rupture at a certain part of the parietes. The base of the follicle continues to be imbedded in the substance of the ovary (*fig.* 379.), but the upper portion projects free above this, being covered only by the usual ovarian investments. Here, at the more salient portion of the projecting vesicle (*fig.* 379.), an increased vascularity is observable. The peritoneum and sublying tissues become exceedingly red, and an abundance of blood is observed in the numerous capillaries which are now visible upon the summit of the vesicle. After this, the fibres of the ovarian coverings become gradually separated, preparatory to their complete laceration. The tunics also of the follicle itself become perceptibly thinner at this spot, which corresponds with the situation of the ovum — always, at this period, lying immediately beneath it.

Fig. 379.

Portion of ovary of the sow. The follicles are in a more advanced stage than in fig. 378. Two of these are preparing for rupture. Already a small aperture is perceptible in the centre, immediately above the spot where the ovum lies; and towards this point the bloodvessels converge. (After Pouchet.)

The same regular sequence of changes, which may always be traced in the Mammalia, though with some slight variations according to species, occurs also in man. If the examination be made in a young and previously healthy woman, who has menstruated regularly up to the time of her death, there will generally be found in the ovary one or more follicles in conditions similar to those just described. The ordinary state in which the Graafian follicle is found has been explained at p. 550. Vesicles in the state there described may be seen at all times in the healthy ovary, sometimes near its surface, and at others buried more deeply; but when they increase in growth beyond this size, and are preparing to rupture, one or more will always be found approaching the periphery of the ovary, or rising above the level of its outer tunics, constituting there a nipple-like prominence, so distinct as at once to arrest attention, and to point out the part of the ovary in which the dehiscence will next occur (*fig.* 380. *a*).

Fig. 380.



Ovary from a woman aged 22, *who died on the tenth day after the commencement of her last menstrual period.* (*Ad Nat.*)

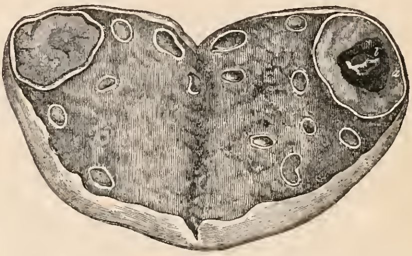
A follicle is preparing for spontaneous rupture at *a*, where a considerable prominence occurs, and where the peritoneal and albugineous coats are almost entirely absorbed.

In general, only one follicle will be found preparing for rupture; but sometimes two, or possibly three, may be observed in the same condition in one ovary. The growth has now been so considerable, that instead of measuring only $1\frac{1}{2}'''$—$2\frac{1}{2}'''$, or even $3'''$, it has now a diameter of $5\frac{1}{2}$—$7'''$, the breadth being usually somewhat less than the length, for it rarely happens that the follicle is perfectly spherical. In consequence of this increased growth the follicle projects from the surface, and causes the swelling just described, whilst the accumulation of fluid within it produces a softness and sense of fluctuation in this part of the ovary, which is very obvious to the touch. Over the centre of this projection the peritoneum is exceedingly thin, and in some places is wanting, partly from absorption, and partly from laceration, the result of overstretching and distension.

The tunica albuginea also of the ovary may be absorbed, or may have become so exceedingly thin, as to permit the blood-coloured contents of the vesicle partially to appear through it, giving to the spot a peculiar brick-red colour. Around the margin or base of the prominence the fibres of the tunica albuginea are often seen to be separated at short distances, forming concentric lines or interrupted circles; the red contents showing through the interspaces, and producing an appearance of alternate white and red lines (*fig.* 380. *b*). Beyond this circumference, the base of the prominence exhibits the usual white colour of the ovarian coverings. Numerous red vessels, chiefly veins (*fig.* 380. *c*), ramify towards the projecting spot, and some of these traverse it to its summit, coursing over the prominence in serpentine lines, and forming here a rich plexus.

A clean section through the centre of the projecting follicle lays open an ovoid cavity,

Fig. 381.



The same ovary (*ad Nat.*) *as in fig.* 380. *laid open, displaying,*

a, the cavity of the enlarged follicle; *c*, the corresponding half of the same; *b*, a blood-clot. Numerous follicles of the ordinary size are seen scattered through the ovary.

(*fig.* 381. *a*), containing usually a deep red clot, *b*, together with a certain quantity of blood and a bloody fluid. The clot has as yet no adhesion to the walls of the cavity, and is easily washed away.

If the ovary has been examined not too long after death, the ovum may possibly be found lying imbedded in the granules of the *membrana granulosa*, immediately beneath the most projecting point of the follicle. But more commonly, the examination not being made until after this delicate membrane has melted down, and its granules have become dispersed by post-mortem change, the ovum cannot be discovered.

After washing out the contents of the follicle, the inner surface of the ovisac is exposed (*fig.* 381. *c*). This I have occasionally seen to be of an intense red colour, from the surface being covered by a rich network of capillaries filled with blood. But most commonly the colour of the ovisac throughout, as far as the outer tissue of the follicle, is at this time a clear, pale, chrome yellow, this coat being now also very soft in texture. It is important to observe that the yellow colour includes the whole thickness of the ovisac, or inner coat of the Graafian follicle, which now measures from $\frac{1}{2}$ to $1'''$ in thickness, but that it extends no further; the outer coat, or theca folliculi, retaining its ordinary condition. Already a slightly wavy outline is perceptible in the follicle (*fig.* 381.), which is due to the growth of the inner membrane having continued after the outer coat has ceased to expand.

The inner coat of the follicle, when it has thus acquired a yellow colour, is seen, by the aid of the microscope, to have undergone an important and yet very simple change. On its inner surface, or that which is turned towards the cavity of the ovisac, it presents the appearance of a transparent and nearly structureless membrane, in the substance of which are imbedded numerous oil droplets, very minute, and aggregated in little masses,

Fig. 382.

Cells filled with oil-granules which give the yellow colour to the inner coat of the Graafian follicle before it has burst, forming the substance termed corpus luteum. (*Ad Nat.* × 350.)

a, separate cells; *b*, the same imbedded in the structureless membrane. (From the same subject as *figs.* 380. and 381.)

with a certain regularity which suggests the idea that they have either been originally deposited around a centre globule, or are contained in cells or vesicles, the cell-wall of which is not very discernible (*fig.* 382. *b*). Deeper towards the outer surface of the ovisac the oil droplets or granules become so numerous as to prevent the recognition of any other structure until the greater portion of the oil has been dissolved out by macerating the part in ether. If, after this process, the tissue which remains be washed in spirit or water, and subsequently treated by acetic acid, it is seen to be composed of numerous blood-vessels, and of developed as well as embryonic fibres of connective tissue, which latter, however, are only faintly indicated, and are connected together by a transparent membrane. The proportion of developed fibres of connective tissue is here very large, whilst in less advanced follicles the embryonic fibres preponderate (*fig.* 375.).

Another and perhaps more satisfactory mode of examining the yellow coat of the Graafian follicle in this stage, consists in slow maceration in a very weak preservative fluid (glycerine and water). The cells, which this coat contains in great abundance, can now be obtained separately for observation. They are seen to consist of a transparent cell-wall, filled with oil granules (*fig.* 382. *a*). The average cells vary in diameter from $\frac{1}{800}''$ to $\frac{1}{2000}''$, but many are smaller, and others larger. Occasionally a cell may be seen to have burst, its contents having escaped; a few oil granules, however, may still be perceived adhering to the cell-wall, the torn margins of which are very readily defined. There can be no doubt that these cells are the "peculiar granules" so frequently described and figured by Barry in his account of the various conditions and stages of development of the ovisac.

The colour of the yellow coat—the so-called *corpus luteum*—is not alike in all animals. In some of the Mammalia it is of a bright orange; in others it inclines to red. In Man, as already stated, the inner surface of the follicle, when ripe, is occasionally so loaded with bright red capillaries that the usual appearance is obscured, but its ordinary aspect presents the clear chrome yellow just described. That this yellow colour, like that of the yolk of the bird's egg, is due to the presence of the oil globules (*fig.* 382. *b*) which everywhere penetrate the tissues of this coat, is rendered sufficiently apparent: first, by the fact that treatment by ether, which dissolves out the oil granules, leaves the remaining membrane nearly white; and secondly, that maceration in water has, to a certain extent, the like effect, but in this case arising from the maceration, causing the animal membrane to swell and become opaque, thus obscuring its previous transparency, and rendering the oily portions only faintly discernible through it, as judged by the naked eye, though they are still readily discoverable under the microscope.

Third Stage. Period of Rupture or Dehiscence of the Follicle, and Escape of the Ovum.—This is termed by Pouchet the period of parturition, in which, after the preparatory changes already described, the ovum quits the Graafian follicle in order to enter the Fallopian tube. It is therefore for the ovisac what the process of parturition is for the uterus, viz., the act by which the ovum, after being matured to a certain point of perfection, is expelled from its cavity.

The process by which the dehiscence of the follicle is effected in Mammalia is in some respects different from that which causes the expulsion of the ovum, from its containing capsule, in the vertebrata below them. In birds, reptiles, and fishes, and, indeed, in the Invertebrata generally, the ovum is of so large a size in comparison with the ovicapsule, that the simple increase of the former, as the time of the ovipont* approaches, is sufficient to cause the bursting of the sac at the point where the coats have been prepared for rupture by previous attenuation. But in the Mammalia the bulk of the ovum bears so small a proportion to its containing follicle, that the ovum itself contributes in no degree to the rupture by which it is enabled to escape. In this process it remains a passive body, at least in a mechanical point of view, though doubtless it is the perfecting of the ovum which gives the vital impetus to that series of changes by which it is finally released from its first abode. But the act of

* I have anglicised the French term *oviponte* (ovipont), to express the escape of the ovum from the ovary; while "ovulation" is employed, in a more general sense, to include also the process of its maturation.

parturition is accomplished by other means. The process by which this is effected has been compared by Blumenbach to the spontaneous bursting of an abscess. Here the process consists in an increasing accumulation of fluid within, conjoined with a gradual attenuation of some particular part of the containing walls. So many points of similarity, indeed, may be traced between these two processes, that the term "inflammation" is employed by some authors in describing the preparatory changes in the Graafian follicle.

The resistance which the ovum and other contents of the vesicle require to overcome before any portion of these can escape consists, it must be remembered, in the combined opposition of no less than four membranes, in addition to any portion of the proper ovarian stroma which may intervene. These are, first, the ovisac; then its capsule, united to the former, and with it constituting the Graafian follicle; thirdly, the tunica albuginea; and fourthly, the peritoneal covering of the ovary. These four, shortly previous to the rupture, become so intimately united together that it is no longer possible to separate, nor is it easy always to distinguish them from each other, with the exception, however, of the innermost layer, which can generally be more easily traced than any of the rest, on account of its peculiar yellow colour.

Upon the surface of the most salient portion of the projecting follicle (*fig.* 380. *a*) the peritoneum, as already stated, may be wanting; the tunica albnginea also beneath has become greatly attenuated, and is sometimes found completely eroded, whilst internally the yellow coat of the follicle is also observed to be thinnest about this spot. Every preparation, therefore, is made for the laceration of the follicle at a given point, the seat of which can also be further determined by the observation that in this place the conjoined membranes, previously highly vascular, have become more transparent, whilst their vessels, having become atrophied by compression, now carry little or no blood.

A very slight force is now sufficient to produce the rupture of the follicle in this precise spot, and such a force is supplied by the gradual accumulation of fluid, whether albuminous or sanguineous, or both, within the cavity.

It is believed by Coste that when the ovisacs have reached this point, which is the full term of their growth, they may remain stationary until a state of excitement arises, produced partly by the maturity of the ovum, and partly by the approach of the sexes, and that it is under the influence of such an excitement that the rupture of the follicle most commonly takes place. What probability there is for such a supposition will be hereafter more fully considered. Whether influenced by any external stimulus, or whether occurring spontaneously, and from causes existing within the follicle, the increase of its fluid contents becomes at length so great that the cavity is distended beyond measure, and its walls can no longer resist the pressure, but give way at the thinnest and most projecting part. But it is probable that another power comes also into operation to aid this process. The wavy outline which has been already noticed (*fig.* 381. *c*) as presented in a slight degree by the still unbroken ovisac, together with a certain amount of thickening of this coat, indicates a growth of this more rapid in proportion than that of the outer layer or tunic of the ovisac. This, therefore, will in some degree add to the pressure, because the outer layer of the follicle not being distensible beyond a certain limit, any increase of the contents, whether fluid or solid, will alike contribute to augment the force which is brought to bear upon the weakest point of the walls.

As soon as the rupture has taken place, and the opening in the coats of the follicle and in the corresponding portion of the ovarian coverings is sufficiently large to admit of the passage of the ovum, the latter escapes, together with portions of the membrana granulosa.

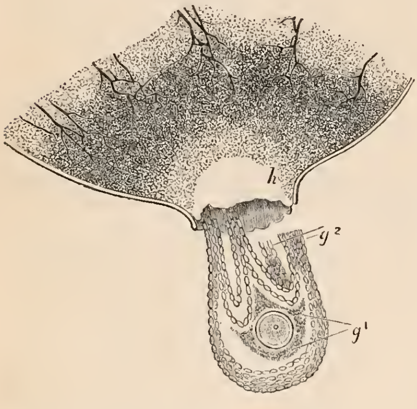
On one occasion Pouchet was so fortunate as to meet with an opportunity of observing the ovum as it was in the act of escaping from the ovisac, and was lying between the margins of the lacerated opening.

Of the five coats which together compose the ovarian and follicular walls, four only, it will be observed, can offer any obstacle to the escape of the ovum; because the membrana granulosa, which is the innermost of all, contains rather than covers the ovum, whose escape cannot be impeded, but will be rather assisted by that membrane. Barry explains the mode in which this probably occurs as follows: — The ovum, imbedded in the cumulus and granular disc which form the centre of the membrana granulosa, at the moment when the laceration occurs, experiences the *vis à tergo* occasioned by the pressure forward of the fluid, endeavouring to escape from within the follicle. This pressure is increased by the thickening of the inner wall of the follicle, amounting in some instances to an exuberant growth, which will act upon the ovum through the medium of this fluid. The obstacle to the escape of the ovum which had up to this moment existed, being removed by the laceration and absorption of the ovarian and follicular walls, that portion of the membrana granulosa which lies immediately behind the lacerated coats, where the ovum is imbedded, presents a surface for the operation of the *vis à tergo* more or less considerable, according to the extent of the rupture.

And now the elasticity of the coats of the follicle, together with some pressure from the weight of the parts surrounding its base, come in aid of this force, and complete the expulsion of the ovum, which escapes together with a portion of the membrana granulosa, and passes into the infundibular end of the oviduct.

Fig. 383. shows the mode in which this process occurs in the rabbit. Here is represented a portion of a ripe Graafian vesicle, which was upon the point of discharging an ovum. The follicle, after being dissected out of the ovary, has been subjected to slight lateral pressure in the compressorium, by which the follicle has been burst at the point (*h*) preparing for rupture. The ovisac has given way at the thinnest point, and the ovum, surrounded by the *tunica granulosa* (*g*, 1.), and dragging after it portions of the *retinacula* (*g*, 2.) is shown in the act of escaping from the follicle.

Fig. 383.

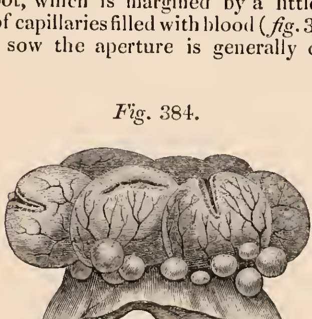


Ovum of the rabbit in the act of escaping from a ruptured Graafian follicle. (*After Barry.*)

The ovum is surrounded by the tunica granulosa, g^1, and draws after it the portion of membrana granulosa termed the retinacula, g^2; at *h*, where the rupture has taken place, the coats of the follicle are attenuated, and towards this spot numerous vessels converge.

The form and size of the aperture by which the ovum escapes varies considerably. In the rabbit it generally appears in the form of a small round aperture in the midst of a bright red spot, which is margined by a little network of capillaries filled with blood (*fig.* 383. *h*). In the sow the aperture is generally oblong

Fig. 384.



Portion of ovary of the sow. Three of the largest follicles have burst simultaneously, and exhibit wide lacerations. Others, less forward, remain unruptured. At the base are several unripe follicles. (*After Pouchet.*)

(*fig.* 384.), and from 1½ to 7‴ in length; the laceration in the latter sometimes extending through the entire diameter of the follicle, and permitting the escape of the whole of its contents, together with the ovum.

The laceration is not necessarily limited to a single follicle. In multiparient animals (*fig.* 384.) all or a greater portion of those follicles which have attained their full development undergo laceration, and emit their ova about the same time. In some of these, however, the effort may prove abortive, and the follicles may remain stationary until another impulse to rupture occurs, and the ova may then be discharged, or may, on the other hand, perish or be absorbed.

In Man, although generally uniparient, two or more follicles may likewise become matured about the same time, and their bursting may take place simultaneously. Of this fact I possess the proof in a case (*fig.* 409. page 605.) in which I found in one ovary three distinct apertures leading to as many developed ovisacs, all of which presented the characters just described as indicating the recently ruptured follicle. In this case the woman died during menstruation.

Such an observation is interesting, as showing in what way multiple pregnancies may occur in the human subject, for the whole of the ova discharged under such circumstances may be impregnated by a single coitus; although it is also possible that the bursting of one follicle only may suffice for the production of twins, since two ova have been several times observed in a single follicle in the Mammalia, and this may also possibly be sometimes the case in Man.

Before proceeding to the consideration of the remaining changes which the Graafian follicle undergoes, it may be useful here to make one or two observations on the conditions already described. Up to the moment of rupture, the progress of the follicle is one of regular advancement from an embryonic condition to a state of full maturity. The object of this progressive advancement is the protection, maturation, and final expulsion of the ovum, in such a manner that this last step may occur at a time when the ovum will be placed in circumstances the most favourable for impregnation.

In order to accomplish this, the ultimate purpose of all these progressive changes, the ovisacs which had been previously set more or less deeply in the ovarian parenchyma reach, one by one, the surface of this organ, and there, swelling rapidly from the increased secretion into their interior, and the growth of their walls, as we have seen, burst and emit their contents. The whole of these changes occur in regular sequence, and affect one or more follicles in succession. These follicles, lying buried in countless numbers in the substance of the ovary, supply, as it were, the pabulum for the morphological changes here described; a certain number only being called into full maturity, whilst the greater portion of those which were originally formed in infancy, or which may continue to form during life, undoubtedly perish. No sexual influence is needful to the production of any of these changes. The whole occur spontaneously, whatever may be the condition of the female.

How far the influence of the male may assist in hurrying on to maturity any of these processes is a question which will be considered hereafter, when the proofs of the statements now made as to the independence of these processes will also be investigated. But it is sufficient here to refer to the fact of the spontaneity of these occurrences, in order to place under one category all the changes which the ovary suffers, up to a certain point, independently of any sexual influence.

Two circumstances here also may be more especially noticed: the one is, that the yellow colour which the proper ovisac or inner coat of the follicle exhibits towards the term of its ripening is distinctly recognisable for some time anterior to the occurrence of the rupture. It occurs in all follicles at this stage alike, both in Man and animals, and under all circumstances, whether coitus be permitted or not; but even when coitus is permitted, it is found at a period long anterior to that at which the act of coition could by any possibility be influential in its production.

The other circumstance which it may be important here to notice is, that the yellow structure is no new nor superadded part, but is the ovisac itself, altered by the gradual deposit in its texture of a yellow oil, which at length accumulates to such a degree as to convert this previously translucent wall of the follicle into an opaque yellow membrane or coat. But neither in any of these stages, nor in any subsequent ones, is there interposed either between the walls of the follicle or between these latter and the surrounding ovarian stroma, any new substance or body of any kind. The yellow colour is confined to the inner coat of the follicle, nor have I ever seen it in any one instance penetrating to the outer coat or covering of the ovisac. There is only one new coat formed, which will be hereafter described; and that coat, often of considerable thickness, is a part entirely superadded, which, after a certain stage in the metamorphosis of the follicle, is applied in the inner side again of the yellow coat, to which it forms a lining. This, although a new formation, is also, as will be presently shown, constructed out of materials existing in the follicle before its rupture.

The final purpose of the Graafian follicle being now accomplished, it may seem a matter of comparatively little interest or importance, in a physiological point of view, to trace its ultimate conditions; for the changes which this structure next undergoes have for their object solely its obliteration. But the process of obliteration or retrogression does not, like the process of development, take place under all circumstances alike. Here the influence of impregnation is exhibited in a degree so remarkable as to have given rise to a general belief that the changes experienced by the follicle, when impregnation has accompanied or followed its rupture, are essentially different in their nature and character from those which ensue when impregnation has not taken place; whereas these differences, it will be shown, are differences chiefly of degree; and yet they are so considerable as to have called forth almost as great a share of attention as has been given, perhaps, to any structure in the human body.

But great as is the interest attached to this structure on account of the evidence which it may afford of the previous occurrence or non-occurrence of impregnation, yet, so various are the views and statements of those who have specially directed their attention to the subject, that neither among physiologists, pathologists, nor medical jurists, can it be said that there is at present any concord of opinion or common ground of understanding.

Admitting, however, for the present that there is a marked difference observable in the changes which the Graafian follicle undergoes, according as impregnation has or has not accompanied or followed the escape of the ovum, we thereby obtain a starting-point, or rather a point of divergence, from which we may follow out these changes in two different series: the one series will include the alterations in the follicle which ensue when impregnation fails, or does not occur; the other, those which it experiences in consequence of impregnation having taken place.

Fourth Stage. Period of Decline and Obliteration of the Graafian Follicles.

A. *Without Impregnation.*—This constitutes the first degree of the descending scale in the history of development of the follicle. Immediately after the escape of the ovum, the inherent contractility of the tunica albuginea of the ovary occasions a diminution in the prominence of the lacerated vesicle. The margins of the opening become approximated in consequence of the collapsing of the walls, and from the edges of the laceration there occurs a slight fibrinous exudation which causes them to become agglutinated. If the aperture has been of considerable size, and no clot remains in the cavity to keep its walls from collapsing, the process of obliteration may proceed rapidly; but if a clot remains, and especially if it is of considerable size, it will serve to support the walls, and prevent them from quickly shrinking.

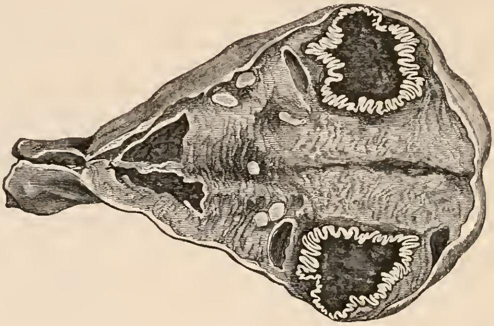
These different conditions will for a time affect the new disposition which the inner membrane of the follicle takes soon after the rupture is complete. In proportion as the cavity is empty, the elasticity of the outer fibrous coat will, by its retraction, occasion a diminution of the cavity; but the inner coat, having already increased during the growth of the follicle in a greater degree than its outer covering, will now, in this collapsed and nearly empty condition of the sac, suffer the same change that would result from enclosing a large bladder within a smaller one.

The inner coat becomes folded, and forms convolutions, which increase and become deeper in proportion as the retractility of the external tunic increases.

These convolutions in the inner and now yellow coat of the follicle are so distinct and striking (*fig.* 385.) as to have suggested those comparisons with the cerebral convolutions which so many authors have employed in describing this change; for the colour, as well as the nature and arrangement of the foldings, constituting ridges and sulci, produce an exact miniature resemblance to the surface of the brain.

If the blood-clot, which is generally found contained within the ruptured ovisac, be of considerable size, its surface will frequently exhibit little furrows, more or less deep, cor-

Fig. 385.



Section of the ovary of a woman who was poisoned by opium. A large Graafian follicle, which had recently burst and discharged its contents, is laid open. The part of the ovary surrounding the aperture was loaded with vessels full of blood. The convolutions of the collapsing follicle are very distinct. The follicle is empty. (*Ad Nat.*)

responding with the convolutions of the ovisac, by contact with which they have been impressed. This clot becomes adherent to the walls of the ovisac; assumes by degrees a pale rose hue; and gradually diminishing by absorption and contraction, it constitutes a centre, towards which the rays of the convolutions from all sides are directed.

But if there be no considerable clot in the centre of the follicle, then its closure proceeds more rapidly. The angles of the convolutions approach each other more nearly, but there still remains a space in the centre which may be empty, or contains only the debris of old coagula.

Lastly, if the cavity is empty, the retractility of its outer coat soon effects its closure. The angles of the convolutions, now compressed one against the other, come into contact across the cavity, and end by adhering together, and so the cavity is obliterated.

If, during the progress of these changes within the follicle, the external surface of the ovary be examined about the seat of rupture, it will be found that the parts in the immediate neighbourhood of the laceration become paler, that the blood gradually deserts the vessels, which were before highly congested, in this situation; and that, as cicatrisation advances, the zone becomes less and less distinct, disappearing, finally, about the time when the last traces of the laceration are effaced.

These changes in the ovarian follicle after rupture exhibit certain differences among the Mammalia, in some of whom, for example, there may be seen to project from the aperture a fleshy mass, sometimes occasioned by the presence of a coagulum, but more constantly by an exuberant growth of the lining membrane of the follicle, which for some time protrudes through the orifice, and may often, at this stage, be drawn out entire by the forceps, without difficulty. Its colour is not alike in all the Mammalia. In the sow, it resembles the liver of a calf; in the cow and sheep, it is of a brick-red.

In Man, the follicle has generally shrunk to very small dimensions by the time that one or more of the next series, which is preparing for development, have reached and protruded from the surface. The cavity by this time is nearly effaced. The chrome-yellow colour of the walls has also disappeared, and the ovisac has gradually become white. Its appearance upon section at this time is very striking and characteristic. In the centre (*fig.* 372. *h*) is still perceptible a small space, which might contain the head of a pin. It is surrounded by a white irregular circle, from which proceed outwardly about a dozen little rays. The circle is formed by the united inner angles of the follicular convolutions. The rays consist each of a double layer of the folded membrane. The apices of the rays are the original outer angles of the serpentine folds or convolutions of the ovisac. The outer coat of the Graafian follicle can now no longer be seen. At this time, the remnant of the shrunken vesicle measures about $1\frac{1}{2}'''$ diam.

Finally, whilst the foregoing changes are proceeding internally, a corresponding alteration takes place at the surface of the ovary.

The closure of the aperture, by cohesion of its opposite sides, occasions a drawing together of the surrounding parts, and the accompanying collapse of the follicles causes the part of the ovarian surface in this situation to sink inwards. The depression thus caused is increased by the continued shrivelling of the follicle, and by its retiring inwards towards the centre of the ovary. This latter change is occasioned not so much by any activity on the part of the now empty follicle as by the approach of new and rising ones to the surface, by which the empty and useless ovisacs are now pressed aside.

By these successive retirings of the follicles after bursting, and by the cicatrisation of their apertures, the ovarian surface becomes gradually indented in all directions so as to exhibit those pits and furrows which are always seen upon the ovary in advanced life (*fig.* 390.); and these, occurring in women under every circumstance alike, afford one of the most convincing proofs that this discharge of ova from the ovary may and does occur independently of sexual congress.

Finally, the stellate remains of the follicle continue to decrease, and become gradually buried in the ovarian stroma, until they are entirely obliterated, thus giving place to other vesicles which pass through the same stages of growth and decadence.

B. *After Impregnation.*—Very different is the progress of the Graafian follicle after impregnation has taken place. Here, although the changes which occur have no other intelligible purpose than that of the final obliteration of the follicles, yet the process takes place much more slowly than it does when the ovipont has not been followed by conception. In this latter case, the metamorphosis of the follicle into the small yellow stellate organ takes place usually within a month from the time of rupture, and its subsequent reduction to the little white cicatrix previous to its total disappearance is completed in about the like period. But the follicle, which has discharged an ovum that has been afterwards impregnated, is not obliterated in a shorter time usually than 13—14 months. During that time it appears to undergo a great and remarkable development. But a close examination shows that this is not true development, in the ordinary sense of the word. It is not a forward movement, progressing towards any new purpose or end, but is only the same process of obliteration, conducted upon a larger scale, and with a greater abundance of materials than in the case of the ordinary follicles when impregnation has not occurred.

Apparently the chief difficulty which has stood in the way of a clear comprehension of this has arisen from a want of sufficient consideration of those altered circumstances in which the generative organs are placed after conception; for, from the moment that impregnation has occurred, all parts of the generative apparatus are brought under the influence of a common stimulus, and all manifest in a greater or lesser degree some progressive change. This is more particularly observable in the internal organs, and especially in the uterus, which very soon receives a larger supply of blood. But the blood-vessels supplying the uterus inosculate so freely with those of the ovary, that the two organs may be practically regarded as deriving their blood from one common source. Each may be injected from the vessels of the other, and though only one set be selected, both are alike filled.

Hence it may be assumed that, although there is no direct continuity of texture between the ovary and the uterus, yet, under the influence of a common supply of formative material, as well as a common innervation, there may be established such a consent of action as will account, in some degree at least, for the differences which we are now about to consider; for when, after the discharge of the ovum from the ovary, impregnation fails, or has not been attempted, the internal organs, previously highly vascular, subside into a passive or quiescent state until the period of the next ovipont approaches, when the uterus again exhibits the same condition of turgescence. But if impregnation has taken place, then the turgescence of the uterus, far from subsiding, only increases, and certain of its textures now become rapidly evolved. The reproductive act, however, does not commence in the uterus. The ovary is the seat of the first changes, and the uterus is only placed in a condition of readiness, on each occasion of the ovipont, to carry on and complete the process which has been commenced in the former organ. The absence of impregnation, on the one hand, is the cause of the failure of the further stages of the process; the occurrence of impregnation, on the other hand, establishes these stages; consequently the ovisac which is about to discharge, or one which has just discharged an ovum, and the uterus which is about to receive or which has just received that ovum, are both placed under similar conditions. Whatever influences the one in the direction of development, affects the other also, to a certain degree, in the same direction. Whatever, on the other hand, determines the retrogression of the one, determines, in like manner, the receding of the other. If the ovum has become impregnated, the follicle which was the first birthplace of that particular ovum, and the uterus which subsequently receives and protects it, continue alike to suffer change. But if the ovum perishes, the recipient organ feels no stimulus, is not excited to further preparation, subsides into its former state of quiescence, and its producing capsule likewise shrinks, and finally disappears. If the inquiry be prosecuted further in the hope of eliciting some more satisfactory explanation of this remarkable series of changes, the investigation will, in the present state of our knowledge, be found altogether to fail. The question, *Cui bono?* continues unanswered, but the fact remains, and the law appears to be invariable.

When conception has followed the discharge of an ovum from the ovarium, the follicle which produced it closes in the same manner as when conception has not occurred, but it does not shrink rapidly, as in the latter case. On the contrary, the inner coat or original ovisac continues to increase in thickness, in consequence of a still larger deposit of yellow oil granules in its substance. The outer coat of the follicle or tunic of the ovisac suffers no change; but upon the interior of the ovisac, and therefore lining the cavity, is formed a membrane, the origin and nature of which will be presently considered; or else it may happen that the cavity becomes obliterated by the organisation of the clot by which it had been at first filled.

After conception it is probable that the actual diameter of the follicle does not at any time materially increase. So great, however, are the variations in its size in different subjects, that this point scarcely admits of being accurately determined. The Graafian follicle may, at the time of rupture, occupy $\frac{1}{4}$, $\frac{1}{3}$, or $\frac{1}{2}$ of the entire ovary. These at least are the dimensions which it is usually found to have, in different instances, during the first four months of pregnancy; but after this period the process of diminution begins to be perceptible. All the changes which are now observable in regard to form, solidity, and other particulars obvious to the unaided senses, and all the histological changes are to be looked for within the outer coat of the follicle. The latter appears to suffer no alteration, but simply to follow the movements of its contained parts, around which it remains loosely applied. The ovisac, however, or inner coat, rapidly increases in thickness, in consequence of a more considerable accumulation in its texture of the same yellow oil whose deposition had begun in it long before the follicle had ruptured, and when it was only approaching the surface of the ovary.

This thickening of the inner follicular coat is followed by a twofold result. The membrane, being confined by its outer tunic, now no longer distensible, as well as by the surrounding stroma into which the vesicle has now begun to sink, becomes more deeply plicated; and since it can no longer extend outwardly, it must of necessity encroach upon the cavity within. The latter thus becomes sensibly diminished, whilst the entire thickness of its boundary wall is in like proportion increased.

At the end of the first two months of gestation, the follicle possesses considerable solidity. The wavy and plicated condition of the yellow ovisac is now less distinct. The whole of this coat exhibits the appearance of a thick yellow layer, still occasionally traversed by numerous little blood-vessels, which run across it in straight lines from without inwards as far as its inner surface. The larger of these vessels probably do not actually pierce the yellow coat, but lie between the sulci, representing the original folds of the ovisac, and which, now pressed back to back without being yet obliterated, would still serve for the conveyance of blood-vessels to different parts of the tunic.

These changes continued to be in a certain sense progressive until the fourth month of gestation, about which time the Graafian follicle is usually considered to attain its highest state of development. But if the term development be admitted, it should be remembered that the only apparent purpose of these and other changes which ensue is still the obliteration of the structures in which they occur. The process of obliteration, however, has at this time not proceeded so far as to have caused the removal or even diminution of any of the original parts composing the follicle, whilst some new structures are superadded or produced by metamorphosis of the original materials.

The follicle at this period generally affords the best opportunity for observing the changes which result from impregnation. It may therefore be selected for a critical examination of the subject.

The external condition of the ovary in which such a follicle is contained serves at once to point out the precise seat which the structure occupies. Not only is the entire ovary larger than that of the opposite side, but it appears more swollen, and is perceptibly harder in one particular spot; over or near this spot a cicatrix may still be visible, and in its immediate neighbourhood are often found some serpentine vessels. If, now, a section be made of the ovary in this situation so as not to pass through the centre, but to include only a portion of the circumference of the follicle, the latter will present the condition represented in *fig.* 386. The follicle, in the

Fig. 386.

Section of the ovary of a woman who died at the end of the fourth month of utero-gestation. The Graafian follicle of the ovum which had been impregnated projects above the stroma. (*Ad Nat.*)

a, outer vascular coat (tunic of the ovisac); *b*, yellow inner coat (ovisac), from which a thin slice has been removed, not deep enough to lay open the cavity, but displaying the brain-like convolutions; *e*, portion of the follicle corresponding to *b*.

form of a little globe, is seen to occupy about a fourth part of the ovary. Its solidity and spherical form cause it to project considerably above the surface of the section. In this way is exposed the outer coat by which the follicle is bounded. Upon this coat numerous blood-vessels, derived from the ovarian stroma, ramify. It is the tunic of the ovisac, the original outer coat of the Graafian follicle, which in all the transformations of the latter suffers no change, until the time arrives when the whole body finally shrinks and disappears. The position and relations of this coat to surrounding parts leave no room for doubt as to its identity. Nothing bounds it externally but the stroma of the ovary. Nothing lines it internally but the yellow ovisac. Neither between its outer nor its inner surfaces, and the corresponding structures just named, is there at any time found any substance or medium interposed. This coat has undergone no material thickening, and its histological elements are simply those of the outer coat of the follicle, the same as before impregnation has occurred.

Proceeding inwards, the next coat is yellow; it has a nearly uniform thickness of $1\frac{1}{2}'''$. In its substance may still be seen traces of the original foldings or convolutions. These are more easily shown upon the surface of the first section (*fig.* 386.), but are less obvious in one carried deeper so as to include the centre of the follicle, where the

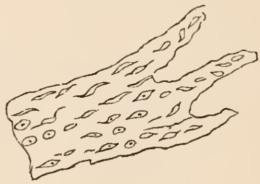
coat shows greater solidity (*fig.* 387.). Up to this time, however, and sometimes later, the vessels still traversing this coat in the lines of its former convolutions may be traced in many specimens, and the capillaries may still be filled by a successful injection to such an extent as to render the whole mass crimson.* Examined by the microscope, the following results are obtained:—The yellow coat, $1\text{-}1\frac{1}{2}'''$ thick, is soft, swells in water, and is easily torn into fragments which nevertheless hang together, being connected by a tough flexible medium. During this process numerous oil droplets escape, and form, with the drop of water in which the preparation is placed, a highly refractive fluid. This fluid, when examined, is seen to contain numerous particles of inappreciable size endowed with molecular motion, minute granules, and oil globules, which are at first also very minute, but soon collect and coalesce into larger drops that float to the surface of the fluid. The substance of the preparation also is everywhere pervaded by the oil drops which obscure its structure, and prevent further examination in this state. The preparation, having been treated next by ether, and subsequently washed in alcohol and replaced in water, it is found that the oil has entirely disappeared. The principal portion of the remaining substance has the appearance of a granular membrane, but in many places slightly wavy lines of connective tissue are perceptible. From the margins project in many places flattened bands composed of 8-10 filaments of common connective tissue, united by membrane, and having attached to them numerous granules. Separate fibres also appear at the margin of the preparation, but only from forcible detachment. Treated further by acetic acid, the oil globules, as well as the fibres, have totally disappeared. The course of the latter is now only indicated by numerous lines of round, oval, or elongated nuclei (*fig.* 388.), which are everywhere abundantly seen attached to a fine, structureless, transparent membrane. The outlines of the

Fig. 388.



× 350.

nuclei are very sharp and distinct, and within them are contained one or two nucleoli. This coat is traversed by numerous blood-vessels and capillaries, and to their coats in all probability many of these nuclei belong.

The yellow coat is bounded internally by a third tunic which is white, having precisely the milk-white colour, and very nearly the consistence, of articular cartilage. It is of variable thickness, but often $\frac{2}{5}'''$ or more in diameter. It is very tough and coherent in texture, and is with difficulty split by needles, breaking into irregular fragments. These, examined by the microscope, are seen to be composed of tough fibres of connective tissue, whose arrangement in wavy lines may be perceived through the mass, but which are so closely connected together, by a semitransparent membranous medium as to be inseparable into distinct fibrillæ, except at the margins of the fragments, where they are tolerably distinct; where also the connecting medium may be seen in the form of a structureless membrane. Minute granules are everywhere seen scattered throughout the mass, and adherent to the detached fibrillæ. Treated by acetic acid, the fibres become transparent and pale, their outlines being hardly distinguishable. Oval nuclei, rather scanty, lie in the direction of the fibres. The whole sub-

* Montgomery, Signs of Pregnancy, p. 227.

stance has the appearance of a tissue which is in a low state of vitality.

It is probable that the presence of this coat within the follicle has been the cause of most of the differences of opinion which have existed regarding both the seat and the nature of the yellow portion of the follicle of pregnancy. It seems to have been assumed, without further examination by many who have written upon this subject, that the coat last described is one of the coats originally composing the Graafian follicle; whereas it is formed by the metamorphosis of the blood-clot, already described as occupying the centre of the follicle before even the ovum escapes. I have seen very distinctly the fibrillation of this clot soon after the follicle has closed. It is then found to be gradually becoming pale, the red particles disappear by degrees, the clot adheres firmly to the inner surface of the ovisac, and the mass is converted into the low form of tissue just described, which may either take the condition of a membrane lining the cavity and leaving a central space filled by transparent fluid, or the whole may be converted into a solid body. Either of these forms may be observed, and the knowledge that each may occur disposes of the speculative question as to the time when the cavity of the follicle is obliterated.

On the other hand, the yellow coat which has been often described by authors as altogether a new formation, deposited either between or external to both of the follicular coats, can be most easily traced through all its phases, beginning in the ascending vesicle, as the original ovisac; its structure filled with nucleated cells, which gradually become charged with oil droplets until the whole tissue assumes the peculiar yellow which is so distinct about the time of bursting of the follicle. And this colour it never loses until the time of its complete obliteration approaches; but through all the subsequent changes of the follicle the same anatomical structure and the same relative position of parts is preserved.

In the original preparation from which *fig.* 387. was taken, nothing served to distinguish the several coats better than their colour. The outer coat or theca folliculi was red; the second coat, or ovisac itself, chrome yellow; the now internal and newly formed coat was milk-white.

It remains to describe the cavity in the interior of the follicle, which, though sometimes obliterated, is more frequently found still existing at the fourth month of utero-gestation. In the specimen represented in *fig.* 387. the cavity measured 3‴ in diameter and contained a clear gelatinous fluid. In other cases a cavity at this time no longer exists, but the centre of the ovisac is occupied by a tough white substance, whose origin has just been explained.

It will not be requisite to follow out minutely the remaining changes which the Graafian follicle undergoes. After the fourth or fifth month of pregnancy a certain diminution in size begins to be perceptible. The walls of the cavity approach nearer to each other, and the white lining becomes thinner, and begins to be folded into plaits which, radiating outwardly, are seen intermingling with the yellow colour of the proper ovisac (*fig.* 389.). The outer boundary of the follicle also now presents an irregular and somewhat angular and occasionally an oval outline. These changes proceed with much variation in different subjects; but usually at the time of delivery the ovisac, though still yellow, has lost much of its brightness, and the cavity, if it had existed, is replaced by a solid white stellate cicatrix (*fig.* 389.) caused by the folding of the white lining

Fig. 389.

Graafian follicle two days after mature delivery. The white lining of the cavity (c, fig. 387.) is here folded into a stellate figure. It is surrounded by the darker yellow ovisac (corpus luteum), whose outline is become angular. (After Montgomery.)

membrane which bounded the ovisac on its inner surface. That the yellow coat is still vascular at this time is proved by the fact mentioned in the preceding page.

In proportion as the entire generative organs subside into a quiescent state, so the remaining changes in the ovary take place more rapidly. The yellow colour of the ovisac passes into a paler hue, and at last into white. The radiating cicatrix may still be traced for some time longer, until, at the end of four or five months after delivery, every appearance of this structure has ceased to be discernible.

Certain physiological questions intimately connected with the foregoing history of the development and involution of the ovarian follicle may now be briefly considered. And first it may be asked—

Does the discharge of ova from the ovary take place independently of sexual intercourse, or of any kind of influence from the male?

This question has long ceased to be agitated with reference to animals lower in the scale than the Mammalia. It need, therefore, now only be considered in its relation to the latter, including Man. And since many have recently undertaken to prove that Man and the Mammalia constitute no exception to the general rule that in all classes of the animal kingdom which produce and emit ova the act of emission of ova is independent of the male, so, whatever form the inquiry may now take, it would naturally have for its chief object the determination of the value of the evidence upon which such an assertion has been based.

Now, the facility with which the process of ovulation may be observed in animals justifies the expectation that in such a case the amount of objective proof, collected by those who have undertaken to establish a law of spontaneous ovulation in Mammalia, would be sufficient to prove that law beyond the possibility of question. But when we turn to the principal writers who have devoted their attention to this point, with the view of collecting and critically examining such evidence, it must be confessed that the result is productive of a certain feeling of disappointment at the form in which the facts have been recorded, and the circumstances under which the observations and experiments have generally been made.

This is more particularly felt when, after examination of the evidence adduced, an unhesitating acceptance of the law, as one of universal application, is demanded. Before, however, the question of universality is considered, it will suffice, for the purpose of proving the possibility of a spontaneous ovipont, to give one or two examples in which all the conditions necessary to establish this fact were observed, viz., absence of coitus, rupture of the ovarian follicle, and the presence of the unimpregnated ovum in the oviduct.

The following case is related by Bischoff.* A lamb which had never received the male, and which had exhibited signs of "heat" about an hour previously, was shut up alone. On the following morning the male was admitted (for the purpose of testing the heat). He several times showed a desire for the coitus, but was prevented. The animal was killed the same afternoon, when it was found that a Graafian vesicle in the right ovary had burst. The spot did not project from the surface of the ovary, but attracted attention by the circle of red vessels surrounding the small opening which constitutes a familiar appearance in dogs and rabbits after bursting of a follicle. The diameter of this opening was about $\frac{2}{5}'''$. As a matter of precaution, search was made for spermatozoa, in order to obtain the negative certainty that no coition had taken place, but none were found. The infundibulum contained a thread of mucus intermixed with granules resembling those of the membrana granulosa. The Fallopian tube was next carefully examined, and at a distance of $5'''$ from its entrance was found an ovum still surrounded by the cells of the granular disc, and possessing all the characters of the unimpregnated ovarian ovum.

But since in this instance the presence of the male was permitted, though coitus was prevented, as was also the case in one half of the instances recorded by Bischoff in his celebrated Treatise from which this example is quoted, it may be well to notice another observation taken from Raciborski †, in which this possible objection was removed.

A bitch which had never been covered, and was just commencing to be in heat, was kept shut up for eight days, apart from other dogs. It was then killed. Only one ovary was examined, the other having been laid aside and forgotten. Three large follicles of a lively red occupied the entire surface of the ovary. One of these follicles was already shrunk, and presented at its summit a distinct fissure. In each cornu of the uterus, an ovum, the size of a poppy-seed, was found, surrounded by bloody mucus, — the one at a distance of about $2\frac{1}{4}$ inches, and the other at $\frac{3}{4}$ of an inch from the extremities of the tubes. Doubtless, if the other ovary had been examined, at least one follicle would have been found to have opened there also.

In order to show that the same process of discharge of the ovum, independent of sexual congress, may take place in the human subject, a case, recorded by Dr. Letheby, may be here quoted*:—"The body of a lunatic, aged 23, who had died in St. Luke's Hospital, was examined. She had been a patient in that institution for eleven months, under circumstances which deprived her of the opportunity of associating with a male for a long period before her death. It was ascertained that the girl had quitted life during a menstrual period; the cavity of the uterus, and the Fallopian tubes, contained a red, jelly-like secretion. On the outer and lower part of the right ovary was a dark livid spot, in the centre of which was a hole. On making a section of the ovary so as to divide it through the spot and an adjacent cicatrix, it was perceived that the hole led into a cavity which was surrounded by a dark-red tissue, and that the cicatrix communicated with a very perfectly-formed *corpus luteum*, having a central cavity containing a dark-red clot. In the right Fallopian tube was discovered a little globular body of the size of a pin's head. This was seen, under the microscope, to consist, in its outer surface, of a mass of nucleated cells. At one end of this mass was a transparent ring, enclosing a rather opaque granular mass, in which there was an eccentric spot." The author had no doubt that this was the ovule consisting of the zona pellucida, yolk, and germinal vesicle. In another case related at the same time, and where the hymen was perfect, similar results were obtained.

The possibility of a spontaneous ovipont having been established by these and like instances which might be quoted, it becomes important next to determine how far the law just enunciated is universal in its application; we may therefore inquire, —

Does the discharge of ova from the ovary always take place spontaneously, and independent of sexual intercourse?

It is in endeavouring to determine this question, so far as the attempt has been made to base this law upon observations and experiments on animals, that the difficulty to which I have just adverted is experienced; for, whilst there is no lack of argument upon the subject, it must be confessed that the number of well-recorded instances proving a spon-

* Beweis, p. 24. See next page.
† De la Puberté, p. 376.

* Phil. Trans, 1852, pt. i. p. 5.

taneous ovipont in mammals is exceedingly small.

It will suffice for illustration to observe the manner in which this question has been handled in the celebrated works of Bischoff*, Raciborski†, Coste‡, and Pouchet.§ The first only of these authors has given in detail the observations and experiments upon which he has endeavoured to found a law of spontaneous ovulation in the Mammalia. In several of these the coitus was permitted; and although it is rendered highly probable, from the circumstances narrated, that in some this had no effect in producing the discharge of ova, yet the introduction in any form of the only condition that could vitiate the experiments detracts certainly from their value. In five, however, of Bischoff's experiments it was known that coitus had not occurred, and in three of these ova were found discharged, accompanied by the usual appearances in the ovaries indicative of the recent rupture of the follicle.|| In a fourth case, the state of the ovaries left no doubt that the ova, which could not be found, had escaped; while a fifth case was examined before the ova had escaped. To these Bischoff adds an example of the ovipont in an animal, in which it was only probable that no coitus had occurred.

The work of Raciborski contains a single example, which has also just been quoted.

The works of Coste and Pouchet contain no examples of a spontaneous ovipont in animals, but the observations of each of these authors are given in the form of results. Each work contains a minute description of the process of ovulation, drawn apparently from separate observations; but these descriptions are not accompanied by any detailed examples, nor any statement of the means used to render these observations proofs of an ovipont, independent of coitus.

But all these authors agree in stating that ovulation occurs independently of sexual union, whilst they differ as to the degree of strictness with which the universality of this law is enforced. Pouchet demands that the law should be received without any exception, and observes with surprise the "unaccountable vacillations" of those among his predecessors who yield to it only a partial assent.

But in the absence of any extensive series of well-recorded observations, whose numerical force shall be such as to compel a universal acceptance of the law, it is not surprising that some who regard it as having been too hastily framed, and as too rigid in its exclusiveness, should withhold their full assent to it. For let it be conceded that the ova, when they have attained their complete development, escape naturally from the ovary, the rupture of the follicle not necessarily requiring the intervention of the male, should it therefore be inferred that the latter is completely inoperative when exercised on opportune occasions?

In this form the question is put by Coste, who maintains that although the coitus may not be the essential cause of the rupture of the follicle, yet it undoubtedly has the power to precipitate that event, and even to prevent its failure. He further considers that there is this difference between the fecundated female and one in whom impregnation does not take place; that in the former the rupture of the follicle is prompt, whilst in the latter it is tardy, or even in certain cases fails to occur.

In order to support this view, Coste cites two observations upon the rabbit. In the first of these, the animal was in heat, and manifested great ardour for the male, but coitus was not permitted. It was kept for forty-eight hours, and then killed. The genital organs were highly congested. Six follicles in one ovary, and two in the other, were apparently ready to burst, but no rupture had yet taken place. In the second experiment, the animal remained in heat for three days; on the fourth day the heat ceased, and on the fifth it was killed. The organs were in the same condition as in the last case, but no follicles had burst. Coste attributes the absence of rupture in these cases to the prevention of the coitus at a time when, if permitted, it would in his view have determined that event.

In whatever light these observations may be viewed, they are important as showing that an animal may sometimes advance far in the period of heat, and even pass through it without any ova escaping from the ovary; but it would require a very much greater number of parallel observations to prove by such negative results the effects of the sexual congress in determining the act of the ovipont. And it is matter for regret that this point has not been more clearly determined; for whilst no satisfactory results can be looked for from any observations upon this part of the subject in Man, this is eminently a question capable of being determined by experiments on animals. All the earlier observers who directed their attention to the condition of the ovaries in relation to reproduction bear unconscious testimony to the fact that the time at which the ova quit the ovaries bears no strict relation to the act of coition. Barry states that, taking the coitus as the starting-point of his reckoning, he was obliged to sacrifice a score of rabbits before he succeeded in meeting with one instance of the ovum at a particular time after its escape, and he had almost given up the attempt in despair.

If means be used to prevent the contact of the seminal fluid with the ova after their discharge from the ovary, or to prevent its arrival at the latter organ before rupture of the follicle, this does not affect the immediate condition of the follicle. The number of ruptured Graafian vesicles which have been found, after experiments made by placing ligatures upon

* Beweis der von der Begattung unabhängigen periodischen Reifung und Loslösung der Eier, &c. 1844.

† De la Puberté, et de la Ponte périodique. 1844.

‡ Histoire du Développement. 1847.

§ Théorie positive de l'Ovulation spontanée. 1847.

|| One of these cases is given above.

the tubes before coitus was permitted, has usually amounted to the sum of the ova discharged. If one side of the uterus be tied, the ova found in that cornu will not have been impregnated, but those on the free side will be developed. The number of ruptured follicles in each ovary will agree with the number of ova found in the corresponding tubes; but no difference will be perceptible between those on the impregnated and those on the unimpregnated side of the uterus. The contact, therefore, of the seminal fluid with the ovary has nothing to do with the discharge of the ova, or with the formation of a " corpus luteum." The only question that can here have place is, whether the excitement of the coitus, or the contact of the seminal fluid with the inner surface of the vagina and uterus, has any influence in precipitating the discharge of ova from the ovary when they are ripe for impregnation. This, however, is, in the present state of our knowledge, an unsettled point. By all the earlier observers down to Barry, it was assumed that the coitus was the sole determining cause of the ovipont. By most physiologists since that time the coitus has been regarded as having nothing to do with the discharge of the ova, or only a limited power has been ceded to it, as in the view of Coste just detailed.

So far as numerical amount of recorded observation goes, it may be asserted that the spontaneity of the act of emission of ova, independent of sexual intercourse, has been more fully and satisfactorily proved in Man even than in animals. In the works and essays upon this subject, to which reference is given in the preceding page, a large amount of evidence will be found; but since some proofs of this fact have been already given, and since it is proposed again to return to the subject in considering the question of menstruation in its relation to ovulation, it will not be necessary to pursue the subject further here. (See page 666.)

In tracing the process of ovulation, it will have been observed that the ovarian follicle passes through a series of changes, so gradually progressive and of such a definite character, that the knowledge of these may be turned to great account in any investigations relating to the ovipont; for, next to the discovery of the ovum itself, whether in the ovary, Fallopian tube, or uterus, the condition of the capsule, from which it is about to be or has been already discharged, will afford the best evidence as to its probable locality and condition, even should the ovum not be found. Doubtless, one of the greatest impediments which has been encountered in investigations of this class arises from the extreme difficulty, and often the impossibility, of finding the ovum in many situations on account of its minute size. Hence, in the absence of this demonstrative evidence, which cannot always be obtained, any other, which, though only inferential, may be made available for a like purpose, is of great value. Wanting the ovum, therefore, the state of the ovicapsule may be made, in part at least, to supply the evidence which is deficient. Now it has been shown that, whatever affects the ovum, to determine its development or the converse affects in a like degree the follicle from which it had been discharged, not on account of any apparent sympathy between the ovum and the follicle which once contained it, but from the whole generative track being more or less brought under the power of one common stimulus, felt alike by all the parts that are employed for the nutrition and protection of the ovum. It will be desirable, therefore, now to determine what evidence the condition of the ovarian follicle affords, first, as to the previous escape of an ovum, and secondly as to the probability or certainty of that ovum having been impregnated or otherwise. But since it is desirable to fix the value of certain terms which are commonly employed to designate particular states of the follicle, it will be needful, first, to determine,

What is a corpus luteum?

This term, as Raciborski has observed, is indicative of the infancy of science. It belongs to a period when anatomists were in the habit of designating by the word body or *corpus* any part of the animal economy whose nature or relation with other parts they did not comprehend, adding to this some distinctive title drawn from the general appearance of the part. Hence the terms *corpus striatum*, *corpus callosum*, *corpus luteum*. It is an unfortunate circumstance that such a term was ever applied to the Graafian follicle, and the more so since it is often employed without any definite meaning.

The Graafian follicle in its progress towards full development, and previous to its rupture, has been described as becoming yellow. This fact has been long known. It is stated by Home, Baer, Valentin, Wagner, and Bischoff. The cause of the yellow colour has been fully explained. After impregnation this yellow colour becomes still more conspicuous on account of the greater thickness of the ovisac or inner coat of the follicle, which is the seat of the change producing this colour. From the greater distinctness, larger size, longer duration, and other peculiarities of the follicle after impregnation, an artificial distinction has been made between the follicle in this state, and all other forms of it, in which it exhibits the yellow colour. The former are arbitrarily called "true," and the latter "false" *corpora lutea*. But there is as little reason for the use of the last term, as there would be for denominating a child a false man; for that which is commonly designated the "true" *corpus luteum* is the follicle in its largest condition of growth, as it appears after impregnation; whilst in all other conditions, when it has not been stimulated to full growth by impregnation, and whether before or after rupture, it has been called a "false" *corpus luteum* so long as it possesses the yellow colour. This distinction, therefore, as far as regards the terms employed, is not only unscientific and arbitrary, but is calculated to mislead by suggesting the idea that the so-called "true" *corpus luteum* is a totally different body from the "false," whereas these terms actually represent the same body, only in different stages of growth or decay. But practically it becomes a question how far it may be possible to determine, from the physical appearance of the follicle, whether impregnation has taken place. And this question is a very important one, especially in its obstetric and forensic bearings.

From the account already given of the several stages of growth and decay of the ovisac, it will have been seen that the yellow colour is common to all these alike, with the exception only of the earliest and the very latest stages. It alone, therefore, can afford no distinctive evidence upon the subject. But, in combination with other signs, the yellow colour, by its extent, may be made available to distinguish those cases in which impregnation has occurred; for when this is the case the ovisac, as stated, continues to increase in thickness; a greater abundance of yellow deposit takes place in its tissues; the follicle, instead of shrinking and disappearing in the course of one or two months, continues to be visible for fourteen or fifteen months. It acquires a new coat which lines its cavity, or else this cavity is entirely closed by a coagulum which becomes organised and solid; it presents the convoluted appearance which gives it a resemblance to the cerebral convolutions, and this convoluted condition gradually passes into one which is characterised by the presence of rays proceeding from a centre. Finally, the whole body constitutes a resisting and more or less solid mass, which can at once be detected by the touch, before the ovary is opened. The distinctions, therefore, are chiefly those of degree: the greater solidity; the greater thickness of the yellow walls; their more marked convolutions; the long persistent cavity, round or oval at first, and subsequently stellate; the milk-white membrane lining the cavity, when the latter exists, or the white dense mass occupying its place, resulting from the transformation of the clot. These last characteristics of the so-called true corpus luteum, viz., the cavity lined by the white membrane or the solid white centre, as well as the large central stellate cicatrix, may be regarded as absolute and not comparative distinctions, for they are not found in the follicle in process of involution when impregnation has not taken place.

With regard to scrofulous tubercles, which have been often enumerated among "false corpora lutea," it is probable that some of the conditions of the ovisac now described have been hastily set down to this score, without sufficient examination; for although scrofula may possibly affect the ovary, as it does the testis, yet a formation there of distinct scrofulous tubercles, unless they are abundant in other parts of the body, is, I am satisfied, a rare, if not an unknown, occurrence. No doubt, however, need at any time exist as to the nature of such bodies, since, if the bright yellow colour of the ovisac is not sufficiently marked, as in those cases where they have become pale, and more nearly approaching the buff colour of tuberculous matter in general, the microscope will at all times determine the question, for in respect of composition there is nothing in common between tuberculous matter and the ovisac in any of its natural stages of growth or decay.

Setting aside morbid states, nothing is ever seen in the perfectly healthy ovary except the stroma and ovisacs or Graafian vesicles in different stages of development or decline. These may be arranged in three series:

Ascending Series.

1. The simple undeveloped ovisac, before it has acquired an indusium from the stroma of the ovary, or from the walls of an already developed follicle, in which it may be formed. It requires at this time the microscope for its examination (*fig.* 373.).

2. The ovisac after it has acquired its outer capsule, by union with which it has become a Graafian follicle.

3. The Graafian follicle of the size of a hemp seed, or rather larger. It contains oil granules in the coats of the ovisac, but not yet in quantity sufficient to produce a yellow colour. In this state numerous follicles are seen in sections of every healthy ovary during middle life (*figs.* 370. and 372.).

4. The follicle when it is approaching the surface of the ovary. It is enlarging, and its inner coat or ovisac has now a yellow colour.

5. The ripe follicle which is about to rupture and discharge an ovum. It is always found at the surface of the ovary, projecting often to a distance of 3-4‴. It is covered by numerous veins, and in the centre of the most prominent part the coats of the follicle, as well as the ovarian coverings, are thinned and partly absorbed. Their thinness permits the contents of the follicle to be partly visible, and thus is produced a brownish red colour at this spot. The follicle contains blood or a bloody fluid, and sometimes a clot. The cavity is of considerable size, 4-6‴. The inner coat is of a bright yellow colour, and exhibits slightly wavy folds (*figs.* 380. and 381.).

6. The follicle which has already ruptured. An irregular lacerated opening extending ½-2‴ is perceptible in the centre of the attenuated part, through which the ovum, together with that portion of the membrana granulosa which lay beneath the seat of the rupture, has escaped, or is about to escape. The follicle is beginning to collapse. Its walls, no longer distended, become folded into numerous small plaits, producing, on section, the appearance resembling cerebral convolutions. The cavity is consequently diminished. It is empty, or contains a little bloody fluid or a clot (*fig.* 385.).

Descending Series. A. Not pregnant.

7. In the follicle which has recently burst, shrinking has commenced. The yellow ovisac is much plicated. The cavity contains a clot which is becoming pale, and exhibits under the

microscope distinct fibrillation, or the cavity is empty and much contracted.

8. The shrinking having rapidly progressed, the ovisac exhibits deep plications, and the rays are beginning to form, but the yellow colour is still distinct.

9. The cavity is nearly or entirely obliterated. The yellow colour is gone, but the rays remain, and the collapsed follicle now forms a white stellate body with a small central point (*fig.* 372. *h*).

10. The follicle itself is reduced to a mere point in which none of the foregoing characters can be traced.

Descending Series. B. After Impregnation.

11. The follicle has not materially diminished in size. The lacerated opening is closed. The yellow coat is much plicated, and the clot when present shows fibrillation, as in No. 7., or the cavity is empty.

12. The follicle has acquired greater firmness and solidity. The yellow ovisac is much increased in thickness. The folds are not so numerous, but are deeper, though not quite so distinct. Vessels contained between the folds appear to pervade the yellow coat. The white lining of the cavity is formed, and within it is a clear fluid, rather viscid, (*fig.* 387.), or the centre of the yellow ovisac is solid, and exhibits no cavity.

13. The central cavity is nearly or entirely obliterated. In the latter case a solid white body occupies its place, extending into the yellow mass in divergent rays. This arises from the plication of the white lining, by which process the cavity is closed. The colour of the principal mass is now a dirty yellow; it is somewhat reduced in size, and its outline is oval or irregular (*fig.* 389.).

14. The more prominent features observable in the last condition may still be faintly traced. In size the body measures 2-3‴. It is of a pale white, and is chiefly distinguishable from the surrounding stroma by the absence of vascularity in its tissues. Its solidity is gone.

To return, then, to the two questions which led to the foregoing considerations as necessary to their solution, viz.—

What evidence does the condition of the ovarian follicle afford, first, as to the previous escape of an ovum, and secondly, as to the probability or certainty that that ovum has been impregnated or otherwise?

It may be concluded that whenever the follicle presents the appearances exhibited in the first series down to and including No. 5., the ovum has not escaped; although it may not be detected, either on account of the difficulty of finding so small a body, or else because it may have perished by absorption or decomposition.

In the condition No. 6., an ovum has just escaped, or is in the act of escaping. None of these conditions of the follicle afford the slightest evidence of previous impregnation. They have all been repeatedly observed both in Man and animals where the coitus has never occurred.

Between No. 7. and No. 11. it may be difficult to draw a positive distinction. No conclusion regarding the question of previous fecundation, derived from the state of the follicle during the first fortnight after the escape of an ovum, would be absolutely safe; although the difference between the unimpregnated and the impregnated is such as to afford in every instance at least strong presumptive evidence, for the follicle shrinks rapidly in the former, while in the latter it undergoes little or no diminution in size.

But after this period there can be no question as to the prior occurrence of a fecundating coitus. Every follicle presenting the conditions described in Nos. 12, 13, and 14 has discharged an ovum, which has been afterwards impregnated. Every follicle in the states described in 8, 9, and 10 has discharged or has contained an ovum which has perished. But this proves only that fecundation has not occurred. It affords no evidence whatever that the coitus has not obtained.

Lastly, it may be observed that if, as is sometimes the case, the follicle fails to complete the process of rupture after the first steps of preparation have been made, the ovum may perish or be absorbed without being discharged, and the follicle will then shrink and become obliterated, as in the first series of changes. And it is further noticeable that although the number of Graafian follicles exhibiting the appearances indicative of the discharge or fecundation of ova, may generally be taken to represent the number of ova also actually discharged or fecundated, yet this will not always furnish a safe guide, because one follicle may contain two ova, or one or more ova may have escaped the influence of the coitus which had fecundated the rest. The number of ruptured or altered follicles therefore will in the first case be less, and in the second greater, than the number of ova or fœtuses found in the oviducts or uterus.

Development and Involution of the Ovary.

The Origin of the Ovary, and the Alterations which it undergoes at different Periods of Life.

The ovary takes its origin in a separate portion of blastema, quite independently of the Wolffian body, with which it is in close contact. It is not indeed until after the development of the Wolffian bodies has made considerable progress, and about the time at which the kidneys first appear, that, according to the observations of Bischoff on the mammalian embryos generally, the ovaries are first perceptible.

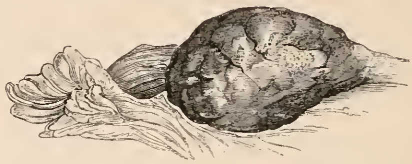
In the human embryo the ovary cannot be discerned earlier than the 5-7th week. Nor is it possible at the time of its first appearance to distinguish the ovary from the testis. Hence the term "generative gland" has been proposed by Kobelt as the most appropriate designation for a structure which, according to him, is then capable of being converted into either organ indifferently. In a human embryo of the fourth week, of which I have given a description in the Transactions of the

Microscopical Society of London *, no trace of an ovary or generative gland was discoverable, but only slight indications of two linear-shaped bodies occupying the dorsal and lumbar regions on either side of the vertebral column, representing the corpora Wolffiana. In another embryo measuring 5‴ in length, the generative gland could just be discerned in front of the supra-renal capsules and kidneys, but its form could be only indistinctly traced. In an embryo, however, which measured 8‴ in length, the gland had already assumed distinctly the elongated figure characteristic of the early formation of the ovary. It measured 0·8‴, and its position was oblique, or intermediate between the perpendicular direction of the Wolffian body and the horizontal one of the fully formed ovary. In an embryo of three months the generative gland or ovary still retained the oblique direction. Its length was 2‴, and its breadth 0·4‴.

From this period the gland, which now begins to assume more decidedly the character of an ovary, gradually acquires the horizontal position in which it is found at birth (*fig.* 440.). In the fœtus at term the ovary has usually attained a length of 4-5‴, and a breadth of 1½-2‴ (*fig.* 441.). Its figure is an extended oval, with flattened sides and base. These meet to form a triangle, whose basal margins are sinuous and sometimes indented. At the age of three years, (*fig.* 442.) the ovary attains a length of 10-12‴, still however preserving its elongated form, with irregular or slightly indented margins. This peculiarity of a fœtal condition the ovary gradually loses as the period of puberty approaches, when it grows more rapidly and acquires the form and dimensions already described as characteristic of the mature organ (*fig.* 369.). At this period of life, however, no feature of the ovary is more subject to variation than its form. Even for some time after the catamenia have been established, the elongated figure is often seen to have been retained, although the rounded or gibbous outline is more commonly observed by the time that adult age is attained.

The ovary is now full and plump ; its surface up to the time of puberty has remained uniformly smooth, even, and shining, and its investing tunics are unbroken.† But it has been seen that, from puberty onwards, through these two tunics of the ovary, the ova periodically escape by a process of dehiscence, resulting from an absorption and rupture of these tunics. The effect of these repeated lacerations is twofold. The surface becomes scarred in all directions by the closing up of

Fig. 390.



Ovary about the time of cessation of menstruation. (*Ad Nat.*)

the lacerated openings, whilst the successive discharges of the contents of the ovisacs gradually diminish the bulk of the entire organ (*fig.* 390.). In proportion as age advances, these cicatrices and indentations become still more numerous, and the once smooth and plump ovary is converted into a small corrugated wrinkled body full of pits and tortuous

Fig. 391.

Ovary in old age. (*Ad Nat.*)

lines (*fig.* 391.). When sections are made of the ovary in this condition, it is found that all traces of the Graafian follicle have disappeared; or one or two only may be observed, degenerated into little masses or sacs of cartilaginous hardness. More commonly, however, nothing now remains but a dense parenchyma.

Besides these changes in the form of the ovary and the condition of its component parts, great alterations also take place in its vascular supply. In early life, and especially from the establishment of puberty up to the critical age, the organ is abundantly supplied with blood-vessels, which are seen everywhere both in the proper parenchyma of the ovary, and also upon the walls of the ovisacs. These have been described as undergoing enlargement, and probably increasing in number in the neighbourhood of the spot at which the rupture of the follicle occurs. Not only, however, is there a local hyperæmia in these situations at each recurrence of the ovipont, but the entire ovary receives a larger supply of blood on these occasions. But when the process of ovulation has entirely ceased, the tissues begin to suffer the wasting of age, the ovary partakes in the general state of pallor of the other pelvic viscera, and the ovarian vessels carry only as much blood as will suffice for the bare nutrition of the shrivelled organ.

* Vol. iii. part ii. p. 65.

† In reference to the human subject, the universally received opinion regarding the discharge of ova by rupture of the ovisac, as an occurrence which commences only at or after puberty, has been called in question by Dr. Ritchie, who, after detailing a series of observations upon the condition of the ovary at various periods of life, asserts that "the Graafian vesicles contained in the ovaries prior to menstruation are found, as they also are in every other period of life, in continued progression towards the circumference of the gland, which they penetrate, discharging themselves by circular-shaped capillary-sized pores or openings in the peritoneal coat; the presence of the catamenia being thus no indispensable prerequisite to their rupture."[1] It should be observed, however, that the facts adduced by Dr. Ritchie do not appear to bear out very clearly the conclusions which he has drawn from them.

ABNORMAL ANATOMY OF THE OVARY.

Effects of extirpating the Ovary.— A natural deficiency of the ovary together with the oviduct of one side is known to prevail in the class *Aves*, but this deficiency, which is occasioned only by a want of development of one half of the generative organs previously existing entire in the embryo, does not affect the reproductive power of birds.

Mr. Hunter, wishing to determine the effect of extirpating one ovarium upon the number of young produced in Mammalia, procured two young sows of the same farrow, and having removed a single ovarium from one of them, he kept both animals under the same circumstances, in order to observe the comparative effects of breeding upon them.

They commenced breeding when two years old. The spayed animal took the boar earlier than the perfect female, and both continued to breed at nearly the same times.

The spayed animal continued to breed until she was six years old, and in that time she had eight farrows, producing in all seventy-six pigs, but she did not take the boar afterwards. The perfect sow continued breeding until she was eight years old, and had thirteen farrows, yielding one hundred and sixty-two pigs. She then ceased to breed. The result therefore of this experiment was, that the perfect animal continued to breed two years longer, and produced in all ten more than double the number of the spayed one, although she had not double the number of farrows.

But few opportunities have occurred for observing the effects produced by the removal of the healthy ovaria upon the human female.

The case in which Mr. Pott removed both these organs at the same time constitutes the best example on record.

A young and healthy woman, twenty-three years of age, was received into St. Bartholomew's Hospital, on account of two small swellings, one in each groin, which had for several months been so painful as to prevent her from following her occupation as a servant. The swellings, which were not inflammatory, were soft, uneven upon their surface, and moveable. They lay directly upon the outside of the tendinous opening of the oblique muscle through which they appeared to have passed. The woman was in full health, was large breasted, and menstruated regularly. On account of the inconvenience occasioned by the presence of these tumours in the groins, Mr. Pott was prevailed upon to remove them. They were found upon examination to be the two ovaria which had descended in the form of a double inguinal hernia. The woman subsequently enjoyed good health, but became thinner and more apparently muscular; her breasts, which were large, were gone, nor did she ever menstruate after the operation; the last observation of her having been made several years subsequent to that event.*

Deficiency of the Ovary. — Complete congenital absence of both ovaries, except in the case of the non-viable fœtus, is of extremely rare occurrence. It is almost always associated with deficiency or imperfect formation of the uterus, and generally with incomplete development of the vagina, nymphæ, clitoris, and mammæ. The sexual appetite in these cases is wanting. Menstruation is absent; the secondary sexual characters are but feebly expressed, and there is of necessity a total inaptitude for reproduction.

The ovary may, however, be deficient on one side only, without any of these accompanying conditions. There may be nothing externally to mark the defect, nor is there necessarily here any impediment to the exercise of the sexual function.

Arrest of Development. — The ovary, like the uterus, long retains its infantile condition, but as the period of puberty approaches it expands and soon attains its full size. This change, however, may not occur. The ovary may cease to grow after the third or fourth year, and, under these circumstances, the whole organism manifests a corresponding tardiness of development. An interesting example of this is preserved in the museum of King's College. The preparation consists of the entire internal organs of a young woman who died at the age of nineteen without having menstruated. The ovaries, as well as the rest of the organs, are no larger than those of a child of three years (see *fig.* 465.). In these cases the mammæ are small, the external organs only partially developed, and the whole frame is formed upon a feeble scale.

Atrophy and Hypertrophy. — Atrophy has been shown to be one of the conditions at which the ovary inevitably arrives when a certain period of life is passed. It is under these circumstances a normal condition, just as the state last described is also a normal condition when associated with a certain epoch, but both become abnormal states when they occur out of their usual course. Thus, an early atrophy of the ovary on both sides will of necessity bring with it a premature failure of procreative power, although an atrophied state of the organ on one side only, like atrophy of one testis, will but little, if at all, affect this power.

Of hypertrophy of the ovary a more particular account will be given in the description of morbid growths and abnormal developments of its special parts.

Displacements of the Ovary. — The ovary, in consequence of its peculiar mode of attachment to surrounding parts, enjoys great freedom and range of motion. This is rendered most conspicuous, when, during the gradual enlargement of the gravid uterus, the ovary is carried upwards from the pelvic into the abdominal cavity. Under these circumstances the ovary certainly vindicates the character assigned to it by the older anatomists, of being an appendage to the uterus, for it necessarily follows the movements of the larger organ to which it is attached. Thus, the ovary is sometimes a pelvic and sometimes an abdo-

* The Chirurgical works of Percival Pott, by Earl, vol. ii. p. 210.

minal viscus. But it may be displaced from its normal position in either of these cavities under various circumstances. The causes of such displacements are chiefly, inflammation of the surface of the ovary terminating in adhesions, displacements of the uterus, and herniæ.

As a result of inflammation of its peritoneal covering, the ovary may be bound down to the side of the uterus, or Fallopian tube, to the recto vaginal pouch, to the brim of the pelvis, to the colon, to the convolutions of the ileum, or to the omentum.

The displacements of the uterus which occasion a dislodgement of the ovary from its normal position are, retroversion, inversion, and procidentia, or complete prolapsus.

In retroversion the ovaries are carried downwards along with the uterus into the hollow of the sacrum, where they occupy a position on either side of the principal organ. In inversion of the uterus, the ovaries, together with the Fallopian tubes, fill the interior of the artificial pouch, which is formed by the reversement of the organ ; whilst in extreme prolapsus the ovaries, together with the uterus, escape almost entirely from the pelvis, and occupy the sac which is formed by the inverted vagina.

But the most remarkable displacements are those in which the ovary constitutes a true hernia. Such a hernia may consist of the ovary only, or may include other organs, as the Fallopian tubes, uterus, intestine or omentum. A true hernia of the ovary alone is of comparatively rare occurrence. It may happen on one or on both sides, and may be either congenital or acquired. The celebrated case of Mr. Pott was an example of a double inguinal ovarian hernia. And this appears to be the form under which this singular displacement has been most frequently met with. In these cases the ovary constitutes a solid tumour of the size of a pigeon's egg, which may be detained at the ring, or lie within the inguinal canal, or even descend to the labium.

An example of this kind of hernia, in which the left ovary has for many years occupied the inguinal canal, has recently come under my notice. Deneux *, who was at the pains to search out all the cases on record up to his time, has collected examples also of crural, ischiatic, umbilical, ventral, and vaginal hernia of the ovary, and to these Kiwisch has added a case of hernia through the foramen ovale.

Diseases of the Tunics.

Inflammation of the ovarian tunics, and particularly of the peritoneal coat, is most commonly associated with acute puerperal metritis. But inflammation, both in the acute and chronic form, may affect the ovary independently of the puerperal state. The resulting anatomical changes in the coats of the organ are vascular congestion in various degrees ; fibrinous exudations upon their surface, followed occasionally by the formation of artificial bands or adhesions with surrounding parts ; and chronic thickening of these coats, whereby the original smooth and even surface, (*figs* 368. & 369.) characteristic of the ovary in early life, is lost. When inflammation of the ovary has advanced to the suppurative stage, and this organ is converted into a bag of pus, the coats may have become so attenuated and softened as to burst when the attempt is made to lift the parts from the body after death.

Ulceration. — *Rupture.* — In the case of large collections of fluid within the ovary, as for example in large abscesses or in ordinary ovarian dropsy, the surface of the ovary frequently inflames and contracts extensive adhesions with surrounding parts, and if the latter happen to be hollow viscera, such as the intestines, uterus, or bladder, a fistulous communication may be established between them and the sac of the ovary, through a process of ulceration or absorption of the common partition wall, and the contents of the ovary may become discharged externally. Or it may happen that by a similar attenuation and rupture, or by a process of ulceration and absorption of these tissues, the ovarian walls give way, in some parts of their free surface, and their contents escape into the abdominal cavity.

Hypertrophy of the ovarian tunics is almost constantly observed in considerable enlargements of the organ, from whatever cause they may arise. In the case of large ovarian cysts, before adhesions have been occasioned by the pressure of surrounding parts, the peritoneal coat of the ovary, though much thickened, retains its smooth, shining, external surface. It may be generally stripped off with ease, and displayed as a dense white membrane of unequal thickness, but having undergone no further change than that of a general hypertrophy of its ordinary component tissues. The tunica albuginea in like manner becomes thickened by simple increase of its ordinary constituents, but in the case of very large, and particularly of unilocular cysts, the cyst wall becomes so intimately blended with the common ovarian investment, that it is impossible to determine how much of the now united membranes was originally furnished by the tunica albuginea, or ovarian stroma, and how much by the proper wall of the cyst. The hypertrophy in these cases is often so considerable that the boundary walls of a large ovarian cyst may measure one or two inches or even more in thickness in some places.

Ossification. — Patches of ossific matter more or less extensive are occasionally found scattered over the surface of ovarian cysts. It is probable, however, that these are deposited in the first instance upon the inner surface, or in the proper walls of enlarged cysts, and subsequently extend to the proper coverings of the ovary, and that the fibro-cartilaginous degeneration which these cyst walls sometimes exhibit, also commence in the original cyst, and proceed from within outwards.

Diseases of the Tissues.

Hyperæmia of the ovary may be limited to

* L. C. Deneux, Recherches sur la Hernie de l'Ovaire. 1813.

the parenchyma, or to the walls of particular follicles, or may affect all these parts together.

Hyperæmia of particular follicles, with considerable enlargement of the sac and effusion of blood into the cavity of the follicle, is not unfrequently observed as an abnormal condition. But hyperæmia of single follicles with effusion of blood into the cavity has been already described, as being also a natural state of the Graafian follicle, which is preparing for dehiscence and discharge of an ovum.*

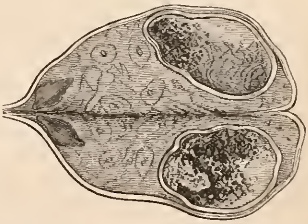
It may be asked, therefore, in what respect does the normal differ from the abnormal state, and by what characteristics may the one be distinguished from the other? It appears to me that Rokitansky, in the account which he has given of hyperæmia of the Graafian follicle †, has included under one head both the natural and the morbid condition; for his description will very well apply to the rising follicle, in its second stage, when the escape of blood into the cavity has been shown to be a normal, and in some animals a constant occurrence. The presence, therefore, of blood within the follicle, for the reasons already fully given (p. 556.), must not be regarded as necessarily affording evidence of a morbid state. There are, however, certain peculiarities in the condition of the unhealthy follicle, by which it may be distinguished from that which is natural. The natural follicle, when preparing for dehiscence, is always near the surface, and often projects considerably above the level of the ovary (*fig.* 380.). Its coats are unequally thick; the thinnest portion being always found at the most prominent point of the follicle. There is considerable vascularity about this point, plainly visible externally, and here the process of attenuation and absorption continues to be progressive until the sac spontaneously ruptures. The walls of the follicle are at this stage of a *bright yellow colour.* The liquor folliculi is either clear and limpid or intermixed with blood, or the centre of the sac is filled by a coagulum, which is at first bright red, and afterwards becomes pale, and at length nearly white. The coagulum may adhere to the walls, and undergo fibrillation and subsequent conversion into a solid body, or into a dense white membrane, or it may be rapidly absorbed.

On the other hand, the morbid follicle, although it may not exceed nor even equal in size that which is passing through its normal changes, may yet be distinguished by many characters which are the converse of those just described. The morbid follicle is often not peripheral, but is more or less central in its position in the ovary. It may attain to the size of $\frac{1}{3}$ or $\frac{1}{2}$ of the ovary, without necessarily causing any distinct prominence above the surface (especially when occurring singly). The walls are equally thick, and exhibit at no part any evidence of attenuation or absorption. No preparation for rupture is indicated externally by any peculiar arrangement of vessel, or by any marked increase of vascularity. The walls do not exhibit the remarkable yellow colour nor the cerebral foldings characteristic of the advancing normal ovisac, but the tissues of which they are composed are simply those of the undeveloped Graafian follicle. The contents of the sac are neither the clear liquori folliculi, nor the bright clot, nor the decolorised fibrin, but generally a collection of dark coffee-ground matter, resulting from the admixture of a quantity of decomposing blood-corpuscles and fragments of membrana granulosa intermixed with a dirty fluid. On washing out these contents, the walls of the cyst, if the ovary has been injected, are seen to carry numerous vessels, irregularly arranged, but never presenting that rich network of capillaries which are visible after a successful injection of a healthy ovisac progressing towards rupture, especially in those cases where the quantity of yellow oil is not so great as to obscure these vessels altogether.

By these characteristics the morbid ovisacs may generally be distinguished from those which are healthy. There is enough of similarity between them to prove their identity of origin, and enough of dissimilarity to show their divergence from a common starting point; the healthy follicle proceeding onward through a course of different changes, which have been already fully described; the morbid follicle exhibiting an apparently unlimited power of growth and deformity, such as will be presently more fully noticed.

Fig. 392. exhibits the morbid follicle in one of its earliest stages of growth. It may be contrasted with *figs.* 381. and 385., for the purpose of showing the points of difference which have just been described. In *fig.* 392. the morbid follicle occurs as a single cyst in the midst of

Fig. 392.



Ovary containing a morbidly distended Graafian follicle in an incipient stage. The rest of the organ is healthy. (*Ad Nat.*)

otherwise healthy tissues. Although occupying more than $\frac{1}{3}$ of the entire ovary, it scarcely disturbs the even outline of that organ. Its coats are of uniform thickness throughout. There is no attenuation nor preparation for dehiscence at any particular spot, nor external sign of increased vascularity in one point. But the walls of the follicle contain numerous vessels, distributed nearly equally over their surface. The cavity is filled with loose flocculi of a dark chocolate colour, consisting of decomposing blood clot mixed with patches

* P. 556.

† Manual of Pathological Anatomy. Sydenham Society. Vol. ii. p. 328.

of membrana granulosa. The walls of the follicle are not yellow, and contain no oil globules. They are slightly thicker than those of the healthy follicle. Their component tissues are precisely those which have been already described as characterising the ovisac in its normal condition; the chief bulk of their texture being made up of granules and embryonic fibres intermixed with a few developed fibres of ordinary white fibrous tissue.

Such a condition may, for want of a better designation, be regarded as hyperæmia of the follicle, or it might perhaps be more appropriately termed hypertrophy of the follicle; but in whatever light it may be regarded, it constitutes one of the early stages of those enormous growths, of which more will be said hereafter.

A more extensive form of congestion, affecting the parenchyma of both ovaries, and associated with a like hyperæmic condition of the uterus, may be sometimes observed about the period of the final cessation of menstruation. The ovaries are then occasionally found of an intense red colour, from the parenchyma, as well as the follicular walls, being deeply loaded with blood. The most marked instances of this I have observed in connection with cardiac disease, and associated with congestion of other organs.

Inflammation of the Ovary.— Ovaritis.— Oophoritis.—Our knowledge of the pathological changes which the ovary undergoes as the result of inflammation, is chiefly derived from examination of the bodies of women who have died of acute puerperal metro-peritonitis. But unquestionably inflammation both in the acute and chronic form may affect the substance of the ovary, independently of the puerperal or pregnant states, and cause various degenerations of the tissues of that organ, as evidenced by those serous, fibrinous, and puriform deposits, or general softening of the ovarian parenchyma, which are occasionally found after death. It is probable also, from symptoms displayed during life, that inflammation, especially in a chronic form, not unfrequently attacks the ovary and terminates in resolution, or in those milder results of inflammation which consist in temporary induration or enlargement of the organ, unaccompanied by serious disintegration of its tissues.

It must, however, be observed with regard to the evidences of inflammation of the ovary either in the acute or chronic form, which are supposed to be afforded during life, consisting in pain and tenderness referred to the seat of that organ, or in obvious enlargements of the ovary, as discoverable by various modes of internal or external tactile examination, and conjoined with more or less constitutional disturbance, that these signs may and do often in the non-puerperal state, accompany the natural process of ovulation, and that such symptoms, recurring with each menstrual period, may affect a woman at intervals in a greater or less degree during the whole of that period of life in which she is capable of childbearing. But in the present state of our knowledge of ovarian processes it is perhaps not possible to determine how much of these symptoms may be regarded as evidence of a natural, and how much of a morbid change in the part; for although in many women the process of ovulation is continually performed without consciousness of local suffering, yet in a great number of instances the act is accompanied by much pain, and there can be no question that the cause of much of this suffering is to be looked for in the changes which the tissues of the ovary undergo in the act of expelling the ova.

How closely this process in its more obvious conditions is allied to inflammation has been already shown. A high degree of vascularity of the part, with increased exudation of fluid, and consequent enlargement and tension of the entire organ terminating in spontaneous laceration of its coats by a process very similar to ulceration, and often accompanied or preceded by a more or less considerable escape of blood: these together form a combination or series of processes closely allied in their nature to inflammation, and frequently evidenced externally by signs usually regarded as characteristic of inflammatory action.

Nor is it yet known how far these symptoms, which have generally been assumed to indicate ovarian inflammation, especially in a chronic form, may be merely the external evidences, not of natural, but of aberrant or disappointed ovulation. For just as an abscess is painful generally in exact proportion to the unyielding nature or tension of the parts by which it is surrounded, so it is probable that when the follicle or the entire ovary becomes tense from the effusions which have been shown to have taken place ordinarily within it, and this tension is not relieved because rupture does not occur at the proper time, so that ovulation is disappointed or is aberrant, the symptoms which might be expected to accompany such an interrupted process would be those which are usually set down as indicating inflammation in a part.

This matter appears hitherto to have been hardly thought of, and yet it is probable that to *abortive or interrupted ovulation* may be referred the commencement of many of those morbid conditions of the ovary which are not either malignant or the direct results of inflammatory action. Probably many of the cystic diseases of the ovary originate in this way. Of disappointed ovulation, as it may be observed in animals, instances have been given at page 568. Here the follicles, although apparently preparing for rupture, were arrested in their progress from some unexplained cause; and although it may be conjectured that such follicles might, under an increase of stimulus, accomplish their final purpose, as Coste has supposed in reference to the instance just quoted, yet it has been shown by the researches of Barry that multitudes of ovisacs perish without accomplish-ing that purpose at all, and it is probable that these, in preference to other and more healthy follicles, become the seat of subsequent morbid changes.

For it must be remembered that the circumstances under which the male and female generative elements escape from the place of their original formation are essentially different. The male secreting organ, the testis, is provided with an excretory duct for the escape of the fertilising fluid ; but the female gland is a shut sac. To the normal escape of its products many barriers are opposed, and it has already been shown by what complicated machinery the shedding of the female product is effected. But it is impossible to regard this complex process without perceiving how easily a failure in any of those steps may defeat the final object for which that process is set on foot. The thickness of the walls of the follicle, the density of the ovarian coverings, or of the parenchyma of the ovary, if the follicle should fail to reach the surface ; the chance of the ovum perishing before it quits the ovisac, and so the stimulus to the healthy development of the latter being lost ; the chance of an excessive accumulation of liquor folliculi or of blood within the follicle, causing damage to the ovum, and replacing a natural by a morbid amount of exudation. In these and other possible interruptions to the natural completion of ovulation we may discover the elements of many future morbid changes. And although it would require a long continued and deep research into the aberrant functions of the ovary to determine the true order and sequence of many of these morbid processes, yet it is impossible to carry anatomical investigation into the structure of the morbid ovary, especially under incipient forms of disease, to any extent without many fragmental observations occurring suggestive of the idea that the ovary, like any other gland, may have its natural functions impeded, and that many of the organic changes which are observed in this part may owe their origin to such interrupted processes. Some of the observations which have led me to the adoption of these views have been already given, and some others will be detailed as suggestive of a better basis for the study of ovarian pathology than has hitherto been employed ; for of all the organs of the body the ovary is perhaps that whose pathological conditions have been regarded with the smallest amount of reference to its natural or deranged *functions*.

From these considerations, then, I have been led to the conclusion that certain conditions of the ovary, which, from their concomitant symptoms during life have been deemed inflammatory, are not necessarily associated with inflammation ; that it is probable, first, that the natural process of ovulation is often accompanied by symptoms very similar to those of inflammation ; and secondly, that the process of ovulation is occasionally disappointed or interrupted, and that the follicles, whose natural development has been interrupted, may, like the hydatiform placenta, become the seat of a low form of nutrition, terminating in effusion and collection of various dropsical fluids.

With regard to the anatomical evidences of inflammation of the ovary as furnished by post-mortem examination, they are chiefly the following, viz.: general redness or hyperæmia of the ovarian parenchyma, or of the walls of the follicles ; swelling of the ovary to the extent of increasing the organ to three or four times its natural size, producing a round, oval, or flattened form of the ovary ; a general tension or hardness of the organ in the early stages of inflammation, and subsequently softening, consequent on degeneration of the tissues and their infiltration by serous or puriform effusions; and lastly, but rarely, gangrene of the ovary.

Of these morbid changes the only one which appears to require a more particular account is

Suppuration of the ovary. Pus may be found in a circumscribed cavity within an enlarged and highly vascular ovary, portions of whose structure may still retain its natural condition. Or the entire ovary may be converted into a bag of pus, the natural tissues being entirely destroyed, and the fluid bounded only by the ovarian tunics. In such cases the abscess "appears to rise from suppuration in the substance of the viscus, similar in every respect to phlegmonous abscess in any part of the body, and not connected with any cyst, or change, or addition of structure, the product of morbid growth."* These abscesses, which are sometimes of enormous size, may burst into the general sac of the peritoneum, or, after forming adhesions with surrounding parts, may discharge their contents externally through the abdominal walls, or into the Fallopian tube, uterus, vagina, bladder, rectum, or other part of the intestine. Portal mentions cases of ovarian abscess as large as an infant's head, and Dr. Taylor † of Philadelphia has recorded an instance in which the ovary contained twenty pints of pus. It is highly probable that these and even still larger collections of pus, which have been found in the ovary, were, as Mme Boivin has suggested, originally cases of encysted ovarian dropsy, but inflammation and suppuration having been set up in the walls of the cyst, the original contents have been gradually intermixed with pus, until the whole fluid has appeared to be of that nature. Probably of this kind also was the case recorded by Vater‡, in which the ovary was as large as the human head, and "contained pus distributed into several capsules." This, therefore, was a multilocular abscess.

Except in connection with acute metro-peritonitis, suppuration of the ovary may be considered as comparatively rare. Dr.

* Seymour's Illustrations of some of the principal Diseases of the Ovaria, p. 40.

† North Amer. Med. & Surg. Journ. 1826.

‡ Haller, Disp. Med.

Hooper* "met with only two instances of abscess" of this organ. "The one was the size of a child's head at birth, the other not larger than an orange. There was nothing in these different from common abscesses; the whole of the internal substance of the ovaries was gone, and the walls were formed of a thick and rather ligamentous cyst, covered by peritoneum." Suppuration occurs also occasionally in those cysts of the ovary which contain hair and teeth, together with other imperfectly formed products. To the same class of suppurative diseases should also probably be referred that singular morbid condition of the part in which the entire ovary is reduced to the state of a diffluent pulp, of a yellow or brownish-green colour, of the consistence, and having somewhat the appearance of very soft putty, immiscible with water, and retaining sufficient tenacity to preserve its semifluid character, and yet not having firmness enough to admit of the part being preserved as a preparation. Of this morbid condition of the ovary, which, however, may possibly be cancerous, I met with a striking example in a case of sudden death occurring in the seventh month of pregnancy. Both ovaries were of the size and form of a bullock's kidney, their natural structure was entirely destroyed, and was replaced by the soft substance just described. The circumstance that both ovaries were thus affected renders it evident that the disease could not have existed in any great degree at the time of impregnation, or that it certainly must have been then limited to one organ.

From the comparatively scanty materials extant relating to ovarian abscess it may be concluded, that suppuration may either commence at separate parts of the parenchyma, forming small collections of matter, which gradually coalesce, or it may be set up throughout the whole of the stroma at once. In these cases the parenchyma of the ovary is gradually consumed, and the organ is converted into a purulent cyst.† Whilst in other cases the Graafian follicle appears to be the seat of the suppurative action, which may either commence originally in the walls of one or more follicles constituting circumscribed abscesses of moderate size, or the suppurative stage of inflammation may be established in the walls of a follicle already considerably enlarged, and thus an ordinary ovarian cyst, with simple transparent contents, may be gradually converted into an abscess of enormous magnitude.

Cysts.—A complete anatomical description of the numerous forms of cystic disease which affect the ovary would occupy a far larger space than the limits of this article will permit. On this account the more important varieties only can be noticed. These are chiefly Simple cysts, Compound cysts, Hydatid cysts, Demoid cysts, or those containing fat, hair, teeth, and bones, and Colloid cysts.

Simple Cysts.—The simple, barren, or unilocular ovarian cysts are composed, as their name implies, of a single sac, which, according to its size, occupies the interior of the ovary, whilst the rest of the organ retains its normal condition; or else the cyst, by enlarging, presses aside and distends the parenchyma and tunics of the ovary, which thus form a common boundary to the sac, or the cyst, having originated in one extremity of the ovary, grows at the expense of that portion of the organ, whilst the rest, retaining its natural structure, becomes by degrees a mere appendage of the sac, and may be seen projecting in the form of a small button-like prominence from its outer surface.

These cysts vary in size from that of a pea to the bulk of the adult head; they rarely, however, attain the latter dimensions without becoming proliferous or multilocular, and they appear never to acquire as single cysts the enormous bulk which the compound cysts not unfrequently exhibit. This more moderate size of the single cyst is less frequently productive of those adhesions with surrounding parts which the pressure of the larger compound cysts so commonly occasions. Hence the precise locality of the single cyst, and its origin in the substance of the ovary, can generally be determined without difficulty. The distended sac is found hanging as an appendage to the ovarian ligament, whilst the Fallopian tube is often seen partly spread out over its surface, one of the fimbriæ being always closely adherent to the sac, and conducting the observer infallibly to any portion of the original ovarian structure which may have remained yet unchanged.

The coats of these cysts vary much in density and thickness. Those of the single kind are more uniform throughout; they are generally thickest towards the base or seat of their vascular supply. Here they vary in thickness from 2‴ to 12‴, but become much thinner in other parts, so as at times to be nearly transparent. The outer coat always consists of peritoneum, which is smooth and shining upon its surface, except when adhesions have been formed with surrounding parts, or when fatal peritonitis has occurred, as from bursting of the sac. The condition of this coat has been already described under the head of morbid states of the ovarian tunics. The variations in its thickness are not generally so considerable as materially to affect the bulk of the sac.

The middle or intermediate coat is that generally upon which the greater or less density of the cyst wall depends. This coat is usually of a brownish-yellow colour, and firm fleshy texture. It is with difficulty split into a number of rough-surfaced laminæ, exhibiting to the naked eye a coarse fibrous arrangement of their constituent parts, which, under the microscope, are seen to consist of inelastic fibrous tissue, mingled with granules, and undeveloped fibre cells in varying proportions.

* The Morbid Anatomy of the Human Uterus and its Appendages, p. 3.

† Rokitansky, Path. Anat. vol. ii. p. 331. Syd. Soc. edit.

To this coat, which appears to retain or increase its thickness by a perpetual new formation of fibrous tissue, is due that support and resistance to the pressure of the increasing contents of the sac, which prevents the more frequent rupture of these cysts. And it is probable that when the latter phenomenon occurs, without the formation of previous adhesions, followed by ulceration, the laceration is due to the gradual attenuation of the middle wall of the sac.

Occasionally portions of these walls are found to be of nearly cartilaginous hardness, so that they can with difficulty be broken up into fragments for minute examination. Such portions are seen under the microscope to be composed almost entirely of close-lying fibres of white fibrous tissue, with scarcely a trace of the embryonic fibres and granules, which are found abundantly in the walls of the softer cysts, and of the normal ovisac. Other portions of these cyst walls, still more dense, present to the naked eye, as well as under the microscope, all the characters of the simpler forms of cartilage; whilst in the walls of other cysts again are found patches of ossific matter, in which the earthy elements of bone are aggregated together, (calcification) but without the definite arrangement characteristic of true osseous structures.

Upon and in the substance of this middle coat ramify numerous arteries and veins, sometimes of considerable magnitude. These distribute their minute branches upon the inner surface of the cyst, where they occasionally present a peculiar straight or rectangular arrangement. Doubtless these vessels are the carriers of those enormous collections of fluids which accumulate within the cysts, and upon their arrangement, as well as upon the nature of the epithelial lining of the sac, depends probably the character of the fluids secreted or effused.

Most variable is the condition of the lining membrane which bounds the inner surface of the cyst. In the smaller cysts it is often composed of one or more layers of simple flattened epithelial cells; the remains, perhaps, of the membrana granulosa. This surface may be free, or to it may adhere fragments of blood clot, degenerating or undergoing fibrillation, by which the sac, when small, is partly filled. This lining of epithelial cells is often seen in a state of fatty degeneration*, and similar cells are found abundantly scattered among the contents of the sac.

In the larger and older cysts the membrane lining the sac is nearly as smooth as that which covers it externally. In these the lining membrane often exhibits but little vascularity, and shows small traces of an epithelial covering in its smoother parts, where it is usually so intimately adherent to the middle walls, as to be separable from the latter only with difficulty. Fragments so obtained are easily split up, and are seen to be composed of developed fibres of connective tissue, intermixed with fine granules and a few embryonic fibres.

After the simple cyst has arrived at a certain period of its growth, and generally when it equals the size of a large orange, it begins to exhibit upon its inner surface patches, more or less extensive, of rough projections, granulations, or vesicles, which will be described more fully under another section.

Multiple Cysts.—I have employed this term to designate a variety of the single cyst which might be confounded with the compound or proliferous kind, and which consists merely in an aggregation of two or more simple cysts that have been contemporaneous in their growth. The distinction between a mere aggregation of simple cysts and the growth of a compound one has been carefully drawn by Rokitansky*, and has been also illustrated by Paget.†

If such cysts are observed at an early period of their growth, they may be seen to occupy different portions of the ovary in which they arise independently of each other, and having distinct portions of ovarian stroma interposed between each. They have at first a round or oval form, but "as they all enlarge together, and sometimes by the wasting of their partition walls come into communication, they are flattened by reciprocal pressure, and "may at length look like a single many-chambered cyst, having its one proper wall formed by the extended fibrous covering of the ovary. Many multilocular cysts, as they are named, are only groups of close-packed single cysts; though when examined in late periods of their growth, and especially when one of the group of cysts enlarges much more than the rest, it may be difficult to distinguish them from some of the proliferous cysts.

Figs. 392. and 393. serve to illustrate the simple and the multiple cyst respectively. *Fig.* 392. has been described at p. 575, where this example is given as an instance of hypertrophy of a Graafian follicle in an early stage, forming a simple or unilocular cyst, still hardly contained within the substance of the ovary. It will be seen that at one part of this preparation the wall of the cyst has become blended with the general investments of the ovary; and it will be easily understood how, by the gradual enlargement of the cyst in this direction, where there will be the least amount of resistance to its growth, the sac may at length become so greatly expanded that the remaining healthy portion of the ovary will appear only as an appendage to it, or may become by pressure and extension altogether obliterated. *Fig.* 393., taken from Dr. Hooper's collection ‡, offers a good example of the multiple cyst. It is composed of a mere aggregation of simple or unilocular cysts, which, by coincident enlargement, have come at length to fill the entire ovary, causing considerable increase in bulk of that organ. From the right ovary (*a*) a portion has been removed

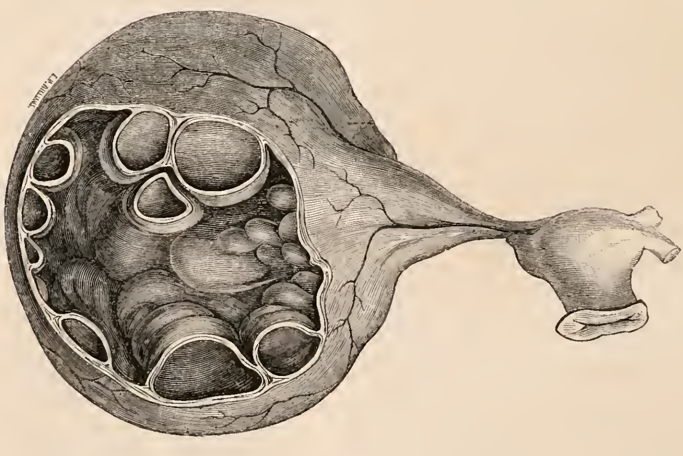
Multilocular, Compound, or Proliferous Cysts.—In these a second, or, it may be, a third, order of smaller cysts are developed, within or upon the walls of a larger or parent sac. From these walls the secondary cysts, at a comparatively early period of their growth, are seen projecting inwardly in hemispherical form, arranged along the parietes of the sac, from which they commonly spring by broad bases. These secondary cysts are invariably and permanently attached to and continuous with the walls of the superior cyst. They are covered by a continuation of the same membrane which lines the principal sac, and which is reflected over them in the same manner that the heart is invested by the reflected pericardium, or the testis by the tunica vaginalis.*

Fig. 394.



The left ovary distended into one large cyst, into the interior of which project numerous smaller cysts of a secondary order. To the right of the figure is the uterus. (*Ad Nat.*)

* Hodgkin, Lectures on Serous and Mucous Membranes. Lect. viii.

The growth of these secondary cysts with broad bases, of which a good example is exhibited in *fig.* 394., is often very irregular, so that one or more of them enlarging with greater rapidity than the rest, encroach upon the cavity of the containing cyst, and fill it more or less completely. This rapid enlargement of the secondary cysts also occasionally causes rupture of their walls and the escape of their contained fluids into the parent cyst, followed by the unrepressed growth of the secondary or tertiary cysts which arise from its surface.

After the appearance of a tertiary order of cyst within the secondary ones, their growth occasions so much disturbance of the even outlines of the walls in which they originate, that it is often difficult to trace the order and manner of enlargement of the different series. Nevertheless, with care, these may be often made out even in the complex forms, of which *fig.* 395. furnishes an example. Here is represented a small portion only of an enormously enlarged ovary, consisting of a primary or principal sac, the greater part of which has been cut away, so as to leave a part of its walls visible at *a*, *a*, *a*, and of a more solid basis which was made up of numerous secondary

Compound or proliferus ovarian cyst. (*Ad Nat.*)

a, *a*, *a*, divided walls of the principal single cyst; *b*, small simple cyst; *c*, *c*, two masses of compound secondary cysts, containing many of a tertiary order.

and tertiary cysts. Both of these orders may be traced in this example. At *a*, *a*, *a* are seen the divided walls of the original parent cyst, whilst springing from these walls at *b* is a single secondary cyst, and at *c*, *c* are two groups of similar cysts aggregated in masses. The latter are, however, examples of compound secondary cysts, for in the interior of each is contained a series of a tertiary order, which are so numerous as to fill completely the secondary sacculi. By Lebert it is deemed to be still an open question whether these cysts, which apparently spring from the interior of the main sac, as represented in *figs.* 394. and 395., are altogether new formations, or whether they were not originally in part developed, and by force of pressure, arising from contiguity of situation, have penetrated and at length grown within the principal cyst, into the interior of which, in this view, therefore, they would form a species of hernia.

Dr. Hodgkin *, whose elaborate descriptions of ovarian cysts has made known all the principal varieties of form which they assume, distinguishes from the broad-based cysts, already noticed, those which arise by narrow or slender peduncles. These sometimes grow from the walls of the principal cyst, and, indeed, in almost all cases which I have examined, after the sac has attained a certain size, patches of these pedunculated sacculi may be observed scattered over the interior in various places, but they are more constantly observed growing from the interior of the secondary cyst. These little sacculi appear at first in scattered patches, under the form of little round grains, thickly covering the lining membrane which they raise above them, and so closely set that two or three hundred may sometimes be counted in the space of a square inch. When these elongate, mutual pressure causes them to assume a filamentous condition; but when greater freedom of growth is enjoyed, their extremities commonly dilate into little pouches, or buds of another order sprout from the sides and extremities of the original growths, and convert them into a multitude of little dendritic processes which roughen the inner surface of the larger cysts, or fill more or less completely the cavities of the smaller ones.

If a section be made of these dendritic processes, they are seen usually to be solid at their base, the white fibrous tissue of the parent cyst wall, from which they spring, being easily traced into their stems and branches. But at their extremities they become dilated into little pouches filled with fluid, similar to the little pediculated cysts, with which they are abundantly intermixed. These little cysts and processes are covered by epithelium, and it is probable that they are the active agents in the elimination of the various fluids by which the ovarian cysts, of whatever order, are commonly filled. These minute processes and vesicles, so abundantly found on the walls of endogenous cysts, are represented in *fig.* 396., which exhibits a portion of a proliferous cyst of the natural size, covered by them on its inner surface.

* Loc. citat. and Med. Chir. Trans. Vol. xv. pt. ii.

Fig. 396.

Part of the thick laminated wall of an ovarian cyst, covered on its inner surface with pyriform vesicles. (After Paget.)

The Contents of Ovarian Cysts.—No cystic formations in any part of the body present such a variety of contents as those which are found in the ovary. These vary in every degree of consistence, from the thinnest fluids to the hardest substances, such as teeth and bones. They may be subdivided according to their densities and different degrees of organisation. And first may be considered :—

The Fluid Contents of Cysts.—The thinnest fluids are usually obtained from unilocular cysts, which have not been previously tapped. The fluid so procured is commonly of a pale straw colour, and resembles in general character the ordinary fluid of ascites. It is to these cases that the term "encysted ovarian dropsy" is most commonly applied. The contents of multilocular cysts are often less fluent, presenting every variety of consistence from a thin gelatinous fluid to one of the density of white of egg, of honey, of thin size, or of soft glue. In the latter cases the tenacity of the fluid is often so great that it may be drawn out into long strings, and it is only in this way that it can be extracted through the canula. All these varieties, which commonly retain more or less transparency, may be found enclosed in different cysts within one common investment.

In other cases the contents, while retaining their fluidity, are rendered turbid or are thickened by the admixture of pus or of blood in various degrees. Thus are produced the yellow and green hues as well as the red, reddish-brown, and dark coffee-ground colours which these fluids often present; the turbid yellow and green colours being generally caused by the presence of pus, the bright red by the admixture of recent blood, and the dark brown or coffee-ground hue sometimes by the addition of blood which has been effused long enough to have undergone putrefaction, although the brown colour is not always due to this cause. Scales of cholesterine are also found intermixed with those fluids, and in the smaller cysts especially, as already stated, recent blood or the blood clot undergoing fibrillation, or breaking down by putrefaction, may be frequently noticed.

The repeated withdrawal of the contents of ovarian cysts affords the opportunity of observing that the fluid contained in the same sac often undergoes a material change in its composition. Thus, that which is obtained by a first tapping is often of the thin straw-coloured variety, whilst that which results from subsequent operations has more frequently the turbid muddy or coffee-ground character last described. This can be explained in two ways : the first, by observing that in multilocular cases there is sometimes a natural communication between the walls of the containing and the contained cysts, or an artificial communication may be established by spontaneous rupture, or by the trocar penetrating through two cysts, and thus the smaller will act as tributaries to the larger sac, and pour their varied contents into it; or secondly, inflammation or ulceration may be set up in the walls of a cyst which has been punctured, or the introduction of air, or of blood flowing into the cyst from vessels wounded during the operation may so modify the contents as to account for those successive alterations in the fluid which are very commonly observed. In the case of cysts containing pus, rough patches, apparently of ulceration, have been observed upon their internal walls.

Quantity of Fluids and Rate of Effusion.—The structure and situation of the ovary permit this organ to suffer a degree of distension which is rarely or never equalled in other parts. Probably the only limit to the increase in size of the morbid ovary, after it has risen out of the pelvis into the abdomen, is occasioned by the pressure which the spine, diaphragm, and abdominal walls exercise upon the cyst ; for the parietes of an ovarian cyst appear in most cases to possess an unlimited capability of multiplying the fibrous element of which they are principally composed, whilst the power of rapidly replacing the fluid after their contents have been drawn off, proves both the unrestricted capability of secretion inherent in the cyst walls, and at the same time the influence which pressure exerts in keeping that secretion for a time within certain limits. Numerous examples might be quoted in illustration of the immense power of growth and secretion of fluid possessed by ovarian cysts. Imhoff* records a case in which the right ovary contained 42 lbs. of fluid. Duret † met with 50 pints of water in

* Acta Helvetica, vol. i., App. p. 1.
† Mém. de l'Acad. de Chir. t. ii. p. 457.

a single ovarian cyst. And in the London Medical and Physical Journal (Aug. 1815) the particulars of a case are given in which the right ovary weighed nearly 52 lbs. But these are moderate examples compared with some of still larger growth. Camper* relates a case in which about 80 lbs. of serum were contained in the left ovary; and Douglas also one in which the left ovary held 70 lbs., besides a considerable collection of fluid in the pleura and pericardium.†

These enormous collections of fluid are generally limited to the ovary of one side, though both organs may be coincidently affected, as in the example given by W. E. L. Müller‡, who found in the body of a woman, aged 36, in the two ovaries together 140 lbs. of fluid. In what proportion either or both of the ovaries are affected by ovarian dropsy may be seen by reference to the tables of Safford Lee and Chereau. The former shows the right ovary affected 50 times, the left 35, and both together 8 times. The latter gives 109 examples of the right, 78 of the left, and 28 of both sides.

Notwithstanding the large amount of fluid which may collect within the distended ovary as shown in the foregoing examples, these yet serve to give but a feeble notion of the enormous quantities which may be effused from the walls of an ovarian cyst in the course of a lifetime, or even of a few years, when the contents are removed from time to time, and are allowed to re-accumulate. Pagenstecher§ removed, in 35 operations, 1132 lbs. of fluid, without reckoning what escaped by allowing the canula to remain. Dr. Mead's patient was tapped 67 times in five and a half years, and lost 1920 pints. Ford || punctured the ovary 49 times, and removed in all 2786 pints of fluid. Heidrich* in eight years punctured 299 times, and removed 3289 Berlin quarts (Berl. Maass), equal to 9867 med. pounds, the death of the woman occurring at the age of 43. And in the celebrated case of Mr. Martineau, of Norwich, in the course of twenty-five years the patient lost by tapping, in 80 operations, 6631 pints, equal to 13 hogsheads of fluid.

Composition of the Fluids contained in Ovarian Cysts.—Although these fluids usually coagulate freely in a greater or less degree on the addition of heat or nitric acid, the proportion of free albumen which they contain is usually considerably less than is found in the serum of blood; they contain, however, a larger quantity in combination with soda than is found in that fluid. According to the analysis of Dr. Owen Rees, who has examined several specimens of ovarian fluids, their chief characteristics are, a considerable excess of water and of extractives, and a deficiency of albumen as compared with the serum of blood. To the presence of a large quantity of extractives, particularly the albumen combined with soda, Dr. Rees attributes that peculiar tenacious mucoid character which these fluids so commonly possess. This is always in relation to the nature of the solid ingredients, and is quite independent of any peculiar proportions of water, to which at first it might be supposed to be due. Again, the alkaline salts obtained from ovarian fluids differ from those of blood in not containing any phosphate which can be recognised even as a trace, unless experiments be made upon large quantities for the express purpose of detecting that substance.

The following table †, by Dr. O. Rees, gives the results of the analysis of four fluids drawn from secondary cysts of an ovarian tumour, compared with an analysis of the serum of blood.

	No. 1. Clear, light straw-coloured Alkaline. Sp. G. 1017.	No. 2. Dark-coloured muddy neutral. Sp. G. 1017.	No. 3. Approaching in character to white of egg Alkaline.	No. 4. † From a valuable paper on Tumours of the Ovary, by Dr. Bright, in the Guy's Hospital Reports, vol. iii. p. 204.

‡ The whole of the Alkaline Salts are estimated together in the analysis of serum as indicated by the line.

So far, therefore, as these analyses may be taken to represent the ordinary composition of the more fluid contents of ovarian cysts, it may be concluded that the action performed in these cases by the walls of the cyst is the separation from the blood chiefly of the watery and saline ingredients, with the exception of alkaline phosphates, whilst the albumen is only in part removed, and none of the fibrine.

Examined by the microscope, the more fluid contents of ovarian cysts frequently exhibit flocculi, composed of patches of epithelium, more or less united together by granular matter. When gelatiniform they often contain faint oval corpuscles, or a few primitive corpuscles. Occasionally an opalescent or opaque creamy appearance is communicated to the jelly by the formation of pus corpuscles or minute granules, and sometimes the contents are wholly filamentous, and mixed with granular cells and other products of inflammation. This jelly-like matter, when consistent, presents all the characters of coagulated *liquor sanguinis*, which has not yet passed into organisation. Acetic acid develops in it, or causes to be precipitated a white membrane having all the characters of fibrous tissue. Frequently granules, cells, and filaments may be observed in it in various stages, as is the case with recent exudations from the serous membranes, or in other simple forms of hyaline blastema.*

Hydatids contained in Ovarian Cysts. — A very perfect example of this rare affection of the ovary (originally in the possession of Dr. Hooper) is contained in the Pathological Museum of King's College. It is the largest specimen of ovarian disease in that collection, and consists of an immense aggregation of compound thin-walled cysts, of the second and third order, many of the latter being stuffed full of hydatids. Several of these have fallen out of the cysts, and lie loosely at the bottom of the glass. They are of the form and average size of pigeons' eggs, and possess the usual characteristics of Acephalocysts. (Barren echinococcus vesicles?) Comparatively few cases of this form of ovarian disease are on record.

The solid Contents of Ovarian Cysts.—These consist of fatty matter, hair, teeth, and bones. Cysts containing such materials are termed dermoid cysts. They rarely grow with the rapidity, or attain the enormous bulk commonly observed in those with fluid or hydatid contents. That such cysts may, however, sometimes equal in size those of a more simple character, is shown by a remarkable example described by Blumenbach.† A girl aged 17 had a swelling of the left ovary, which after 21 years' growth measured four ells in circumference, and reached below the knees. Death occurred at the age of 38, when the sac of the ovary alone weighed 14 lbs., and contained also 40 lbs. of a thick, fatty, honey-like substance, mixed with short and long hairs, some two feet in length, and matted together in locks. Besides these the sac contained several irregular portions of bone, some of large size. In one of these were fixed six molars and one incisor tooth, completely formed. The inner surface of the sac was beset with short hairs.

The composition of these cysts, and especially of their lining membrane, will in a great measure account for the differences which are observable in their progress and mode of growth. The dropsical cysts are closely allied in their nature to serous membranes, and, like these in a morbid condition, they possess the power of separating and collecting into their cavities the thinner constituents of the blood. And as the only apparent limit to this process is the resistance offered by the walls of the sac, and the parts external to them, so the distensibility of these, and the capacity of the walls of the cyst to meet the increasing pressure by a correlative hypertrophy of its tissues, will determine the form, size, and general condition of the tumour. But the non-malignant cysts, whose contents are of a more solid nature, and possess a higher organisation, are tegumentary in their character. Their contents are chiefly tegumental products, which, once formed, have attained the limit of their growth. Such cysts, therefore, are more stationary in their character; or if occasionally they approach in bulk the watery cysts, as in the example just quoted, this arises mainly from the addition of a fluid secretion, and the necessity for circumscribing it by hypertrophy of the walls. But more often the cysts with solid contents, if they do not remain passive, contract adhesions with surrounding viscera, and by the aid of fistulous openings discharge their harder parts, such as bones, through the nearest natural orifice.

The tegumentary character of these cysts has been clearly shown by Cruveilhier*, Kohlrausch †, Lebert ‡, and Paget. § "Upon their inner surface is produced a growth of skin, with its layer of cutis, subcutaneous fat, epidermis, and all the minute appended organs of the proper hairy integument of the body;" whence the term "dermoid cysts." It is possible that at the commencement of their formation such cysts may have a general tegumentary lining, a part or the whole of which may afterwards become obliterated. For in the condition in which they generally come under our notice, the tegumentary structure is confined to patches of the lining membrane, while in many the hair is found entirely detached and lying in the form of a loose ball in the centre of a smooth-walled sac.

Sebaceous and Sudoriparous Glands have been shown by Kohlrausch and Heschl to be present in these cysts, where they have the same general arrangement as in the skin (*fig.* 397. *c*).

Fatty Matter. — This occurs under two forms: first, as a loose granular fatty sub-

‡ Traité d'Anat. Pathol.

§ Lectures, vol. ii. p. 83.

stance, of the consistence and aspect of lard or butter, in the midst of which are imbedded those coils of loose hair with which it is usually associated (*fig.* 397. *d*). This fatty material is of a white or yellowish hue, and is commonly inodorous, but sometimes it exhales an intolerably fetid odour, especially in those cases where air has been admitted into the sac, and partial decomposition has taken place, or where fœtid pus has been formed within the cyst. The second condition under which fat is found is that of masses ½—1″ in thickness, lying beneath the general lining of the sac, which is protruded before them, causing irregular elevations into the interior of the cyst (*fig.* 397. *a*). These present the ordinary character of adipose tissue, but possess a smaller proportion than usual of the cellular element.

Hair is found in ovarian cysts also under two forms, either still attached to the walls or lying in loose tangled coils in the centre of the cavity. Those attached to the walls are seen to spring from follicles, which may be scattered evenly over the cyst wall, in which case the hairs are usually short, or they may arise from a group of hair follicles, closely set, and imbedded in a substance clearly possessing the characters of ordinary skin. In the latter case the portions of integument from which they spring are generally elevated upon a mass of subcutaneous fat, as just described, and the hairs, which are well nourished and long, form at their free ends a tangled coil, intermingled with the loose fat already mentioned (*fig.* 397.). In these cases the hair often attains to a considerable length; it is fine and smooth, and resembles the long hair of the back of the head, exceeding sometimes in length two feet. The colour of the hair is usually red, dark brown, or black; it bears no resemblance to the hair of the individual in whom it occurs. Thus, in the case of an ovarian cyst occurring in a negress, Andral observed numerous hairs differing essentially from the woolly hair of the head; they were soft, smooth, red, or blonde, and some were silvery, like the hair of children of white races.

The loose hairs may be easily detached by maceration in turpentine or ether, from the mass of fatty substance in which they are entangled. They are then sometimes seen to be destitute of bulbs. They are usually more crisp and shorter than the attached hairs, except when the latter occur singly.

Teeth are very commonly found associated with hair and fat. These may possess the perfect character of incisor canine or molar teeth, but more frequently the resemblance is only general, and a more accurate examination discovers in them some imperfection of form. The resemblance is sometimes greatest to the deciduous, and sometimes to the permanent set. In the less perfect forms the crowns only are developed, the roots being deficient. But in most cases the intimate texture of the tooth differs in no respect from the ordinary dental structure.*

Ovarian teeth are generally found associated with portions of irregular-shaped bone, in which they are often imbedded. They may, however, be attached to the tegumentary lining of the cyst walls, and more rarely they have been found connected to portions of cartilage.

Bone.—The bones found within ovarian cysts differ from the ossified portions occasionally observed in the cyst in this respect, that, while the latter consist of merely crystalline or amorphous aggregations of earthy matter, the former, although irregular in shape, yet exhibit a true osseous structure, in which may be readily detected the usual arrangement of concentric lamellæ, Haversian canals, lacunæ and canaliculi. Such bones often bear a sufficient resemblance to fragments of jaws and vertebræ to admit of a general comparison with those parts of the skeleton; but well-shaped and perfect bones are not found, except in cysts of whose nature and origin some doubts at least may be entertained.

In *fig.* 397. are represented several of the solid structures commonly found in an ovarian cyst. A long coil of tangled hair, mixed with lardaceous matter, is seen springing from a portion of the cyst wall at a part which is lined by common integument. Here many

Fig. 397

Ovarian cyst containing hair, loose fatty matter, adipose tissue, sebaceous glands, and hair follicles. (After Cruveilhier.)

hair follicles are observed, some being empty, and others containing short hairs. The parts

* This is illustrated by Plate 124. of Professor Owen's "Odontography," exhibiting the microscopic structure of a tooth, from an ovarian cyst in my collection. Five other teeth were contained in this cyst, together with a portion of tegumental structure, subcutaneous fat, bone, and hair.

of the cyst covered by integument are seen to be elevated, and it is in the substance of and beneath such elevations that the fatty tissue and bones are usually found imbedded, whilst the teeth have only their roots concealed, their crowns projecting free above the surface.

Origin of the Solid Contents of Ovarian Cysts.—It has been conjectured that these are examples of the "fœtus in fœtu," or that such remains may be the product of an imperfect ovarian conception. To the former of these suppositions, viz., that such formations result from a cohesion or intus-susception of two or more germs, coincidently impregnated, but of which one only has been perfectly developed, it may be objected that this view fails altogether to explain the circumstance that their formation occurs far more frequently in the ovary than in any other part of the body; nor does it account for the fact that here a particular class of structures only is developed, whilst in the case of penetration of germs one within the other, various portions of a second fœtus, more or less completely formed, and by no means limited to a certain class of structures, are found within the body of the first.

The explanation that these are examples of extra-uterine gestation of the ovarian kind is equally unsatisfactory; for even if the possibility of such a form of gestation be ceded, the fact alone that hair, teeth, and even bones, contained in cysts of the kind under consideration, are never found associated with the smallest trace of the membranes peculiar to the ovum, would be fatal to this view. But it can be shown further that such structures are observed in cases where previous impregnation was highly improbable, as in the examples where they were found in conjunction with a perfect hymen*, or where it was impossible, as in the case related by Dr. Baillie of a girl aged 12, whose generative organs were still undeveloped, but one of whose ovaries was filled with hair, teeth, and fatty matter.

The two additional circumstances that there is scarcely any portion of the body, such as the subcutaneous tissue, the brain, lung, kidney, bladder, and testis, in which similar structures have not been found, and that such formations, though most commonly found in the ovary, are yet not even limited to the female, but have been also observed in the male, completes the catalogue of objections to the argument, in whatever form it may be advanced, that these productions are in any way the offsprings of a spermatic force newly applied to the organisms in which they are formed.

The discovery of the fact that a tegumentary structure forms the basis out of which many of these products spring, appears to carry us a step further towards comprehending the mode in which some at least of the solid contents of ovarian cysts are formed, by exhibiting a connecting link between structures which are elsewhere naturally associated, but it obviously fails to satisfy any inquiry as to the nature or quality of the cell-force which determines the development of such products.

Fœtus, more or less perfect, contained in the Ovary(?)—Ovarian Gestation.—Graviditas Ovaria.—Few facts in physiology have been more readily assumed without sufficient examination than that the fœtus may be developed within the proper structures of the ovary, and so constitute a form of extra-uterine gestation.

So long as it was generally believed that the coitus was the efficient cause of the escape of the ovum from the ovary, and that therefore the act of impregnation preceded that of ovulation, there was nothing in such a belief to challenge inquiry as to the probability of the ovum being first impregnated, and still by some mischance detained within the proper structure of the ovary, where it might become developed. But more accurate views of the nature of ovulation and of the true seat of impregnation have led to a stricter inquiry regarding the seat of supposed ovarian gestation.

Among the earliest to call in question the accepted views upon this subject was M. Velpeau, who, previously a believer in ovarian gestation, laid before the Philomathic Society, in 1825, four examples supposed to be of this kind. An expression of doubts as to the possibility of this fact on the part of many members led to a more perfect dissection of the parts, in which examination MM. Blainville and Serres were appointed to assist. It was ascertained with certainty that three of the tumours were external to the ovary. With the fourth more difficulty was experienced; but at length, after isolating the Fallopian tube, which was sound, the detritus of conception was found to occupy a special sac between the peritoneal and proper coat of the ovary, which was entirely distinct.

In the following year, M. Geoffroy St. Hilares, in a report upon the subject of Breschet's Memoir upon "Interstitial" Extra-Uterine Gestation, expressed his entire disbelief in the ovarian variety, and the same views have been advocated by M. Pouchet in his work on Spontaneous Ovulation, and in this Cyclopædia by Dr. Allen Thomson*, who has there stated the general objections to the doctrine of an ovarian form of gestation.

The cases which appear to favour the belief in ovarian gestation may be divided into two classes, viz., those in which the embryo is yet small, and is contained in a sac of moderate size, which has not yet contracted adhesion with adjacent parts; and those in which the fœtus has attained or approached to full growth, and the sac by which it is surrounded has already contracted adhesions.

All the examples that I have had the opportunity of dissecting, or of seeing examined, have been of the latter class, and of these it may at once be said that nothing can be learned from them which could determine, with any degree of accuracy, so difficult a question as that under consideration.

* Royal Coll. of Surg. Pathol. Collect. prep. No. 2625.

* Vol. ii. p. 456.

The impediments to such determination which recur again and again in these cases are the following. It is easily ascertained that the sac containing the fœtus is external to the cavity of the uterus, and is in some way or other connected with some portion of the internal generative organs; the Fallopian tube, ovary, and broad ligament of one side being chiefly involved in the tumour, while the corresponding parts of the other side may remain free. Dissection may serve to unravel these parts to a certain distance, beyond which nothing satisfactory can be determined, on account of the alteration which the tissues have undergone both in form and arrangement; the hypertrophy of some, and the wasting or blending together of others, rendering further research fruitless for the object in view.

To these impediments, other and still greater difficulties are generally superadded. These arise from the death of the fœtus, which often takes place several months or even years previous to that of the mother. In the decomposition which follows, the harder parts of the contents of the sac fall asunder, and make their way by fistulous openings into surrounding viscera, whose surfaces inflame and give rise to serous and fibrinous effusion, while in the few hours which succeed to the final destruction, the parts decompose so rapidly that the post-mortem examination, however early it may be made, often reveals nothing but a semi-putrid mass perfectly unsuited to the determination of a difficult anatomical question.

For this purpose the cases of the former class can alone suffice. Here the parts are small, and as yet comparatively unchanged, and admitting of dissection. The results of four such examinations have just been given. The following additional examples, which are selected from the best recorded cases supposed to be ovarian, will suffice to exhibit the class of evidence upon which a belief in this species of gestation is demanded.

Cruveilhier* has described and figured a case in which the entire skeleton of a four months' fœtus † is seen hanging external to a sac, occupying the seat of the right ovary, in which it is supposed to have been once contained. The sac said to be in the inner and lower part of the ovary is lined by a serous membrane. The two external thirds of the pouch were filled by a spongy areolar yellowish-white mass presenting all the characters of placental tissue. The outer half of the surface of the ovary was enveloped in a cartilaginous shell. No attempt appears to have been made to trace the entire outline of the ovarian tunics, or to show the condition of the ovarian ligament, or of the Fallopian tube of the same side. The latter, indeed, is not mentioned, but from the representation of the parts it appears to be blended with the cyst, so that this is quite as likely to have been an example of tubal, or ovario-tubal, as of ovarian gestation. The fact also that the cyst had apparently burst and permitted the escape of the fœtus when it had attained the size which is seldom exceeded in tubal cases, lends additional probability to this view.

* Anat. Pathol. livr. xxxvi. pl. vi.

† Said in the description to be between one and a half and two months, at which time, however, no such complete skeleton is ever seen.

Dr. Granville * has published a case, accompanied by drawings, which he regards as an "undisputed case of purely ovarian fœtiferous ovum." The uterus is considerably enlarged, but empty. "The left ovarium presented a large swelling which contained within its own covering an ovum bearing a fœtus with all its appendages, of about four months' growth. The ovarian covering burst in three places, and allowed the protrusion of the ovum, whereby the adhesion of the placenta to the inner surface of the ovarian envelope was torn asunder," causing death by hæmorrhage. A blood-vessel, the size of a large crow-quill, which penetrated the dense portion of the tumour, was ascertained to be a branch of the left spermatic artery, and a smaller and much shorter vessel, arising from the tumour, was found to communicate with the spermatic veins. "The corresponding Fallopian tube was perfectly sound and loose, particularly at its fimbriated extremity, which had no connection whatever with the embryoferous tumour in its neighbourhood. Like its fellow tube, it was pervious only from its loose extremity inwards to about half its length. "A placental mass with distinct cotyledonous vesicles connects the child with the inner covering of the ovarian cyst. The secreting or transparent involucra are quite distinct. The *cortex ovi* is almost wholly absorbed, as it ought to be at such an advanced period. The fœtus is perfect." In the explanation of the plates mention is made of "fragments of the corpus luteum which surrounded the ovum, and was broken to pieces by the enlargement of the fœtus. Some of these fragments adhere to the inside of the ovarian coats, others are among the placental cotyledons." No account is given of the ligament of the ovary, nor of such a dissection of the parts having been undertaken as would satisfactorily prove that the sac containing the fœtus was not a cyst attached to the ovary. But the evidence in favour of ovarian gestation consists chiefly in this, that the fœtus-bearing cyst occupied the region of the ovary, and was independent of the Fallopian tube. Nevertheless this case constitutes the nearest approach to the form of gestation which it claims to represent with which I am acquainted.

In the same work (Graphic Illustrations †) is contained a description and representation of a second case termed "ovum fœcundum in receptaculo ovarico." "Through a transversal aperture in the left ovarium are seen the remains of some membranes, three in number at the least, lining a cavity which measures transversely one inch and a quarter, and about an inch vertically." The preparation belonged to Sir C. M. Clarke, who assured Dr. Granville "that a small embryo hung pendulous

* Phil. Trans. 1820, and Graphic Illustrations of Abortion, Plates X, A, and B.

† P. 27. pl. viii.

from the yet visible rudiment of an umbilical cord. That embryo, however, is not now to be seen." The female from whom this was taken was unmarried, but acknowledged herself to be pregnant. The uterus was larger than in the unimpregnated state. The Fallopian tube was not in the least involved in the enlargement. The fimbriæ were free.

A case which, in the opinion of Dr. Campbell *, "in so far as anatomical accuracy is concerned, ought to satisfy those who are still sceptical regarding the reality of ovarian gestation," is recorded in the Transactions of the College of Physicians.† From the description and drawing which accompanies it the following chief particulars are learned. The uterus, from a woman aged 30 who had committed suicide, was larger than the ungravid organ ; its body somewhat globular ; its substance, except the cervix, spongy. A decidua nearly ½″ thick, soft, pulpy, and of yellowish-white appearance, lined the interior of the uterine body. The cervix was filled with gelatinous matter, but not sealed up. The vessels of the broad ligament and appendages were remarkably distended ; on the posterior part of the left ovary, which was considerably larger than the right, was a round prominence distinct from the general fulness. The tunics of the ovary at this point were numerously furnished with tortuous blood-vessels ; and from careful examination it was clear that there had not been any aperture in the external membrane ; its surface was perfectly smooth. On dividing the membrane which covered this prominence, a distinct cyst was exposed, which contained an ovum. The internal surface of this cyst was smooth and polished, its external firmly adherent to the substance of the ovary. The ovum was simply in contact with the cyst in two-thirds of its circumference ; in the remaining third it was united to it so closely as to be inseparable. The chorion and amnion were perfectly distinct, and by the aid of a magnifying glass, vessels filled with blood were seen ramifying on the former. A yellowish honey-like matter filled the amnion, but the embryo could not be distinguished. Around the ovum for some distance the ovary was loaded with blood effused into its substance.

Except for the statement regarding the decidua there is nothing in this account which would be considered significant of pregnancy at the present time when a more perfect knowledge has been obtained of the various conditions of the ovary in health and disease. Changing the names employed to designate the cysts, this description would apply either to a follicle preparing to burst ‡, or to an incipient stage of cyst formation. To the latter it approximates more nearly. The smooth and polished inner surface of the containing cyst ; the union, "so close as to be inseparable," of the cyst termed the ovum by a third of its base to the larger one ; the presence of a honey-like matter filling this inner cyst, which is represented in the engraving as not larger than a pea, and the vessels ramifying on the cyst wall, are all conditions commonly observed in early stages of the morbid follicle.

On the other hand, the following are among the conditions which oppose the conclusion, that the ovary was in this case the seat of impregnation, viz., the absence of all trace of an embryo ; the so-called chorion, entirely wanting villi, which, in all known cases of the early ovum, more or less cover its surface ; the firm adhesion by a third of its circumference, at a time when the ovum naturally lies free and unattached even by any part of its little flocculent villous coat ; the impossibility of accounting for chorion-vessels, without an embryo to form them, and still more of explaining how the seminal fluid could reach the ovum through a membrane which is described as "perfectly smooth," and in which, "from careful examination, it was perfectly clear that there had not been any aperture ; " the absence of all mention or representation of any of those conditions of the walls of the ripe follicles which in an earlier part of this article have been shown to be always present in the follicle preparing for or soon after rupture, and which must have been present in some degree if this had been a Graafian vesicle containing an impregnated ovum. These together constitute insuperable objections to this case being received as one decisive of impregnation in the ovary, and justify its being regarded rather as an example of cystic formation, which, according to the engraved representation of the parts, it very accurately resembles ; notwithstanding that the description of the uterus and decidua would give a strong bias and indeed wish to receive this as a case in which impregnation had obtained, if the state of the parts found in the ovary had corresponded with what is now known to be characteristic of the structures formed in the earliest stages of pregnancy.*

* Memoir on Extra-Uterine Gestation, p. 33.

† Vol. vi. p. 414. 1820.

‡ See *anté*, p. 557.

* I am enabled to add in a note the following particulars relating to two of the four cases quoted above as examples of supposed ovarian gestation, and of which it may be remarked that neither are of recent date, the one having occurred thirty-eight years ago, and the other at least as early — at a time, therefore, when ovarian gestation had not been questioned, and the ovarian ovum in man had not yet been discovered. The preparation, described and figured by Dr. Granville as belonging to the late Sir C. M. Clarke, is now in the possession of Mr. Stone, by whose kindness a more particular examination of it has been permitted. For this purpose, the preparation was recently placed in the hands of Professor Owen, by whom it was removed from the bottle, and minutely examined under spirit. At this investigation, I was also present, together with Mr. Stone and Dr. John Clarke, and I had the opportunity of making repeated microscopic examinations of every portion of the ovarian structures. The result of the investigation showed that the structure supposed to be an impregnated ovum contained in the ovary, although it had such a general appearance as might without this examination have borne the interpretation which had been originally put upon it, was nothing else than an ordinary ova-

It is not necessary to multiply these examples, for no additional points of evidence could be produced which are not contained in the foregoing cases. They have been selected from instances related or quoted by various authors who have been strongest in their advocacy of the doctrine of a strict ovarian gestation, and they serve to exhibit the kind of evidence upon which that doctrine is founded. All the cases which have been employed to support this view* will be found on examination to belong to one or other of the following divisions: —

1. Cases of cysts without any embryo, and in which some supposed resemblance has been traced between the cyst walls and fœtal membranes, without any conclusive evidence of the presence of these structures being given.

rian cyst. The walls of the sac showed no separation into distinct membranes, and no trace whatever of the structures characteristic of either chorion, chorion-villi, amnion, or decidua could be discovered in them.

The outer surface of the cyst was so firmly adherent to the surrounding ovarian stroma that it could only be separated from it by considerable traction. The connecting medium was the common stroma of the ovary. The walls of the cyst, when portions were examined by transmitted light, exhibited the arrangement of vessels peculiar to ovarian cysts. The little slender depending fragment, supposed to be a rudimental umbilical cord, and very faithfully represented by Dr. Granville in Plate VIII. of the work quoted in the text, proved to be a narrow flap of the same cyst wall which had been left hanging from the edge of the sac where a portion had evidently been originally cut away in order more fully to display the preparation (the sharp edge left here by the knife or scissors being very distinctly seen). Upon transverse section of this little fragment, no trace of umbilical vessels could be found in it.

It should be observed that Sir Charles Clarke never published an account of this case.

The additional particulars which I am enabled to give with regard to the last of the four cases quoted in the text, and described in the Transactions of the Royal College of Physicians for 1820, are of another kind. That this preparation was formerly preserved in the anatomical museum of St. Bartholomew's Hospital, where the author of the case was also the lecturer on anatomy, can scarcely be doubted, from the description, exactly according with it, which appears in the first edition of the Catalogue drawn up by Mr. Stanley. (See Description of the Preparations contained in the Museum of St. Bartholomew's Hospital, 1831. Edited by Edward Stanley, Esq. Preparation 64, series xx. p. 27.) This preparation is no longer contained in the museum; and by those who are most likely to be informed upon the subject, it is not known to be in existence. The only clue that I can obtain as to its fate is derived from Mr. Paget, who informs me that, as a step preliminary to the formation of the new catalogue, printed in two volumes in 1846-51, the entire anatomical collection was carefully reexamined; and that those preparations which were found, upon such examination, not to bear out the descriptions given of them in the catalogue, or which did not serve to illustrate any point of interest, were put aside and condemned. There is, therefore, every probability that this preparation, which can now no longer be appealed to in support of the possibility of ovarian gestation, has been subjected to a similar ordeal to the former, and with a like result.

* A large collection is contained in the work of Dr. Campbell just cited.

2. Cases of dermoid cysts containing fat, hair, teeth, and bones, the nature and origin of which, independent of pregnancy, have been already considered.

3. Cases in which the evidence is more or less complete that a fœtus is or has been contained in a cavity of, or connected with the ovary.

Of the latter, as already stated, those alone suffice for examination in which the cyst has continued unattached to surrounding parts, and has remained unaffected by disintegrating and destructive processes. In this category would still be found, in all probability, a sufficient number of cases amply to have determined the question in dispute, if such methods of investigation had been pursued as the present state of anatomical and physiological science demands for the settlement of doubtful points; for in a considerable number of cases it is rendered evident that the fœtus is contained within a sac in some way connected with or occupying more or less the usual seat of the ovary. Here, therefore, the question is reduced to very narrow limits, Are these sacs formed within and at the expense of the proper ovarian structures, or are they adventitious cysts growing externally to, although connected with these structures?* If strictly within the ovary, and formed of it or of its parts, then ovarian gestation in the strict sense obtains. But this has not yet been anatomically demonstrated in such a manner as to set all objections at rest; for neither have the blood-vessels been injected in order to ascertain their new relations and distribution, nor have the tissues been microscopically examined, without which examination it would be hardly possible to determine of what parts the fœtus-bearing sac is composed. Nor have the exact limits of the serous and albuginean coats, nor the relations of the sac to the remaining ovarian tissues, nor the precise mode of connection of the fœtal membranes with the sac, been accurately traced. Nor has the condition of the yellow or corpus luteum coat of the follicle, of which brief mention only is made in one instance, been carefully examined; yet this is a point of the greatest interest and importance, because, if true ovarian gestation ever occurs, then the yellow ovisac would become the *decidua*, and the outer fibrous coat of the follicle, together with the ovarian tunics and stroma, would be the *uterus* of the ovum. But in the present state of our knowledge it cannot be said that the subject of ovarian gestation stands in any other position than that of an open question, the chief points of interest regarding which may be thus stated:—

The unimpregnated ovum is known to quit the ripe Graafian follicle by passing through an aperture spontaneously made in the walls of the follicle and of the ovary, in order to enter the Fallopian tube and uterus, in one of which canals it is afterwards impregnated.

* It is thought by Boehmer that these cases might be divided into external and internal.

It becomes a question whether this law, which has been established by ample testimony, admits of the exception that the ovum may be impregnated before quitting the follicle, and therefore whilst still contained within the ovary.

The records of various cases, in which the fœtus is apparently contained within the ovary, raise this question. For if the fœtus is found strictly contained within structures properly ovarian, then the ovum must have been impregnated within the ovary, and the seminal fluid must have entered the Graafian follicle*, for it cannot be supposed possible that the ovum, having quitted the follicle unimpregnated, should again enter it after being impregnated.

The cases, however, which have been recorded as examples of ovarian gestation do not suffice to demonstrate that the sac containing the embryo or fœtus and its membranes is strictly within the ovary, and is composed of structures strictly ovarian; and until such demonstration has been given, ovarian gestation, in the most liberal view that can be accorded to it, cannot be held to have any other signification than that of the development of the embryo or fœtus in a sac connected with or occupying the usual seat of the ovary, but not yet proved to be developed within the proper structures of that gland.

Origin of Ovarian Cysts in general. — It has been often asserted, and as frequently doubted or denied, that these cysts derive their origin from an unnatural enlargement or dilatation of Graafian follicles. Such a contrariety of views is observable equally with general pathologists, as with those who have studied the special histology of this subject. Of the latter both Rokitansky and Wedl may be considered as still holding uncertain opinions; for Rokitansky, who regards it as probable that the simple cysts are in many cases developed from the follicles, doubts that such is their origin in those instances in which their number far exceeds the usual number of Graafian vesicles, holding them to be new formations; and Wedl says that of the cysts in the parenchyma of the ovary no direct proof has ever been given that they originate in the Graafian follicles; and with respect to those which contain hair and teeth, he regards their origin in this way as "extremely doubtful."

It is obvious that a question of this kind cannot be definitively settled except by minute examination of the morbid cyst in all the early stages of its growth; an examination for which opportunities cannot very frequently arise. The choice lies between the classing of such cysts with those, on the one hand, which originate in the dilatation of natural sacculi and ducts, or with such as have their commencement in the enlarging of areolar spaces, or in the growth of primary cells or nuclei into cysts.

In the case of the ovary, it happens that the settlement of this question is more difficult than in that of most other organs; for with regard to the formation of cysts upon the latter plans, whether the views of Wedl be adopted, that they consist in an excessive augmentation of volume of the areolæ of the areolar tissue, or those of Rokitansky, that a cyst proceeds from an elementary granule which grows, by intus-susception, into a nucleus, and this into a structureless vesicle, in both views such cysts come to be composed ultimately of a cell-wall compounded of fibrous tissue and lined by epithelium — a structure which is, in fact, identical in composition with the Graafian vesicle itself.

With regard to any doubts as to the origin of cysts in Graafian follicles, which may be founded upon their number exceeding the average number of healthy follicles in an ovary, it need only be observed that the latter have been shown by the microscope to be innumerable; and with respect to secondary cysts, springing from the walls of primary ones, numerous observations prove that the impulse to cystic formation once given in an organ, even by the primitive enlargement of normal cavities, a marked tendency to the antogenous formation of cysts follows.* But even if no other explanation could be offered, the discovery of Barry, that the walls of a Graafian follicle in a natural state often contain numerous follicles of a second order, would sufficiently demonstrate the capacity of these for secondary cell-growth.

In giving the preference to that view which regards the cystic diseases of the ovary as originating in a dilatation of the Graafian vesicles, I have been guided chiefly by the following considerations.

In those cases where I have been able to discover cysts in the ovary in a stage of early formation, these have not been of less size than the average dimensions of the developed Graafian follicle.

They occur intermixed with healthy follicles, and exhibit with them the same histological formation; their tissues being altered sometimes only in such slight degrees as still to admit of their common origin with the Graafian follicle being shown.

There is sometimes exhibited in the same ovary, or in the ovaries of both sides together, a sufficient number of grades of enlargement to constitute a series of cysts, evidently composed of similar parts and tissues in various stages of growth.

Beginning with the smaller cysts, still contained in part or entirely within the ovary, there may be traced cysts of precisely similar formation and structure in every gradation of size up to those examples in which the ovary itself comes to be a mere appendage of the

* There is nothing in this supposition incompatible with the known facts relative to the spontaneous opening of the follicle, and the power of penetration of the spermatozoa occasionally as far as the distal extremity of the oviduct, or even to the surface of the ovary.

* Lebert, loc. cit. p. 244.

cyst, or in which the tissues of the healthy organ are entirely expanded and lost in the walls of the sac.

And lastly, the occurrence of these cystic formations is limited to that period of life when the Graafian follicle is in a state of activity. They are not found as new formations after the usual time at which the follicles have ceased to be discoverable in the ovaries as natural structures, nor do they occur before the period of puberty has arrived, except in cases much more rare than those of an unusually early development of these follicles, or of precocious puberty.

These arguments apply more particularly to cysts with fluid contents. How far they may also serve to explain those which contain more highly organised products is less obvious. But it must still be remembered that cystic formations of all kinds occur far more frequently in the ovary than in any other part, whilst there is nothing peculiar in the stroma of the ovary, or that portion which is external to the follicles, which would render it more peculiarly liable to cystic formations arising out of dilated areolar spaces, than similar fibrous structures occurring in other portions of the body where cysts occur.

Solid Enlargements of the Ovary. — These consist of formations of fibrous, and occasionally of imperfect cartilaginous tissues, and of osseous concretions, but more frequently of cancerous growths, formed at the expense of, or deposited within, the tissues of the ovary.

Of formations of *fibrous* tissue some account has been already given in the description of the growth of cysts. The new formations of fibrous tissue which take place in the ovary occur chiefly in the cystic parietes, where they are deposited for the purpose of strengthening the walls and enabling them to resist the increasing weight and pressure of their growing contents. But as fibroid tumours, or solid growths of the entire ovary, such formations, except those of very small size, are certainly rare, unless they are of a cancerous or cancroid nature.

It is probable, indeed, that, excepting the cancerous and cancroid cases, most, if not all, of the specimens which have been described or preserved in museums as examples of *large* fibrous tumours of the ovary, have been formed at the expense of the proper tissue of the uterus, and have had nothing to do originally with the ovary, although the latter may be so involved in the mass that its proper tissues can no longer be distinctly traced.

Such I had no difficulty in determining to be the case with a specimen preserved in King's College Museum as an example of fibrous tumour of both ovaries; each supposed ovary being of the size of an ostrich's egg, and presenting all the characteristics of the ordinary fibrous tumour of the uterus. It was rendered evident, by dissecting the parts and opening the uterus, which had not been done previously, that these large tumours which hung on either side of the uterine body had been formed at the expense of the latter, for the natural tissues of the fundus and corpus uteri were in great part absorbed into and had evidently contributed to form these masses; and out of the apex of one of these sprang the uterine end of the Fallopian tube; a clear proof that this was not an ovary.

In this way may be explained the remark of Cruveilhier, that fibrous tumours of the ovary are so perfectly identical with those found in the uterus, that it is sometimes impossible to determine to which of the organs they have originally belonged; and also the remark of Dr Baillie, that they resemble in texture the tumours which grow from the outside of the uterus. The absence of the muscular element from the natural tissues of the ovary, and the now well-known fact that the uterine fibrous tumours contain, as one of their characteristic constituents, more or less abundantly the smooth or organic muscular fibre of the uterus, forbid the belief that tumours of similar composition to those found in the uterus can be formed within or at the expense of the proper tissues of the ovary.

Cartilaginous and Osseous Formations, especially the latter, are not rare in the ovary. They are found chiefly in the parietes of cysts, and also intermixed with cancerous deposits. The process of deposition of earthy matter, which should be termed calcification rather than ossification, occurs here under three principal forms.

In fine sections of the more solid structures, or in the thin walls of cysts which are slender enough to be examined without cutting, may be often seen, with a moderate amplifying power, little aggregations of crystals in the form of clavate spicula, clustered round a centre, and forming groups scattered through a fibrous basis. Such tissues are sensibly rough to the finger, and grate under the knife.

In the second form the same calcareous materials, consisting of phosphate and carbonate of lime, combined with a small proportion of animal matter, occur as plates or laminæ, strengthening the walls of cysts; or in the shape of grains, or larger aggregations, or layers intermixed with the tissues of more solid tumours.

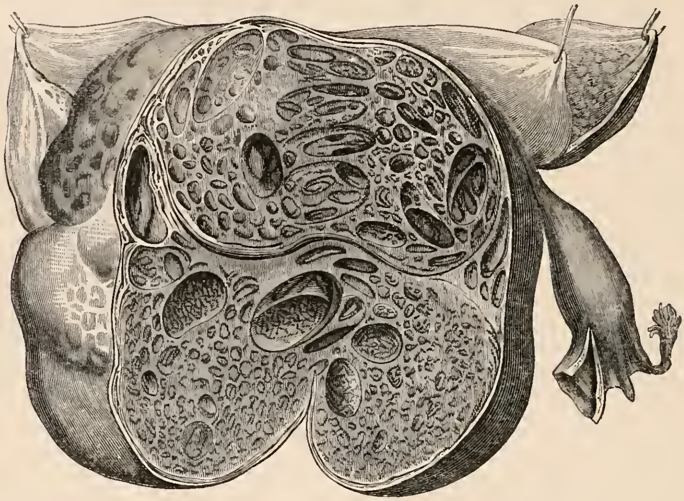
In a third form the calcareous matter may constitute an oval or solid mass contained within a small cyst, and resulting apparently from an entire calcification of the inner walls of the cyst.

The condition under which true bony structures are found in the ovary has been already considered in another section. (*See* Dermoid Cysts.)

Cancer of the Ovary occurs under the three principal varieties of Colloid, Medullary, and Scirrhous or hard cancer. Most of the large tumours of the ovary, and such of the encysted class as remain still to be described, belong to the variety of

Colloid or Alveolar Cancer, generally associated with Cysts.—These might have been classed, as has been done by Rokitansky and Lebert*, with the other forms of cystic disease of the ovary, on account of the frequency with which this form of cancer is found associated with ovarian cysts, especially of the larger class. But such an arrangement, whilst recognising an important feature, often, but not always, observed in colloid cancers of the ovary, of necessity dissociates these cases from other congeneric forms of disease. In this particular respect colloid cancer appears to stand between the various cystic diseases already described, and those forms of cancer which are not colloid, in the position of one of those "osculent groups" which have been sometimes employed in classifications of the animal kingdom as connecting links, to bring into juxtaposition objects which, though exhibiting certain near affinities, could not be included in one common group, without violence to the principles upon which a natural arrangement should be based.

Fig. 398.



Colloid cancer of the ovary. (*After Cruveilhier.*)

Not, however, to enter further upon the disputed question of the nature of alveolar cancer of the ovary, it will suffice to notice those peculiarities which are generally to be observed when the disease affects that organ.

Since colloid cancer of the ovary does not generally destroy life until the disease has made great progress, the specimens of ovaries so affected which come under our notice are often of large size, filling the pelvis and abdomen, and equalling in bulk the masses of cyst formation of a more innocent type. Such a mass, when incised, may be found to include the entire ovarian structure, which is converted into a collection of cysts, or alveolar cavities, varying greatly in size and in the thickness of their walls. Such a variety is often seen in different portions of the same structure. The surface of a section may present in some parts the appearance of a fine sponge, the alveolar spaces being condensed and somewhat flattened, in consequence of the profusion with which the alveoli have been developed. In other portions of the same tumour, and occasionally as it were in separate lobules of it, the alveoli are more expanded, and take a round or oval form, assuming the condition of distinct cysts, some of which may considerably exceed the rest in magnitude. These larger cysts may occupy a seat within the mass, or project from its surface; and probably in this way arise those still larger cystic formations in which one or more large sacs occur, having connected with them masses of alveolar structure such as those just described.

The interstitial substance, which constitutes also the boundary walls of the alveoli and follicles, is composed of a white, shining, fibrous tissue, upon the density of which chiefly depends the general hardness or softness of the mass. This intermediate substance is in some instances so thick that the cysts appear like excavations in a dense medium, but often the cyst walls are so thin that the peripheral follicles project in the form of thin-walled sacs from the surface, and the whole mass is sometimes so feebly supported as to assume the appearance of a trembling jelly. The thin-walled cysts are generally richly supplied with blood-vessels.

These cysts are filled with a viscid mucous-like material, resembling half-liquid jelly, which is sometimes colourless, but oftener of a grayish amber, yellow-green, or reddish hue. Im-

* Rokitansky, however, regards these cases as decidedly cancerous; while Lebert asserts that they have nothing in common with colloid cancer except the gelatinous contents of the cells.

bedded in the jelly-like substance may be found opaque white masses resembling blanc-mange or thick cream. Intermixed with these contents, in varying proportions, are found nucleated epithelial cells, oval corpuscles, oil granules and molecules, and delicate filaments.

Besides these contents of the alveoli, there may be often observed hanging into their interior, and sprouting from their walls, clusters of leaf-like clavate or villous processes, such as are observed in that variety which has more particularly received the name of villous cancer.

But it frequently happens that the alveolar type of structure is not generally diffused through the mass. This may form only a small portion of the diseased ovary, whilst the greater part is composed of one or more large cysts, with contents similar to those just described.

Within such cysts, or growing from the walls of those which present no other type of malignant structure, may be observed round or oval bosses, bearing no inapt resemblance to the uterine cotyledons of the cow, and exhibiting in section the compact areolar texture characteristic of the closer forms of alveolar cancer.

Colloid or alveolar cancer is occasionally found associated with medullary disease in the same ovary, whilst its presence there may be accompanied by other varieties of carcinoma in other organs, and attended by a well-marked constitutional cachexia.

Medullary Cancer of the ovary is of less frequent occurrence than the preceding variety, but like it is also occasionally associated with the formation of cysts.

Medullary cancer may occur either in the form of a general infiltration of the entire ovary with encephaloid matter, or in that of distinct tumours, bounded by a fibrous envelope, and having the carcinomatous matter distributed through an interior cellular substance, or confined there by cellular septa. These tumours may attain the size of an orange or more. Their growth appears to be in the first instance repressed by their fibrous sheaths, but these occasionally burst and allow of the diffusion of their contents. This form of cancer often affects both ovaries together, and is found associated with cancer in other and especially adjacent parts. Notwithstanding the number and variety of the contiguous structures which may be thus involved, the ovary may sometimes be traced as the centre or focus from which the cancerous deposit has spread. This was remarkably the case in an example of medullary cancer, which was for some months under my notice, where the disease commenced apparently in the left ovary, and was found to have spread from this point upwards along the chain of absorbent glands on the corresponding side, as far as the pancreas, and outwardly through the ischiatic notch to the glutæi, and all the adjacent muscles, including in its destructive march the os innominatum, which could be cut with a knife like cartilage. A medullary tumour the size of a walnut was found in the fundus of the uterus, but the rest of that organ, as well as the opposite ovary, had escaped the general destruction.

The *melanoid* variety of medullary cancer is occasionally observed in the ovary. (Roy. Coll. of Surg., No. 2642. and A.) It differs only from the foregoing in having pigment cells, of a black or brown colour, scattered through the carcinomatous matter.

Scirrhous or Hard Cancer and *Cancroid* are by no means so common as the two former varieties. Yet it is not rarely that one meets with the ovary, of one or both sides, in a hard white nodulated condition, resembling somewhat the human kidney, both in size and shape, and having its entire tissue converted into a form of cancroid, characterised by the development of a peculiar kind of stiff close-set fibres, containing between their meshes numerous nuclei (Fibro-nucleated cancroid). Such a condition of the ovary is sometimes found associated with hard cancer in other parts of the body.*

Of *Scrofulous Tubercle* in the ovary I can give no account. Most authors who refer to the subject mention it as rare, but give no decisive instances. Boivin and Dugès, however, have figured an example (*fig.* 16. Atlas) occurring in a girl of 16, associated with tuberculous disease of the mucous membrane of the uterus. In cases of my own, which I had regarded as examples of scrofulous ovary, until submitted to the microscope, I could find no trace of tuberculous matter. By Rokitansky the existence of tubercle in the ovary is altogether denied.

THE PAROVARIUM.

Syn. *Corpus Conicum. Neben-Eierstock. Organ of Rosenmüller.*

These names have been applied at various times to an organ which has hitherto received little attention, but which is nevertheless invariably present in close proximity to the ovary. The first discovery of this body is due to Rosenmüller †, who termed it the corpus conicum. It has since come under the notice of many observers, and particularly of J. Müller. And it has recently been re-examined, and very accurately described by Kobelt ‡, in an essay devoted to this subject, in which the author expresses his surprise that a structure so easily distinguished both by sight and touch, should have attracted comparatively so little attention up to the present time.

The Parovarium is most readily found by holding up the broad ligament between the observer and the light. Within the folds of this membrane, at the part where the layer

* For an example see Roy. Coll. of Surg. prep. 2636.

† Quædam de Ovariis Embryonum et Fœtuum humanorum. Leipsiæ, 1802.

‡ Der Neben-Eierstock des Weibes. Heidelberg. 1847.

of peritoneum, after investing the Fallopian tube, passes off towards the ovary, to form the posterior duplicature which encloses the vessels proceeding to that organ, will be found a small plexus of white tortuous tubes, (*fig.* 403. *a*, *b*, *c*) arranged somewhat in the form of a cone whose apex is directed towards the hilum of the ovary *l*, and its base *a c a* towards the Fallopian tube *h*. The entire organ measures about one inch in breadth, and is composed of 12—20 tubules 0·15—0·2‴ in diameter.

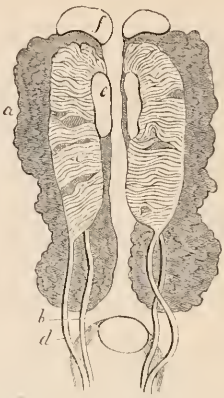
The tubes which contain nothing but a clear fluid consist of fibrous membrane, lined by a single layer of pale, cylindrical, epithelial cells. These tubular canals are not known to have any direct communication with the ovary.

That the parovarium is formed out of the Wolffian body does not now appear to admit of doubt. It has been usually considered that the Wolffian bodies are organs peculiar to fœtal life, and that they afterwards entirely disappear in both sexes. Hence no special investigations have been undertaken with a view to ascertain their ultimate fate. Meckel indeed compared them to the epididymis. Rathke believed that they became epididymis in the male, and disappeared in the female; while Rosenmüller, who discovered the parovarium, compared this body to the epididymis. Some general conjectures also have pointed in the male sex to the *vascula aberrantia* of the epididymis, and in the female to the organ of Rosenmüller and the ducts of Gärtner, as the supposed remains of the Wolffian body. Nevertheless it is, according to Kobelt, an undoubted anatomical fact that each pretended ephemeral structure not only exists through the whole of life in both sexes, but that it absolutely increases up to its highest state of perfection, and first suffers a gradual retrogression, after the extinction of the reproductive function, but never entirely disappears.

The signification and true homologies of this singular organ cannot be understood without first briefly examining the mode of formation and development of the Wolffian body, and tracing its relation to the generative gland and Fallopian tube. In this examination it is also of consequence to compare the progressive steps of formation of those parts with the corresponding structures in the male.

The Wolffian body is most readily examined in the chick, (*figs.* 399, 400.) Here during the third day of incubation are formed two canals which extend along the sides of the vertebral column, from the heart to the posterior extremity of the body. To the inner side of each canal is attached a series of blind pouches (*fig.* 399. *c* and 400. *b*), which during the next two days become lengthened and convoluted. These together constitute the Wolffian body. Behind them, and formed independently at a somewhat later period, lie the kidneys (*fig.* 399. and 400. *a*) and suprarenal bodies, (*fig.* 399. *f*, 400. *d*) and as these increase, the Wolffian bodies diminish. The testes (*fig.* 399. *e*) and ovaria (*fig.* 400. *c*) are developed upon the inner border, and in front of the corpora Wolffiana.

Fig. 399.

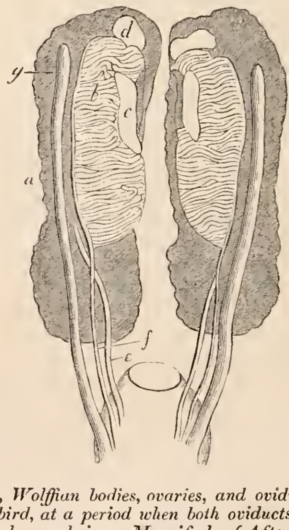


Kidneys, Wolffian bodies, and testes of an embryo bird. Magnified. (After Müller.)

a, kidney; *b*, ureter; *c*, Wolffian body; *d*, excretory duct of the latter, which, according to the views of Müller and Kobelt, afterwards becomes the vas deferens; *e*, generative gland, afterwards becoming testes; *f*, supra-renal capsules.

In the female chick, according to Müller, there is always seen an oviduct (*fig.* 400. *g*),

Fig. 400.



Kidneys, Wolffian bodies, ovaries, and oviducts of a fœtal bird, at a period when both oviducts are still of nearly equal size. Magnified. (After Müller.)

a, kidney; *b*, Wolffian body, *c*, ovary, the right * rather the smaller; *d*, supra-renal capsule; *f*, excretory duct of the Wolffian body, which in the female becomes obliterated, but in the male is converted into vas deferens; *g*, duct of Müller, afterwards oviduct or Fallopian tube.

* The drawing has been reversed in engraving. The left, therefore, should be here the right side.

distinct from the duct of the Wolffian body (*fig.* 400. *f*). In the male, however, he has been able to detect no vas deferens distinct from the excretory duct of the corpus Wolffianum; but on the contrary, the testis and the excretory duct of the former body seem to become connected by means of vasa efferentia. This is an important point, because it will be found so far to bear out the views of Kobelt regarding the homologies of these structures.

In the mammalia generally, and in man, the Wolffian bodies are less extended. They, however, possess the same arrangement of transverse cæcal tubes (*fig.* 401. *a—d*), terminating in the side of a common excretory duct (*e*), which leads from the lower extremity of the organ to the uro-genital sinus.

These structures are all formed independently of the kidneys and supra-renal capsules, as well as of the ovaria and testes, which parts occupy the same relative position in mammalia as in birds.

But here, according to Müller's researches, a different arrangement is observed in regard to the efferent duct of the generative portion of these structures. At first the oviduct and the vas deferens have each the same conformation, and each terminates by a free extremity. This, in the female, merely acquires an open mouth, and thus the Fallopian tube is formed, the ovary continuing, as at first, distinct and separate. But in the male the efferent tube and the testis become connected by transverse vessels, which are afterwards converted into the coni vasculosi of the epididymis, whilst the rest of that organ is composed of the convolutions of the efferent tube itself. "The Wolffian bodies entirely disappear in both sexes, and are not converted into any other organ." *

These views, however, leave unexplained many peculiarities which are observable in the permanent condition of the parts or organs developed from the fœtal structures; and it is the great merit of Kobelt's researches that they serve to render these intelligible.

According to this observer, there exists, in the earliest periods of intra-uterine life, a condition of indistinction of sex in every individual. This depends upon a temporary co-existence in each individual of all the elements of the reproductive structures. For at the highest point of sexual indifference, that is, shortly before the beginning of the division of sex, the Wolffian bodies consist of —

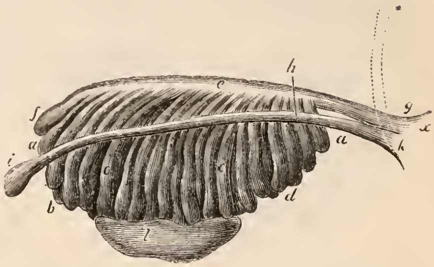
1. The so-called cæcal tubes (*fig.* 401. *a—d*).

2. Of the common duct (*e*) running along the outer side of this body, into which the cæcal tubes open.

3. And of a second longer cord (*h*), which begins in a blind pouch (*i*), and takes its course inwards over the Wolffian body, parallel with the excretory duct of the latter (*e*), in order to enter the uro-genital canal (*x*), by a separate orifice (*k*). This last cord, discovered by John Müller, is throughout destitute of any connection with the cæcal pouches. (See also *fig.* 400. *g*.)

* Müller's Physiology, by Baly, p. 1637.

Fig. 401.



The left Wolffian body at the period of indistinction of sex. (*After Kobelt.*)

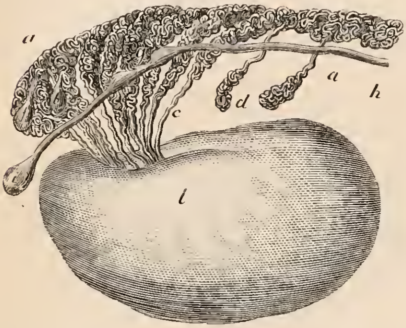
a a, entire collection of its component tubules divisible into three sets, viz., *b*, upper; *c*, middle; *d*, lower set; *e*, excretory duct of the Wolffian body into which all the tubules open, subsequently converted into vas deferens in the male, and becoming atrophied in the female; *f*, terminal bulb of the same, becoming afterwards the so-called hydatid, often seen attached, in the male, to the head of the epididymis (*fig.* 402. *f*), and in the female to the broad ligament (*fig.* 403. *f* and 408. *g*); *g*, opening of the Wolffian body into *x*, the uro-genital canal; *h*, duct of Müller, afterwards Fallopian tube in the female, and becoming atrophied in the male; *i*, terminal bulb of the same, becoming the hydatid of Morgagni (*fig.* 402. *i*) in the male, and the hydatid often seen depending from the mouth of the Fallopian tube in the female (*Fig.* 403. *i* and 368. *ee*); *k*, junction of the duct of Müller with the uro-genital canal; * shows the subsequent horizontal position of this duct when it has become Fallopian tube.

The organ destined for the preparation of the reproductive material, the generative gland, (*fig.* 401. *l*), consists of a longish, clearly defined structure, lying upon the inner side of the Wolffian body, so as to cover a portion of the bulbs of the cæcal pouches. Its white colour serves to distinguish it, at a glance, from the yellowish brown Wolffian body. As yet, no material nor actual distinction of sex can be discovered in any one of these parts; and yet the whole already contains all the elements of the male, as well as of the female, reproductive apparatus, without any true exhibition of bi-sexuality.

The nature of the first impulse towards a division of sex, in one or other direction, is unknown, but the subsequent separation manifests itself with the commencing distinctive development, and correlative retrogression of each several element; for the cardinal organ, the generative gland (*fig.* 401. *l*), may be converted into testis (*fig.* 402. *l*), or ovary (*fig.* 403. *l*), and through the doubly existing excretory duct of this gland, viz. the duct of Müller (*fig.* 401. *h*), for the female, and the excretory duct of the Wolffian body (*fig.* 401, *e*) for the male, the capability of conversion into either sex exists at this time in every individual.

The division of sex begins to be anatomically discoverable by the development of one,

Fig. 402.



Adult testis and epididymis, anterior view. (*After Kobelt.*)

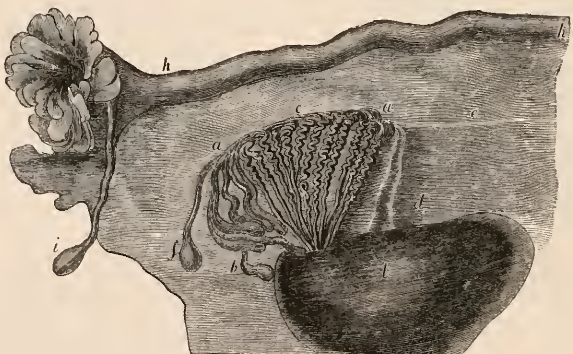
a a, entire series of metamorphosed tubules of the original Wolffian body; *b*, remains of the upper set, converted into the hydatid in the head of the epididymis; *c*, the middle set converted into the coni vasculosi; *d*, the lower set converted into the vasa aberrantia; *e*, excretory duct of the Wolffian body, now the canal of the epididymis and vas deferens; *f*, bulb of the same, now a so-called hydatid; *h*, duct of Müller, not destined to be developed in the male; *i*, terminal bulb of the same, now the hydatid of Morgagni; *g*, hydatiform swellings of the same in the border of the epididymis; *l*, generative gland, now testis.

and the stationary condition or disappearance of the other of these ducts. From this point, therefore, the course which each of these organs takes, is different for either sex. The male Wolffian body never disappears in all its parts, but is converted into the epididymis in such a manner that the middle line of cæcal tubes (*fig.* 401. *c c*) is transformed into the 18—20 coni vasculosi (*fig.* 402. *c*); while their straight and open ends, as vasa efferentia, establish a communication with the rete vasculosum testis. The upper blind pouches (*fig.* 401. *a*, *b*) and the bulb (*f*) of the excretory duct disappear, or become converted into the hydatids (*fig.* 402. *b*, *f*) upon the head of the epididymis, while the inferior pouches (*fig.* 401. *d*) disappear in part, and in part become elongated and tortuous, without forming any connection with the testis. These constitute the hitherto enigmatical vasa aberrantia of Haller (*fig.* 402. *d*).

The excretory duct of the Wolffian body (*fig.* 401. *e*) is converted into the canal of the epididymis, (*fig.* 402. *e*), and ultimately into the vas deferens, and whilst the retrogression and final obliteration of the terminal part of this duct takes place normally in the female, (*fig.* 403. *e*) it constitutes a pathological condition when it occurs in the male. The terminal bulb (*fig.* 401. *i*) of the duct of Müller is converted into the hydatid of Morgagni (*fig.* 402. *i*), whilst its inferior portion (*fig.* 401. *h*) still exists, at a later period in the anterior border of the epididymis (*fig.* 402. *h*).

Tracing the development of the corresponding structures from the same point of departure as in the male, we find that in the female, also, the Wolffian body never disappears entirely, but is employed in the formation of the parovarium. Its middle blind

Fig. 403.



Adult parovarium, ovary, and Fallopian tube. (*After Kobelt.*)

a a, entire series of tubules of the original Wolffian body; *b*, remains of the upper set, which occasionally become distended by collections of fluid, and constitute one form of dropsy of the broad ligament; *c*, middle set of tubules forming the principal part of the parovarium; *d*, lower set atrophied, answering to the vasa aberrantia in the male; *e*, atrophied remains of the excretory duct of the Wolffian body; *f*, terminal bulb of the same, converted here into the hydatid often seen attached to the broad ligament; *h*, the former duct of Müller, now Fallopian tube, with its infundibulum, from which hangs *i*, the terminal bulb, now converted into a pedunculated hydatid; *l*, generative gland, now the ovary.

These three last figures are from Kobelt, whose views they illustrate. The letters refer to corresponding parts in each.

pouches (*fig.* 401. *c c*), are converted into the 18—20 tubules of the parovarium (*fig.* 403. *c*), and these secerning tubes become organically connected with the hilum of the ovary, *l*. They are the homotypes of the male coni vasculosi, and vasa efferentia, but which constitute here vasa adferentia.

The superior blind pouches and the bulb of the excretory duct disappear, or contribute to form the hydatids at the outer border of the parovarium (*fig.* 403. *f b*), which are so commonly mistaken for morbid structures.

The inferior blind pouches (*fig.* 401. *d*) remain and represent the vasa aberrantia of Haller (*fig.* 402. *d*), in the male. Several of them become elongated and intermingled with the vessels of the spermatic plexus (*fig.* 403. *d*).

The excretory duct of the Wolffian body (*fig.* 401. *e*) in the female, undergoes a retrogression in its whole length, and the lower end disappears entirely. (*Fig.* 403. *e*).

The duct of Müller (*fig.* 401, *h*) is converted into the Fallopian tube (*fig.* 403. *h*), and its bulb (*fig.* 401. *i*) becomes the terminal hydatid of the same (*fig.* 403. *i*). This latter structure, of which a very excellent example, as occurring on both sides, is given in *fig.* 368. *e e*, is very constantly present in the adult. Like the so-called hydatid (*fig.* 403. *f* and 408. *g*) at the outer border of the parovarium, it is frequently mistaken for a morbid product, and is often so designated in descriptions of these parts; an error which the improper title of hydatid tends to propagate.

The interruption or deficiency of the Fallopian tube in the female is a malformation, which represents a normal condition in the male.

The parovarium exhibits parallel stages of development and retrogression with its corresponding ovary at different periods of life.

Abnormal Anatomy of the Parovarium. — So little attention has been given to this structure in its natural condition that accurate information regarding its morbid states can hardly be looked for. The so-called hydatids, which are found at the outer border of the parovarium in most adult specimens, and which are constructed out of the superior blind pouches and bulb of the excretory duct of the Wolffian body, have been already just noticed as normal structures. These are found pretty constantly in younger subjects, while the hydatids of later formation in the alæ vespertilionum are formed of the remains of the canals of the retrograde parovarium. Within the walls of these canals is collected occasionally a considerable amount of fluid, and it is probable that this is the origin of those larger accumulations to which the term dropsy of the broad ligament has been applied.

FALLOPIAN TUBE OR OVIDUCT.

Normal Anatomy.

Tubæ uteri vel Fallopianæ; oviducti; vasa spermatica vel ejaculantia, Lat.; *Muttertrompeten*, Germ.; *Trompes utérines, Trompes de Fallope*, Fr.

The Fallopian tube (*fig.* 368. *c c*, and 404. *a b c*) is the excretory duct of the ovary, as its homotype, the vas deferens, is the excretory conduit of the testis. And while in an anatomical point of view the tube is an appendage of the uterus, in a physiological sense it must be regarded as the proper appurtenance of the ovary. But the Fallopian tube differs from the vas deferens, as well as from every other excretory duct in the animal economy, in this important particular, that it is entirely detached from its proper gland, between which and the uterus it serves to establish only a temporary communication.

This separation of the oviduct from the ovary is associated with a higher type of general structure than that which accompanies the blending of these parts. It is first observed in the cartilaginous fishes, and prevails in all classes of the animal kingdom above them; while in the osseous fishes and in the invertebrata possessing distinct ovaries, the oviducts are directly continuous with those bodies.

The Fallopian tube or oviduct is developed equally on both sides of the body in all vertebrate animals, except in the class Aves, where the right tube becomes atrophied at an early period, while the left alone is developed.

In the human subject each ovary is provided with its proper oviduct, which serves to convey the ova from either side to the central organ, the uterus. But the detached position of the oviduct permits so great a range of motion in its free extremity, that, not only can this be applied to every part of the surface of the corresponding ovary, but the tube of one side may occasionally serve as a conduit to the opposite gland, and receive its product. The action of the tube, however, is then imperfect; and, when impregnation obtains, an abnormal form of gestation usually results.

Form and dimensions. — Each oviduct has the form of a conical tube, the base of which is free and directed towards the ovary, while its apex is attached to the corresponding superior angle of the uterus, out of which it appears to arise.

The form of the tube was compared by Fallopius to that of a horn or trumpet, which instrument, when straightened or only slightly curved, it sufficiently resembles. Issuing from the upper angle of the uterus, at the point of junction of the superior and lateral borders, the oviduct commences round and narrow (*fig.* 404. *c*), and proceeds outwardly gradually and regularly widening up to its distal extremity, where it contracts somewhat suddenly just before terminating in a widely expanded funnel-shaped orifice. In the latter half of its course the tube exhibits certain flexuosities, which produce an appearance of contraction at intervals. But that no such contractions really exist is rendered evident by

Fig. 404.

Left Fallopian tube from an adult. (*After Richard.*)

a, pavilion and fimbriæ; *b*, body of the tube; *c*, abdominal orifice; *d*, tubo-ovarian ligament and fringes; *e*, commencement of the tube; *f f*, tubal mesentery; *g*, ovary; *h*, ligament of the ovary; *i*, uterus; *l*, round ligament.

distending the tube with air or water; a process which invariably removes this appearance, and serves to demonstrate the uniform and equable enlargement of the canal.

The length of the tube varies in different subjects, and to a slight extent on the two sides of the same subject. But this difference is not nearly so marked as that often observed between the respective distances of the two ovaries from the uterus. The ordinary range of length of the tube, measured between its extreme points and disregarding the flexuosities, is $3\frac{1}{2}$—$4\frac{1}{2}''$; but the curvature and flexuosities add usually 1—$1\frac{1}{2}''$ to this length.

The breadth of the tube is considerably greater at the distal than at the proximal end. Just at the point of emergence from the uterine border, where the tube is firm and cord-like (*fig.* 404. *e*), its external diameter is $1\frac{1}{2}$—$2'''$. From this point it gradually increases in breadth, and becomes softer, so as to assume the general appearance of an intestine. The mean diameter of the tube is found at about three-fifths of its length (*b*) from the uterine end, where it measures $2\frac{1}{2}'''$; from this point the enlargement is more rapid, until the greatest diameter is attained just before the terminal contraction occurs, and here the transverse measurement is $5'''$.

Situation and connections. — Of the three structures termed appendages which arise in a triangular form from the superior angle of the uterus, the Fallopian tube occupies the apex of the triangle, while, at nearly equal distances from it are inserted the ligament of the ovary, and the round ligament; the former posteriorly, and the latter anteriorly. In the natural position of the parts, the tube, viewed from without, appears to spring from the uterine angle with a slight downward curve (*fig.* 404. *e*), and then inclining horizontally forwards and outwards, it describes an irregular semicircle, whose inner side looks backwards towards the ovary (*g*), which is placed nearly opposite to the centre of its length (*figs.* 368. and 404.). Such at least are the relative situations which these parts exhibit when spread out equidistantly from each other: although it is probable that during life they are more collapsed and lie closer together, — the anterior wall of the tube then being in apposition with the sides and back of the bladder, while its posterior wall corresponds, at its centre, with the ovary, the superior border with the small intestine, and the inferior with the fold of peritoneum by which the tube is attached to the broad ligament. The mouth or abdominal end of the tube is generally directed inwards and backwards, towards the distal extremity of the ovary, in close proximity to which it is preserved by means of the tubo-ovarian ligament (*figs.* 368. *n* and 404. *d*).

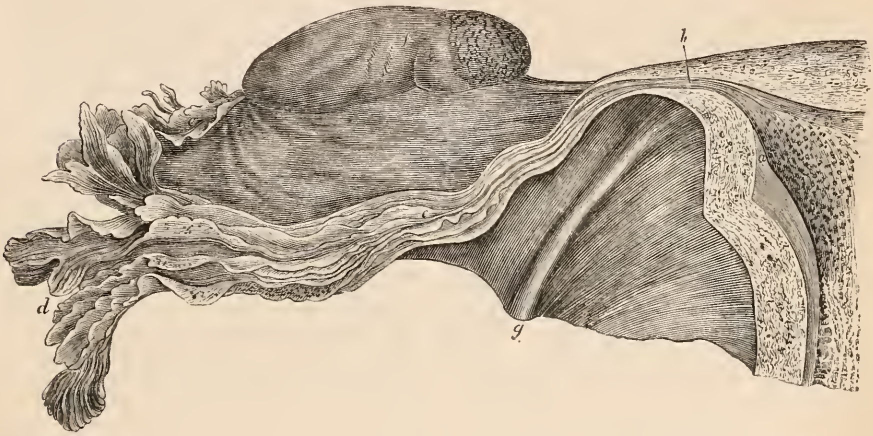
The fold of peritoneum (*fig.* 404. *f*), which connects the tube with the main portion of the broad ligament resembles a mesentery and serves to convey blood-vessels and nerves, as well as to sustain the tube in its place, and to limit its movements. It constitutes that portion of the broad ligament termed the middle wing. The Fallopian tube occupies the entire upper border of this wing, and receives from it a complete peritoneal investment, except along the lower border or line of junction of the two surfaces of membrane composing it, at which line the vessels and nerves enter. Thus the tube resembles an intestine in the mode of its investment, but with this difference, that the peritoneal coat is more loosely applied, especially in young subjects; where the convolutions of the tube are more distinctly marked, and lie free within the sheath, which does not follow their windings (*fig.* 418.).*

The tubal mesentery (*fig.* 404. *f*) is triangular, or somewhat falciform in shape. Its narrow pointed end is directed towards the uterus, where the tube has scarcely any capacity for independent motion; but as the depth of the mesentery increases outwardly greater freedom of movement is permitted. The greatest breadth of the mesentery is found at a distance of two thirds of its length from the uterine extremity, and here it measures $1\frac{1}{2}''$. From this point a slight narrowing occurs, and the membrane terminates in an abrupt margin $1\frac{1}{4}''$ in length, which extends from the lower border of the mouth of the tube to the bulbous extremity of the ovary.

This border, which is thickened by the addition of a layer of mucous membrane derived from the mouth of the Fallopian tube, constitutes the tubo-ovarian ligament (*fig.* 404. *d*).

Separate parts and divisions. — The full extent of the Fallopian tube cannot be ascertained until the entire canal, in its interior, has been laid open. The tube which, externally viewed, appears to spring from the

Fig. 405.



Right Fallopian tube laid open. From an adult who had not borne children. (After Richard.)

a, funnel-shaped canal leading from the uterus to *b*, uterine portion of the tube; *c*, point at which the large plicæ commence; *d*, infundibulum covered by plicæ, continuous with those lining the canal; *e*, tubo-ovarian ligament and fringes; *f*, ovary; *g*, round ligament.

superior angle of the uterus, is thus seen to commence by a small orifice, *ostium uterinum*, upon the inner surface of the uterus. This orifice conducts to a narrow canal (*figs.* 405. *b* and 406.) which, after traversing the walls of the organ, and constituting the *pars uterina*, expands into a gradually widening tube (*fig.* 405. *c*), whose form nearly corresponds with the external configuration of the part. Towards the extremity of this canal, a sudden contraction occurs, constituting the external orifice of the tube, *ostium abdominale* (*fig.* 404. *c*). But this does not form the termination of the oviduct, for the latter immediately widens into the trumpet-like orifice (*infundibulum*), whose margin, split up into numerous fringed processes, (*fimbriæ*), (*fig.* 404. *a a*) give to that part the torn and jagged appearance suggestive of the idea that it has been bitten or torn, as expressed in the name, *morsus diaboli*, applied by ancient writers to this part. Each of these parts exhibit peculiarities of structure, requiring a special description.

Internal, or uterine orifice, ostium uterinum. — This orifice, which ought to be regarded as marking the termination rather than the commencement of the tube, is found at the extremity of a short, funnel-shaped conduit, (*fig.* 405. *a*) which leads from the general cavity of the uterus into the upper and outer angle on either side of that organ. Here, while there is no abrupt line of demarcation to indicate the point of commencement of the canal, the characteristic structure of the uterine mucous membrane gradually ceases. The peculiar arrangement of its capillary vessels and the orifices of the uterine glands,

* For a further account of the reflections of peritoneum, which enclose the uterine appendages see "Ligaments of the Uterus," in this article.

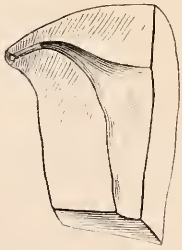
can no longer be discerned, and a slightly plaited condition of the lining membrane of the canal begins to be distinguishable (*fig.* 405. *b*).

At this precise point is found the true uterine orifice of the canal, the diameter of which varies in different subjects, but is rarely of larger size than suffices for the easy passage of a common bristle. The true diameter of the tubal cavity at this point is best exhibited by a transverse section; for when the canal is laid open longitudinally, and its walls are separated as at *b*, in *fig.* 405. this portion of the interior of the tube appears to have a greater diameter than it actually possesses when the parts are closed, and in a natural state. In some subjects, however, and in certain conditions of the tube, the uterine orifice may be sufficiently patulous to admit of the passage of a fine probe.

Uterine portion of the tube, pars uterina. — This, as just stated, is the portion of the oviduct which traverses and is included in the substance of the uterine walls. Its length will vary, in some degree, with the varying thickness of those walls, in different subjects; yet not entirely so, because this canal does not pierce the uterine parietes in a direction perpendicular to their surface, but traverses them in an oblique manner, while the tissues become gradually attenuated around it, in a direction from within outwards (*fig.* 405. *b*).

But the course of the tube through the uterine walls may be still more satisfactorily traced by the aid of a section made down to, but not laying open, the canal. The peculiar white colour of the tube is thus made to contrast strongly with the surrounding darker uterine tissue; and this peculiarity is rendered more striking when a fine injection of the part has been made. The canal of the tube may thus be readily traced from its infundibular-shaped commencement running, in the first half of its course, in a direction obliquely upwards and outwards, and in its remaining half, either horizontally outwards,

Fig. 406.



Entrance of the Fallopian tube into the uterine cavity, dissected down to the mucous membrane, which is left unopened. (*Ad Nat.*)

or more commonly turning rather suddenly downwards, and forming, with its first direction, an angle of 60° (*fig.* 406. and 431.).

Strictly, the Fallopian tube should be deemed to commence at this point; and this should be regarded as the true *ostium uterinum*, while the short infundibular canal leading to it from the uterine cavity should be considered a portion of that cavity, representing, in fact, the cornu of the uterus in mammalia. The peculiar form of this portion of the tube is not without interest, for it appears to me to offer a probable explanation of the occasional detention of the impregnated ovum, in its passage through this division of the oviduct, where its development produces the variety of extra-uterine pregnancy termed by Breschet interstitial.

Canal of the body of the tube. — While the portion of the Fallopian tube already described, as contained within the substance of uterine walls, is rightly termed its uterine or fixed portion, the main part, which is external to them, constitutes the free portion. This also is traversed in its entire length by a canal, the form of which corresponds generally with that of the tube itself. It is occupied by numerous longitudinal folds of the lining membrane (*fig.* 405. *c*), which are so closely placed as to convert the channel of the tube into a series of minute capillary canals. These folds never disappear by distension like the folds and furrows upon many mucous surfaces, such as the œsophagus, bladder, &c.; but they are true plications, like the valvulæ conniventes of the small intestine, as pointed out by M. Richard, who has very accurately described their arrangement.* Each of these is composed of two layers of mucous membrane united together by cellular tissue. Their direction is constantly parallel with the axis of the tube. In the uterine region of the oviduct, they constitute two or three small projecting and rigid crests, forming the little capillary channels, but in proportion as they advance towards the outer part, they become more elevated and numerous, and at 2 or 3 fingers' breadth from the uterus commence the large floating folds which are prolonged as far as the pavilion. These floating plaits are from 4 to 6 in number; they acquire a breadth of 2—3‴, and are themselves covered by an infinite number of little crests, often imbricated the one upon the other, and intercepting between them little capillary canals. On a level with the abdominal opening these large folds cease, the small ones only remaining; but still one of these large folds always extends beyond the orifice.

External orifice, ostium abdominale. — This occupies the bottom of the funnel-shaped expansion or trumpet-like end of the oviduct, and is formed simply by a constriction of the tubal walls at a short distance from the irregularly notched margin in which they terminate. The aperture is fringed in its entire circumference by the plications of the membrane already described (*fig.* 405.). These radiating towards the centre appear nearly to obstruct the entrance of the tube,

* Thèse, p. 35.

which, however, during the middle period of life is usually of sufficient capacity to admit easily of the introduction of a moderate-sized catheter. The constriction which forms this aperture is not occasioned by any thickening nor other alteration of texture in the walls of the tube, so that after the parts have been laid open, it is often difficult to determine the exact seat of the previously existing orifice by any mark except that of a slight diminution in breadth of the walls at this spot.

The Pavilion, or Infundibulum consists of the expanded or trumpet-mouthed portion of the tube which lies between the orifice just described and the fringed margin in which the tube-walls actually terminate. No portion of the Fallopian tube is so variable in form and construction as this, and yet none is of such importance, for upon the peculiar construction of this part depends the special action of the oviduct in grasping the surface of the ovary, and receiving and conveying away the ovum.

The representations which in illustrated works usually accompany the description of this part serve to give but a feeble notion of the beauty of its construction, apparently because the advice of De Graaf, that their structure should be examined under water, has been commonly neglected. But without the support derived from a fluid of greater density than the atmosphere, the extremely delicate plicæ and fringes with which the expanded mouthpiece of the tube is beset, collapse and exhibit nothing more than a general indication or outline of their true form.

When thus examined, the pavilion in young and healthy subjects is observed to be funnel-shaped, and to have arranged upon its inner surface numerous folds and leaflets, which are merely continuations of the larger and smaller plicæ lining the cavity of the tube. These folds, which are irregularly though often very closely set, converge towards the centre of the orifice of the tube, and in some cases appear by their profusion almost to block up the entrance of the canal. The office of these folds is doubtless to receive and entangle the delicate ovum in one of the numerous channels which are formed between the sets of leaflets, and so to conduct it infallibly into the common orifice towards which they all converge.

So great is the variety perceptible in the conformation of this structure in different subjects, that it would be difficult to find any two in which a precisely similar arrangement of parts obtained. Even in the same body there is often a material difference in the pavilion of the two sides. And these varieties are not attributable to mere individual peculiarities of form, but they appear to bear a certain relation to the age of the person in whom they are found*, and consequently to the period of functional activity or otherwise of the structures of which they form an importart part. Thus in young subjects, after the age of puberty, and in those who have borne few children, the pavilion exhibits that richness and profusion of folds and fringes which is represented in *figs*. 404. and 419. while in multiparæ and those advanced in life a greater simplicity of form in this part is commonly observed ; but between these extremes every variety of arrangement may be observed.

In the fœtus, and in very young subjects, the margin of the pavilion is nearly evenly circular. This form is also seen in adults in those rare cases where the prolongation of one of the fimbriæ along the tubo-ovarian

Fig. 407.

a, external surface of the fimbriæ; *b*, line of demarcation between the mucous and serous membranes; *c c*, body of the tube; *d d*, tubo-ovarian ligament, presenting scarcely any trace of the fringes.

ligament does not occur, but commonly the margin is uneven or scolloped, as shown in *fig*. 407.

At this point, the opportunity occurs of examining an arrange ment of parts which is unique in the animal economy, viz., the conjunction of a serous with a mucous membrane. The line of junction of these two

* Richard, Thèse, Anatomie des Trompes de l'Utérus chez la Femme. 1851.

surfaces may here be traced along the margin where the tube wall terminates. Here the peritoneal or outer covering of the tube may be observed to cease suddenly in the form of a distinct boundary line, as in the example represented in *fig.* 407. But occasionally the peritoneal coat is prolonged upon the base of the principal leaflets which crest the end of the canal, and in that case a closer examination is necessary in order to discover the line of union between the mucous and the serous surfaces.

The fimbriæ, laciniæ (λακίς), *or morsus diaboli.* —The structure and composition of these appendages differ in no respect from those of the plicæ or folds of which they are merely continuations. These fimbriæ present many varieties of form, but are generally either petiolate, lanceolate, or simply filiform. Their margins are in some cases coarsely crenate, like those of the tubal plicæ, while in other instances they are so finely indented, as to require the use of a lens for their examination. The greater number of these fimbriæ are attached to the sides or margins of the infundibulum by their narrower extremity only, like leaves thickly clustered on the branches of a tree, while the more obtuse extremity of each leaflet is left free, apparently with the object of increasing the extent of surface of the tube-mouth, which may be applied to the superficies of the ovary. But very commonly one or two fimbriæ are observed to be firmly attached by both ends, while the body extends horizontally in the form of a flattened band among the rest of the fringes, as at *fig.* 408. *d.* The backs of these are always covered by a continuation

Fig. 408.

a, fimbriæ irregularly formed; *c c*, bristle passed through an accessory pavilion; *d*, horizontal band across the mouth of the tube formed by one of the fimbriæ having both ends fixed; *g h*, peduncle ending in fringed processes, probably the terminal portion of the Wolffian duct. (See *fig.* 401. *f*, and explanation.) *i*, body of Fallopian tube; *k*, ovary. The tubo-ovarian ligament and fringes are well developed in this specimen.

of the serous membrane. It is difficult to imagine a use for them unless they are placed there as a safeguard to diminish the risk of a retrograde movement and escape of the ovum after it has entered the tube along one of the furrows formed between the plicæ.

The length of the fimbriæ ranges from $\frac{1}{2}'''$ to $\frac{3}{4}''$. The principal leaflets, being continuations of the 4 — 6 main plicæ of the tube, exceed the rest in size, and these, spreading like rays, form the more salient points of the fringes, while the intermediate spaces are filled up by the smaller appendages.

Intermixed with the latter are often seen minute pedunculated cysts, and especially little white hard grains, the size of millet seeds, first noticed by De Graaf. Similar grains are often observed upon the mesentery of the tube, or attached to the outer surface of the tube itself (*fig.* 404.).

The Tubo-ovarian ligament and fringes. — This so-called ligament (*fig.* 408.) consists of one of the fimbriæ, which is almost constantly prolonged upon the outer margin or base of the triangular mesentery of the tube. Extending in the form of a slight furrow or channel (*fig.* 404. *d* and *fig.* 405. *e*), between the outer extremity of the ovary and the inner or lower border of the tube, it is margined on either side by a row of leaflets, possessing shapes as variable as those which characterise the rest of the lesser fringes. These leaflets, as well as the furrow between them, are backed by a continuation of the peritoneal fold or mesentery, which, after enclosing the tube, here terminates abruptly on a level with its mouth, and thus is produced the appearance of a ligament, whose use is simply to preserve the tubal orifice in contiguity to the ovary; but there is no reason to think that it performs, as the ancient anatomists supposed, the office of a muscle in drawing these parts together.

The length of the tubo-ovarian ligament determines the distance to which the mouth of the tube can be separated from its corresponding ovary. This, in most instances, is sufficient to permit the tubal orifice to be easily applied over any portion of the gland of the same side; so that from whatever part of the surface of the ovary an ovum is discharged, the reception of the latter by the tube is rendered possible by the range of motion which the mouth of the tube enjoys in relation to the ovary. The average length of this ligament, measured from its commencement at the margin of the ovary to the centre of the tubal orifice is $1\frac{1}{2}''$.

Structure of the coats or tunics. — The Fallopian tube is composed of three coats: — viz., 1. an external investment of peritoneum; 2. a proper coat composed of fibrous tissue; and 3. a mucous lining covered by epithelium.

The tube has been already described as running horizontally within two folds of peritoneum, formed by the upper border of the lesser wing, or ala of the broad ligament, which serves also to form its mesentery, and to connect it with adjacent parts. This fold encircles the tube somewhat loosely, and constitutes the peritoneal coat.

Between this covering and the middle or proper fibrous coat of the tube is found a small quantity of fine and rather tough connective tissue, which serves to bind these coats together. This intermediate tissue being more abundant in quantity towards the uterine end, permits a greater freedom of movement of the serous investment of the tube in this region than at the opposite or free extremity, where, in most subjects, the serous and proper coats cannot be separated without much difficulty.

The middle or fibrous coat has been very generally regarded as containing muscular fibres, and as having a contractile power. Santorini described external, longitudinal, and internal circular fibres, and his statement has been reasserted by Meckel, Boivin, Velpeau, and many others. By Kölliker, also, the middle layer of this tube is regarded as a smooth muscular coat, composed of a double layer of fibres. These statements have been called in question by Robin and Richard, who assert that there are in the proper walls of the oviduct only fibres of cellular tissue and fibro-plastic elements, but no muscular fibres of organic life. M. Richard declares that it is impossible to recognise two distinct layers, at least they can be only artificially produced. The number of longitudinal fasciculi appears always to exceed that of the transverse fibres, but these elements are interlaced in every direction, both longitudinally and transversely.

The question is important, for unless we consider, with Haller, that the proper tissue of the tube resembles the cavernous body of the penis and clitoris, and that, as some have supposed, the tube, when filled with blood, is capable of erection, for which conjecture there appears to be no good foundation, it is impossible, in the absence of a contractile fibrous coat, to explain those movements of the oviduct, which must necessarily occur whenever the abdominal orifice is applied to the surface of the ovary — or that peristaltic action of the tube, witnessed by Bischoff in the Guinea-pig, by means of which the ova are carried backwards and forwards within the canal. See p. 611.

With a view of resolving the doubts raised by these conflicting statements, I have microscopically examined the fibrous coat of the oviduct in the human subject at different periods of life, as well as in several genera of mammalia, and especially in Simia, Bos, Cervus, and Delphinus. With regard to these latter examples, I find the evidence of the presence of a smooth muscular layer, constituting the middle coat of the oviduct, more or less decisive in different genera, but the existence of such a coat was most satisfactorily determined in Delphinus phocæna (pregnant). Here not only were the smooth muscular fibres, collected into long bundles, easily distinguished, but they were still more distinctly shown at the broken extremities of the latter, which exhibited the characteristic fusiform terminations of the individual fibre in such a manner as to leave no doubt as to the muscular nature of the tissue forming the principal portion of this coat, which contained besides an abundance of nuclear elements and common fibres of connective tissue.

With regard to the human subject, it appears to me that the assertion that the middle coat of the oviduct contains only fibrous tissue, may have been based upon the examination of specimens taken from females advanced in life; for, applied to such specimens, the statement is generally true, but in younger subjects, and when the proper reagents have been used, I have experienced no difficulty in finding more or less satisfactory evidence of the presence of smooth muscular fibres, provided only that a sufficiently high power, and the mode of illumination suitable to the discrimination of such tissues, were employed.

It must be observed, however, that the condition of this tissue is very variable. In some subjects, the greater portion appears to consist of nuclear elements which here and there are seen intermixed with fusiform fibres of greater or less length. In other instances, the tissue is more distinctly fibrillar, the fibres being collected in bundles consisting of flattened filaments with distinct fusiform terminations intermixed with bundles of white fibrous tissue; while in some, and, I believe, generally in older subjects, the latter form of fibre, as just stated, abounds, and appears to constitute the principal portion of the middle coat of the tube.

The arrangement of the fibres constituting this coat is chiefly in the direction of the axis of the tube. This, indeed, appears to be entirely so at the surface; but deeper towards the central canal, numerous flat bundles crossing the former at right angles are encountered, and these become more abundant still nearer to the mucous membrane, although, so far as I have been able to trace them, they do not constitute so distinct and separate a layer as the outer longitudinal stratum.

The general condition of the lining membrane of the tube, and its peculiar arrangement, having been already described, it is only needful here to explain the composition and texture of this coat. This membrane, although commonly regarded as a mucous membrane, contains neither discoverable glands nor villi. It is composed of a very delicate pink or white soft layer, consisting of undeveloped connective tissue, mixed with numerous fusiform formative cells.

This thin layer is united to the fibrous coat by a small quantity of submucous tissue, which is also found lying between the folds of membrane forming the plicæ, or ridges, and serving to connect together the two layers of which they are composed.

Covering this coat upon its inner surface is a thin layer of long cylindrical epithelial cells of a form peculiar to the Fallopian tube, of which Henle has given a minute account.* These, which are conical or filiform, are furnished with an oval flattened nucleus, and have at their broad, unattached end a distinct row of cilia. These cells may be traced through the entire length of the tube, from the uterus to the free border of the fimbriæ, where they gradually diminish in size, and, at the point of junction with the peritoneum, acquire the flattened form of the cells of pavement epithelium.

Under ordinary circumstances, and when the organs are healthy, the canal of the Fallopian tube contains only a small quantity of slightly viscid mucus. But when death has taken place during a menstrual period, the fluid is found to be replaced by blood which is usually of a dark colour, and uncoagulated. This fluid presents, under the microscope, the characters of ordinary blood, with which numerous epithelial scales, derived from the walls of the containing tube, are intermixed.

Blood vessels and nerves. — M. Richard is, so far as I am aware, the only author who has been at the pains to examine and describe with anything like minuteness the precise arrangement and distribution of the blood-vessels supplying the Fallopian tube. The following is his account, the general accuracy of which I have verified by frequent injections of these vessels.

"There exists always a special artery for the tube. Springing from one of the numerous branches of the uterine artery, near the angle of the uterus, this vessel takes a direction from within outwards, from the commencement of the oviduct, as far as the neighbourhood of the pavilion, describing, like the tube itself, a curve, the concavity of which looks towards the side of the ovary. The artery, which is lodged in the substance of the mesentery of the tube, takes a slightly sinuous course, parallel with the oviduct, and at the distance of one or two finger breadths from it. Situated in the middle of the filamentous cellular tissue, which exists between the two layers of peritoneum, it passes constantly behind the organ of Rosenmüller; so constantly, that keeping this relation in mind, one could immediately, if the neighbouring organs were removed, distinguish the anterior from the posterior face of the lesser wing of the broad ligament. The artery is accompanied by the two veins of the tube, and surrounded by very delicate nervous filaments.

"The branches furnished by this artery are lateral as well as terminal. The lateral branches are generally three in number. The first enters the inner third of the body of the tube, at a distance of three or four centimetres from the uterus; the second supplies the middle, and the third the outermost extremity of the oviduct. These three branches before arriving at the tube bifurcate, the twigs resulting from which bifurcations are directed the one to the right and the other to the left to inosculate with each other. From this results a series of arches furnishing branches to every portion of the body of the tube. The innermost bifurcating branch anastomoses with a branch derived from the proper artery of the uterus, so that a well-marked analogy between the distribution of the tubal artery and that of the mesentery is here observable. The terminal division is distributed to the pavilion. It separates into a greater or less number of tortuous branches, each of which goes to supply a fringe of the pavilion; the tubo-ovarian fringes also receive each a twig of the tubal artery. Sometimes, however, a small branch of the utero-ovarian artery, from which it is detached opposite to the external extremity of the ovary, establishes one of the anastomoses between the uterine and the utero-ovarian vessel. From the concavity of the tubal artery very small branches proceed to the organ of Rosenmüller, and to the neighbouring cellular tissue."

But no adequate notion can be formed of the extreme richness of supply of vessels to this and the neighbouring organs until, after a successful minute injection, the parts have been dried and preserved in balsam. Numerous vessels which the opacity of the parts had previously concealed are then brought into view. They are seen running parallel with the surface of the tube, and mostly converging towards the fimbriæ, upon and in the substance of which they lie as thickly as the pile of velvet, previously to their dispersion into their final capillary terminations. It was probably this exuberance of vascular supply that led some former observers to imagine that the tube possessed an erectile tissue, a structure of which the most minute injections do not suffice to exhibit a trace.

The veins, which follow the same course

* Encyclop. Anat. Gen. t. i.

as the arteries of the tube, frequently anastomose with one another by transverse branches, which serve to connect together the two principal trunks. These gather the returning blood and carry it into the plexus of uterine veins placed along the sides of the uterus.

The lymphatics of the tube have the same common source as those supplying the rest of the internal generative organ.

The nerves, which are very slender, follow the course of the arteries. They are derived, according to Dr. Snow Beck, from the hypogastric and aortic plexuses.

FUNCTIONS OF THE FALLOPIAN TUBE.

It has long been determined, with as much precision as the nature of the subject apparently admits, that the Fallopian tube performs the double office of receiving the ova from the ovary, and conveying them into the uterus, and of receiving the spermatic fluid from the uterus and conveying it in the direction of the ovary: the tube itself being, if not constantly, at least generally, the seat of impregnation; or, in other words, the precise spot in which the material contact of the male and female generative elements takes place.

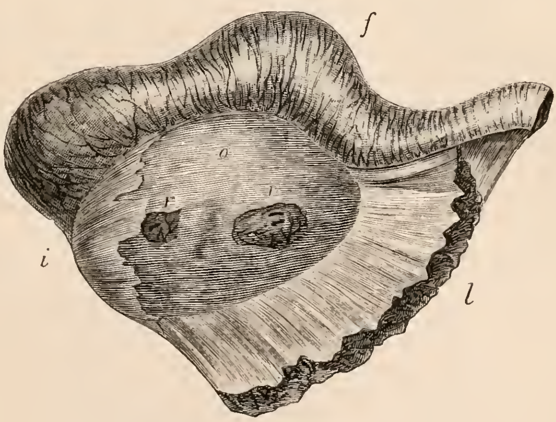
These conclusions regarding the offices of the oviduct, are deducible from various observations and experiments, both of a positive and negative kind, made upon mammalian animals, and the close correspondence which has been observed between these and similar observations, so far as they can be made upon the human female, leads also to the conclusion that there is little or no material difference between the mode in which these offices are performed in man and in the mammalia generally.

With regard to the demonstrative evidence furnished by experiments and observations upon animals, as well as by observations upon the human subject, relative to the precise offices of the oviduct in the conveyance of the ova from the ovary, the following points may be considered as established.

The infundibular orifice of the Fallopian tube, together with the fimbriæ by which its margin is fringed, at the time of the discharge of ova, becomes expanded over a certain portion of the ovary, the extent of the surface covered varying according to the form and proportions of the infundibulum relatively to the size of the ovary.

In some mammalia, the cat for example, the infundibulum is sufficiently large to encompass the entire ovary, so that an ovum escaping from any portion of its surface would fall within the receptacle thus provided for it, and be conveyed to the orifice of the tube, and thence into its canal. But in many animals of this class, as well as in man, the size of the infundibulum does not suffice to cover more than a portion of the ovary at any one time, half or a third it may be of the entire surface of the gland; so that in all these cases a selection must be made of the exact spot from which the discharge of an ovum is about to take place, or else the ovum would be lost, by falling into the cavity of the abdomen. That this occasionally happens is rendered evident by those cases in which the infundibulum is glued as it were to a portion of the ovary by morbid adhesion. But while the extremity of the oviduct is thus immoveably fixed, the process of ovulation still goes on from all parts of the ovarian surface indifferently, so that those ova only which might happen to be discharged from the particular spot to which the tube is affixed, would by any possibility enter its

Fig. 409.



Ovary of a woman who died during menstruation.

The coats of the ovary are attenuated in two places. Three apertures, *r r*, two being in juxtaposition, lead to as many Graafian vesicles from which ova have been recently discharged, escaping apparently into the cavity of the abdomen. The infundibulum is glued to the extremity of the ovary by morbid adhesion. The tube is distended by accumulated fluid; *o*, ovary; *i*, infundibulum; *f*, Fallopian tube; *l*, broad ligament. (*Ad Nat.*)

mouth, and all the rest would be lost. I have already adverted at p. 560. to such an example, and of this case a drawing is here subjoined. In this instance, three ripe Graafian vesicles had burst on one side of the same ovary, and had discharged their ova, while the mouth of the corresponding oviduct was inseparably united by morbid adhesions to the outer extremity of the gland, and was thus effectually prevented from receiving any ova except such as might be discharged from the spot to which the tube was attached.

By what power the mouth of the tube is directed to the particular portion of the ovary from which an ovum is about to be discharged remains entirely unknown, as, indeed, does also, to a certain extent, the precise nature of the mechanism effecting this movement. The part termed the tubo-ovarian ligament (*fig.* 404. *d)* will at all times serve to keep the infundibulum in contiguity with the ovary, but by what agency the orifice of the tube is drawn towards, and its fimbriæ become expanded upon, the ovary, cannot be very satisfactorily explained. These movements can only be referred to the contraction of the low form of fibre of which this part has been shown to be chiefly composed ; and although it is certain that in a great many of the invertebrata, a similar form of contractile fibre constitutes the sole agency by which their active and sometimes very rapid movements are effected, yet this is not commonly found to be associated with any considerable degree of movement in the higher animals.

The temporary adhesion of the infundibulum to the surface of the ovary when an ovum is about to be discharged, appears to be effected by the interposition of a slimy mucus, which possesses sufficient tenacity to require the employment of some slight force in drawing the parts asunder, and which is furnished, probably, by those numerous minute folds or plicæ so plentifully covering this portion of the tube.

It was formerly supposed that this apposition of the mouth of the tube to the ovary occurred only under the influence of the sexual orgasm ; an inference which was natural so long as the belief remained general that the ova were discharged from the ovary only as a consequence of sexual congress. But this circumstance admits of a modified explanation, now that the discharge of the ovum in mammalia is known to occur during the "heat," or that period in which alone the coitus is permitted by the female. The apposition of the Fallopian tube to the ovary at such times is to be regarded as a movement providing for the safe passage of the ova to the uterus, and, in regard to time, as preceding the act of impregnation, although it might endure until after a fertilising coitus had taken place, and so the parts would occasionally be found in such a state of apposition in an animal killed immediately or shortly after that event ; thus appearing to warrant the conclusion that the venereal orgasm had been the cause of this movement. The mode in which the ovum is expelled from the ovary has been already described at p. 560. In the form there represented, the ovum is received into, and is conducted along, the Fallopian tube ; and, on account of the interest which attaches to the earlier developmental changes occurring here, it has, perhaps, been more frequently examined in this situation than in any other portion of the generative track. Barry's tables include the particulars of ninety-three ovula, found in various parts of the tube in the rabbit, between 10 and 70 hours post coitum. Bischoff's observations were made upon 60 or 70 ovula within the tube in the same animal, as well as upon many more in other mammalia. Several instances of the same kind have been already quoted, two of these being in the human subject; and almost every anatomical collection contains examples of the human ovum abnormally arrested and developed in the tube.

In what way the ovum, after its reception by the mouth of the tube, is conveyed along that canal into the uterus, is explained by the peculiar construction of this part. The tube being lined longitudinally by slender folds which divide it into numerous capillary canals, and having every part of its inner surface covered by cilia, vibrating, according to Henle, in a direction towards the uterus, appears admirably adapted for the conveyance of the minute ovum downwards from the place of its formation to its seat of normal development. The peculiar form of the oviduct, which is more or less funnel-shaped, especially in the human subject, further conduces to this direction of the ovum downwards, while, in many instances, its course appears to be aided by that peristaltic action of the walls of the tube which many observers have noticed, and of which a further account will be presently given.

The period of time occupied by the descent of the ovum through the tube does not usually exceed a very few days. This, however, appears to be a variable feature in different mammalia, and regarding which, even in those animals admitting of the readiest observation, it appears very difficult to arrive at definite conclusions, chiefly on account of the uncertainty belonging to the determination of the precise moment at which the ovum quits the ovary.

In the bitch the ovum, after quitting the ovary, is supposed to remain in the tube susceptible of impregnation during 6 or 8 days; and its passage is probably quite completed in 10 days. In the guinea-pig the ovum makes its passage in a much shorter time, as it usually enters the uterus at the end of the third day. In the rabbit the time is nearly the same. The ovum, surrounded by a thick layer of albumen, passes from the oviduct into the uterus at the end of the third or beginning of the fourth day. While in the roe, although the time occupied is probably longer, yet, at the most, in a few days, the ovum, unaltered in size, as in other cases where it receives no albumen in the tube, reaches the uterus, and there, if impregnation has taken place, it remains four and a half months without undergoing any positive change. In man little is known accurately respecting the time occupied by the passage of the ovum through the tube. Only two instances have been recorded in which the human ovum has been actually seen in the tube (see p. 567.), with the exception of abnormal cases.

The attempt to determine this point in the human subject has generally proceeded upon a comparison of the condition of early ova found in the uterus, or prematurely expelled from it, with the last known date of intercourse or of menstruation; but neither of these modes of calculation can afford any certain information: for it is obvious that the first can give no more than the date of insemination (as, for example, when a single intercourse has occurred), but will throw no light upon the question of the time which may have elapsed since the ovum quitted the ovary, and how long it may have remained unimpregnated in the tube; while the second mode is rendered equally uncertain for want of more precise knowledge than we at present possess of the actual relation in point of time between menstruation and ovulation. See p. 669.

The analogies which other mammalia furnish justify, to a certain extent, the supposition, that the time occupied by the passage of the ovum through the tube in man is not materially different. But the circumstance that, in man, the periods of capacity for impregnation are not restricted to definite occasions, to the same extent that they are in brutes, greatly diminishes the value of any calculations which might be based upon these analogies.

We may next examine the evidence by which it may be shown that the Fallopian tube serves, on the other hand, as a conduit for the spermatic fluid towards the ovary. That it performs this office, in addition to that of conveying the ova downwards into the uterus, is abundantly proved by the direct observations of Prevost and Dumas, Bischoff, Barry, Wagner, and many others; whose experiments serve to show, also, to what extent the spermatozoa are capable of penetrating within the tube, and of retaining their power of motion there.

Bischoff, after repeatedly finding spermatozoa in active movement in the vagina, and particularly in the Fallopian tube of the bitch, though in this latter situation the movements had ceased, was so fortunate as to trace them in an animal that had been lined on two successive days, and was killed half an hour after the last coitus, not only in the uterus, but also in active motion through the whole length of the tubes, and between the fimbriæ, and finally in the sac or capsule which the peritoneum forms around the ovary, and even upon the ovary itself. Wagner also found in a bitch, killed forty-eight hours after coitus, spermatozoa motionless in the vagina but active in the uterus, in whose cornua, as well as in the Fallopian tubes, their number and activity conspicuously increased as far as the abdominal extremity, where they completely filled every fold of membrane, and were seen moving among the fimbriæ, but none were found in the capsule or pouch that surrounds the ovary. By Barry the same fact of the possibility of the spermatozoa penetrating to the utmost extremity of the tube, and even as far as the surface of the ovary, has been demonstrated. Of the latter he gives two instances; but that the seminal fluid does not commonly penetrate so far as the ovary may be inferred from the statements of Prevost and Dumas, who could never find them in this situation, and of Barry, who, acknowledging the accuracy of those observers, says himself, that in seventeen out of nineteen instances in the rabbit, he was unable to detect the spermatic fluid upon the ovary, and in one of the two cases in which he had observed it there, the only evidence of the fact was the presence of a single spermatozoon.

By no observer, so far as I am aware, have spermatozoa ever been detected within the ovary of any mammal.

The rapidity with which the spermatic fluid is capable of reaching and entering the tube is sometimes very considerable. Bischoff has observed spermatozoa within the oviduct of the Guinea-pig immediately after the coitus; in one instance, indeed, he traced them as far as the middle of the tube, in little more than three quarters of an hour after that event, though it had been commonly supposed that a period of nine or ten hours was requisite for the penetration of spermatozoa to the extremity of the tube.

The power by which the semen reaches the oviduct is partly the act of ejaculation, which may suffice to carry it to the end of the uterus, partly the peristaltic action of the uterus and tubes, in those animals in which these parts have flexible walls; partly, also, the movements of the spermatozoa themselves. But the cilia lining the tubes can in no way contribute to this effect, since their action would create a current in the contrary direction to the ascent of the fluid.

Thus it has been shown that the Fallopian tube, or oviduct, performs the double office of conveying the ova from the ovary towards the uterus, and of serving as a conduit for the passage of the spermatic fluid from the uterus towards the ovary; and the conclusion is almost inevitable, that, by these combined operations, the encounter of the generative elements will most probably take place at some point within the tubal canal. It may, however, be objected, that since the spermatic fluid has been known occasionally to reach as far as the ovary, impregnation may occur there; or, on the other hand, that inasmuch as this fluid must necessarily, in part at least, fill the uterus before it can occupy the oviduct, the ovum may not become impregnated until after it has reached the principal cavity of the generative track.

In order, therefore, to determine as nearly as possible the precise limits of the functions of the oviducts, it will be necessary to examine more particularly the evidence, which serves to show, that while the ovary is the part in which the ovum is formed, and the uterus that in which it is developed; the Fallopian tube, besides being the conductor of the ovum from the formative to the recipient organ, is also the seat of the second most important step in the process of generation, namely, its fertilisation.

Here human physiology is so much at fault that it again becomes necessary to resort to the evidence furnished by experiments, and observations made upon the mammalia generally.

Now, one of the most remarkable circumstances relating to the generative process in the mammalia is, that the periods of separation of the ova from the ovary, and of their passage down the Fallopian tube, are coincident with the œstrus. Bischoff, indeed, has ascertained, in the bitch, that by the time the ovum has reached the uterus, or even the lower end of the oviduct, the period of heat, or desire for sexual congress, has passed away, and consequently the opportunity for impregnation is lost. In the Guinea-pig also it appears certain that the opportunity for impregnation is already gone by the time the ovum has quitted the tube, and has reached the uterus; for the œstrus is then long passed, the coitus has long ceased to be permitted, and even the vulva is at this time again contracted. And although doubtless these conditions vary in different genera, yet a variety of circumstances, of which a more particular account will be presently given, renders it probable that the rule is general among the mammalia, that insemination shall occur coincidently with the passage of the ovum down the Fallopian tube.

Next, it may be shown, by the experiments of Cruikshank, Haighton, Blundell, and Bischoff, which consisted in deligation or excision of portions of the tube, that whenever the obliteration of the canal was complete, and had been effected prior to the act of copulation, fertilisation of the ovum was rendered impossible.

These experiments were most satisfactory when performed on one side only of the generative organs, so as to leave free play for the natural functions of the other; and thus the negative results obtained on the one half of the body being set off against the positive ones of the other, served to enhance the value of both. By such experiments it may be shown that mechanical obstruction of the tube, while interfering in no respect with the spontaneous separation of the ovum from the ovary, or its reception by the mouth of the tube, and descent as far as the seat of obstruction (provided indeed that care is taken in the experiment not to destroy the vascular supply of the parts), prevents the completion of the reproductive act, and stops it at this stage, by impeding the access of the spermatic fluid to the ovum.

But the results of such experiments will necessarily vary according to the time and place of application of the ligature. Thus while division or deligation of the tube before, or even very shortly after, intercourse prevents impregnation of the ova, yet, according to Haighton, the same experiment performed sixty hours after coitus had no effect whatever in impeding the development of the embryo, for in that time the encounter of the generative elements would have already taken place.

But although these experiments may be infinitely varied, they cannot afford such satisfactory information as may be derived from the actual examination of the contents of the tube where natural impregnation has been allowed to obtain, especially when these examinations have been conducted with the aid of the microscope. In this way may be obtained an amount of collective evidence that leaves little to be desired for the purpose of fully elucidating the history of the ovum during that brief but important period which intervenes between its quitting the ovary and its entrance into the uterus. But since an account of the development of the ovum does not come within the scope of this article, only so much of the subject will be given here as will be requisite to continue the argument for the purpose of showing what is the precise part which the Fallopian tube takes in the process of impregnation.

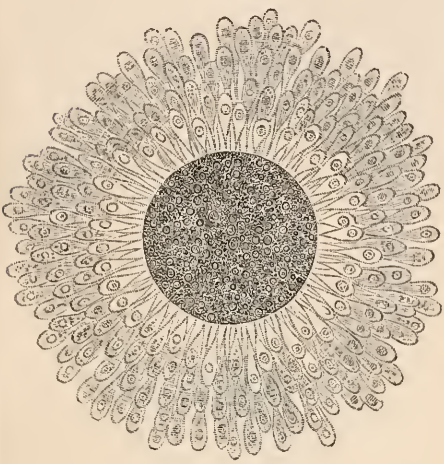
There can be no question that the mammalian ovum, after an efficient coitus, enters the uterus in a condition differing in many important particulars from that in which it ordinarily quits the ovary. And although a certain amount of variation is perceptible in regard to the actual changes experienced by the ovum in different species, during its passage through the tube, yet so constantly are the main features preserved, that the observations made upon any one species will generally serve as a type of the rest, and certainly the aggregate of these observations, agreeing closely as they do with one another, render the conclusion in the highest degree probable, that changes not very different from these occur also in the ovum in man.

Barry asserts that "there is no condition of the ovum, uniform in all respects, which can be pointed out as the particular state in which it is discharged from the ovary." Nevertheless the ripe ovum which is about to be expelled, or one which has been just discharged, presents certain well-marked characteristics, of which the following are the most important.

The ovum is closely invested by a layer of nucleated cells. These form a portion of the granular membrane or lining of the Graafian follicle in which it is imbedded, and when the ovum is discharged from the follicle, as described at p. 560., a portion of these granules is carried with it into the mouth of the Fallopian tube.

In ova which are not quite ripe, these nucleated cells are round, but during the œstrus, in the riper ova, the cells become elongated and fusiform, having their pointed ends attached to the zona pellucida or bounding membrane of the ovum. They present a glassy swollen aspect, by which the fully ripe

Fig. 410.



Ripe ovum from the ovary. Guinea-pig. (After Bischoff.)

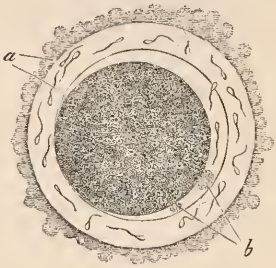
ova acquire an appearance of being surrounded by rays. This change occurs in most mammalia, as the dog, rabbit, sheep, rat, roe, and kangaroo. It is characteristic of the mature ova, and may be regarded as a certain sign of their ripeness.

Corresponding with this external alteration in the appearance of the ovum, are certain internal changes, of which the chief is the disappearance of the germinal vesicle. This indeed seems to be an almost constant phenomenon throughout the mammalia, though, as to the precise mode, or even time, of disappearance of this important constituent of the ovum, observers are by no means agreed. By Barry it was considered, after close observation, that the vesicle was not dissolved nor ruptured, as many now suppose, but that it became lost to observation by retiring to the centre of the ovum, where it was changed in character by an internal process of cell development.

These changes, external and internal, are the precursors of impregnation, and characterise the ovum shortly prior to and at the period of its quitting the ovary.

Arrived within the Fallopian tube, the first alteration which the ovum experiences is the stripping off of the ray-like appendage of nucleated cells with which it quitted the ovary. This change results apparently from a bursting and diffluence of these cells, now no longer capable of serving any useful purpose; for the conjecture that they might furnish materials for the construction of the chorion has not been supported by any direct observations. On the contrary, numerous observations of Bischoff show that this process of freeing the ovum from its surrounding layer of cells, takes place very soon after its entrance within the tube, and generally in the upper third.

Fig. 411.



The ovum on first arriving in the Fallopian tube. The ray-like appendages are nearly stripped off. (After Bischoff.)

a, zona pellucida; *b*, granular bodies between the zona pellucida and yelk. Rabbit.

And now, if the coitus does not obtain, and no contact of the generative elements occurs, the ovum perishes; observations at least relative to its further fate are wanting. But should the ovum have become fertilised, then a noticeable series of changes takes place, of which the following are the most important.

The zona pellucida, or transparent bounding membrane of the ovum, having been freed of its external granular investment, the entire ovum presents the condition represented in figure 412. Deprived now of all encumbrance, the surface of the ovum is in a condition eminently favourable for the passage through it of the spermatozoa, which penetrate readily that soft outer coat, and thus gain admission to the yelk.

The fact of the penetration of the outer coat of the ovum by the spermatozoa, which has been so often asserted and denied, may now, after much controversy, be considered as established. In the mammalian ovum, this passage may take place apparently through any portion of the outer coat, just as it does in the ova of amphibia, and not through a special pore or microphyle, such as exists in the ova of osseous fishes.

Following this act of penetration occurs a change which apparently affords the first distinct evidence that the power of the spermatozoa has been efficiently exerted upon the ovum. The yelk, which had previously completely filled the zona, is observed to have become contracted, so that an interspace is left between it and the zona, termed by Newport, who has carefully watched its formation in the ova of amphibia, the "respiratory chamber." Such a retiring of the yelk, so as to leave an interspace between the latter and the zona pellucida, which interspace is filled by a transparent fluid, has been noticed in many mammalia, as the Guinea-pig, rabbit, &c.

Fig. 412.

The ovum a little more advanced in the tube. (After Bischoff.)

The surface is perfectly smooth. Spermatozoa have penetrated the zona pellucida. The respiratory chamber is formed between the latter and the yelk. The rotation of the yelk has commenced, as indicated by the arrows. The granular bodies appear preparatory to the segmentation of the yelk. Several of these stages are seen commencing in the preceding figure. Rabbit.

This change is preliminary to another occurrence, which has been observed in the ova of many animals, both vertebrate and invertebrate, viz. the rotation of the yelk within the interspace just described; — a rotation which is effected by the aid of cilia clothing the surface of the yelk.

About this time may be observed one, or perhaps two, small granular bodies, whose formation has given rise to many and varied speculations regarding their signification and use. They occupy a portion of the space between the yelk and zona pellucida, and appear to be common to the mammalian ovum and that of other classes. The most probable supposition regarding their use connects them with the division or cleavage of the yelk which follows their appearance.

Whatever doubts may be entertained as to the dependence of the phenomena already described upon a preceding act of impregnation, all question is set at rest at this point, by the direct experiments of Newport, who

Fig. 413.

The ovum still more advanced in the tube. (After Bischoff.)

The first stage in the segmentation of the yelk has taken place. Rabbit.

ascertained beyond doubt, that segmentation of the yelk is the result of impregnation alone, and that it never takes place in the unimpregnated ovum.

This segmentation of the yelk consists in a spontaneous cleavage of that body, at first into two, and then into four, equal parts; the process of division continuing in geometric progression until the whole is broken up into a mass of finely nucleated particles, between which the original sperm-force is probably equally divided.

Segmentation of the yelk of the mammalian ovum has never been observed in its commencing stages anywhere but in the tube. The extent to which it proceeds before the ovum quits the oviduct to enter the uterus appears to vary in different species. Bischoff never saw more than four yelk-divisions in the ovum of the Guinea-pig by the time that

Fig. 414.

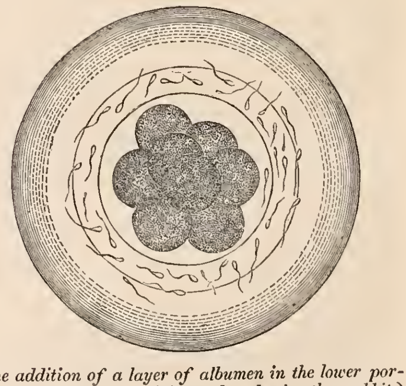
The ovum from the lower or uterine end of the Fallopian tube. (After Bischoff.)

The yelk exhibits four divisions. Rabbit.

it had reached the lower portion of the tube; and it is probable that a further division into eight parts occurs in the extreme end of the duct, since, in the next condition of the ova found in the uterus, the yelk exhibited 12—16 divisions.

The only remaining change in the condition of the ovum during its residence in the ovi-

Fig. 415.



The addition of a layer of albumen in the lower portion of the tube—(observed only in the rabbit.) (After Bischoff.)

The yelk exhibits eight divisions.

duct, which it is necessary here to notice, is the addition, sometimes, of a thick layer of albumen around the zona pellucida, which is formed upon it in the middle and lower portions of the tube. But this is certainly not a constant, and apparently not even a common occurrence. It occurs in the rabbit, but not in the bitch, Guinea-pig, or roe.

These are the principal and more obvious changes which the ovum experiences in its passage down the Fallopian tube until it enters the uterus. So regular is the order with which they succeed each other that particular portions of the tube may be assigned as the seat of each occurrence. Thus the first, or upper third of the oviduct is appropriated to the reception of the ovum, which, soon after quitting the ovary, is here deprived of its adventitious covering of nucleated cells, and is thus prepared for the full operation of the spermatozoa, whose active movements in this part of the tube have been frequently noticed. Here also spermatozoa have been frequently seen upon, and even within, the ova; and here the first changes characteristic of the commencing operations of the sperm force, such as the formation of the respiratory chamber, and rotation of the yelk, may be noticed. In the middle of the tube the ova commonly exhibit still more decided evidences of impregnation. The cleavage of the yelk has already commenced, and one or more granular bodies occupy the space between it and the zona. The ova found in the lower third, except those which may be destined to perish, always show unmistakable signs of impregnation, of which the segmentation of the yelk, now advanced to the production of 12—16 divisions, is the most expressive.

If the views of Bischoff be correct, it is in the upper third, or at farthest in the middle of the tube, that impregnation must occur, unless indeed it takes place at the ovary. For in the lower end of the tube the more definite developmental changes of the ovum occur, or otherwise the ovum perishes. In the dog and Guinea-pig, by the time the ovum has reached this spot, the œstrus is past, and the animal will no longer permit the coitus.*

Connected apparently with some of the foregoing steps in the process of generation, though it does not appear precisely with which, is a phenomenon described by Bischoff as occurring in the Guinea-pig. Several times Bischoff had the good fortune to observe with a lens, and also under the microscope, a peristaltic action in the walls of the oviduct, by which the contained ova, visible through them, were moved backwards and forwards. The ova appeared to be surrounded by a transparent fluid, in which they floated.

Now, such an observation is interesting, when viewed in connexion with two circumstances, specially observed and proved by Newport, namely, that in the artificial impregnation of the ova of amphibia, although the process of impregnation is *commenced* at the instant of contact of the spermatozoa with the ova, yet a certain duration of contact is essential to its *completion*. And further, that although an exceedingly minute quantity of spermatozoa suffices to impregnate the ovum, yet impregnation takes place more tardily when the number is extremely limited than when the number is in full abundance; while when the quantity is reduced below a certain amount, or the duration of contact is limited, then the phenomenon is incomplete, and partial impregnation, evidenced by imperfect segmentation of the yelk, and arrest of the further stages of development, is the inevitable result.

Since, then, it cannot be supposed that a less perfect or complete contact of the ova with the spermatozoa is needful to their impregnation in the higher than in the lower vertebrata, there seems to be good ground for conjecturing that this peculiar peristaltic movement in the walls of the Fallopian tube, which has been noticed also by other observers, may have for one of its objects the more perfect commingling of the two generative elements, the spermatozoa and the ova, which, proceeding as they do in opposite directions, and encountering each other in some portion of the canal, would thus be carried backwards and forwards, and thus a certain permanence of contact, such as Newport has shown to be necessary in the amphibia, would be insured to them. And this supposition may be further strengthened by the reflection that while an onward movement in either direction would serve for the conveyance of each element singly along the tube, a backward and forward motion alternating could only retard either or both processes, and that there could be only one apparent advantage in such retardation, namely, the retention of both elements for a longer or shorter time in permanence of contact.

To sum up the offices of the Fallopian tube, the following may be said to have been with certainty ascertained to belong to that division of the generative organs: To receive the spermatic fluid from the uterus and convey it upwards through the entire canal, and as far sometimes as the ovary; To receive contrariwise the unimpregnated ova, as they are discharged from the ovary, by means of its expanded open mouth, which in these cases, where the entire ovary cannot be grasped, is guided, by a process hitherto unexplained, to select and apply itself to that

* Pouchet (L'Ovulation Spontanée) places the seat of impregnation lower down in the oviduct. He asserts that it is only about the middle of the tube, or more particularly in its lower portion, and even in the cavity of the uterus itself, that the material contact of the ova with the spermatozoa can occur. And he regards the passage of the semen as far as the extremity of the tube, and its arrival at the ovary, as an "excessively rare anomaly." But these statements are based upon examinations directed only to the detection of the presence of spermatozoa in the oviduct, and are not connected with microscopic observations of those developmental changes in the ovum, which are indisputably the results of impregnation, and of which an account has been given in the text.

particular spot from which the ripe ovum is about to be expelled; to convey the ovum in a direction opposite to the course of the fertilising fluid, so as to ensure the meeting and commingling of the generative elements, an event to which the limited calibre joined to the peristaltic action of the oviduct probably in a great degree contributes; to afford protection to the ovum during that brief sojourn in which the first effects of fertilisation are manifested upon its constituent parts; to aid probably in certain changes which are operated upon the surface of the ovum, consisting first, in all cases apparently, in a stripping off of the adventitious covering with which the ovum is invested on entering the tube, and secondly, in some instances, in the addition of certain materials which increase slightly the bulk of the ovum; and lastly, in transmitting onwards the ovum, so altered and prepared for more complete development, to the cavity of the uterus, or in conveying away those which, for want of impregnation, are destined to perish.

In reference to these conclusions regarding the offices of the Fallopian tube, which the present state of physiology appears to warrant, the question here naturally arises, how far they are applicable to the female of man, or to what extent her case may be viewed as exceptional on account of certain differences in her organisation and habitudes.

One of the most observable of these differences is the absence of that marked distinction of periods alternating with each other, such as are shown in a greater or less degree in the females of most mammalia in regard to the activity of the sexual functions.

That these alternating periods of desire and aversion to the coitus are strictly significant of corresponding temporary states of physical capacity and incapacity for conception, is placed beyond doubt, by the results of examination of the internal organs and their contents at these respective periods.

In those animals in which the œstrus returns at short intervals, the male generally remains potent at all times. The temporary incapacity is on the side of the female, and occurs in the *intervals* between the successive acts of ripening and discharge of the ova from the ovary, together with their passage down the tube. It has been shown that during these events only will she receive the male, and therefore, on that account also, is conception then only possible.

This circumstance is rendered more striking in animals in whom this interval is longest, as in the roe-deer, where the œstrus returns only once annually, and in whom the capacity for procreation is limited to a few weeks, for the reason stated by Bischoff, that then the ovary contains ripe ova and the testes ripe semen, and at no other time.

But in the human female, whatever views may be entertained regarding the connexion of a separate act of ovulation with each menstrual period, it is certain that here a marked œstrus is wanting, and that although the capacity for impregnation is apparently greatest about the times of menstruation, yet, notwithstanding the assertions of those who maintain that there is a perpetual recurrence of temporary incapacity for procreation, there is no period at which the healthy human female can be shown to be positively incapable of conception during any part of menstrual life.

It may, however, be asked whether the occasional occurrence of impregnation during an intermenstrual period, at a date more distant than usual from the last menstrual act can be explained consistently with a strict interpretation of the law that menstruation and ovulation are contemporaneous acts.

This appears to be reconcilable with the circumstance that although these acts, so far as observation has yet gone, are very frequently and perhaps usually coincident, yet exceptionally an ovum may be emitted during an intermenstrual period, the *ripening* and not the time or the act of emission of the ovum being probably the essential feature, or that the ovum, supposing it to have been emitted from the ovary at the time of menstruation, may possibly remain in the tube susceptible of impregnation longer in the human female than in the mammalia generally, or may even be impregnated after reaching the uterus. *

That the Fallopian tube in the human subject is, occasionally at least, the seat of impregnation, is demonstrated by the occurrence of the tubal form of extra-uterine gestation; while the numerous examples already quoted of other mammalia render it highly probable, by analogical reasoning, that this is the *normal* seat of that function in man.

That the first encounter of the generative elements may also take place either in the uterus or upon or even within the ovary, is plainly possible. That it occurs sometimes at or near the ovary is evidenced by the varieties of extra-uterine gestation termed ovarian and ovario-tubal. It is even possible that, in some of these, insemination may have been so coincident with the spontaneous opening of the Graafian follicle, that the spermatozoa, penetrating further than usual, may have reached the ovary at that precise moment when a passage had been prepared for the ovum, and some may have actually passed into the follicle and have impregnated the ovum there. No argument certainly can be opposed to this on the ground of physical impossibility †; while, on the other hand, it is also conceivable that impregnation may be delayed until after the ovum has entered the uterus, as in the case just suggested of a fertilising coitus occurring later than usual after the menstrual period; but I am not aware of any good anatomical or physiological reason for regarding the uterus, as by pre-

* These points are more fully considered under the head "Menstruation," p. 668.

† See the argument regarding the anatomical evidence for this form of gestation at p. 586.

ference, the seat of normal impregnation; while such a view is opposed to those numerous observations upon the mammalian ovum generally, which show, that before the ovum quits the oviduct, the developmental changes in it are already advanced many stages, while, by the time that it arrives at the uterus, the opportunity for impregnation has already passed away for that occasion.

Development of the Fallopian Tube.

Whatever difference of opinion may exist regarding the origin of the excretory duct of the male generative gland, there appears to be no doubt, that in birds at least the corresponding part in the female has its commencement in a structure which, as soon as it can be recognised as a distinct tube, is altogether separate from the Wolffian body. This is called after its first observer, the duct of Müller * (*fig.* 400. *g*).

The mode of origin of this duct has been already partly described in the account which has been given of the formation of the Parovarium (p. 594.). Its development may be most conveniently traced in birds, where it can be easily shown that the oviduct is not a metamorphosis of the excretory duct of the Wolffian body, but may be distinguished lying near it, in the form of a tolerably thick tube; which at first ends in a closed extremity, but afterwards exhibits a wide orifice. It runs along the outer side of the Wolffian body, while its infundibulum, which is soon distinguishable, extends beyond and is entirely separate from that body.

The oviducts appear from the first in the form of white cylinders on both sides. They do not grow from below upwards, but are formed in their entire length from the commencement; nor are they constructed out of a membranous lamina, rolled together, as Meckel supposed; but are in the beginning solid, and become gradually hollowed out into a tube. In this way also is formed the infundibular opening of the tube into the abdominal cavity.

Two oviducts exist originally in all birds, but as in this class the right ovary shrinks and disappears, so the right oviduct becomes lost, by gradually contracting and shortening from above downwards. †

In mammals, before the distinction of sex becomes apparent internally, there is seen, running along the Wolffian body of each side in every embryo, a duct, which, according to Müller, may represent either a vas deferens, or an oviduct. These ducts lie upon opposite sides of the germ glands, which may become afterwards testis or ovary.

Soon afterwards the internal organs begin to exhibit a distinction of sex. This is indicated in the future male by the duct, which runs along the outer side of the Wolffian body, sending off a white granular projection, extending towards the testis, which is met by a similar projection, given off by the upper end of the testis, and these two by their union form the rudiments of the epididymis. So that in the male mammal a new connexion is established between the duct, which afterwards becomes vas deferens, and the testis, without any agency from the Wolffian body, but through the development of new material.

In the female these projections are wanting, both from the excretory duct and from the ovary. The latter remains attached only to the Wolffian body by a simple fold. The upper end of the duct, which runs over the Wolffian body, projects somewhat beyond that body inferiorly, and terminates here in a globular swelling, in which an aperture is formed at a later period.

As the Wolffian body becomes atrophied the portion of the duct which takes its course over it, and which was previously straight, begins to be tortuous in the male, while in the female it remains straight, but becomes wider. Out of corresponding portions of the duct are formed, in the male, the head of the epididymis, and in the female the infundibular end of the tube, while the inferior free portion of the duct, after it has quitted the Wolffian body becomes converted, in the male, into the vas deferens, becoming at the same time more and more elongated; but in the female the corresponding portion of the duct is transformed into the inferior division of the tube, or into the cornu of the uterus.*

In this stage of its development the incipient Fallopian tube is only beginning to be recognisable. It circumscribes the diminishing Wolffian body on its outer side in the form of a bow. Above the superior opening extends beyond that body, while below the short free portion becomes conjoined with that of the opposite side to form a single tube. These ducts have throughout the same breadth up to their union with each other.

A division of the duct into uterus or cornu, and narrower Fallopian tube, is still nowhere perceptible, and the place of this latter division is only as yet indicated by the addition of the substance which afterwards becomes ligamentum rotundum. Between the oviduct and the ovary lies the atrophied Wolffian body of a dirty yellow colour, in part surrounding the ovary; but notwithstanding this contiguity the tubuli of the Wolffian body form no union between the Fallopian tube and the ovary. The duct, or future Fallopian tube, which had previously preserved a perpendicular direction, now takes, with the rest of these parts, a more sunken position. But it still lies close to the Wolffian body, from which it is separated by a narrow fold of peritoneum.

* See Müller's Bildungsgeschichte der genitalien. Düsseldorf, 1830.

† Prof. Quekett has pointed out to me, in the collection of the Royal College of Surgeons, a remarkable preparation by Mr. Tegetmeir, in which the right oviduct is developed in the common fowl.

* The researches of Kobelt upon this subject have been already explained under the head of development of the Parovarium.

a, middle portion of the uterus; *b*, cornua; *c*, Fallopian tubes or oviduct; *d*, ovaries; *e*, remains of the Wolffian bodies.

Wolffian bodies, much reduced in size, may be found lying in a duplicature of peritoneum, between the ovaries and the oviducts. The inferior portion of the latter becomes widened, and the division between the tubes and the horns, or *cornua*, of the uterus is established; although the tube still remains relatively very broad, even up to its abdominal end.

In the human subject the opportunities for observation upon very early embryos being of not very frequent occurrence, the foregoing changes have not been so accurately traced in the first stages as in the embryos of birds and mammals; but all the examinations which have yet been made lead to the conclusion that the Fallopian tube has its origin in a duct similar to that already described. This, with the rest of the internal organs, is sufficiently developed by the third month of utero-gestation to leave no longer any doubt as to the sex. By this period the oviducts have nearly acquired that horizontal position which, from the fourth month onwards, becomes a more marked characteristic. In embryos of the fourth month the tubes run parallel with the now horizontally placed ovaries, whose elongated form corresponds with the tube in the greater portion of its length. By the end of this month the abdominal end of the tube is seen to be wide open, and traces of the fimbriæ are discoverable in its already fringed margin. The lower ends of the tubes are still not so completely united but that an indentation is perceptible at their point of junction, giving evidence of the still bi-corned condition of the uterus. From this period onwards the proper structure of the tube wall appears to grow with greater rapidity than the fold of peritoneum by which it is invested; so that in advanced embryos, and in the fœtus at term, the oviduct is usually found of a tortuous or serpentine form, its windings being easily distinguishable through the peritoneal sheath. The tube now much exceeds the ovary in length, and its infundibulur end is beautifully margined with delicate fimbriæ (*fig.* 418.).

Abnormal Anatomy of the Fallopian Tube.

Defect and Imperfect Development. — Absence of the Fallopian tube is of infrequent occurrence, and is usually observed in cases where there is a coincident deficiency of the uterus or ovary.* But when the two latter

* Meckel, Handbuch der Patholog. Anatomie, B. I.

organs are perfectly formed it is exceedingly rare to find a deficiency of the oviduct.

The oviduct may be deficient either upon one or both sides. Heusinger * has recorded an example of deficiency of the ovary and Fallopian tube of one side.

Chaussier † met with a remarkable example of a woman who, notwithstanding the absence of one ovary and tube, and even of one side of the uterus, bore ten living children; and whose death shortly after her last confinement afforded him the opportunity of ascertaining this peculiar condition of the parts.

After the observations which have been made regarding the function of the Fallopian tube, it is hardly necessary to observe here that deficiency of both tubes will be necessarily productive of permanent sterility; although absence of the tube of one side, as in the case of Chaussier, just quoted, need not entail any such consequence.

Unusual shortness of the tube and the absence of the fimbriæ have been also accounted as causes of sterility; but the former, if associated with a very short ligamentum ovarii, would have no such effect, and could be only accounted a relative deformity when the ovary is placed at an unusual distance from the uterus, so as to be beyond the grasp of the infundibulum; while the latter peculiarity, as already shown, may be merely the result of age.

Peculiarities of Construction. — Several Pavilions on the same Tube. — M. Richard, to whose researches regarding the Fallopian tube reference has been already made, has pointed out a previously unobserved condition of this part. In examining the appendages of the uterus in thirty women, he met with no less than five examples of this singular formation, which he thus describes:

"At a distance varying from several millimetres to 2 or 3 centimetres behind the normal pavilion, are observed upon the course of the tube one or more accessory pavilions, formed like that which terminates the oviduct, of a mucous membrane divided into fimbriæ. When the fringes of this pavilion are floated under water, they are observed to be pierced by an aperture leading into the canal of the tube; and a probe introduced into this orifice may be made to escape either by the ostium abdominale, or by the ostium uterinum, according to the direction in which it is passed. Thus, then, the canal of the tube can, in certain cases, open into the cavity of the peritoneum by several distinct orifices."

The first of M. Richard's cases occurred in an adult, and is represented in *fig.* 408.

"There is a normal pavilion of somewhat irregular form, and below it, at several millimetres distance, a small opening, surrounded by two small fringes, covered on their inner surface by mucous membrane; while the serous membrane terminates abruptly on their outer surface as in the true pavilion. A probe introduced escapes by one or other orifice indiscriminately."

The second example (*fig.* 418.) occurred in a fœtus at term. The tube of the left side terminates in a single pavilion, but that of the right, besides its terminal pavilion, exhibits also two little secondary pavilions, communicating each by a special orifice with the canal of the tube.

But the most interesting example is that shown in *fig.* 419. from a woman who aborted at the sixth month. The terminal pavilion, represented here of the natural size, exhibits a richness of fringes and folds rarely seen.

Fig. 419.

Extremity of Fallopian tube (human) having two pavilions. (After Richard.)

a a, fimbriæ of the terminal or normal pavilion, exhibiting an unusual richness of folds; *b b*, accessory pavilion in the side of the tube, having two distinct orifices separated by a valvular fold; *c c*, a bristle introduced at the terminal pavilion escapes by one of these lateral orifices, but cannot be made to pass out by the other, or to enter the uterus on account of the valve; *d d*, a second bristle introduced from the lower end of the tube escapes by the other orifice of the accessory pavilion, but cannot be made to penetrate as far as the terminal infundibulum.

* Heusinger's Zeitschrift für die organische Physick, II. 2.

† Busch. Das Geschlechtsleben des Weibes, B. IV. p. 348.

Below this large pavilion is another, the fringes of which are large and floating. This abnormal pavilion exhibits two orifices separated from each other by a valve, which, being prolonged into the canal of the tube, interrupts all communication between that part of the canal placed above and that below it. The valve is formed of a fold of mucous membrane. A probe introduced by the abdominal orifice of the tube escapes by one of the two orifices of the supernumerary pavilion, whilst one passed from the uterus appears at the other orifice of the same accessory pavilion.

M. Richard points out a very important influence which these abnormal openings may have upon the functions of the oviduct. An ovum having entered the terminal pavilion, if while endeavouring to gain the uterus it is directed along the wall of the canal which is opposite to the accidental opening, it will reach the uterine cavity; but if, instead of coursing along the wall opposite to the solution of continuity, it descends along this wall itself, then it will almost inevitably escape by this abnormal orifice, and will fall into the peritoneal cavity. Now, if this ovum has not been fertilised, nothing remarkable will ensue upon its escape into the peritoneum; but if the contrary, then it is possible that the fertilised ovum having escaped from the canal which should conduct it to the uterus will give rise to an abdominal pregnancy.

Displacement of the Fallopian Tube. — This is, perhaps, one of those conditions of parts which would be the least likely to be detected during life, and it may on that account have been often overlooked. It is of necessity associated with displacements of certain other organs, whenever such displacements occur; as, for example, with prolapsus inversion and retroversion of the uterus. In extreme prolapsus or procidentia uteri the tubes, along with the ovaries, are carried down and occupy a position on either side of the prolapsed organ, and between it and the walls of the inverted vagina, while in inversion the tubes are contained in the pouch formed by the reversed uterus.* In this latter case the relative situation of all the parts is so altered that the uterine orifices of the Fallopian tubes may be sometimes discovered as forming oblique openings in the upper part of the vagina.† But displacement of the Fallopian tube may occur alone, and constitute a true hernia. Such an occurrence is recorded by M. A. Bérard.‡ In this case the displacement took the form of a crural hernia, which was at first reducible, but after gradually increasing in size it could be no longer reduced. As fluid was distinguishable within the hernial sac a puncture was made, but peritonitis ensued, followed by death; and upon examination it was found that the sac contained nothing but the hypertrophied Fallopian tube.

* See *figs.* 470 and 471.

‡ Revue Médicale, Mai 1839.

Meissner* has collected three other cases of hernia of the tube, one of which was congenital. These are all instances of inguinal hernia of the tube. In the "Journal für Geburtshelfer†" an instance of displacement of another kind is recorded. The left Fallopian tube had escaped through a rent in the walls of the vagina near the os uteri, and descended as far as the labia, so that the fimbriæ could be easily distinguished during life.

The most common displacements of the Fallopian tubes are those which result from adhesions consequent upon inflammation of their peritoneal coat. Such adhesions constituted by bands or extensive surfaces of false membrane, tie down the tubes to surrounding parts, and in most instances effectually prevent the performance of their proper functions; as where the tubes are adherent to the uterus, the sides of the pelvis, or the bladder or intestines. But the union is most commonly found to have taken place between the extremity of the tube and some part of the surface of the ovary, so that these are inseparably united together (*fig.* 409.), and very frequently in some abnormal position (*fig.* 420.)

Obliteration of the Fallopian Tube. — In advanced life a natural contraction of the tube takes place, and the fimbriæ also diminish and lose their luxuriance of form; but it frequently happens that, independently of these natural changes, and even at an early period of life, the tubes are found nearly or entirely obliterated. Such obliteration may be occasioned by tumefaction of the lining membrane of the tube, or by a collection of inspissated mucus in some part of the canal; or the entire calibre of the tube may be obliterated by cellular formation (atresia tubæ).

Occasionally calcareous concretions have been found obstructing the tube; and the same result has been produced by growths of a malignant kind.

The occlusion, however, is generally confined to the abdominal end of the tube. In these cases, usually, the fimbriæ are destroyed, the opening into the abdomen is completely closed, and the tube ends in a blunt cul-de-sac. Such a condition of parts is generally associated with an enlarged and tortuous state of the tube, the walls of which are usually thickened, and its canal filled with fluid. In such cases the obliterated end of the tube may remain free and unattached, but it is far more often found united inseparably to the ovary. This junction of the tube with the ovary by artificial adhesion is the most common of all the morbid conditions of the oviduct. It has been supposed by some to be the result of certain libidinous habits and practices; but this conjecture is not supported by any statistical evidence. The explanation given by Rokitansky, that this form of adhesion results usually from an extension of ca-

tarrhal inflammation along the lining membrane of the tube, which, spreading to the fimbriated extremity, gives rise to peritoneal inflammation in the vicinity of the orifice, so that the free terminations of the tube are bound down to the adjacent parts, seems to offer the truest explanation of the nature and origin of this peculiar condition of the parts. See *fig.* 409.

In some of these cases, however, there appears to have been something more than a mere process of exudative inflammation at work. The parts upon examination appear to have become blended by a combined process of absorption of the fimbriæ, and at the same time of firm agglutination of the infundibular base to the surface of the ovary; so that it may be difficult to find any precise line of demarcation between these parts, except that which a difference of colour may furnish.

Hyperæmia or congestion of the tissues of the tube is very commonly observed. It is apparently a normal state during healthy menstruation, but may be regarded as morbid when associated at other times with deep congestion of the uterus and ovaries.

A state of hyperæmia of the tube has been found associated with effusion of blood into its canal, and the escape of a portion of this fluid into the abdomen through the infundibular orifice.

Hyperæmia of the tube occurs as a seminormal condition in cases of tubal pregnancy.

Inflammatory lesions of the tube may present the characteristic conditions of acute or of chronic inflammation. The former is commonly seen in cases of puerperal metro-peritonitis, where the inflammation attacking usually the uterus first has extended to the ovaries and tubes. "The tubes are tumified and infiltrated; their mucous membrane is variously reddened, discoloured, excoriated, softened and everted at the fimbriated extremity. The passage of the tube is dilated, especially at its outer end, and filled with various products, purulent and sanious fluids, and in uterine croup with coagulable lymph, assuming the shape of a tubular concretion, the exudative process having extended from the uterus to the tube."*

But more commonly the traces of inflammation are found in the peritoneal coat, which highly congested and covered by flakes of lymph, partakes in the general inflammatory condition of the adjacent serous surfaces.

In the non-puerperal state, or as a sequel of puerperal affections, inflammation usually takes the form of catarrh or blennorrhœa of the mucous membrane of the tube. The usual evidences of such an affection are, a certain amount of tumefaction of the mucous lining, with thickening of the delicate plicæ covering it, and dark congestion of the capillary vessels. Within the tubal canal are found collections of mucus variously coloured, being sometimes viscid, or occasionally cream-like, yellow and purulent (*fig.* 421.).

The chronic inflammations of the serous coat of the tube, which result in various adhesions of this part to surrounding structures, have been already noticed.

Collections of fluid within the tube result from a combination of two or more of the foregoing conditions. These fluids consist of blood, menstrual fluid, mucus, serum, or pus, and sometimes of these in various states of admixture.

Collections of blood, or of a bloody fluid within the tube, are occasioned by hyperæmia of

* Rokitansky. Patholog. Anat. Vol. II. p. 326.

the tube-walls, whose over-distended capillaries relieve themselves by sanguineous effusion. In such a case, if both the orifices of the tube are patent, the fluid may escape into the uterus, or possibly, by the infundibulum, into the cavity of the abdomen. Of such

Fig. 421.

The Fallopian tubes thickened by inflammation, and distended by collection of fluid. (After Hooper.)
a, uterus; *b*, distended tubes; *c*, thickened lining of the same; *d*, round ligament.

effusions there are many examples on record. Or should the abdominal end of the tube be closed in the manner already described, and should the uterine end also be temporarily obstructed, as, for example, by slight congestion of the mucous lining at this point, then the blood, having no outlet, will continue to accumulate within the tube, and a distension of the parietes, more or less considerable, will result.

But all collections of blood within the tube are not necessarily the result of hæmorrhage. The menstrual fluid has been frequenly observed to have accumulated here. And these accumulations may occur under various circumstances. Thus, in the case of imperforate hymen, when the menstrual function has been established for some time, this fluid, after collecting behind the obstructed orifice of the vagina, gradually collects in and distends the walls of the uterus, and ultimately mounts up into the Fallopian tubes, distending them also in the same manner as the uterus.

But atresia of the vagina or uterus, causing such accumulations, is not necessarily congenital, but may be consecutive on adhesive inflammation attacking these parts; as in the instance of a woman, whose case is related in the American "Journal of Medical Sciences,"* and who, after her second confinement, had an attack of metritis, terminating in cohesion of the uterine walls and consequent occlusion of the cavity of the uterus. Behind this obstruction the menstrual fluid accumulated until the Fallopian tubes became so enormously distended that at length one of them burst, and death resulted from the escape of the blood into the abdominal cavity.

Or lastly, the menstrual fluid may collect in the tube after the manner of the blood in the case just described, where both the orifices of the tube are obstructed. Of such accumulations I have met with many examples; and it is interesting to observe that here, as under many like circumstances, the walls of the tube usually become hypertrophied in proportion to the degree of pressure caused by the accumulations of fluid which they are called upon to resist.

These collections of menstrual fluid within the tube, which I have found to be considerable in some instances, where I have ascertained beyond question that death had taken place during a menstrual period, are instructive, as showing, upon strong probable evidence, that the menstrual fluid is supplied in part by the walls of the Fallopian tube as well as by those of the uterus itself. For I have seen it in cases where both orifices of the tube were obstructed; and therefore in cases where it was not probable that the fluid could have regurgitated from the uterus into the tube.

Collections of serous fluid. Hydrops tubæ Hydrosalpinx.—In catarrhal inflammation of the mucous lining of the tube, whether oc-

* No. XXXV.

curring in the acute or chronic form, the fluid, secreted more abundantly than in a state of health, may find vent by either or both of the tubal orifices, so long as these remain pervious.

It is probable that in this affection the superabundant fluid flows generally by the lower orifice into the uterus, and so escapes per vaginam, constituting one of the numerous forms of "leucorrhœa." But if both extremities of the tube are closed, then, as in the case of hæmorrhage or menstruation occurring under like circumstances, the fluid collects within the tube and mechanically distends its walls.

The pressure producing this distension, when operating in only a slight degree, causes a nearly equable enlargement of the tube, so that its natural conical shape is still preserved. But as the quantity of fluid increases, the thinner and less resisting portions of the walls, which lie towards the distal extremity, give way more rapidly than those at the proximal end; and the tube, after becoming irregularly tortuous, is at length converted into a series of sacculi, the largest of which, usually of a pyriform shape, occupies the extremity of the tube (*fig.* 422. *d*).

From the irregularity with which different portions of the tube walls dilate under the pressure of the accumulated fluid, it often happens that several angles are formed by the sudden bending of the parietes, and at these points the tube walls, extending inwards, constitute so many valvular projections which partition the tube into several irregular chambers, communicating together by narrow orifices. Such a condition of parts may be frequently observed upon both sides of the body, as in *fig.* 422., where both tubes are affected in the same manner although in unequal degrees.

Fig. 422.

Distension of the Fallopian tubes, with obliteration of both orifices. (*After Hooper.*)
a, uterus; *b*, vagina; *c*, os uteri; *d* and *f*, Fallopian tubes; *e*, ovary.

When these dilatations have attained to any considerable size the condition of the lining membrane of the tube becomes altered, so that the mucous gradually acquires the character of a serous surface, and the fluids collected within these sacculi present the ordinary condition of the fluids of serous dropsies.

The more simple of these fluids are thin, serous, and nearly colourless, and may be more or less albuminous. Not infrequently, however, they contain flocculi, or are thickened by the admixture of various yellow, brown, or chocolate coloured denser fluids, consisting chiefly of pus and disintegrated blood.

The quantity of fluid does not commonly exceed a few drachms, and in ordinary experience six or eight ounces would be a rather large accumulation. Yet it is certain that sometimes a much more considerable collection has been observed.

Thus in "Bonnet's Sepulchretum Anatomicum *," a case is given in which one of the tubes held thirteen pounds of fluid; and De Haen † mentions an instance in which the hypertrophied tube weighed seven pounds, while the quantity of fluid contained in it amounted to thirty-two pints.

Other cases, of more or less authority, have been recorded, in which the collection of fluid has been estimated at 112, 140 and 150 lbs. But it is exceedingly doubtful if the tube walls are capable of dilating to the extent that would be necessary to support so large an amount of fluid without laceration. For it is very well known that in tubal pregnancy rupture of the tube almost always occurs before the middle period of gestation is reached; and even in those cases where the reports are founded upon post-mortem ex-

* Lib. III. Sect. XXI. Obs. 39.
† Rat. Med. Tom. III. p. 29.

amination it is very possible that a part of the fluid was contained in the ovary, for a concomitant enlargement of both tube and ovary is a very common occurrence, as in the case represented in *fig.* 422.; and on this account no record of any very considerable dropsy of the Fallopian tube should be considered as complete, unless the condition of the corresponding ovary is also mentioned.

Collections of puriform fluid in the tube. — *Abscess of the tube.* — The presence of pus in the Fallopian tube is most frequently associated with suppurative puerperal inflammation of the uterus and its appendages generally. But it may also occur independently of the puerperal state, and as a consequence of catarrhal inflammation of the mucous lining of the tube which may have passed into the suppurative stage. These cases differ from the foregoing, not only in the nature of the contents of the tube, consisting here of pus or of puriform fluids with admixture of other inflammatory products from the lining membrane of the tube; but also in respect of the great tendency which is here observable to the formation of adhesions and the establishment of fistulous openings into adjacent parts, as into the bladder, intestines, or peritoneum, into which cavities these fluids are occasionally discharged.

Cysts containing fluid attached to the tube.— Very commonly there may be observed one or more cysts containing a small quantity of transparent fluid, attached by a narrow peduncle to the tube, and particularly to the distal extremity (*fig.* 368. *e*). The nature of these cysts has been already explained. (See p. 597.) They can only be regarded as morbid when they attain to an unusual size, as in *fig.* 421. They are occasionally found as large as a nut, but they very seldom exceed, and indeed do not often attain even to this size.

Fibrous tumours. — One of the most remarkable points of difference between the morbid conditions of the Fallopian tube and of the uterus respectively is the very great rarity of the occurrence in the former of those fibroid growths, which in the latter constitute its most common abnormal peculiarity. Nothing can mark more distinctly the difference of texture between these two parts than this very characteristic circumstance: since it is now known that the peculiar fibrous tumour of the uterus is formed at the expense of the natural tissues of that part. Occasionally, indeed, small fibrous tumours are found in the parenchyma of the tube, but these never attain to any considerable size. These occasionally undergo calcification, from a deposit of earthy material in their texture, and thus form little masses of stony hardness which project from the walls of the tube, and are covered by its peritoneal coat.

Tubercle is occasionally formed in the Fallopian tube. It occurs there usually in the form of tuberculous infiltration, which, in the opinion of Rokitansky, affects chiefly the mucous membrane of the tube. The occurrence of tubercle here presents nothing remarkable enough to call for further special description.

Cancer of the tube is not a common occurrence. I have never met with it independently of cancer of the ovaries or uterus; but when either of the latter organs are extensively affected, the tubes are also occasionally involved. Upon the malignant diseases of the Fallopian tube most pathological writers are nearly silent; nor has our literature been enriched by any considerable number of special records bearing upon this point in Pathology.

Rupture of the Fallopian tube.— Spontaneous laceration of the walls of the tube occurs sometimes as a result of over-distension, or too great attenuation of its tissues, whereby the parietes are rendered no longer capable of resisting the increasing pressure of the fluids accumulated within. In this way large collections of serous, purulent, or sanguineous fluids are sometimes poured out into the cavity of the abdomen, unless, indeed, by the previous adhesion of the walls of the tube to surrounding parts, the point of rupture is directed to some neighbouring hollow viscus by which the fluids escape externally. But rupture of the tubes will most frequently happen in connexion with the tubal form of extra-uterine gestation, which is next to be described.

Detention and abnormal Development of the Ovum in the Oviduct. Tubal Gestation. Graviditas tubaria. — This constitutes a second species of those aberrant forms of gestation, commonly termed extra-uterine, one of which has been considered under the title of Ovarian Gestation, (p. 586.)

It has been already shown, that one principal office of the Fallopian tube is the conveyance of the ovum from the ovary, or place of its first formation, to the uterus, or seat of its final development; and that the ovum, whilst in transitu, not only becomes impregnated, but also exhibits certain indisputable evidences of commencing development, which, however, has usually advanced only a few stages by the time that the ovum enters the uterine cavity. The tube, therefore, as well as being an oviduct, is also the seat of normal impregnation; whilst, in addition, it serves to protect and possibly, in some slight degree, to add to the material of the ovum, although the actual operation of the tube walls upon the surface of the ovum in this respect must necessarily be very slight in the mammalia, since it so rarely happens that any increase in its size is perceptible from the time of its quitting the ovary to that of its reaching the uterus.

But the impregnated ovum, instead of entering the uterine cavity, may be accidentally detained in the tube, and undergo further development there. The extent to which this development may proceed will depend in a great measure upon the capability of expansion of the tube walls; a circumstance which seems to vary greatly in different individuals, and also in some degree according to the portion of tube which the ovum occupies.

The differences observable in this latter respect have led to a division of cases of tubal gestation into three varieties, viz. tubo-ovarian, tubal, and interstitial.

In the first variety, *graviditas tubo-ovaria*, the ovum becomes developed in a sac, of which a principal portion appears to be furnished by the hypertrophied walls of the infundibular end of the tube, and the proper tissue of the ovary combined. In the second, *graviditas tubaria*, the developed ovum occupies some part of the canal of the free portion of the oviduct; while in the third, *graviditas interstitialis*, the seat of development of the ovum is that part of the tube which traverses the uterine walls.

In the first, or *tubo-ovarian* variety, the parts supplying the principal foundation of the cyst, which surrounds the fœtus, are in the first instance probably chiefly normal structures; and it is easy to understand how, during the progress of growth of the ovum, when the limit of expansibility of these parts has been reached, there may be superadded to them materials for the extension and further growth of the cyst walls; and in this way are apparently formed these large sacs, or artificial uteri, which have been sometimes observed to surround a fully developed fœtus, and which in the course of their growth have come to include omentum, mesentery, or intestine, and other portions of the abdominal viscera or parietes, by which the sides of the sac become strengthened and enlarged.

As in the case of ovarian gestation formerly described, so in the varieties termed ovario-tubal, it is only when death has taken place during the early stages of formation of these embryo-bearing cysts that the exact nature and relation of the parts originally composing them can be made out. Hence the difficulty of determining, in more advanced stages of gestation, when other parts have been superadded, in what precise situation the development of the ovum was commenced. And hence the probability that some at least of those cases which have been recorded from time to time as examples of the fœtus developed in the cavity of the abdomen, and among the intestines (*graviditas abdominalis*), may have been originally cases of the tubo-ovarian variety, in which the cyst walls, commencing their formation by the artificial union of the expanded termination of the oviduct with a portion of the ovarian parietes, have in the course of their growth come to include many other parts.

The second variety, which includes all cases strictly termed tubal (*graviditas tubaria*), constitutes by far the most common of all the forms of extra-uterine gestation. Here the ovum is developed within some part of the free portion of the tube, whose walls appear, from the examples which most of our museums furnish, to be capable of a very limited degree of expansion in most individuals. Hence, when the ovum has attained to a certain size, and usually by the time that the second or third month of gestation has been reached, rupture of the tubal wall occurs, followed by rapid death from hæmorrhage. And thus the parts are usually obtained for examination in such a state as to leave no room for question regarding the precise seat which the ovum occupies, and the nature of the parts enclosing it. For in these cases of early rupture the tube has contracted no adhesions with surrounding parts, and the walls of the embryo-bearing sac are formed of the parietes of the oviduct alone.

The third variety of tubal gestation, distinguished by M. Breschet under the title of *Graviditas in uteri substantia;* and by Professor Mayer, of Bonn, as *Graviditas interstitialis*, has been made known, particularly by an essay of the former devoted to this subject.*

This variety differs from the last mentioned chiefly in the circumstance, that the seat of development of the ovum is that portion of the canal of the tube which passes through the solid walls of the uterus. Here the sac surrounding the fœtus is formed in a great measure at the expense of the proper uterine tissues, and consequently the parietes of these cysts exhibit under the microscope a very different composition from that which the tube walls show in the second variety.

In interstitial cases the walls of the sac surrounding the ovum sometimes attain in parts a thickness nearly equal to that of the gravid uterus. On section of these portions the appearance which they present is precisely similar to that of the gravid uterus itself. There is here seen precisely the same arrangement of large vascular openings, being the divided canals or sinuses which everywhere permeate the solid walls, in whose composition may be traced the same abundance of smooth muscular fibre, as in the ordinary gravid uterus.

Within such a sac, formed out of the walls of the tube in the first instance, and in the case of this third variety further strengthened by the addition of a large quantity of tissue derived from the uterus, the ovum lies, presenting its ordinary character of an external chorion and inner amnion; the fœtus or embryo itself, according to the period of gestation, being perfectly formed. The walls of the sac, being in this case usually much stronger than when the ovum lies nearer to the distal end of the tube, resist pressure for a longer time, and consequently the fœtus may attain a greater growth.

One of the most interesting questions connected with this subject is, whether a decidua is here formed. Schrœder van der Kolk, in his recent most valuable work on the structure of the Placenta †, answers the inquiry in the affirmative, in contradiction to the statement of Virchow ‡, by whom it is asserted that in the case of tubal gestation no decidua

* Mémoire sur une nouvelle espèce de grossesse extra-utérine. Par M. Breschet.

† Waarnemingen over het Maaksel van de Menschelijke Placenta. Amsterdam, 1851, p. 88. *et seq.*

‡ Virchow, ueber die Puerperal Krankheiten Verhand. der Ges. für Geburtshelfe. Berlin, 1848, B. III. s. 180.

is to be found in the tube. According to Schrœder, a decidua is here formed in tubal pregnancy, notwithstanding that in the walls of the tube glandulæ utriculares are entirely wanting. The villi are here embedded in little hollows of the decidua, upon whose walls the blood vessels terminate in open mouths, and thus the blood is poured out into the placenta. The decidua is, indeed, in this case firmer, and does not exhibit so many valvular openings as are present in an ordinary placenta; probably from the absence of the utricular glands. In this case, also, an epithelial layer derived from the decidua covers the villi, and serves at the same time as a means of junction between the parts.*

Associated usually with the abnormal development of the ovum in the oviduct is the formation of a decidua in the uterus, the nature of which structure will be considered in a subsequent portion of this article (pp. 635. 652).

And here it naturally occurs to inquire into the probable causes of the development of the ovum in a situation so unfavourable to its further and complete evolution. Since, notwithstanding the wonderful power of adaptation which is in these cases exhibited by the parts immediately surrounding and containing the ovum, it is plain that the oviduct however altered, yet, on account of its peculiar form and texture, can but inadequately supply the offices of a uterus. It can serve but imperfectly for the nutrition and protection of the fœtus, and not at all for its expulsion, even should the latter reach the term of its dependent or intra-uterine life.

One of the most remarkable circumstances relating to this curious subject, is the fact first noticed, I believe, by Dr. Oldham, that in a large number of cases of tubal gestation, the corpus luteum, corresponding with the ovum impregnated, is found in the ovary of the opposite side to that of the tube in which the ovum is developed. Thus if the left Fallopian tube contains the ovum, the right ovary will often display the corpus luteum of a corresponding date, and *vice versâ*. Not being at first aware of Dr. Oldham's observation, I had myself noticed the same circumstance in repeated instances, and had arrived at the same conclusion as he has done in explanation of it, namely, that at the time of the ovum quitting the ovary, the tube of the one side embraced the opposite ovary, and conducted away the ovum, which being impregnated in the ordinary way, and then being delayed at the angle formed by the bending of the tube, has its further progress obstructed at that point until it attains too great a size to admit of its subsequently passing the lower orifice and entering the cavity of the uterus.

If it be objected that this explanation is not satisfactory, because it assumes the apparent improbability of the fimbriated extremity of one Fallopian tube being able to grasp the opposite ovary, then I can point to a preparation in the Cambridge University Anatomical Museum *, in which both the Fallopian tubes grasp the same ovary to which their extremities are affixed by morbid adhesion.

Another and very different explanation of this remarkable circumstance of the impregnated ovum and corresponding corpus luteum being found on opposite sides, has been given by Dr. Tyler Smith †, who believes that the ovum, after descending the Fallopian tube of one side, traverses the upper part of the uterine cavity, and ascends the opposite oviduct, where it becomes developed. I might also furnish the advocates of this doctrine with an argument founded upon a most interesting and curious observation of Bischoff, which appears to have been overlooked, but which would at first sight seem to support this view. Bischoff, in his essay on the development of the ovum in the dog and rabbit, frequently noticed a remarkable apportioning of the ova between the two cornua of the uterus, so as to equalise their number on the two sides, when these had been originally unequal, as shown by the number of corpora lutea found in the ovaries. Thus, in the case of a bitch whose right ovary exhibited one, and the left ovary five corpora lutea, each half of the uterus contained three ova, so that two of the ova must have travelled across from the right to the left side. But it must be observed, that in the cases recorded by Bischoff the ova never ascended the Fallopian tube, but only travelled from one cornu of the uterus to the other.

When, therefore, we take into consideration the great difference between the solid uterus of man and the intestine-like organ of the mammalia, on which these observations were made, there appears to be great difficulty in supposing that the ovum could after once arriving at the uterus again enter an oviduct, especially when also it is remembered that while the conical form of the Fallopian tube, whose smallest aperture is towards the uterus, constitutes a provision for ensuring the arrival of the ovum there, this arrangement would greatly diminish the possibility of a retrograde movement taking place in the human subject, if indeed it would not altogether prevent it.

But to those cases of tubal gestation in which the corpus luteum is found in the corresponding ovary, neither of these explanations would apply. Here it is only necessary to suppose, that either the developmental changes already described as occurring normally to the ovum in the tube, have proceeded more rapidly than usual, or else, that the ovum, having been accidentally delayed for a longer time than ordinary in transitu, had acquired too great a magnitude to admit of its passage by the uterine orifice, even admitting, as some have supposed, that this orifice may, to a certain

* Upon this point I do not here give any observations of my own, as I am preparing these for publication in another form.

* No. 722.

† Lancet, No. xv. vol. i. 1856.

extent, dilate, for the purpose of allowing the ovum to pass, just as the os uteri dilates at the time of labour.

UTERUS.

Normal Anatomy.

(Syn. *Womb*, *Mother*, Eng.; Μήτρα, Ὑστέρα, Δελφύς, Gr.; *Uterus*, *Matrix*, Lat.; *Utero*, Ital.; *Matrice*, Fr.; *Bärmutter*, *Gebärmutter*, *Fruehthälter*, Germ.; *Baarmoeder*, *Lijfmoeder*, Dutch.)

The uterus is that segment of the generative track which lies between the lower extremities of the Fallopian tabes and the fornix or upper end of the vagina. In man it is normally formed by the complete coalescence of the two uterine cornua, which in most of the mammalia remain more or less distinct constituting the bicorned or divided uterus. These, in man and the quadrumana, unite to form a single symmetrical organ, serving for the passage of the seminal fluid, and for the reception, protection, nutrition, and final expulsion of the mature ovum.

The uterus is not altogether peculiar to the female. Like the mammary gland, it has its representative in the male, though only in a rudimental state. The existence of such a rudimentary organ is more easily shown in the male of many mammalian animals than in man, in whom, perhaps, it is the least conspicuous, and where its presence, as a type of structure, can only be proved by a close study of homologies, and by the aid of those occasional exemplifications of the true relations of this part which the comparatively rare occurrence of hermaphrodite forms affords.

Situation and position.— The unimpregnated uterus is situated entirely within the pelvis, where it lies deep among the other pelvic contents, with many of which it is in immediate relation; the bladder lying anteriorly, the rectum posteriorly, the ovaries and Fallopian tubes laterally, the small intestines superiorly, and the vagina and perineum inferiorly with regard to it. These several parts, aided by the broad and round ligaments, serve to support the uterus and maintain it in its natural position. But this position will of necessity vary according to the condition of the neighbouring organs, and in some degree also with the varying postures of the body.

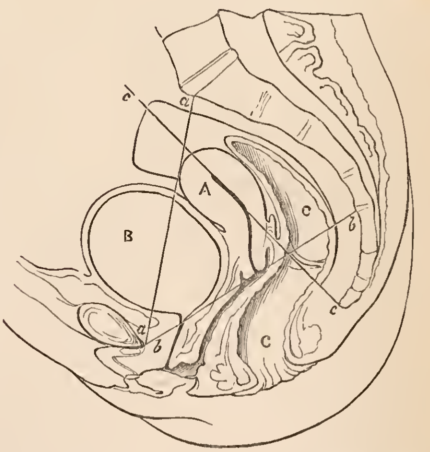
The nature and degree of the variations in regard to situation and position of which the uterus is susceptible will be more easily understood after the ligaments and other connections by which these movements are restrained have been described. At present it will be only necessary to observe that the motions of the uterus are restricted chiefly to three directions. First, the broad ligaments, which maintain the organ nearly in the median line, permit by their laxity a slight deviation towards either side. Secondly, a certain amount of ascent and descent is allowed by the structures which attach the uterus to the lower part of the pelvis. But the former of these movements will be limited by the utero-sacral ligaments, and the weight or pressure of the superincumbent viscera; and the latter also especially by the same ligaments, and to a certain extent by the support derived from the posterior wall of the vagina and the parts which close the pelvis below. Thirdly, the uterus enjoys a certain range of motion in the direction of a line drawn from pubes to sacrum in order to accommodate it to the state of fulness or emptiness of the adjacent viscera. For when the bladder is full and the rectum empty, the uterus will be carried nearer to the sacrum; and conversely, with an empty bladder and a distended rectum, the position of the uterus will be proportionately nearer to the pubes; and these alterations of position will be constantly and daily repeated.

But an equal degree of mobility does not belong to every part of the uterus; for while the movement of the cervix is limited by the attachment of the vagina and utero-sacral ligaments, the fundus is left entirely free to follow the alternate fillings and emptyings of the bladder. Thus a movement of nutation will result, the fundus uteri approaching the pubes and sacrum alternately; and this is probably the greatest range of motion of which any portion of the uterus is normally susceptible.

But allowing for these variations, there will still be an average position which the uterus occupies in the pelvis, and this may be assumed to occur at the time when the bladder and rectum are both moderately distended.

Under these circumstances, the position of the uterus relatively to surrounding parts will be in accordance with the accompanying sectional diagram (*fig.* 423.), representing the pelvic contents. Here A represents the uterus, B the bladder, and C the rectum, both of the latter being moderately distended.

Fig. 423.



Sectional diagram to show the normal position of the uterus in the pelvis.

At such a time the uterus, supported between the folds of the broad ligament, which constitutes a moveable dissepiment, dividing the pelvis transversely into two unequal parts, and sustained by the parts attached to it around and below, lies with its fundus directed obliquely upwards and forwards, while the cervix or neck looks downwards, and very slightly backwards towards the orifice of the rectum. The relative heights of these several parts are determined by two lines: the one, *a—a*, drawn from the lower border of the symphysis pubis to the promontory of the sacrum; the other, *b—b*, from the same point to the lower margin of the fourth sacral vertebra. Upon the latter the cervix will rest at a point near the centre of the line. The direction of the uterine body will be more conveniently shown by a third line, *c—c*, drawn through its axis. This line, if produced, will pass out of the pelvis upwards at a distance of $\frac{3}{4}''$ in front of the sacral promontory; and downwards, after traversing the posterior wall of the cervix, it will pass out about the centre of that wall, and impinge upon the extremity of the coccyx. The lower portion or cervix of the uterus being curved upon the body in the manner hereafter described, the direction of its canal will be downwards, and will be represented by a line drawn nearly perpendicular to the horizon.

Form. — The uterus belongs to the class of hollow muscles, with which it is associated on account of its cavity and the muscular character of its proper parietes. In many of the mammalia, the elongated form and general arrangement of the tissues gives to the uterus a resemblance to an intestine; while in man and the quadrumana, in whom it possesses a considerable degree of firmness and solidity, the shape more nearly resembles that of the urinary bladder.

The uterus has been compared to various objects, such as a flask, a little gourd or calabash, a pear, or a truncated cone. There is enough of similarity to these several objects, to excuse the comparison, yet the resemblance is not sufficiently close to render any of them an exact representative of that body; but perhaps the flattened pear conveys the best idea of the uterine figure, although the pyriform outline is somewhat broken by the attachment to its lateral borders of the parts usually termed appendages (*fig.* 368.). These should be, therefore, removed in order to display the proper boundaries of the organ (*fig.* 424. and 431.).

Dimensions. — The uterus does not attain to its full development until after the establishment of puberty. Previous to this period it remains but little altered from its infantine condition; but as the period of puberty approaches, and about the time when the mammæ, which have also until then retained their infantine state, begin to enlarge, the uterus rapidly increases in bulk and weight. It then soon reaches the size which, if unemployed, it maintains through the rest of life, only wasting, and becoming somewhat altered in figure by absorption of its tissues, as age advances; or, if employed in the process of reproduction, then undergoing a degree of temporary enlargement unparalleled by any other growth of structure in man, and subsequently returning, in part, though never entirely, to its former state.

The following are the average dimensions of the virgin or nulliparous uterus. The entire length from the centre of the fundus (*fig.* 424 *a*), to that of the anterior lip *b*, which gives the longest diameter, is $2''$, $3'''$—$7'''$.

Of this one half usually belongs to the body, and the remainder to the neck or cervix; but the proportional length of either of these parts may exceed the other by $1'''$—$2'''$.

The greatest breadth of the organ is found opposite to the point of attachment of the Fallopian tubes. Here the transverse diameter is $1''$, $3'''$—; at the point of junction of the cervix with the body $10'''$; about the centre of the cervix $12'''$; at the extremity of the cervix, opposite to the point of junction with the vaginal walls, $11'''$—$12'''$.

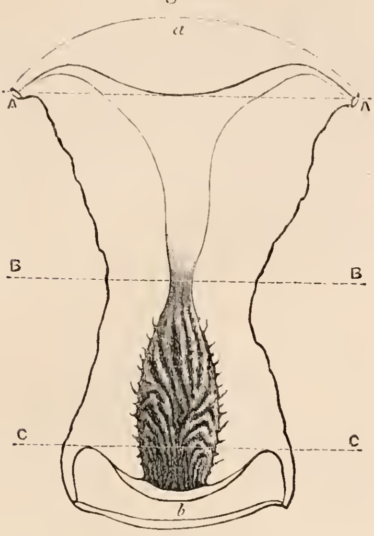
The antero-posterior diameter of the uterus is greatest about the centre of the body, where it measures in the nulliparous organ $11'''$—$12'''$.

Weight. — The weight of the adult virgin uterus, deprived of the appendages, is 9—12 drachms.

Regional divisions. — The uterus is divided primarily into a body and neck or cervix. Each of these is again subdivided, the upper portion of the body being termed the fundus, while the lower or terminal part of the neck is distinguished as its vaginal portion. These divisions, though to a certain extent artificial, are necessary, not only to facilitate description, but also to distinguish parts which exhibit great and important differences both of structure and function. So great, indeed, is the amount of structural and functional difference between the body and neck of the womb, as almost to justify these being regarded as two distinct organs.

The *fundus* is that portion of the body of the uterus which lies above an imaginary line, (*fig.* 424. A A,) drawn transversely across the organ from the point of attachment of one Fallopian tube to that of the opposite side. This portion of the uterus is of a very dense and firm texture. It is very slightly convex in the virgin state, but becomes considerably arched and expanded during pregnancy, when it forms, as it were, a vaulted roof to the organ. After parturition the fundus does not regain its former figure, but retains more or less of the rounded form which constitutes one of the points of difference between the nulliparous and multiparous organ. The fundus is that part of the uterus which, from its concealed position within the pelvis in the unimpregnated healthy state, is the least capable of being examined during life. It is of all parts of the uterus that which is the least subject to destructive disorganisation by malignant growths, frequently remaining unaltered in texture after the whole of the cervix has been destroyed by carcinomatous ulceration. On the other hand it is the part

Fig. 424.



Section showing the regional divisions of the uterus. (*Outlined ad Nat.*)

from which polypi, that are not cervical in their origin, most frequently arise; and it is very commonly the seat of those large hypertrophic growths of the uterine tissue, which are usually termed fibrous tumours. The fundus is also the part to which the upper portion of the placenta is most frequently attached.

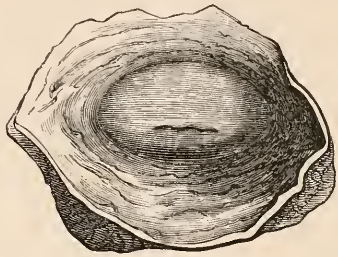
The body is included between the line above indicated, and another, B B, drawn through the narrowest part of the organ, or that point at which the tapering lateral walls of the uterus approximate in the greatest degree before they again diverge to pass into the cervix. The body of the uterus constitutes its principal portion. It is that part which, more than any other, expands to invest the ovum. It is freely supplied with blood-vessels, which, entering by the lateral border, ramify abundantly through the anterior and posterior walls. These walls are usually half an inch in thickness. They are separated from each other by a scarcely appreciable cavity, to be hereafter described, lying between the inner surfaces of the parietes. The extreme narrowness of this cavity is shown in *figs.* 427 — 430., which represent transverse sections of the uterine body, at various points between the fundus and internal os.

The cervix, or neck, (*fig.* 424. B—C), is a cylindriform prolongation of the uterine body, to which it serves as an excretory conduit. It is composed in part of tissues similar to those of the body, but the arrangement of these is materially different. The walls of the cervix measure $4'''$ in average thickness. Their inner surfaces are not in immediate contact like those of the uterine body; but diverge slightly to enclose a flattened spindle-shaped cavity, termed the canal or cavity of the cervix.

The situation of the widest or central part of this canal is indicated by an external lateral bulging of the walls of the uterine neck. The posterior part of the cervix receives a loose investment of peritoneum; but the whole or the greater portion of its anterior wall, as well as the lower or vaginal portion, is uninvested by that membrane.

The vaginal portion.—The lower extremity of the cervix (*fig.* 424. below, C C) projects

Fig. 425.



Os uteri, and vaginal portion of the cervix. Virgin. (*Ad Nat.*)

into the vagina in the form of a flattened cone. The length of this conical projection is about $4'''$. It is of unequal diameter. Transversely it measures $11'''$—$12'''$ at the base, and $6'''$—$7'''$ at the apex; but its antero-posterior diameters are only $7'''$—$8'''$ at the base, and $5'''$ at the apex; so that a section of this part will represent an ellipse. Around the base of this conical portion the walls of the upper end of the vagina are attached. The vaginal attachment constitutes the line of demarcation between the lower or vaginal and the upper or supra-vaginal division of the cervix. It should be observed that the end of the cervix does not lie, as is commonly supposed, exactly at the extremity of the vaginal canal, but that it projects into its upper wall, so that the upper vaginal wall is shorter than the lower by the whole antero-posterior diameter of the cervix (*fig.* 426. and 433.). This explains the difficulty which is sometimes experienced in bringing the cervix into view when a tubular speculum is employed, the sides of which are all of equal length. There can be no doubt that this peculiar position of the extremity of the cervix prevents the part from suffering injury in coitu, because the impulse of the intromittent organ is received upon the end of the vagina, and is distributed upon the adjacent parts, through the intervention especially of the utero-sacral ligaments. See further, p. 689.

At the apex of this conical mamelon is observed a transverse fissure $3'''$—$4'''$ in length. This is the lower or terminal orifice of the cervical canal, the os externum uteri, *fig.* 425., as distinguished from the os internum, *fig.* 431, *i*, which marks the commencement of that canal. The os externum is bordered in front and behind by two smooth lips, whose commissure on either side forms the lateral boundaries of the orifice. The lips constitute the terminations of the anterior and posterior cervical walls respectively. They are accordingly distinguished as the anterior and posterior lips of the os uteri. Their position and form are most conveniently shown in a vertical section of the part (*fig.* 426. and 433.). The anterior lip is the smaller; it projects but slightly into the vagina, but it lies at a lower level than the posterior one, on account both of the greater length of the anterior wall of the uterus, and also from the inclination of the upper part of the organ forwards. In an antero-posterior view, the anterior serves to conceal the posterior lip, which lies higher in the pelvis, both from the comparative shortness of the posterior uterine wall, and also from the tilting forward of the entire organ; nevertheless the posterior lip makes a greater projection into the vagina, because the walls of that canal are reflected off at a higher point upon the cervix posteriorly than anteriorly. This unequal form of the two lips doubtless gave origin to the term os tincæ, by which the older anatomists designated the part.

In no portion of the uterus is the difference between the nulliparous and multiparous organ so marked as in the vaginal portion of the cervix. After the birth of many children, this part becomes much enlarged, soft, flaccid, and of irregular form, with notched margins; but in the virgin it has uniformly the smooth, even, conical figure just described, while its consistence is nearly that of soft cartilage.

External surface.—The uterus, being a hollow or cavitary organ, possesses both an *external* and an *internal* surface. The external surface exhibits two faces, anterior and posterior; three borders, one superior and two lateral; and three angles, two superior and one inferior.

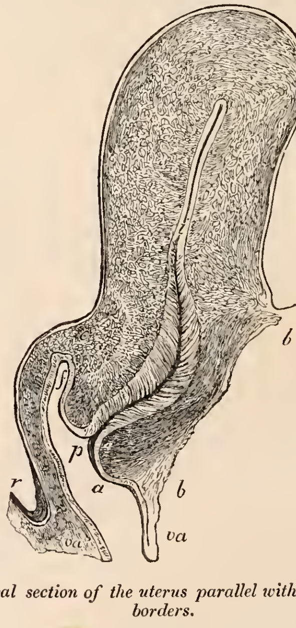
The anterior face is smooth, and gently convex in the transverse direction (*figs.* 427—430.), but often slightly curved from above downwards (*fig.* 426.). It is covered by peritoneum in all but its lower part, where this membrane is reflected off to give a covering to the bladder at a distance of not less than one fourth of the entire length of the uterus from its lower extremity. The posterior face is more decidedly convex; and in some subjects, especially in multiparæ, it exhibits a marked prominence along the median line, from which the walls proceed outwardly in two nearly level planes. These, meeting the less convex anterior walls at the lateral border, give to a transverse section of such an organ an outline more or less triangular (*fig.* 428.). The posterior face also receives an investment of peritoneum. The membrane here, after covering the entire posterior surface of the uterus, usually dips down to cap the upper extremity of the vagina. (*Fig.* 426. *c*—*r*.)

The superior uterine border is moderately convex; it extends from the point of entrance of one Fallopian tube to that of the other (*fig.* 431. *f f*). This border is entirely covered by peritoneum. The two lateral borders extend from the point of entrance of either Fallopian tube downwards to the lower extremity of the uterine neck, as far as the margins of the os uteri. These borders are flexuous, being convex above, concave towards and below the centre of the organ, again slightly convex about the middle of the cervix, and finally terminating at the os uteri, after having their continuity interrupted by the circular attachment of the vagina near the termination of the uterine neck. The lateral borders are uninvested by peritoneum; for it is here that the two laminæ of that membrane, which form the broad ligament, meet to inclose the uterus; and by these two lateral borders, the blood-vessels and nerves supplying the organ enter it without penetrating its outer or serous coat (*fig.* 428.).

The two superior angles are formed at the points of entrance of the Fallopian tubes. The inferior angle is occupied by the vaginal portion of the cervix and the os uteri.

Internal surface and cavities of the body and cervix. — It has been stated that the walls of the uterine body are in nearly close apposition internally, leaving only a small intermediate space, termed the cavity of the uterus, which is easily displayed by cutting through

Fig. 426.



Vertical section of the uterus parallel with its lateral borders.

a, anterior, and *p*, posterior, lip of cervix; *i*, internal os uteri; *v a*, vagina; *f*, fornix; *c*, loose connective tissue immediately above the fornix; *r*, point of posterior reflection of the peritoneum on to the rectum, forming the retro-uterine pouch or space of Douglas; *b b*, line of attachment of the cervix to the bladder. The peritoneum ceases at the upper *b*, in front. (*Ad Nat.*)

the substance of the organ. No just conception, however, of the real form or capacity of this interspace can be obtained by examining it with the aid of sections made in one direction only.

In order to obtain a correct notion of the form and extent of this cavity, it is desirable first to make a longitudinal section through the centre of the entire organ parallel with its lateral borders. The cavity or interspace is then indicated by a line running from below upwards, and terminating within half an inch of the fundus (*fig.* 426.).

The upper half of this line indicates the cavity of the *uterus;* the lower half, that of the *cervix.* The latter alone exhibits a true cavity; for here the parietes of the cervix are

Fig. 427.

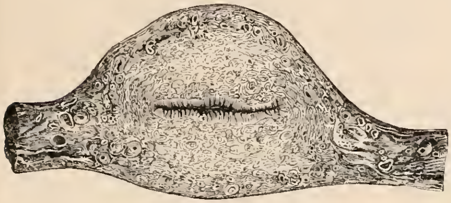


Fig. 428.

Fig. 430.

Series of horizontal sections of the uterus.

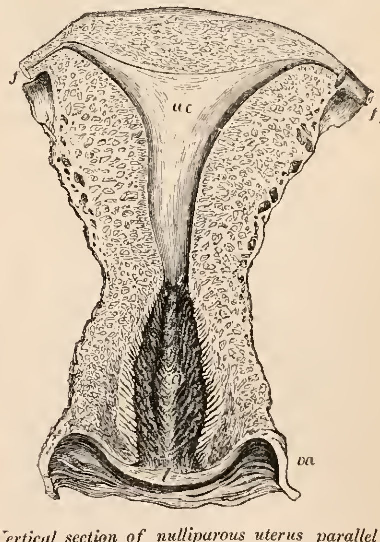
Fig. 427., just above the entrance of the Fallopian tubes. *Fig.* 428., in the centre of the cavity. *Fig.* 429., close to the internal os uteri. *Fig.* 430., the centre of the cervical canal. The upper or more convex border marks the posterior surface in each section. (*Ad Nat.*)

observed to diverge slightly, so as to leave a spindle-shaped canal traversing the whole length of the uterine neck (*fig.* 431. *c c*).

A second view is obtained by cutting completely through the uterus in the direction of its transverse diameter, and parallel with its extremities. If the entire organ be cut up into many such segments (*fig.* 427—430.), it is then seen, from the length of the central line, that the cavity varies in breadth, its widest part being in the segment which includes the extremities of the Fallopian tubes; whilst from this point downwards the line diminishes in length, until at the narrowest portion of the uterus, or that representing the commencement of the cervix, it measures only $1\frac{1}{2}'''$—$3'''$ in diameter.

But the most complete view of the interior of the uterus is obtained by a section carried through the centre of the organ, dividing it midway between its anterior and posterior walls. The entire cavity which is thus exhibited at one view is seen to be of a triangular form; its boundaries being formed superiorly by the fundus, and on either side by the two lateral borders, whilst in each angle is observed an aperture. The two superior openings are the lower orifices of the Fallopian tubes. The inferior opening leading to the cervical canal constitutes the os uteri internum (*fig.* 431. *i*).

Fig. 431.



Vertical section of nulliparous uterus parallel with its anterior and posterior walls.

u c, uterine cavity; *c c*, cervical cavity or canal; *i*, internal os uteri; *e*, external os uteri; *f, f*, Fallopian tubes; *v a*, vagina. (*Ad Nat.*)

Since the cavity in the interior of the uterine body has a triangular form, whilst externally the shape of the organ is more or less pyriform, it is evident that the parietes of this "hollow muscle" cannot have everywhere an equal thickness, for otherwise the form of the cavity would correspond with that of the external surface. But whilst the anterior and posterior walls exhibit an average and nearly uniform thickness of about 6‴, that of the lateral boundaries and of the fundus varies from 6‴ to 1‴. Hence the section of this cavity represented in *fig.* 426., which exhibits the organ as divided from before backwards, is described by a right line; whilst the section (*fig.* 431.) shows the cavity as bounded by three curves, the degree of curvature varying in different subjects, and being generally supposed to be always greatest and most marked in women who have never borne children.

This point has been much dwelt upon as serving to distinguish the nulliparous from the multiparous uterus. I have reason to think, however, that this observation has been again and again repeated without confirmation by an appeal to facts. For although the sides of the virgin uterus are often strongly incurved, yet in some uteri in my possession from young subjects who had not borne children, the walls of the cavity are nearly straight, and this is the form which they have in the fœtus (*fig.* 442.), and in undeveloped uteri (*fig.* 465.); whilst in other specimens, taken from women who had borne many children, the sides and fundus may be incurved in various degrees. Much will depend upon the mode in which the sections are made; for unless, in dividing the organ, the knife has passed exactly through the median line, a portion of either the anterior or posterior wall will be included in the section, and the apparent form of the cavity will be materially modified thereby.

Thus the uterine cavity in the unimpregnated state is nothing more than the narrow interspace between the flattened walls which are normally either in immediate contact, or are separated from each other by only a small quantity of mucus. The triangular form results from the confluence of three ducts or channels; viz., the two oviducts above, and the cervical canal below. The tubal canals, having passed through the substance of the uterus, expand trumpet-like into the uterine cavity, whilst in the same way the cervical canal traced upwards is prolonged, though more gradually, into the same cavity. But the perpendicular diameter of the uterus being always greater than the transverse, the form of the cavity, in so far as it is triangular, represents not an equilateral, but an isosceles triangle with incurved sides (*fig.* 431.).

By reference to these particulars regarding the form of the interspace between the uterine walls, we are enabled to explain many phenomena relating to the first entrance of the ovum into the uterus, and its mode of detention there, before it has become organically united to the uterine walls.

The cavity of the uterus is lined by a mucous membrane, the peculiarities of which will be afterwards more fully described. This membrane appears to the unaided eye nearly smooth, and is usually of a pale pink colour, except in those cases where death has occurred during menstruation, when it is of a deep red hue, and more or less plainly vascular. A moderate amplifying power, however, suffices to show that the mucous membrane is not smooth, but is perforated everywhere by minute apertures, which are the orifices of numerous ramified canals or follicles occupying the substance of the mucous membrane, and lying for the most part in a direction perpendicular to the surface upon which they terminate. A few folds are occasionally perceptible in the mucous membrane, these being seen chiefly in the neighbourhood of the tubal orifices.

The apertures by which the Fallopian tubes enter the upper angles of the uterus are so small as only to admit of the passage of a fine bristle (*fig.* 406.). That by which the cavity of the body communicates at its inferior angle with the canal of the cervix has an average diameter of 1½‴—3‴. This orifice is the os uteri internum (*fig.* 431. *i*).

The following are the dimensions of the uterine cavity:—length 11‴—12‴; breadth between the points of entrance of the Fallopian tubes 11‴—12‴; at the centre of the cavity 4‴; at the os internum 1½‴—3‴.

The cavity of the cervix consists of a flattened fusiform canal running through the centre of the uterine neck. The widest portion occurs about the middle, where the canal measures transversely 3½‴—6‴ (*fig.* 431. *c c*), whilst towards either extremity the parietes gradually approximate so as to leave a narrow aperture at each end; the superior aperture being the orifice already described as the os uteri internum, the dimensions of which have been given;—the inferior being the os externum, or os tincæ, which measures 3‴—4‴ in transverse diameter. The antero-posterior diameter of the canal at its widest part is not more than 1½‴—2‴. The entire length of the cervical cavity is 12‴—13‴.

The mucous membrane lining this cavity is probably not greatly inferior in extent to that of the uterine body. But on account of the smaller space in which it is contained, instead of forming an even layer, the membrane is here thrown into numerous folds or plicæ, having intermediate furrows, often traversed by lesser plicæ, which extend the secreting surface, and furnish a more considerable seat for those numerous mucous crypts which abound upon almost every portion of this structure.

The forms which the cervical folds or plicæ assume are sufficiently remarkable to have attracted the attention of anatomists at all periods. They are, however, so variable, that if twenty specimens be compared together, scarcely two will be found to present precisely the same arrangement. On this account it is difficult to furnish any description of them which shall be universally applicable.

Nevertheless, two forms appear to me to be more prevalent than others. In one a single prominent raphé occupies the centre of each wall of the cervix. (*Fig.* 431. *c c.*) Commencing sometimes at a distance of $1\frac{1}{2}'''$—$3'''$ above the margin of the uterine lip and extending upwards either centrally or to one side of the median line, and reaching as far as the internal os, it terminates here in a bulbous expansion, or branches out into numerous small ramifications. From either side of this median perpendicular fold are given off lateral plicæ, varying in number, but being usually not less than 6—9. These soon bifurcate once or twice, so that the number of folds will vary considerably, according as they are counted immediately at, or at some distance from, their line of junction in the central raphé. The uppermost pair of lateral plicæ, or those next to the raphé, often exhibit the same bulbous extremity; and these together fill the upper or narrowest portion of the cervical canal. Lower down, where the canal becomes wider, the lateral plicæ spread out on either side of the central raphé, the upper ones in an oblique, the middle and lower ones in a more horizontal direction. These soon bifurcate, and form a series of oblique, horizontal, or arched laminæ, whose arrangement varies much according to the fulness of the folds, the depth of the furrows between them, and the distance by which the laminæ are separated. If the latter are prominent and very closely set, their margins may overlie each other, like the branchial laminæ of a fish, so that no intermediate furrows are perceptible; or the folds, not being very prominent, may merely lie in apposition, leaving no visible interspace until they are drawn asunder; but when the plicæ are less full and prominent a furrow is perceptible between each. These furrows of necessity take the same direction as the plicæ by which they are bounded.

In another common form which the plicæ assume, the general lines of folds and intermediate furrows take a more vertical direction, so that sometimes as many as six or eight of the more central laminæ may be traced running down side by side to the very margin of the cervical lips (*fig.* 424.). Here often the two most central folds appear to run up from one end to the other of the cervical canal; but still commonly one of these is more fully developed than the rest; its upper bulbous extremity occupying the position in the narrow portion of the cervical canal, already described, while its lateral divisions being more numerous than those of the plicæ next adjoining, it takes the office of a raphé, though its position may be, as it often is, more or less eccentric.

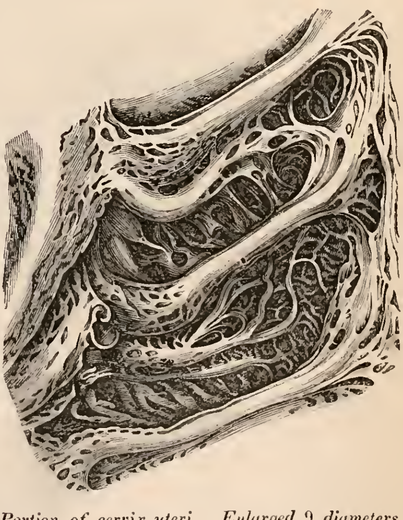
On either side of this principal fold the lateral plicæ arrange themselves, inclining more outwardly in proportion as they occupy a still lower place in the cervix. But in these cases the curves of the lateral plicæ are often very abrupt — the laminæ rising obliquely upwards, and then making a sudden downward bend like the ends of the leaves of a lily. This arrangement of the plicæ I think I have more often observed upon the posterior wall of the cervix, where the laminæ are usually thicker and bolder than upon the anterior wall, upon which the arrangement first described appears more commonly to prevail. But so various are the forms which the principal folds of the mucous lining of the cervix assume, that it is not possible to fix upon any one instance whose description, however minute and accurate, will serve as a strict example of the rest.

The more perpendicular the arrangement of the plicæ, the nearer is the approach to that form which is most commonly found in the terminal part, or neck of the uterus, in the mammalia generally, where the folds almost invariably take the direction of the long axis of the canal, reminding us of the arrangement of the plicæ in the Fallopian tube already described.

After repeated pregnancies these plicæ become much thickened and the folds more prominent, while their extremities exhibit a swollen and bulbous appearance resembling leaflets attached to the branch of a tree. Hence, apparently, the origin of the old term *arbor vitæ*, by which this structure was commonly designated; while to the more closely arranged plicæ, springing from a central shaft or raphé, the term *penniform rugæ* is more strictly applicable; and to those cases in which several parallel folds, after ascending obliquely, form a series of lateral arches, or suddenly bend over and then downwards, the title of *plicæ palmatæ*, or as some employ it, *palmæ plicatæ*, seems more appropriate.

Thus upon both walls of the uterine cervix the mucous membrane, being of greater extent than the surfaces which it lines, is gathered

Fig. 432.



*Portion of cervix uteri. Enlarged 9 diameters. (After Tyler Smith, and Hassall.)**

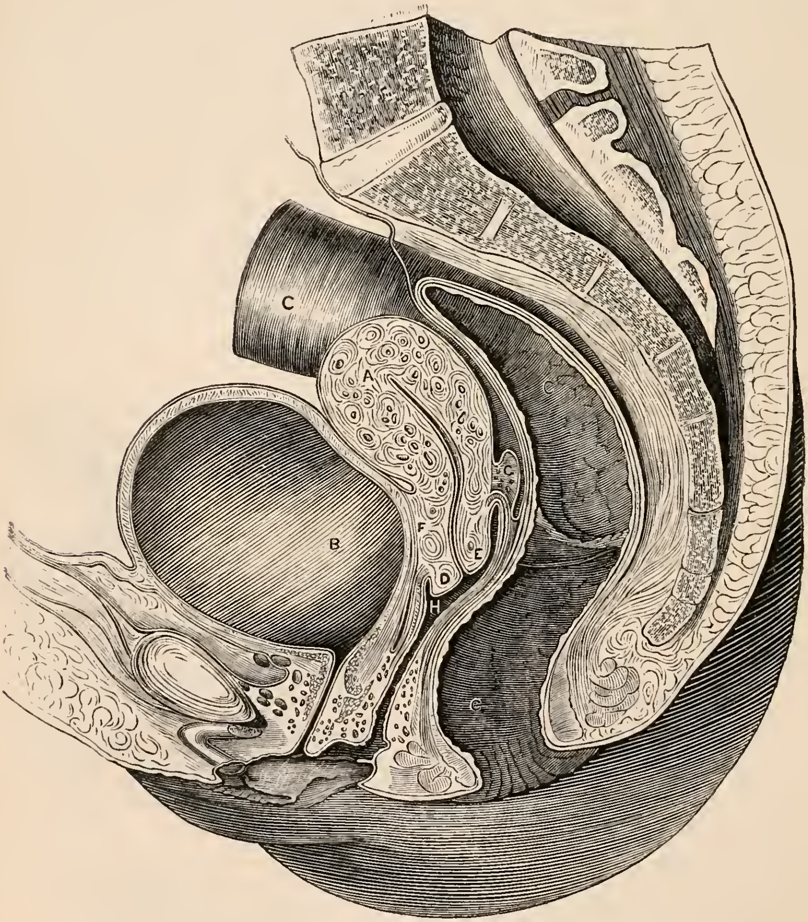
* This figure is from a valuable Memoir on the Pathology and Treatment of Leucorrhœa, in vol. xxxv. of the Medico-Chirurgical Transactions, 1852; where will be found also a description, with illustrations, of several of the natural and abnormal forms and conditions of the cervix.

into folds whose offices will be presently more specially considered. At the lateral lines of junction of the two cervical walls, where a crease or furrow is formed by the sudden bending of the parietes, an imperfect raphé is sometimes found, uniting a portion of the plicæ; but more commonly the laminæ of one surface either pass over and become united at their extremities with those of the opposite side, or else upon reaching the lateral angles they split up into smaller divisions, which are again gathered into the single folds upon the opposite side, their junction being then effected by the interposition of a cribriform surface.

The central raphé and lateral plicæ proceeding from it, under whatever form they may appear, constitute together a series of primary folds, from which others of a secondary order are produced. These emerge from either side of the lateral plicæ, and, crossing the furrows between them, subdivide again and again until the whole surface presents that cribriform aspect which can be just discerned by the naked eye, but cannot be accurately examined without the aid of the microscope. Here also are found in countless numbers these mucous crypts, which apparently furnish the peculiar secretions of this portion of the uterus (*fig.* 432.).

Structure and arrangement of the tissues composing the uterus.— The uterus is usually described as consisting of three coats, viz., an outer or serous, a middle or muscular, and an inner or lining membrane, commonly termed the mucous coat. But these coats cannot, like the three coats of an intestine, for example, be separately displayed, because each passes so imperceptibly into the others, that although to the naked eye an apparent distinction may

Fig. 433.



Section of female pelvis and its contained viscera. (*After Kohlrausch,*—reduced.*)

A, uterus; B, bladder; C C, rectum; D, anterior, and E, posterior lip of cervix uteri; F, connective tissue uniting the anterior wall of the cervix to the bladder; G, lax tissue between the posterior wall of the cervix and the peritoneum; H, vagina.

be observed, this distinction in a great measure vanishes under the application of the microscope.

Peritoneal coat. — The outer serous coat, which constitutes the thinnest of the three component tissues of the uterus, is formed of the centre of the principal fold of the broad ligament, which is closely applied to the uterine body and fundus, and to a portion of its neck.

It is of great importance to the comprehension of certain points in the pathology of the uterus, to be hereafter considered, that the relations of this peritoneal covering to the proper structures of the organ, as well as to adjacent parts, should be accurately determined. The most important of these relations are shown in *fig.* 433., representing a vertical section of the pelvis and its contents. In this view the reflexions of peritoneum over the centre of the uterus are shown. The membrane, after lining the abdominal walls, and covering the fundus, and a portion of the posterior surface of the bladder, is suddenly arrested in its descent at a point very nearly opposite to, but sometimes a little below the internal os uteri, and therefore about the seat of junction of the body with the neck of the uterus. Here the membrane forms a sharp fold or angle, and becomes immediately applied to the anterior face of the uterine body, while the cervix, which lies in great part, if not entirely, below this level is left uninvested. The peritoneum, then, after ascending over the anterior uterine wall, covers the fundus and sides of the organ, and descending upon the posterior surface, it remains closely adherent to the tissues beneath, until it reaches the level of the anterior point of reflexion. At this point the peritoneum becomes much more loosely connected with the uterus by the interposition of a quantity of lax connective tissue which intervenes between it and the posterior cervical wall (*fig.* 433, G). The membrane, however, still descends, covering first the posterior wall of the supra-vaginal portion of the cervix, and then a part of the fornix, or upper end of the vagina. The extent of peritoneal covering which the vagina receives, varies in different subjects from half an inch to nearly an inch. The membrane then, as before, turns upwards, but at a more obtuse angle, to invest the rectum, so that a pouch is formed, termed the recto-vaginal or retro-uterine pouch, which is sometimes of considerable size.

The adhesion of the peritoneum to the uterus is closest along the median line, and over the whole of the fundus, at which points its separation by dissection from the tissues beneath cannot be effected without the aid of prolonged maceration; but towards either side of the organ the connection is less intimate, so that here the membrane may be made to glide to a limited extent over the sub-lying structures. At the two upper uterine angles the peritoneum is continued on to the uterine appendages; viz., the Fallopian tubes, round ligaments and ligaments of the ovaries. After sending off extensions to invest these parts, the portions of membrane which cover the anterior and posterior faces of the uterus respectively come nearly into apposition along the lateral borders of the organ (*fig.* 427.), where they are conjoined by a quantity of lax fibrous tissue, which serves to bind them loosely together, and at the same time to give support and protection to the numerous blood vessels entering the uterus on either side along the whole of this border.

A similar portion of lax fibrous tissue serves to connect the anterior wall of the uterine cervix, where it is uncovered by peritoneum with the posterior surface of the bladder, with which it lies in contact.

The sectional views of the uterus in three directions already given serve to explain the whole of the relations of the outer or peritoneal coat of the uterus to the muscular or proper coat.

Fig. 426. shows the mode of attachment of this membrane to the anterior and posterior surface and fundus along the median line, and also the parts which are left uncovered by peritoneum. Commencing from the os uteri the vaginal portion of the cervix forming the anterior lip (*a*) receives an investment of mucous membrane as far as its point of attachment to the anterior wall of the vagina (*v a*). Beyond this the whole of the remaining portion of the anterior wall of the cervix, measuring above one inch in length (*b b*), is left uncovered either by mucous or serous membrane. At the termination of this space the peritoneum, reflected off from the bladder, reaches the uterus, and after investing the organ, is continued down to and beyond the fornix of the vagina (*f*). But at this point the mass of loose connective tissue before referred to separates the peritoneum from the posterior cervical wall to a great extent (*c*), while finally a much larger portion of the cervix is contained within the vagina, posteriorly than anteriorly, and is consequently covered by mucous membrane (*p*), because the vaginal walls are attached at a much higher point here than anteriorly.

Fig. 431. serves to exhibit the relations of the peritoneum to the fundus, and the absence of that membrane from the lateral borders of the uterus, while *figs.* 427.—430. exhibit the relative proportions of the covered and uncovered parts as seen in a series of horizontal sections of different portions of the organ.

The middle or smooth-muscular coat, upon which depends the remarkable firmness and solidity of the uterus, constitutes the principal bulk of the organ. This coat upon section appears of a pale pink colour, mottled with irregular white lines, and permeated by vessels which are particularly numerous near its lateral borders. The following are the component tissues of the middle uterine coat, viz.:—

1st. *Smooth-muscular fibres.* — These are found in every portion of this coat, and consist of fusiform fibres of the kind termed by Kölliker contractile fibre-cells, in which a single elongated oval nucleus may be occasionally brought into view with difficulty. They all contain minute dark granules easily distinguished, and they sometimes exhibit upon their surface slight longitudinal folds or markings. These fibres have an average length of $\frac{1}{1000}''$, and breadth of $\frac{1}{6000}''$. They are deeply imbedded in the uterine substance from which they are with difficulty obtained separate, but they may be commonly seen projecting to the extent of about half their length from the torn margin of the preparation, and they are easily rendered

Fig. 434.

Smooth-muscular fibre of uterus.

a, fibres united by amorphous matrix; *b*, separate fibre and elementary corpuscles. (*Ad Nat.*)

visible in its substance by the aid of dilute acetic acid. These fibres do not apparently possess any distinct cell membrane. In very thin sections the ends of the fibres which have been transversely divided are seen as if solid, and the cut fibres do not collapse, nor have I ever been able to detect any appearance of a flowing out of fluid contents, which would be the case if the individual fibres consisted of a cell wall containing fluid (*fig.* 434. *a*).

2. *Round and oval nuclei, or elementary corpuscles.* — These measure $\frac{1}{6000}''$ in diameter. They are found in many parts intermixed with the fusiform fibres, but they are most abundant towards the inner layers of the muscular coat. They are apparently the elementary or embryonic condition of the fusiform fibre-cells just described. For although the two extreme forms of round corpuscles and fusiform fibres are the conditions under which these constituents of the muscular coat are most numerously seen, there may yet be traced a sufficient number of apparently intermediate stages to justify the conclusion that the one is but the embryo form of the other; the round corpuscles becoming at first oval, and then being lengthened out into the fusiform state (*fig.* 434. *b*).

3. *Amorphous or homogeneous connective tissue.* — A considerable portion of connective tissue exists in certain parts of the uterus in the unformed state, constituting a transparent matrix in which the fibre-cells and nuclei are embedded, and by which they are so intimately united together, as to render their isolation, even with the aid of nitric acid, a work of great difficulty. The fibre-cells and nuclei which form the innermost laminæ of the muscular coat, as well as the laminæ themselves, appear to have scarcely any other connecting medium but this, especially in young subjects, while in the middle and outermost laminæ a large portion of fibrillated tissue is added, and the amorphous substance uniting the individual fibres into bundles is proportionally less in quantity.

4. *Fibrillated connective tissue* (white fibrous tissue). This, as just stated, is found chiefly among the middle and outer muscular laminæ, serving here the purpose of a connecting medium between the several layers, and supporting the blood-vessels ramifying between them. The presence of this form of fibrous tissue is most readily exhibited by taking a thin perpendicular section from the outer muscular layer, and slightly drawing the laminæ asunder, after submitting the preparation to the action of acetic acid. The layers and bundles of muscular fibre, as shown in *fig.* 437., are then seen to be surrounded by, and imbedded in, a quantity of white fibrous tissue which conceals the fibre-cells, and renders the distinguishing of them difficult.

The fibres of this tissue have clear and sharp edges, appear to be of indefinite length, are independent of each other, and are clearly not mere foldings in an amorphous substance. Among them, however, and especially at the points where the laminæ are separated, are seen numerous thin flat transparent bundles, marked by deep longitudinal wavy lines, to which the above explanation of the cause of the appearance of wavy lines in this tissue which many physiologists have adopted might be more safely applied. Occasionally these wavy bundles exhibit an appearance of sharp curling lines, such as would indicate the intermixture of a small quantity of elastic tissue.

5. *Elastic fibrous tissue.*—The elastic form of fibrous tissue is also present in the uterus, as just stated, though not in great quantity. Besides the occasional presence of strongly curled fibres there may be seen in many places developed single fibres matted together, of the finer kind, commonly known as nucleus fibres; and also more abundantly the peculiar fusiform formative cells from which these arise. I have frequently had the opportunity of tracing these peculiar dark-bordered cells in process of transformation into the finer elastic fibres, and so far of confirming those views which ascribe to this form of fibre a cell origin.

These several tissues together with the uterine vessels and nerves, the former being in great quantity, make up the middle coat of the organ. And it is to the arrangement of these in laminæ and bundles which are separated from each other, and perforated as it were in all directions by numerous vascular channels, that the mottled appearance of the unimpregnated uterus, as seen in sections, is due.

The foregoing constituents of the middle uterine coat exist in different proportions in the body and neck of the organ respectively. In the body, notwithstanding the considerable amount of fibrous tissue by which the several component elements are connected together, the muscular fibre, either in its elementary or more developed condition, constitutes the largest portion, while in the cervix the fibrous element predominates, and the muscular fibre is proportionally less abundant.

Course of the muscular fibres. — Regarding the precise plan of arrangement of the constituent tissues of the middle uterine coat, and especially of its muscular element, in the unimpregnated state, numerous microscopic examinations have satisfied me that it is not possible to do more than to indicate these in a very general manner. Mme. Boivin attempted to describe the special course of the muscular fibres in the unimpregnated organ; but she appears to have abandoned the attempt after giving an account of what is seen upon the surface of the organ when the peritoneum has been stripped off after prolonged maceration. More recently the course of these fibres has been described by Kölliker, Gerlach, and others, in the deeper seated, as well as in the superficial layers.

In investigating this part of the subject it appears to me that a sufficient distinction has not been made between the course of the individual fibres, and the arrangement of the laminæ or bundles into which they are collected, for these are by no means necessarily the same.

According to my observations the contractile fibre-cells are not distributed in equal proportions through all parts of the muscular coat, nor are they found everywhere in the same condition. It has been already stated, that no strict line of demarcation is discernible by the microscope between the three several coats, of which the uterus is said to consist. And this is particularly the case in respect of the muscular fibres which permeate all of them. In the so-called mucous membrane the muscular fibre-cells are loosely arranged in an amorphous tissue, in which they lie embedded, intermixed with the elementary nuclear corpuscles, constituting their embryonic condition. Here the fibre-cells form bundles, situated between the ramified canals or utricular glands of the uterus, and take a direction more or less oblique or perpendicular with regard to the inner uterine surface. But at the level of the base of the uterine follicles, where the proper muscular coat is considered to begin, and the mucous membrane to terminate, the contractile fibre-cells assume a different direction and arrangement. Here at once they begin to exhibit a certain order of stratification, the strata being very closely superimposed, and arranged for the most part in such a manner as to lie parallel with the walls of the uterine cavity, which is therefore surrounded by them.

These strata exhibit certain differences of composition and arrangement sufficient, for the sake of description at least, to justify an artificial division of them into three orders.

The innermost of these may be termed the dense muscular strata. They commence immediately external to the mucous membrane, and extend outwardly through about half or two thirds of the thickness of the muscular coat.

When preparations that have been preserved in weak spirit, or those that have been finely injected, are examined by the naked eye, or with a hand lens, a peculiar mottled appearance is presented by sections of this part,

Fig. 435.

Thin section of a portion of the uterine walls, commencing from the peritoneum and extending inwards, showing the irregular course of the strata of uterine fibre, and the divided vessels between them. (*Ad Nat.*)

caused by the intermixture of numerous minute white lines ramifying within a darker substance, and dividing it into a multitude of small lozenge-shaped spaces. The whiter lines mark the course of the finer uterine vessels, together with the bundles of white fibrous tissue which accompany them. The browner lozenge-shaped spaces consist of the fusiform contractile fibre-cells, united together by amorphous tissue into short bundles, which by their superposition constitute the laminæ just mentioned. When horizontal sections are made of this portion of the muscular coat, such as are represented in *fig.* 428., these bundles or strata are seen to be arranged in a concentric manner, forming interrupted circles surrounding the uterine cavity. But this appearance must not be regarded as indicative of any corresponding direction of the muscular fibre-cells, within these bundles or laminæ, for all appearance of a concentric plan, as regards the fibres, at once vanishes under the use of the microscope.

Fig. 436., representing a fine section taken from the inner muscular laminæ, serves to exhibit the mode in which the contractile fibre-cells are arranged in this portion of the uterine walls. The individual fibres and embryonic corpuscles are imbedded in an amorphous substance (the unformed connective tissue already described), by which they are aggregated together, so as to form bundles and laminæ. In these strata the fibre-cells appear to remain distinct, and to be separated from each other by a distance not greater usually than their own diameters.

This is best shown in fine sections, previously prepared by acetic acid; but it should be observed, that as this agent causes the intermediate tissue to swell, the normal distances between the cells may, to a certain extent, be thus artificially increased. The relation of the fibre-cells to the uniting material is most clearly exhibited in those parts of the preparation where the knife has divided the fibres transversely to their long axes. Here the relation of these two structures to each other may be exemplified by that of the harder and softer ingredients in certain portions of those geological formations termed conglomerate.

Fig. 436.

Portion of uterine tissue from the internal muscular layers. (*Ad Nat.* × 150.)

At the points where the knife has cut the fibres obliquely, a corresponding change is observable in the outlines of the divided fibre-cells, which present in these bundles the figure of caudate cells, while in other places, where the course of the fibres has run parallel with the surface of the section, the fusiform outline of the entire length of the fibre is distinguishable.

All these varieties of direction are noticeable in *fig.* 436., in a portion of uterine tissue not more than $\frac{1}{50}''$ in diameter. The fibres which are here seen forming bundles and layers, run in some instances parallel with the surfaces of the laminæ, and in other places spread out fan-shaped, or incline towards each other, like the component fibrillæ of the penniform muscles. The bundles and layers of fibres are close-set and compact, and a comparatively small amount of developed or fibrillated connective tissue is found between or among these elements of the innermost strata of the muscular coat. The fibre-cells also are here apparently softer and more fleshy, and appear to be of newer formation than those forming the layers which lie nearer to the peritoneum.

External to and surrounding these may be distinguished a second order of strata, among which the primary and secondary ramifications of the principal uterine arteries and veins are freely distributed; so that sections taken from this region do not present the same compact appearance as those from the inner layers, but are seen to be everywhere permeated by vascular channels, which are particularly conspicuous in the multiparous uterus. These numerous vessels, ramifying among the muscular fibres, make the course of the latter very irregular. When the section has been made parallel with the broad ligament, the tortuous arteries, entering the uterine texture between the folds of the latter, may be often traced to a considerable depth among the laminæ; while sections made in an opposite direction more frequently exhibit the gaping orifices of these vessels, and of the divided veins surrounded by laminæ of muscular fibres, and of a more lax and fibrillated form of connective tissue, than is found among the inner strata. This intermixture of the larger uterine vessels with the muscular strata constitutes here a very characteristic feature, and hence these middle strata may be distinguished as the vascular laminæ of the muscular coat.

External to these again lie a series of thin sheet-like laminæ (*fig.* 437.), forming a tegumental stratum which does not entirely surround the organ, nor cover it in all its parts. It consists of 6—12 thin close-lying layers of fibres, whose course is parallel with the uterine surface; the most external laminæ being inseparable from the peritoneum by which they are covered. These flat, thin, layers are continuous with and extended upon and into the broad and round ligaments, the Fallopian tubes, and the ligaments of the ovary, from which they spread out fan-shaped over the fundus and upper portion of the anterior and posterior uterine walls; meeting at length in a central perpendicular raphé, in which a few longitudinal bundles may be generally seen.

These tegumental laminæ are composed almost entirely of fusiform fibres, with very few embryonic corpuscles. They are united together by a large proportion of strongly fibrillated connective tissue, which is, however, sufficiently lax to permit a certain amount of artificial separation of the laminæ.

Fig. 437.

Portion of uterine tissue from the external muscular layers close to the peritoneum. (*Ad Nat.* × 150.)

Within these laminæ the fibre-cells are arranged in a manner somewhat different from that which characterises the internal strata. The amount of amorphous connecting matrix is here so small that the fibre-cells lie apparently in close apposition, their extremities interdigitating with each other, so as to form an imbricated pattern (*fig.* 434.). These fibres do not so frequently change their course as the fibres of the innermost strata, but form a more continuous series; so that sections of this part of the muscular coat are easily obtained, exhibiting the appearance of longitudinal strata, or bundles of fibre, such as are represented in *fig.* 437. The course of the individual fibres within them is, however, traced with difficulty, on account of the large quantity of fibrillated connective tissue by which these layers are surrounded and conjoined.

Immediately beneath the peritoneum all the constituents of the muscular coat are condensed into a tissue which cannot be easily unravelled. Through this, however, numerous fibres may be seen to run in a direction more or less perpendicular to the surface, apparently for the purpose of connecting the peritoneum with the coat beneath.

The mucous or deciduous coat; Lining membrane of the cavity of the uterus.—This forms a moderately thick and soft layer which lines the entire cavity of the uterus, and is continuous with the lining membrane of the Fallopian tubes, and of the cervical canal. On account of the large supply of capillary vessels which it receives, the mucous membrane is usually distinguished from the rest of the uterine parietes by its brighter red colour. It presents also to the unaided eye, when horizontal sections are examined, an appearance of being thrown into minute folds running perpendicular to the uterine cavity (*fig.* 438.). These apparent foldings, however, are shown by a strong lens to consist of a series of ramified canals, which constitute the most remarkable peculiarity of this membrane. The proportionate thickness of the mucous membrane relatively to the rest of the uterine walls, though variable in respect of age and other circumstances, is usually about $\frac{1}{8}$th of their diameter. Its greatest thickness is found about the middle of the cavity, while towards the internal os uteri, and still more in the region of the fundus, the thickness is slightly diminished.

To the unaided eye, the mucous membrane lining the body of the uterus, when viewed from the uterine cavity, is apparently smooth, or is seen to be perforated by minute apertures, but it rarely presents the appearance of deep folds or plicæ such as are always found in the cavity of the cervix. Occasionally the surface is roughened and flocculent from the exfoliation of its epithelial covering. The appearance of minute perforations is then lost, and a tomentose or apparently villous condition of the surface occasioned by the loosening out and partial detachment of the capillaries which freely ramify within this membrane is observed.

The lining membrane of the uterus differs from mucous membranes in general in having no sub-mucous tissue, so that it cannot, like that of the intestines, be made to glide upon the sublying tissues, nor be dissected off from them so as to be displayed in a distinct layer. When very thin sections from spirit preparations are examined by transmitted light with a common lens, or with a low power of the microscope, the mucous is distinguishable from the muscular coat chiefly by its greater opacity and peculiar greyish colour, as well as by the numerous tortuous canals which permeate its substance, running chiefly in a direction perpendicular to the inner surface of the membrane, and strongly resembling in their general contour the cerebral convolutions.

Under the application of dilute acetic acid this comparative opacity and grey hue immediately disappear, and the tortuous canals alone serve to mark the boundary between the two coats. When an amplifying power sufficient to discriminate the component tissues is employed, the distinction between the two coats becomes still less apparent, because their constituent elements are then seen to pass from the one to the other by almost imperceptible gradations, the difference between them being then shown to be morphological rather than structural, at least, at the points of their confluence.

The mucous membrane lining the uterine cavity is composed of the following elements, besides the utricular glands, capillary vessels, and epithelium, viz., — free elementary corpuscles or nuclei, contractile fibre-cells, and amorphous connective tissue.

1. *Free elementary corpuscles or nuclei.* — These are in all respects precisely similar to the elementary corpuscles already described as constituting apparently the embryonic state of the contractile fibre-cells in the muscular coat. They form in conjunction with the amorphous matter the principal portion of the uterine lining membrane towards its inner surface. Here they are arranged in nearly close apposition, being imbedded in an amorphous blastema, yet not so closely as to cause any mutual disturbance of their round or oval forms.

2. *Fusiform fibres or contractile fibre-cells.* — In the account which has been already given of the muscular coat, the contractile fibres are described as existing in all the coats of the uterus. In the mucous membrane they are very abundant, especially towards the outer surface, or that part in which the muscular and mucous coats become conjoined, and where the transition from the one to the other is almost imperceptible, and is chiefly observable on account of the difference in the arrangement of the constituent tissues of each. The fusiform fibres of the mucous membrane are gathered into loose bundles, united by amorphous tissue and intermixed with the elementary corpuscles from which they are developed. These bundles, the form of which is sometimes like the head of an arrow, are usually found between the utricular glands, pointing in a direction perpendicular to the uterine cavity.

The individual fibres have here a softer, paler, and more fleshy aspect than in any other portion of the uterine coats; they are apparently the youngest and most newly formed of the muscular fibres composing the uterus.

3. *Amorphous connective tissue* constitutes the chief bond of union between the several elements of the uterine mucous coat, and enters largely into the composition of the utricular glands. It presents no special character requiring a more particular description than has been already given of it in the account of the muscular coat.

Utricular glands or follicles. — These structures, which were first more particularly described by E. H. Weber and Professor Sharpey, constitute the most remarkable characteristic of the uterine mucous membrane.

By Reichert *, who has also investigated the subject, they were found present in every mammal which he had examined. The uterine glands or follicles consist of involutions or depressions of the mucous membrane, which are exceedingly numerous, and lie tolerably close together. They generally present the form of canals taking their course from the muscular walls of the uterus, through the substance of the parenchyma of the mucous membrane towards its free surface, where they terminate each in a separate orifice.

In Ruminantia and Pachydermata they are large, and take a serpentine direction, so that they may be easily mistaken for vessels. By Burckhardt †, indeed, who has described them in the cow, they were termed vasa spiralia. Their spiral course is more obvious in the rodentia and carnivora. In the rabbit they are short and wide. The orifices by which the utricular glands terminate upon the surface of the mucous membrane are in some animals large enough to be distinguished by the naked eye, as, for example, in ruminants, and occasionally in man; but more frequently these require the aid of a lens for their detection.

In the dog, two sorts of glands are described by Professor Sharpey ‡, simple and compound. The simple glands, which are the more numerous, are merely very short unbranched tubes closed at one end; the compound glands have a long duct dividing

* The composition of the mucous membrane of the uterus has been carefully investigated by Robin and Reichert; vide Robin, "Mémoire pour servir à l'Histoire Anat. et Path. de la Memb. Muqueuse Utérine; Archiv. Gen. de Méd. iv. série, tom. xvii.; Reichert, Ueber die Bildung der hinfälligen Häute; Müller's Archiv für Anat. Phys. 1848.

† Observ. anat. de Uteri Vaccini Fabrica.

‡ Müller's Physiology, by Baly, 1837, p. 1574.

into convoluted branches; both open on the inner surface of the membrane by small round orifices, lined with epithelium, and set closely together.

In man the form of the uterine follicles is by no means so definite as in the dog; nor is it possible by any mode of dissection with which I am acquainted to isolate and display them separately.* They form in fact a system of tortuous canals ramifying in the substance of the mucous membrane, in which they seem as it were to be excavated. They are so closely set as apparently to possess no distinct boundary wall, but each canal is separated from those contiguous to it by a variable thickness of parenchyma, consisting chiefly of the elementary corpuscles and amorphous tissue just described, together with a certain admixture of fibre-cells, usually found near the basal ends of the glands. No section that I have ever made has succeeded in exhibiting even a single gland divided longitudinally in such a way as to lay open the canal in its entire length, but every section made perpendicular to the surface presents the same appearance of numerous close-set meandering canals laid open for short distances, and giving to the surfaces of the section an outline

Fig. 438.

Section of the entire thickness of the uterine mucous membrane (decidua) in the unimpregnated state, with a small portion of the muscular coat attached.

The pale tortuous lines exhibit the course of the canals, termed uterine glands, the darker intermediate substance forms their walls. The finer lines are the capillaries of the mucous membrane injected. (*Ad Nat.*)

exactly resembling the cerebral convolutions. On account of this peculiarity it is difficult to determine whether these so-called glands consist of single isolated canals, or of a series communicating with each other. For the same reason it is also difficult to ascertain the precise mode of their termination towards the muscular coat, whether in a blind extremity in every case, as Weber represents them, or whether by any indirect communication with the uterine vessels, which many considerations both physiological and pathological seem to point out as at least possible. The difficulties attending this part of the enquiry have been ably illustrated by Dr. Sharpey, and my own investigations fully confirm his statements upon this point. Nevertheless I have in many instances succeeded in distinctly observing the blind termination of these canals towards the muscular coat.*

When sections of the mucous membrane are made parallel with, instead of perpendicular to, the surface, these canals are seen divided across. The appearance then presented is that of numerous round or oval apertures, which are more distinct in proportion as the section is made nearer to the uterine cavity.

The uterine glands are lined by a fine dentate epithelium, the cells of which are only slightly coherent at their margins.

The orifices by which they terminate upon the surface of the uterine cavity vary in diameter from $\frac{1}{200}''$ to $\frac{1}{500}''$.

In addition to the glands or canals already described, there may be often observed intermixed with them short mucous crypts, or even closed follicles. These appear to have been little noticed in the uterine cavity, but they are very distinctly seen when accidentally distended by accumulation of fluid. They then constitute a variety of those growths, which in more advanced stages have been designated by Dr. Oldham channel polypi.

The arrangement of the *capillary vessels* of the uterine mucous membrane is peculiar and

Fig. 439.

a, from the body; *b*, from the canal leading to the Fallopian tube. In the centre of each of the meshes is the orifice of a uterine gland. (*Ad Nat.*)

characteristic. The capillaries, which are of large size, usually descend between the canals of the uterine glands, giving to them a few

* It appears to me that the well-known representations of the human uterine glands by E. H. Weber (Zusätze zur Lehre vom Baue und den Verricht der Geschlechtsorgane, Taf. viii. f. 4, 5.) are too definite, and should be regarded rather as diagrams than actual representations of what is seen in any mere section. Though it should be observed that these figures are taken from the pregnant uterus where the glands have enlarged and become more distinct.

* Upon this subject see further, p. 666.

small branches in their course. Having reached the surface of the mucous membrane they spread out into a meshwork of round oval and hexagonal spaces, in the centre of each of which may be usually observed the orifice of a uterine gland. This is most easily seen in the neighbourhood of the Fallopian tubes, where the capillary network and glandular orifices are usually arranged with greater regularity than in other portions of the uterine cavity.

In many places, however, the small vessels furnishing the capillaries of the mucous membrane may be seen in injected preparations, lying close beneath the surface with which they run parallel, and if the veins have been filled, one or two principal ones may be noticed on each half of the median line, running in the longitudinal direction, and communicating by short branches with the capillaries just mentioned, from which the blood is thus conveyed away through the muscular walls to the larger veins.

The network of capillaries thus formed lies very superficially with regard to the uterine surface. The layer of epithelium covering them, and the nuclear corpuscles and amorphous tissue supporting them, appear to have so little cohesion, and to form so slight a protection, that the vessels are often seen to be nearly bare, while in some instances the individual capillaries may be observed hanging out loose into the uterine cavity, and giving to its surface a villous appearance. This constitutes one of those conditions which have led many anatomists to assert, and more to deny, that the mucous membrane of the cavity of the uterus is furnished with true villi.

Structure and arrangement of the tissues composing the cervix. — The cervix is composed of nearly the same elements as those which form the body of the uterus, but they are differently proportioned and arranged in the two organs.

The cervix cannot be said to consist, like the body, of three coats. It receives a covering of peritoneum only upon its posterior surface, while the anterior wall, as well as the lateral borders, remain uninvested. With the exception, therefore, of this partial covering, the cervix consists of a muscular and a mucous coat only (*fig.* 426—431.).

Muscular coat of the cervix. — On account of the large admixture of fibrous tissue with the muscular element here existing, this might with almost as much propriety be called the fibrous coat of the cervix. The muscular element of the cervix consists of the same fusiform fibre-cells as in the body; but the elementary corpuscles are here scantily seen. The fibrous element consists of long detached fibrils or of bundles of fibres of white fibrous tissue intermixed with much unformed material of the same kind, but stronger and tougher than that which unites the constituents of the muscular and mucous coats of the uterine body.

These several tissues are arranged in a manner not materially different from the plan already described as observable in the body of the uterus. But the thin external strata which form the tegumental layers of the body are wanting in the cervix. There may, however, be distinguished an outer and more vascular, and an inner and more dense series of laminæ. The laminæ of the outer series are intermingled with numerous divisions of the cervical branches of the uterine vessels which traverse them obliquely in a direction from above downwards and from without inwards. From the abundance of these vessels the external laminæ present a more spongy appearance, and when the part has been injected a much deeper colour than the inner layers, which are paler, more dense and closely set, and exhibit at the same time fewer sections of vessels, and these only of the finer kind. The large amount of white fibrous tissue, and the density and compactness of the laminæ here formed around the cervical canal, give to clean sections of this part an appearance of circles concentrically arranged. But a low magnifying power is sufficient to resolve these into the lozenge-shaped spaces already described, consisting of bundles of contractile fibre cells bordered by fibrous tissue, and intermingled with bundles of the latter and blood-vessels of various sizes. Within these laminæ and bundles the fibres take their course with as many variations in direction and plan of arrangement as are noticeable in the muscular fibres of the rest of the uterus. (See *fig.* 436.)

The larger proportion of the fibrous element in the neck as compared with the body of the uterus, which the microscope serves to display, and which to a certain extent is observable to the naked eye, may be more satisfactorily shown by the operation of dilute acetic acid; this agent causing thin sections of the part rapidly to swell out and assume a gelatinous appearance.

Mucous coat of the cervix. — This is composed of epithelium, basement membrane, and the usual fibrous and vascular tissues, together with certain papillæ and follicles. It is of a more dense and uniform texture upon the outer or vaginal portion of the cervix than within the canal, where it is more delicate, but being here thrown into numerous folds and rugæ, an appearance is given of greater thickness than the membrane really possesses. The average thickness of the mucous membrane upon the lips of the cervix is $\frac{1}{2}$ — $\frac{1}{3}'''$; that of the membrane within the cervical canal, regardless of the folds, is somewhat less. The general plan of arrangement, and some of the more prominent forms which this membrane assumes within the cervical canal having been already considered, it only remains here to describe the minuter structures of which it consists.

The epithelium of the outer or vaginal portion of the cervix is tessellated or squamous. It gives a smooth and even covering to the two lips of which this part of the cervix consists. Outwardly, this scaly epithelium is continuous with that of the vagina, but towards the os uteri it terminates at the margin of either lip. Within the cervical canal the epithelium changes its form. It has been described here as constantly cylindrical or dentate; but upon all the finer structures here found, such as the filiform papillæ, this so-called epithelial covering consists, as Reichert has well described, and Kilian accurately represented it, of elementary cells, whose cell membranes are closely united together, having a polyhedral outline, and without undergoing such an amount of flattening as to lose their spherical form. They contain a slightly flattened nucleus with several nucleoli, surrounded by a clear somewhat thick fluid intermixed with molecular bodies, and sometimes oil globules.

Some difference of opinion exists as to the part of the cervical canal in which the epithelium first becomes ciliated. Drs. Tyler Smith, and Hassall, who have examined numerous uteri at an early period after death, with a view to anticipate post-mortem changes, state that the ciliation of the epithelium commences in the rugose portion of the canal, and extends up to the fundus, while the epithelium just within the os, though also cylindrical, is not ciliated.* It should be observed, however, that there is no particular portion of the cervical canal in which the membrane constantly becomes rugose, but that the rugosities often extend quite down to the margin of the os. According to Henle †, the cervix is provided with ciliated epithelium from the middle upwards, and with pavement epithelium from that point downwards.

One peculiarity or variety in the arrangement of the epithelium upon the vaginal portion of the cervix requires special notice here on account of the singular degree of importance which has of late years been attached to it, and still more from the remarkable pathological speculations to which it has given rise.

It occasionally happens that the tessellated epithelium of this part, instead of extending as far as the os, abruptly ceases at a distance of one or two lines from the inner margin of either or both lips, leaving a single or double crescentic patch where the ordinary pavement epithelium is replaced by a crop of close-set filiform papillæ, projecting very slightly, if at all, above the general surface, and presenting to the touch that velvety feel, and to the eye, on account of their great vascularity, that florid aspect, which has often led to the supposition that this mere morphological variety of structure is the result of a pathological change, and that it constitutes a form of ulcer peculiar to the os uteri.

Beneath the epithelium is a *basement membrane*, which, upon the outer portion of the cervix, extends in a smooth lamina over the papillæ that everywhere crowd this part, but within the cervical canal it dips into the furrows and follicles, or covers its numerous rugosities and projections.

An unequal layer of *fibrous tissue*, traversed by vessels, and supporting and containing the numerous papillæ and mucous crypts of various forms and sizes which characterise the cervical mucous membrane, completes this structure. Tough and coriaceous upon the outer portion, and thinner and more delicate within the canal of the cervix, it forms the chief substance of the mucous membrane, and lies immediately upon the muscular coat, the fibres of which become intermingled with it.

The papillæ, or villi, as they are sometimes termed, of the cervix, exhibit considerable varieties of size and figure, being conical, verrucose, or tuberculated, dentate, clavate, and filiform. The clavate papillæ are usually found fringing the surface and margins of the thinner plicæ. The dentate usually form a border to those which are a little more fleshy, and are commonly seen at the margins of the lateral and upper mucous folds. The verrucose papillæ are seen in various situations, but are most constantly observed in the sharp lateral furrows which constitute the lines of demarcation between the two cervical walls. The filiform papillæ are the finest of all. They are more slender and pointed than the clavate. They occur under two forms, and in two situations.

One of these forms is invariably present on the outer or vaginal part of the cervix. The whole of this portion, from the margins of the os outwardly, is covered by numerous short close-set thread-like papillæ, invisible to the naked eye, but with the help of a sufficient amplifying power easily distinguished by their white colour, through the somewhat dense layer of pavement epithelium and basement membrane that closely covers and binds them down. Similar papillæ clothe the inner surface of the vagina, and form, with those just described, a continuous layer.

The filiform papillæ constituting the second variety are larger and longer than these, so that they may be discerned by the naked eye. They occur usually at the margins of the os, and may be traced to a variable distance within the canal. But their presence here is uncertain, while that of the former variety is constant in the situations indicated. These larger filiform papillæ may be sometimes seen to form the terminations of the longitudinal cervical plicæ in those cases where parallel folds run down to the very margins of the os uteri. Here the folds, each ending in a little tuft or tassel, form by their junction a close-set crop of villi, which may merely border one or both lips with a narrow fringe, or form a velvetty patch extending outwardly upon the lips of the cervix, and being here uncovered by the ordinary dense epithelial layer of this region, which, as just stated, sometimes, terminates at this spot with an abrupt margin, they may present the appearance already described as simulating an ulcer.

Regarding the *minute structure and composi-*

* Memoir on the Pathology and Treatment of Leucorrhœa, based upon the microscopical anatomy of the os and cervix uteri.—Med. Chir. Trans., vol. xxxv. 1852.

† Allegem. Anatom., p. 246.

tion of the papillæ, all but the finer kinds may be viewed as consisting of the same elements as the mucous membrane itself, for they appear to be produced by mere notchings or indentations, extending more or less deeply into that membrane; they are, in fact, little more than repetitions of the plicæ and sulci upon a smaller scale, with a slight difference of form. They serve to extend the secreting surface, and possibly to expose a larger aggregate superficies of vascular and nervous tissues.

One or more long and slender blood-vessels may usually be traced from the muscular coat running into each papilla. These are sufficiently conspicuous in thin sections without the aid of injections. By the aid of the latter they may be seen to terminate in vascular loops upon the ends of the papillæ, just as similar vessels may be observed to form wavy coils upon the crests of the plicæ by which the cervix is lined.

The filiform papillæ, both larger and smaller, are more finely-constructed than the rest. They often end in a slightly bulbous extremity. Those upon the outer portion of the cervix are usually single, their length being from two to six times that of their breadth. The free uncovered filiform papillæ of the cervical canal and margins of the os are relatively much longer. These latter are commonly branched, and in conformation occasionally resemble the early villi of the chorion. Each villus, whether single or ramified, contains usually a single capillary loop, which returns upon itself, and at the base passes on to another villus. Covering the capillary loop is a delicate basement membrane, uniting together the clear granule-holding nucleated cells, which constitute the epithelial covering as well as the substance of the villi, and of which a description has been already given.

No nerves have been traced into the papillæ, though Kilian* is of opinion that they are specially tactile or sensitive structures, and from various circumstances to be hereafter considered, it will appear probable that they are connected with the special nervous attributes of the cervix. I am disposed, however, to regard the sensibilities of the cervix, such as they are, as resident chiefly in the filiform papillæ.

The *mucous crypts or follicles* of the cervix are, for the most part, simple depressions in the mucous membrane, although in certain situations they penetrate more deeply, and approach in form the ramified and tortuous canals of the uterine body. Scarcely any portion of the cervical canal is free from these follicles, which serve to increase the extent of mucous surface, and apparently to furnish the special secretions of this part. They not only fill all the interspaces between the primary and secondary folds, but they are dotted over the ridges and prominences of the cervical lining membrane in countless numbers, extending from the internal to near the external os uteri. They commonly cease at a short distance from the margins of the latter, where a smooth space is often observable in one or both cervical walls. But they may be sometimes perceived at the very border of the lower orifice, and when in such a case one or both lips are slightly everted, as for example in certain hypertrophies of the cervical lining membrane, this follicular portion becomes protruded, while its florid colour, limited by an abrupt margin of the unaltered and paler squamous epithelium here suddenly commencing, an appearance is produced which may also easily be confounded with an ulcer.

The mucous crypts seldom extend beyond the border of the os, except in the cases just quoted, when, in fact, the relative situation only of the parts is changed. A few, however, may be sometimes seen scattered at tolerably regular intervals over the vaginal portion of the cervix. They sometimes also occur here, as well as within the cervix, and even in the uterine cavity, in the form of closed vesicles containing an opaline fluid, and perhaps may be regarded as in some instances pathological new formations.

The cervical mucous crypts are lined by epithelium and basement membrane. They contain a small quantity of mucus, together with granule cells. Those upon and near the margins of the os uteri may be sometimes observed to contain short papillæ within their margin.

Blood Vessels of the Uterus.

The Arteries are derived from two sources, viz. from the internal iliac and the ovarian or spermatics.

The vessels supplied from the former source are termed the uterine arteries. These are two in number, one for each side. They arise from the anterior division of the internal iliacs, and proceeding downwards and inwards pass between the folds of the broad ligament to the neck of the uterus. Here they take an upward course along the lateral border of the organ, describing several flexuosities, and giving off, in succession, branches to the upper part of the vagina, the neck, body, and fundus of the uterus; the latter inosculating with the branches derived from the spermatics. Free inosculations also take place in the substance and upon the surface of the uterus between the branches of the two sides, so that the entire uterus may be injected from either set of vessels.

The branches derived from the spermatic or ovarian arteries also enter between the folds of the broad ligament, and inosculate with the superior divisions of the uterine vessels near the fundus of the organ.

When, after a successful injection, thin slices are cut from the substance of the uterus and dried, and afterwards placed in Canada balsam, the whole appears to be a mass of vessels; the arrangement of which, however, may be easily

* See a valuable paper by Franz M. Kilian, entitled, Die Structur des Uterus bei Thieren, in Henle and Pfeufer's Zeitschrift, IX. Bd.

observed by a hand lens or a low power of the microscope. Many of the arteries down to $\frac{1}{10}'''$ or $\frac{1}{15}'''$ in diameter are still seen to take a remarkable corkscrew course, with numerous very close spirals, especially in the outer half of the sections. Beyond these the vessels take a straighter course, and at length, in their finer divisions, run in parallel lines, sending off minute twigs at right angles, which cross the ultimate fibres of the tissue, in the manner peculiar to muscular structure.

When the finer vessels of the *body* of the uterus have reached the mucous membrane, they dip down between the walls of the canals, termed uterine glands, and spread out in a network of capillaries; the meshes of which surround the orifices of those canals in the manner delineated in *fig*. 439. *a* and *b*.; and from these the blood is again collected by the small superficial veins, the course of which is described at p. 637.

The arteries which supply the *cervix* penetrate that part in a direction downwards and inwards, pursuing the same corkscrew course until they have nearly reached the mucous surface, where they break up into finer vessels and capillaries, which ramify over the rugæ in lines more parallel than those of the uterine body. Both the arteries and capillaries of the cervix are far less numerous than those of the body of the uterus; and, indeed, the cervix generally in respect of its composition exhibits a lower degree of organisation than that of the principal portion of the organ, although it appears to receive the largest supply of nerves.

The *veins* of the uterus take a course corresponding with that of the arteries, and are distinguished by the same names. They are considerably longer and more numerous than the latter. They form along the sides of the uterus and within the folds of the broad ligament a very considerable plexus (the uterine plexus), which, together with the venous channels or sinuses ramifying in the uterine substance, are more conveniently examined in the gravid organ, where they undergo great enlargement. See *figs*. 444. 449. and 453., and the descriptions of these.

Lymphatics. — These vessels are far more easily examined in the gravid than in the unimpregnated uterus. They are very numerous, and are divided by Cruveilhier into two orders; the superficial, which lie immediately beneath the peritoneum; and the deep-seated, which ramify in several places in the substance of the uterine walls. The lymphatics of the cervix terminate in the pelvic and sacral glands. Those of the body of the uterus, after traversing the broad ligaments and uniting with the lymphatics proceeding from the Fallopian tubes, ovaries, and round ligaments, empty themselves in the glands situated in front of the aorta and vena cava.

Nerves. — The nerves which supply the uterus are derived partly from the spinal, but principally from the sympathetic system. According to the dissections of Dr. Snow Beck *, the nerves which compose the hypogastric plexus, consisting of gelatinous and tubular fibres derived from the lower part of the superior aortic plexus *, on approaching the neck of the uterus begin to separate, and on a level with the os uteri are joined by branches which accompany the superior hæmorrhoidal artery. The anterior portion of the hypogastric plexus, after receiving branches which accompany the iliac arteries, passes inwards by the broad ligament, and supplies the lower half of the uterus. These nerves, which are continuations of the hypogastric plexus, as they approach the body of the uterus separate, and each pursues a different distribution. They lose the plexiform character and form a number of distinct fine cords.

These nerves, like all the nerves supplied to the uterus, are chiefly composed of gelatinous fibres, although some tubular fibres accompany them; but they are few in number, and appear to be far from forming the essential element of the uterine nerves.

The middle portion of the uterus is supplied by a distinct branch from the inferior aortic plexus; which, without communicating with the hypogastric branches, passes to the upper part of the uterine body and then divides, to supply the part between the previously described branches and the Fallopian tube, sending also a branch to the ovary.

The fundus is supplied sometimes by a

* Phil. Trans., 1846, part ii. p. 219.

* According to Dr. Snow Beck, the white tubular fibres which enter, pass through, and emerge from the *semilunar ganglia*, are all derived from cerebro-spinal nerves through the medium of the *splanchnic nerve*, while none of the tubular fibres actually arise from the ganglia (as Bidder and Volkmann suppose). The same was found to obtain in every instance of sympathetic ganglia examined; the tubular fibres could always be traced to the white connecting cord between the spinal and sympathetic nerves, and thence to the branch of the spinal nerve from which it is derived. The gelatinous fibres, on the other hand, all take their origin in the corpuscles of the ganglia. In the white cords connecting the spinal and sympathetic nerves, commonly regarded as roots of the sympathetic, the tubular fibres composing these, on being traced back to the spinal cord, were found to be derived from the motor and sensitive roots in apparently equal proportions. The elements of the lower part of the *superior aortic plexus* resemble those which form the semilunar ganglia, viz. tubular fibres derived from the lumbar nerves, and gelatinous fibres from the sympathetic ganglia.

The *inferior aortic plexus* is a continuation of the branches from the plexus last described. These divide to form the two lateral hypogastric plexuses, and here a crossing of fibres of the opposite side takes place.

The *lateral hypogastric plexus* is composed of gelatinous and tubular fibres derived from the superior aortic plexus. The distribution of nerves to the uterus from this, their main source, is described in the text.

The *sacral nerves*, although they supply the vagina, clitoris, labia, sphincter and levator ani, bladder, and rectum, send no direct branches to the uterus; nor is there, according to this author, any anatomical evidence to support the supposition which some have entertained, that filaments derived from these nerves might by a circuitous route reach the uterus after their union with the *pelvic plexus*. Phil. Trans., 1846, part ii.

branch which proceeds from the renal plexus in company with the spermatic artery, and is distributed also to the ovary.

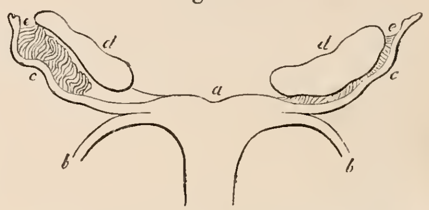
Another set, distinct from these nerves, comes also from the same continuation of the hypogastric plexus, but forms a plexiform arrangement around the vessels; and among these are found here and there minute ganglia. These nerves are very minute.*

The Development of the Uterus, and the Metamorphoses which it undergoes at Different Periods of Life.

a. The origin of the uterus, and its condition during fœtal life. — In the human embryo, according to the observations of Müller, during the transformation of the Wolffian bodies, the efferent tube of the generative apparatus undergoes the following modifications. In the male, all that portion of the efferent tube which passes along the outer border of the corpus Wolffianum is thrown into strongly marked convolutions, and this part contributes to the formation of the epididymis, while below this point the convolutions cease; and here a band or ligament, the gubernaculum testis of Hunter, which had been developed at a still earlier period, passes off to the inguinal canal. In the female, the following transformation occurs. The tube here remains free from convolutions, but a ligament, resembling that of the male, which is afterwards converted into the ligamentum uteri teres, passes off from the same point, to be extended to the inguinal ring. The part of the tube which lies below this point becomes the cornu uteri, and it is by the coalescence of the two cornua at their lower extremities that the body of the uterus is formed in man; while in those animals in which no middle portion or body exists, the cornua remain ununited. As the development of the uterus proceeds, the two cornua become gradually shorter, until at length they are lost, or, as it were, absorbed into the body or fundus of the uterus, which is thus at the same time developed.

The accompanying figure, representing the

Fig. 440.



The entire internal generative organs, from a fœtus of three months. (After J. Müller × 8.)

a, uterus; *b*, round ligaments; *c*, Fallopian tubes; *d*, ovaries; *e*, remains of Wolffian bodies.

condition of the fœtal uterus at about the end of the third month of gestation, serves to illustrate these particulars. The ovaries possess the elongated form characteristic of the early condition of these organs. Parallel with them run the Fallopian tubes, and between these are the remains of the Wolffian bodies. At the point where the round ligaments are given off, the cornua uteri begin, and by their junction, which is here not yet complete, so that a slight indentation is left, the uterus is formed.

From this period of embryonic life, the uterus keeps pace in its growth with the other

Fig. 441.

á, pavilion of the left side; *a*, the same of the right side (below it, in this specimen, is the remarkable variety of two separate accessory pavilions *b* and *c*); *d*, Fallopian tube, exhibiting numerous sinuosities in its outer half; *f*, round ligament; *e*, ovary.

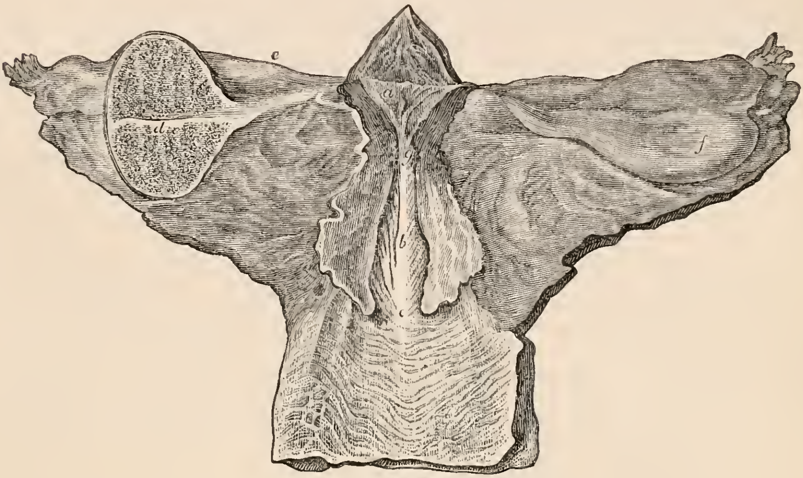
viscera; and at the time of birth it forms an organ of considerable size, lying high up in the pelvis, and occupying a conspicuous place midway between the bladder and rectum. The form, however, of the generative apparatus, at this stage of life, is very different from that which characterises it at a later period. The vagina, cervix, and body of the uterus constitute one nearly straight stem or canal, from which diverge, at right angles, the Fallopian tubes and ovaries with their ligaments, much in the form of the letter T. Of the two divisions of the uterus, viz. the body and cervix,

* Upon the subject of the origin and distribution of the uterine nerves, consult also Fr. Tiedemann; Tabulæ nervorum uteri, Heidelberg, 1822; and the works of Dr. Robert Lee, quoted at page 651., where the condition of these nerves in the gravid uterus, and the question of their enlargement during pregnancy, is considered. And for the minute anatomy of the sympathetic filaments and ganglia, see the Art. "Sympathetic Nerve."

the latter is the more considerable, for the body has not yet acquired breadth; while the cervix, forming a tube of nearly equal calibre with the body, possesses almost twice its length. This greater length of the cervix, as compared with the body of the uterus, is one of the most striking characteristics of fœtal life (*fig.* 441.), one also which continues to be observed for many years after birth.

b. The uterus from the time of birth to puberty.—From the time of birth until the approach of puberty, the internal generative organs undergo but little change. Gradually, but slowly, increasing in size, they still retain the principal characteristics of the fœtal period. The uterus consists still chiefly of cervix, the body being that part which is last developed. Thus in a child of three years (*fig.* 442.), in whom the entire length of the uterus is 15‴, the cervix measures 11‴, and

Fig. 442.



Uterus and appendages of an infant.

a, cavity of the body laid open; *b*, of the cervix; *c*, anterior lip of the cervix; *d*, left ovary opened; *e*, Fallopian tube; *f*, right ovary; *g*, internal os uteri, marking the division between the body and cervix. (*Ad Nat.*)

the body only 4‴. These dimensions do not materially differ from those of the uterus in the first year of life, nor do they much exceed those of the same organ at birth.

But as puberty approaches, the relative proportions of the cervix and body of the uterus are found to have changed, and the latter now preponderates over the former. For while the body now equals the cervix in length, the breadth of the former much exceeds that of the latter. The walls of the upper chamber now become thicker from the more rapid development of the uterine muscular fibre, which is their chief constituent. This not only increases the external dimensions of the organ, but, at the same time, causes the parietes to become incurved, and so to encroach upon the cavity contained by them, which, up to this period, preserves the form of a nearly equilateral triangle (*fig.* 442.), but now gradually acquires the shape already described as characteristic of the cavity of the adult uterus (*fig.* 431.).

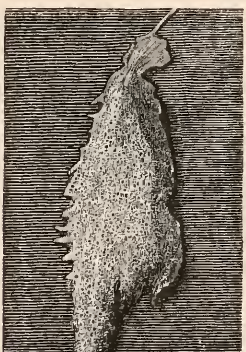
The folds or plicæ also (*fig.* 442.), which, in infantile life, are distinguishable upon the anterior and posterior walls of the cavity in the uterine body, resembling somewhat those in the cervical canal, gradually disappear; their former situation being now indicated by only a slight groove or raphé in the median line, and one or two gentle elevations diverging towards either Fallopian tube. These traces in the cavity of the body of its original construction out of two symmetrical halves, become generally lost after the uterus has been once impregnated, and indeed cannot always be distinctly seen in the nulliparous organ. One peculiarity in the form of the infantine uterus may be mentioned here, although it will be subsequently more particularly noticed. This consists in a curvature or inclination forwards of the upper part of the uterine body (*fig.* 467.). It is constantly more or less seen in infancy and childhood, and is usually partly retained in the virgin adult, but becomes lost after one or two pregnancies. In an excessive degree, it constitutes the condition hereafter described as antiflexion of the uterus.

From the time of birth to puberty, the component elements of the uterus remain nearly unchanged. They consist of granules and cells in various stages of development, from the round granular corpuscle to the elongated and ultimately fusiform fibre-cell; the two latter being often drawn out, at their extremities, into long filiform threads. These are all imbedded in a semitransparent formless matrix, and differ in no respect from the corresponding tissues in the adult, except that they are generally softer and less tenacious in proportion as they are younger.

c. The uterus during menstrual life. — The average duration of menstrual life is thirty years. It occupies usually the interval between the ages of fifteen and forty-five. The uterus in healthy women, throughout this entire epoch, is maintained in a state of perfect aptitude for the reproductive office, being, so to speak, under the control of the ovaries, with which it manifests so direct a sympathy, that every periodic change in the condition of the latter is, so far as the present state of our knowledge justifies the assertion, represented by a corresponding preparatory change in the former. But the menstrual phenomena being reserved for subsequent notice, it is only necessary to remark here that the uterus undergoes usually a slight alteration in size about the time of each catamenial flow, when its tissues are opened up, and become more spongy from the larger afflux of blood to them.

The lining membrane appears to suffer a variable amount of disintegration. In the uterus of women who have died during menstruation, the interior may present a slightly roughened appearance in certain places, or this may extend over the greater portion of the cavity. In women who menstruate painfully, it not infrequently happens that the entire uterine lining, to a greater or less depth, is exfoliated and discharged; the process of expulsion being accompanied by much suffering and a greater escape of blood than occurs in ordinary menstruation. These dysmenorrhœal membranes (*fig.* 443.) present all the charac-

Fig. 443.



*Portion of the lining membrane of the uterus cast off during painful menstruation. (Ad Nat.)**

teristics of a true decidual structure, having upon their inner side, or that which had corresponded with the uterine cavity, the fine cribriform surface occasioned by the orifices of numerous utricular glands, and upon the reverse side the usual rough flocculent appearance characteristic of the outer surface of membranes ordinarily discharged, along with the ovum, in abortion.

In other respects, the uterus, throughout menstrual life, exhibits little or no alteration in form or bulk, but continues to present those characteristics of constant aptitude for its greatest and most important office, which have been explained in the description already given of the adult organ; and these characteristics, if no pregnancy intervenes, it preserves until the period arrives at which menstruation, together with the capacity for procreation, finally ceases.

d. The uterus during gestation. The fully developed uterus. — The gravid uterus is only another term for the fully developed uterus; for, although the latter designation is commonly applied to the unimpregnated organ, when it has reached its ordinary size in the adult, the uterus does not attain the greatest amount of development of which it is normally susceptible until the term of gestation is complete.

The case of the uterus is perhaps in certain respects *sui generis;* for it is the case of an organ which, having reached a certain period of growth, remains in a nearly passive condition, so far as mere growth is concerned, until a further amount of development is evoked by a new stimulus. There are, indeed, two notable periods in the history of the development of the uterus, at which the influence of such an additional stimulus is perceptible.

For, first, as already shown, the uterus, like the mamma, remains without any material change from birth to puberty. The establishment of the latter condition is characterised by a correspondingly rapid evolution of both these organs. But the pubertal age may not arrive; the individual may retain, in respect of reproductive capacity, the pre-pubertal condition; and the uterus, in these cases, does not proceed beyond its first stage of development.*

Again, the second stage, having been reached at puberty, may be continued through menstrual life, until, with the cessation of procreative power, the period of natural decline in the organ commences, and this is the condition which the part retains during the periods or intervals when it is not employed in the process of reproduction, as well as throughout life in those cases in which it is never so employed. This degree of growth of the uterus is evoked by the full development of the ovary and the commencing discharge of ova, and is coexistent with the establishment of menstruation and the other conditions of puberty.

But a third stage of development of the uterus is produced normally by the stimulus of impregnation, and partly by the growth of the ovum, and abnormally by the formation of

* For this illustration I am indebted to Dr. Oldham.

* Compare *fig* 465., representing the pre-pubertal uterus in a woman aged nineteen, with *fig.* 442., of the uterus of a child at three years.

any substance within the uterus, such as a polypus, which may cause distension of its walls; or by the accumulation of fluid in its cavity, such as the menstrual fluid collected in cases of atresia or imperforation of the vagina.

The development of the uterus which is occasioned by the stimulus of pregnancy, takes place whether the impregnated ovum arrives within the uterine cavity or not; although this does not occur in equal degrees in the two cases. In the case of extra-uterine pregnancy, a very considerable thickening of the uterine substance usually takes place, together with a general enlargement of the entire organ, fully equal to that which is observed in the third month, and, in some cases, when gestation is not interrupted, even in the fourth month of ordinary pregnancy.

In cases where gestation follows an ordinary course, the development of the uterus is such, that the weight, at the end of the period, is found to be increased about twenty-four-fold, and its length about five-fold.

This development, as it affects the size, weight, form, and position of the entire organ, as well as the physical condition of its special parts, will now be considered.

There is no example in man, and few in the animal kingdom generally, of a development of any organ or structure comparable in rapidity with that which takes place in the uterus during gestation, although the periodical growth of the deer's horn, and the formation of the placenta, may be quoted as in some respects analogous cases.

Size. — The rate of increase of the uterus, during pregnancy, is subject to great variations. But, with due allowance for these, which are dependent chiefly upon the size of the fœtus and placenta, the quantity of liquor amnii, or the number of ova fertilised, an approximate estimate may be formed of the average alterations in size and bulk which the organ exhibits at different periods of normal gestation.

These may be expressed in calendar months as follows: —

RATE OF INCREASE IN SIZE OF THE GRAVID UTERUS ACCORDING TO MONTHS.

	Length.	Breadth.
End of 3 months	4½—5 inches	4 inches.
" 4 "	5½—6 "	5 "
" 5 "	6—7 "	5½ "
" 6 "	8—9 "	6½ "
" 7 "	10 "	7½ "
" 8 "	11 "	8 "
" 9 "	12 "	9 "

The antero-posterior has usually an average of one inch less than the lateral diameter.

Weight. — The weight of the gravid uterus, when fully developed, is most correctly ascertained in cases where death has taken place during, or soon after, labour at term. In twelve examples, estimated by Meckel, the minimum weight was 2lbs., and the weight, relatively to the unimpregnated organ, was as 24 to 1.*

Form. — The form of the uterus undergoes many changes in the course of gestation. During the first three months, although there is a considerable increase of size, the primitive figure is retained with only slight alterations. After the third month, the body rapidly enlarging, while the cervix remains nearly unaltered, the figure of the former approaches that of a sphere. For the perpendicular and transverse diameters of the body then become nearly equal, and the only deviation from the spherical form is occasioned, first, by the cervix, which increases the vertical diameter of the entire organ by one inch; and secondly, by the more tardy expansion of the body in the antero-posterior diameter, producing the form of a flattened sphere. After this, the perpendicular increasing more rapidly than the transverse diameter, and the upper segments widening faster than the lower ones, the uterus gradually acquires the ovoid figure which characterises it at the end of pregnancy.

Alterations, nearly corresponding with these, take place in the cavity of the uterine body. The walls of this flattened triangular chamber begin to separate from each other; and by their gradual expansion, the angles and superior and lateral lines, by which the cavity was at first bounded, are unfolded, so that the triangular is gradually exchanged for the pyriform shape, and this again for the figure of a flattened sphere — as in the fourth and fifth months of gestation; after which period the figure of the cavity corresponds very accurately with the general external form of the organ.

During these alterations, the fundus becomes strongly arched; while the sides undergo a slighter relative expansion, so that they exhibit only a gentle swelling; but the anterior and posterior walls become curved and prominent — sometimes the former, and sometimes the latter, according to Dr. W. Hunter, showing the greater amount of convexity.†

It has often been asked whether, during these changes, the walls of the uterus increase in thickness, or the contrary. In other words, whether the dilatation of the uterine cavity is to be regarded as a mere passive distension, with thinning of the walls; or whether the process of enlargement consists of an active excentric hypertrophy.

In order to determine this point, Meckel examined the average thickness of the uterine walls at different periods of gestation. From observations which he had made in sixteen uteri, at all periods of gestation, he concluded that the walls increase a little in thickness in the beginning, but that this increase is not very considerable, and that towards the end of pregnancy they become gradually much

* The estimates of Heschl, given at page 658., differ somewhat from these.

† W. Hunter. An anatomical description of the human gravid uterus, page 5.

thinner. He found the thickness of the uterine walls, three weeks after conception, $6'''$;

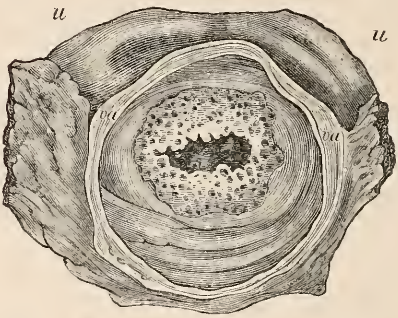
a, commencement of the cervix; *b b*, portion of the body corresponding with the brim of the pelvis; *c c*, Fallopian tube concealing the ovary; *d d*, round ligament; *e*, hypogastric artery, and *f*, vein; *g*, spermatic artery, and *h*, vein.

at the commencement of the third month, $5'''$; at the commencement of the fourth month, $4'''$. At the end of the fourth month, in two cases, $4'''$; in a third, $3'''$ at the upper, and $4'''$ at the lower part; in a fourth, $5'''$. At five months, in one case, $3'''$; in another, $2'''$ superiorly, and $4'''$ inferiorly. At six and seven months, rather less than $3'''$; at eight months, in one case, $2'''$, and $2\frac{1}{2}'''$; and in another, $3'''$ above, and more than $4'''$ below. At nine months, they appear to be still rather thinner.

In several uteri, which I have examined at all stages of gestation, I have found the thickness of the uterine walls exceedingly variable in different instances, even at corresponding periods of pregnancy, and particularly variable also in different parts of the same uterus.* According to my measurements, the extremes of thickness range from $2'''$ to $9'''$.

During these changes, which take place in the uterine body in the course of pregnancy, similar, but much slighter, alterations occur in the cervix. For the latter, being only the excretory channel of the uterus, undergoes no further modification than is necessary to prepare it for transmitting the fœtus when fully developed. Accordingly, in the early months of gestation, while the body is rapidly enlarging, the cervix undergoes but little change. Its tissues, however, become slightly expanded, so that the whole part is thicker, softer, and more elastic than in the virgin state. The margins of the os externum are consequently rendered more cushiony, and the orifice itself is enlarged. The canal of the cervix is also widened, and the palmæ plicatæ become unfolded, and project in the form of frill-like expansions (*fig.* 446.); while an unusual activity, occurring in the crypts and follicles, by which these parts are covered, a tough gelatinous secretion is poured out, which

Fig. 445.



Os and cervix uteri in the eighth month of pregnancy.

collecting here in the form of a plug, assists in shutting out the uterine cavity and its contents from contact of external air and other influences.

The increase in size of the os and cervix, which is gradually progressive through the whole of gestation, will be sufficiently expressed by comparing the dimensions of these parts in their two extreme states. The virgin cervix measures usually at the base $7—8'''$ in its shorter, and $11—12'''$ in its transverse diameter, and has an aperture of $3—4'''$ wide. It projects into the vagina to the extent of $4'''$ (*fig.* 425). At the end of pregnancy, the whole vaginal portion of the cervix would fill a circle of $1\frac{1}{2}''$ diameter; the orifice measures transversely $10—11'''$; and that part which formerly projected into the fornix of the vagina, is now reduced nearly to the level of the vaginal walls.

During these changes, it is often observed, especially in a first pregnancy, that, as gestation advances, the projection of the cervix

* This circumstance is remarkably exemplified in prep. No. 3605, in the Museum of the Royal College of Surgeons, London.

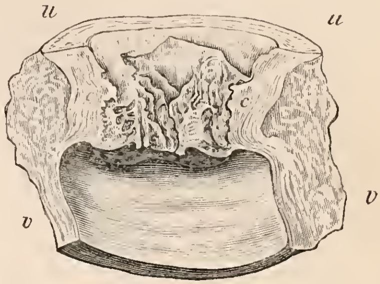
uteri into the upper part of the vagina becomes gradually less and less distinctly ascertainable by the finger. The latter change is commonly termed the "shortening of the cervix;" but the conditions upon which it depends, have not been very accurately examined, and they are certainly not at all clearly or adequately represented by the figures by which the description of this process is usually accompanied. As much importance is usually attached, in works on forensic and obstetric medicine, to the changes in question, it will be necessary here to examine a little more closely the process by which this apparent shortening of the cervix is produced.

It is commonly said that no material alteration, in the length of the cervix uteri, occurs before the fifth month of gestation; that, at the sixth or seventh month, the uterine neck has begun to shorten; at the eighth month, it is nearly, and at the end of the ninth month, it is quite, obliterated.

But while it is true that a lessening of the projection of the cervix into the vagina commonly takes place in pregnancy (*fig.* 446.), I can hardly coincide in the explanation which is usually offered of this circumstance, namely, that it is due to a gradual drawing up, as it were, of the cervix, by which its walls become added to those of the body of the uterus, for the purpose of increasing the capacity of the uterine cavity; and that in this way the uterine neck is gradually shortened, until it finally disappears.*

The accompanying *fig.* 446. exhibits the condition of the cervix in a woman aged thirty-seven, who, having previously borne children, died of phthisis in the eighth month of pregnancy. Here it will be perceived, that, without any actual diminution of the length of the cervix, which measured rather more than one inch, still there is no projection of it into the vagina; but that it forms a flat roof to that canal in the mode which is usually described and explained as indicating the entire absorption of the uterine neck. The true explanation of this, as it appears to me, is, that the apparent shortening of the neck is caused not, at first, by any diminution of its actual length, but by an increase of its breadth, or its extension in the lateral direction, whereby the projection of the lips into the vagina is reduced to the smallest possible amount. The rest of the process, upon which the shortening of the cervix depends, may be explained by the variable condition of the internal os uteri, or upper orifice of the cervix. If this remains unyielding until the time of labour,

Fig. 446.



Vertical section of the os and cervix uteri represented in the last figure.

v, walls of vagina; *c*, of cervix, and *u*, of uterine body. The cervical canal is nearly filled by the expanded palmæ plicatæ. Half the natural size. (*Ad Nat.*)

then the finger, on being placed within the cervix, traverses the whole length of the canal before it reaches any part of the child; and the general form and substance of the cervix being retained, the neck is said to be unobliterated. Such is usually the state of parts after repeated pregnancies. But if the internal or upper os yields readily, as it usually does in the more advanced stage of a first pregnancy, then the head of the child gradually settles down upon the lower orifice, pressing aside the soft and yielding wall of the cervix, which thus forms for it a shallow, cup-like, or funnel-shaped recess, that may be so far said to be added to the uterine cavity; and the finger, on passing within the os readily, touches the child, without having to traverse any length of cervix.

When, therefore, the term, shortening of the uterine neck, is employed, it should be understood to imply that change which takes place from the hypertrophy and lateral extension of the vaginal portion of the cervix, combined sometimes with a separation of the cervical walls from each other, occasioned by the descent of the head of the child; the degree of this descent being regulated by the amount of yielding of the internal os uteri. But it does not signify any alteration in the anatomical condition of the cervix and body of the uterus, which in every case retain their distinctive characteristics to the end of pregnancy: while the dilatation of the cervical canal is only an occasional occurrence, limited to the last stage of pregnancy, and having nothing to do with that apparent shortening which begins after the fifth month.

Position actual and relative. — The enlargement which the uterus undergoes during gestation, occasions of necessity very considerable alterations in its actual and relative position. On the occurrence of pregnancy, the organ, at first concealed within the pelvis, sinks, by its increased weight, lower than usual within that

* See description of the figures in Gooch: "An account of some of the most important diseases peculiar to woman," p. 212; and Beck's Elements of Medical Jurisprudence, 5th edit. p. 128.

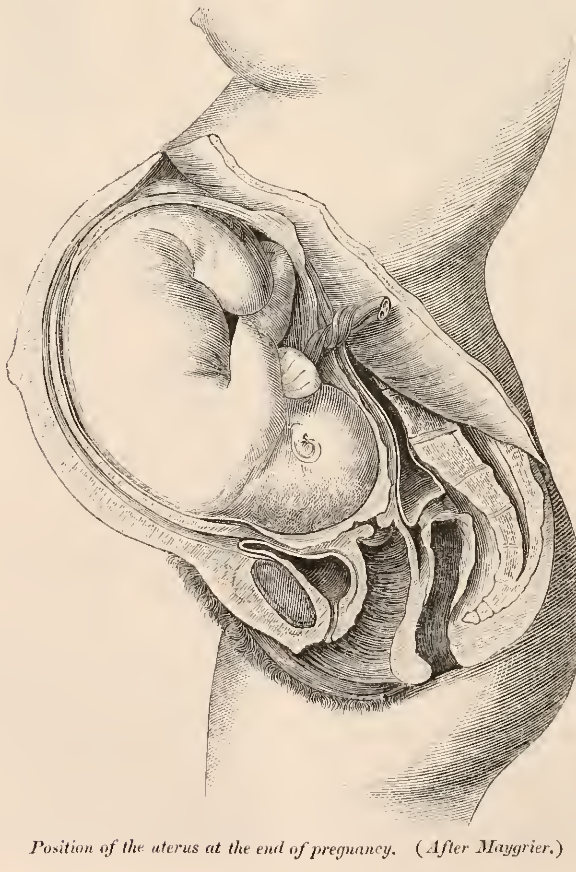
Regarding this explanation, which had been given by many preceding authors (see Mauriceau, tom. i. p. 97.; Smellie, vol. i. p. 183. *et seq.*), but which Gooch was, I believe, the first to illustrate by diagrams, it appears to me that much imagination has been exercised. The illustrations usually given are evidently diagrams supplied for the purpose of aiding the description of the process, as it has been supposed to occur, from examination of the part by the finger during life, but they give a very imperfect notion of the actual state of the cervix in pregnancy, as ascertained by dissection.

cavity; and, pressing upon the bladder and rectum, occasions sometimes an irritable condition of these parts. But usually at the end of the third month, the fundus may be felt emerging from the pelvic cavity; and in the course of the fourth month, it is always easily distinguishable in the lower part of the hypogastric region, having then risen to the height of about three fingers-breadth above the pelvic brim. In the fifth month, the hypogastric region is completely filled; the abdomen then acquiring a considerable rotundity in this situation. By the termination of the sixth month, the umbilical region also is filled, and the fundus uteri may be felt on a level with, or a little above, the navel. In the course of the remaining three months, the uterus rises gradually, until its fundus reaches the level of the ensiform cartilage. And this is very nearly the limit of its ascent, though it occasionally, and chiefly in first pregnancies, rises slightly above that point. In women who have a roomy pelvis, and in those cases where the natural form of the uterus is not altered by over-distension nor mal-position of the fœtus, there usually takes place, a few days or shortly before labour, a certain descent of the uterus, which has the effect of partially emptying the epigastric region, and relieving it from the pressure which it had sustained, especially during the last month.

The direction which the uterus takes in rising from the pelvis into the abdominal cavity, is determined by various circumstances; and it is interesting to observe in what way the addition of so large a body as the fully developed uterus to the already occupied abdomen, is provided for, without any of the viscera suffering injurious pressure, and without that impediment to the circulating and respiratory systems, which, in the absence of such a provision, must inevitably take place.

The oblique direction of the uterus, upwards and forwards, is determined, firstly, by the corresponding obliquity of the pelvis, the plane of whose brim forms with the horizon an angle of 60°. But as the fundus gradually, after three months, emerges from the pelvic cavity, the oblique direction of the uterus is maintained by the symphysis pubis in front, and the sacral promontory behind. Between these, the superior portion of the uterus continues to ascend, supported next by the abdominal walls anteriorly, and the spine posteriorly. The intestines, being bound down by the mesentery, cannot be displaced, and will

Fig. 447.



Position of the uterus at the end of pregnancy. (After Maygrier.)

therefore occupy a position midway between the spinal column and the posterior uterine wall. The pressure of the sacral promontory, and of the lumbar vertebræ, will still give to the uterus a forward tendency, which, on the other hand, will be prevented from becoming excessive by the elasticity of the front walls of the abdomen. If these have not been previously much distended, the fundus glides upwards, and ultimately fills the epigastric hollow; but if the abdominal walls have been much relaxed, as by frequent child-bearing, or if the pelvis is much deformed, the fundus uteri is usually turned directly forwards, or even downwards.

At the end of pregnancy, the whole of the fore part of the abdomen is occupied by the uterus; on either side lie the ascending and descending colon; the transverse arch, together with the omentum and stomach, fill the space between the fundus of the uterus and the diaphragm, while the rest of the abdominal viscera lie laterally and posteriorly to its hinder wall.

Thus it results, that in pregnancy, and especially in its last stages, no injurious pressure is exercised, either upon the great vessels, the aorta and vena cava, or upon the intestines, liver, or stomach, whilst the descent of the diaphragm, and, consequently, the act of respiration, is not materially impeded, and space is left for the bladder and rectum to perform their appropriate acts.

The situation and direction of the pregnant cervix, are necessarily affected by the increase of the principal organ, as well as by its contents. So long as the weight of the uterus causes it to descend lower into the pelvic cavity, as in the second and third months, the cervix is more readily reached, lying in the lower part of the hollow of the sacrum; but when the greater part of the uterus lies, as it does at a more advanced period, above the pelvic brim, the cervix is felt with greater difficulty, being more withdrawn from the entrance of the vagina. If the lower segment of the uterus is more than usually spread out, as in transverse presentations, or in the case of twins, or of excessive distension by liquor amnii, then the cervix and os are drawn up so high as sometimes to be quite beyond the reach of an ordinary finger; or, if the pelvis is very narrow, or the abdominal walls so lax as to cause the falling forward of the womb, the cervix will be equally beyond reach, and in these cases no part of the uterus can be said to be within the pelvic cavity. On the other hand, where the pelvis is unusually roomy, and the vagina and ligaments are lax, the cervix may lie immediately upon the perineum, or even project beyond the orifice of the vulva. In most cases the cervix lies lowest in the pelvis at the earlier and latter periods of pregnancy, and highest about and after the time of quickening. Its projection into the vagina is not always in the direction of the median line, but is more often inclined to the left side, as that of the fundus is towards the right. This obliquity in the position of the uterus may be caused by an unequal length of the ligaments, or more commonly by the projection of the lumbar vertebræ, which naturally gives to the body of the organ an inclination towards one or other side.

Alterations in the special coats and tissues.—*The Peritoneum* is that coat which suffers the least alteration during pregnancy, yet the changes which it exhibits are not inconsiderable. They consist chiefly in a simple multiplication of the component elements of the tissue, whereby it is enabled to keep pace with the enormous rate of growth of the uterus, so as still to invest all those portions which were covered by peritoneum in the unimpregnated state. During this process of growth, the membrane does not become attenuated, as would be the case if it suffered mere distension, but its thickness is rather increased, so that the addition of new matter must be in the aggregate very great.

Dr. W. Hunter imagined that this investment of the gravid uterus was accomplished by an unfolding of the layers of the broad ligament, for he asserts that, "in proportion as the circumference of the uterus grows larger, the broad ligaments grow narrower, their posterior lamella covering the posterior surface, and their anterior lamella covering the anterior surface of the uterus itself." He arrived at this conclusion from observing the altered relative situation of the appendages, and their appearance of clinging to the sides of the uterus in advanced stages of pregnancy. But the latter circumstance is due to the arching of the fundus, already described, which gives to the appendages a downward direction; while that the broad ligament does not disappear, as Dr. Hunter asserts, may be shown by measuring the alæ, or cutting them off, and comparing them with the same parts in the unimpregnated state, when little or no difference in respect of dimensions will be found between them in the two conditions.

Beneath the peritoneum of the gravid uterus is always found a large development of strong *fibrous tissue*, arranged in irregular cords and bundles. These sub-peritoneal fibres serve to strengthen the coats, and probably greatly contribute to prevent rupture of the organ, especially during labour.

The muscular or middle coat.—The tissues of which this coat is composed, together with their mode of arrangement in the unimpregnated uterus, have been already fully described. And it is to an increase of these, but especially of the vascular and muscular elements, that the enormous growth of the uterus during pregnancy is chiefly due. This growth consists partly in a greater development of the already existing structures, and partly in new formations.

The growth of the contractile fibre cells is here of especial interest. The elements of this tissue have been shown to consist, from infancy onwards, of fusiform fibre cells, intermixed with the round, oval, and elongated nuclei (*fig.* 434.), which constitute their embryonic condition. These, up to the time of impregnation, form the special and sole elements of the muscular tissue; yet some physiologists even of the present day refuse to recognise in these a muscular character, although it is plain that the uterus so constructed has a contractile power. The occurrence of abortion, sometimes at the very beginning of pregnancy, the expulsion of polypi and dysmenorrhœal membranes, and the painful contractions termed uterine colic, prove that the unimpregnated uterus is so endowed. This non-recognition of a muscular character in the uterus before pregnancy has arisen from the minute size of the individual fibres, and from the difficulty of explaining why these should grow to a given point, and then cease to be developed. But F. M. Kilian has given a happy illustration of this point, derived from the observation of Kölliker, that the contractile fibre cells which are found in the coats of the smaller blood-vessels, preserve a relative proportionate size to those of the larger ones, wherein they are more fully developed. So also the contractile fibre cells of the uterus proceed to a certain point of development in the unimpregnated organ, and there stop. And in this respect it makes little or no difference whether the organ examined has been taken from an infant or an adult.

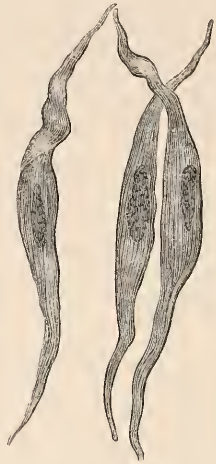
But when pregnancy takes place, the fibres proceed to a further stage of development. Their growth is now so considerable, that the contractile fibre cells, instead of a length of 0·002—0·003‴, and width of 0·002‴, in the fifth month, present a length of 0·06—0·12‴, and width of 0·0025—0·006‴, or even 0·01‴, and in the second half of the sixth month, a length of 0·1—0·25‴, a width of 0·004—0·005‴, and a thickness of 0·002—0·0028‴; consequently their length is increased from seven to eleven times, and their width from twice to five times.*

But in addition to this greater development of pre-existing fibre cells, a new formation of muscular fibre also takes place. This is observed, according to Kölliker, chiefly in the inner layers, although it may also occur in the external ones. The time of this new formation is chiefly the first half of pregnancy, the earlier forms of the fibre cells being no longer discernible after the twenty-sixth week. From this time onwards, the muscular coat contains only colossal fibre cells.

According to my observations, the individual fibre cells increase gradually in breadth throughout pregnancy, but their length is so variable, that the measurements just given can only be regarded as examples. The length, indeed, of the greater number of fibre cells after the third month cannot be determined with exactitude. A great many are thrown into numerous folds and contortions. Some exhibit transverse wrinkles, and the majority, when unbroken, end in long drawn out filaments, whose terminations become intermingled with the adjacent cells. Fine longitudinal markings are often distinguishable, and some fibres exhibit an elongated nucleus. The interior of the fibre is finely granular, and the margins show often a sinuous outline.

* Kölliker, Manual of Human Histology, Syd. Soc. vol. ii. p. 259.; and Siebold and Kölliker's Zeitschrift, 1848, bd. I. p. 72.

Fig. 448.

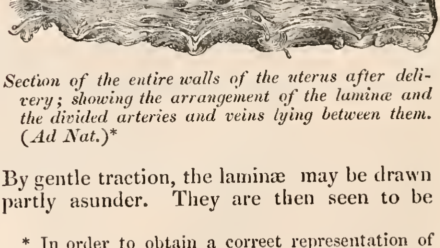


Fibre cells of gravid uterus fully developed. (*After Wagner.*)

The fibrous tissue uniting the several layers of muscles appears also to increase considerably, and towards the end of pregnancy to exhibit a distinct fibrillation.

These muscular and fibrous elements of the gravid uterus are arranged in numerous thin lamellæ, a good view of which may be obtained by cutting a thin slice perpendicularly out of the walls of the uterus at term.

Fig. 449.



Section of the entire walls of the uterus after delivery; showing the arrangement of the laminæ and the divided arteries and veins lying between them. (*Ad Nat.*)*

By gentle traction, the laminæ may be drawn partly asunder. They are then seen to be

* In order to obtain a correct representation of the course of the laminæ, I have here pinned out the preparation under spirit, and afterwards photographed it for engraving, of the natural size. By the stretching, the breadth of the preparation is doubled, and the laminæ are separated and rendered more distinct.

most densely and closely united towards the inner and outer surfaces, but to be more easily separable in the centre or vascular layer, where the laminæ are connected by a looser fibrous tissue, and are everywhere permeated by numerous large and small venous canals. These laminæ are superimposed the one upon the other, in layers parallel with the two surfaces of the uterine walls, but neither the laminæ themselves, nor the fibres composing them, can be said to take any definite course. Within the laminæ the fibres are arranged in flat bundles, which cross in all directions, as in the unimpregnated organ, but can seldom be traced in the same direction for any considerable distance. This is especially the case in the middle or vascular layer. In the superficial laminæ, the tendency of the fibres is to converge towards the angles to which the appendages are attached, while internally an apparent disposition to the formation of concentric circles around the orifices of the Fallopian tubes has been sometimes observed upon inverting the organ after labour. But nothing like a continuous arrangement of muscular fibres in the form of circular or longitudinal bands surrounding or investing the organ, can anywhere be demonstrated by the aid of the microscope.

The blood-vessels of the uterus undergo a marked increase in length, and especially in breadth, during pregnancy. The arteries pursue a remarkable spiral course whilst traversing the uterine walls. The veins form flattened channels between the muscular laminæ. The enlargement of the latter is accompanied partly by a growth of the muscular fibre cells already existing in their *tunica media* before pregnancy, and partly by a transformation of their inner and outer coats. Kölliker has observed, that in the fifth and sixth month, the fibres of the middle coat undergo an enlargement as considerable as those of the uterine walls, so that between these two scarcely any difference can be discerned. But besides these, both the inner coat, from the epithelium outwards, and the outer coat, acquire muscular fibres, which, except that they take a longitudinal direction, do not otherwise differ from those of the middle coat. This structure is found in the trunks of the uterine veins within the broad ligament, in the internal spermatics, and in all the veins of the uterine substances, which exceed 2‴ in diameter. In the smaller veins the muscular layer becomes less developed. Still, in those of ⅓‴ in diameter, a longitudinal layer of muscular fibre next the epithelium may be found. The only exceptions consist of those veins which, in the placental region, penetrate the inner layers of the uterus, to become continuous with the maternal veins of the placenta. These, notwithstanding their great width, instead of containing three, possess only one layer of muscular fibre, which, together with the epithelium, composes the entire coat of the vein.*

* Siebold and Kölliker's Zeitschrift, *loc. cit.* p. 81.

Do the nerves of the uterus enlarge or multiply during pregnancy?—This question, which once excited much controversy, has lost its chief physiological interest, since it has been determined that if any enlargement of the uterine nerves take place during pregnancy, this is nearly or entirely confined to the neurilemma, or fibrous nerve sheaths. Upon this point all observers are nearly or entirely agreed. Dr. Robert Lee states*, that whilst engaged in making dissections of the gravid uterus, he "discovered that the neurilemma was the constituent tissue of the ganglia and nerves which chiefly enlarged during pregnancy." Dr. Hirschfeld remarks, "this increase of volume does not occur in the nervous tubules, but in the neurilemma." M. Jobert de Lamballe having traced the nerves of the uterus in man and animals, both in the unimpregnated and gravid state, says, that he "never observed any modification of their physical condition. They appeared more voluminous in consequence of an infiltration of the cellular tissue which surrounds them, but they had not undergone any actual enlargement." Dr. Snow Beck removed the neurilemma, leaving only the bundles of nerve fibres or nerve tubules. On comparing the nerves of the gravid uterus with those of the unimpregnated organ, both dissections having been similarly conducted, he found that "the size of the nerves in both dissections is essentially the same; and when the nerves are carefully compared, no doubt is left that the nerves of the gravid uterus have undergone no change in size, nor any change in position, except that consequent upon the development of the organ."

But the neurilemma consists entirely of fibrous tissue, such as is common to most other parts of the body. It exhibits no structures specially nervous. Its offices, in relation to nerves and ganglia, are to support, protect, and bind together the nerve tubules and ganglionic nerve corpuscles.

Now the real point of interest to be determined is, whether during pregnancy the innervation of the uterus is increased in any degree proportionate to the augmented supply of blood to the organ. But the neurilemma has never been regarded as either a generator

* The Lancet, No. xvii. vol. ii. 1854, p. 349. M. Kilian, "Die Nerven des Uterus"; Zeitschrift, für Rat. Med., Henle und Pfeufer, Bd. X. 1851; M. Hirschfeld, "Note sur les Nerfs de l'Utérus;" Gazette Médicale, Oct. 1852, No. 44.; C. F. J. Boullard, M.D., "Quelques mots sur l'Utérus," 1853.

or conductor of nerve force, the former property belonging exclusively to the nerve centres, and the latter to the nerve tubes or nerve fibres. It is therefore necessary to ascertain if either nerve centres or nerve fibres become in any way multiplied or enlarged during the process of utero-gestation.

Regarding a new formation of nerve centres, there is at present no anatomical proof that any fresh ganglionic corpuscles are formed during pregnancy within the ganglia or plexuses from which nerves proceed to the uterine tissues.

Regarding the changes which take place in the nerve tubes or fibres during gestation, much interesting information is obtained from the researches of the late Dr. Franz M. Kilian, who devoted a considerable time to the investigation of this point. Dr. Kilian discovered, that in the unimpregnated uterus a successive diminution of the nerve fibre, whether in bundles or isolated, takes place as it approaches the point of distribution. If broad, the fibre, after a certain portion of its course, begins to lose its greater breadth, distinct double contour, and strongly marked granular contents, and then continuing as a pale fibre of intermediate size until it approaches nearer to the uterus, it ultimately assumes an embryonic character; that is, the extremely attenuated pale-margined fibre which traverses the tissues as a slender transparent band, has ceased to form a cylinder filled with nerve granules, and constitutes now only a pale slender stripe, or empty non-medullated sheath. Within this empty sheath there still occur, at distant intervals, little collections of granular fatty contents.

Now, in the early periods of pregnancy these embryonal forms are observed to become gradually more distinct between the muscular fibres, and at a later period many of the fine tubes become filled with medulla, which was wanting in the unimpregnated condition; the little collections of granular fatty contents just mentioned constituting the commencement of the nerve cylinders. For it is by the confluence of these isolated drops within the sheath that the medullated cylinder is formed, so that medullated fibres not only proceed as far as the uterus, but also become developed with continually increasing distinctness during pregnancy between the muscular fibres.

These observations correspond exactly with changes which Kilian observed to take place also in young animals, when the nerve fibres in the neighbourhood of the uterus are all in the embryonic condition, but become gradually medullated up to a certain point, in proportion as the development of the animal proceeds, so that the nerves may be said to grow forward in the direction of the uterus.

It should be understood, however, that in all these cases, the dimension of the nerve fibre never exceeds that of the branch whence it is derived, but that, on the contrary, a law of gradual diminution of the nerve is found to obtain in all cases, although the changes now described cause the rate of this to be different in the unimpregnated and gravid uterus respectively.

Kilian had no opportunity of examining the condition of the nerves in the human uterus at different periods of pregnancy, but he doubts not that the alterations are analogous to those which he found in animals.

The lining membrane of the uterus. Development of the decidua.— The last, and at the same time the most interesting, transformation of the uterine tissues remains to be described. It is that which takes place in the lining membrane, and which has for its object the formation of an immediate covering and protection to the ovum. By the aid of this membrane, the fertilised ovum, on arriving loose in the uterine cavity, is re-attached to the parent body, and is enabled to receive from it the supplies necessary for nutrition and growth.

But before the ovum enters the cavity of the uterus, the lining membrane of the latter swells and becomes softer and at the same time more vascular.* This augmentation in bulk of the uterine inner coat takes place in almost all cases when an ovum has been fertilised. That it does not depend upon the presence of the ovum in the uterus, is proved by the fact, that in cases of extra-uterine gestation, with rare exceptions, a development of decidua occurs within the uterus, forming there, in some cases, a more profuse growth even, relatively to the size of the uterus, than takes place in ordinary gestation.

The phenomena which ensue immediately

* In a paper on the Structure of the Placenta, by John Hunter, published in 1786 (Animal Economy), the decidua is described as composed of *coagulable lymph*. In another paper, 1794, on "the case of a young woman who poisoned herself in the first month of pregnancy," the pulpy substance lining the uterus, into which the blood-vessels of the uterus passed, and upon which they ramified, is stated to have consisted evidently of *blood coagulated*. The statements and descriptions in these two papers constitute the basis of the Hunterian hypothesis regarding the source of the decidua. But Dr. William Hunter had, even at that early period, a clearer perception of what the decidua really was, for in his posthumous work entitled "An Anatomical Description of the Human Gravid Uterus," edited by Dr. M. Baillie in 1794, the decidua is described in the following phrases: — "This membrane is an efflorescence of the internal coat of the uterus itself." . . . "It may be said to be the internal membrane of the uterus." . . . "It is really the internal lamella of the uterus." That the decidua constitutes simply a higher stage of development of the lining membrane of the unimpregnated uterus, in the same way that the muscular coat of the gravid organ is only a more advanced condition of the same coat before impregnation, is now proved beyond question. Upon this subject consult, in addition to the works quoted at p. 636., Sharpey, in "Müller's Physiology, by Baly," 1837, p. 1574.; Eschricht, "De Organis quæ Respirationi et Nutritioni Fœtus Mammalium inserviunt," 1837; F. M. Kilian, "Die Structur des Uterus bei Thieren," in Henle and Pfeufer's Zeitschrift, bd. ix.; Schrœder van der Kolk, "Waarnemingen over Het Maaksel van de Menschelijke Placenta;" and Coste, "Histoire Générale et Particulière du Développement des Corps Organisés."

upon the arrival of the ovum within the uterine cavity are, in the human subject, as yet unknown. Direct observation of the earliest stages are still wanting, and, unfortunately, the difference between these first steps in the mammalia (except Quadrumana) and man is so considerable, that only a limited aid can be derived from comparative observation. The ovum, when first found in the human uterus, is lodged in a small closed cavity, forming a continuous structure with the decidua which lines the rest of the uterine walls. In this little chamber, which may be formed at any part, but is most frequently seen near one or other of the tubal orifices, the little spherical ovum lies loose and unattached. In various examples which have been preserved and figured by different authors of the decidua at this stage, the size of this chamber varies from that of a pea to a hazel nut, and this size it acquires in the second week.

The walls of the cavity containing the ovum, and those forming the lining membrane of the uterus, are nearly alike in appearance and texture. They both consist of decidua, the former constituting the *decidua reflexa*, the latter the *decidua vera* of Dr. W. Hunter. For greater distinctness, those names are sometimes exchanged for *decidua chorii* or *ovuli*, and *decidua uteri*. The latter, according to a suggestion of Dr. M. Baillie, is also occasionally termed *parietal decidua*.

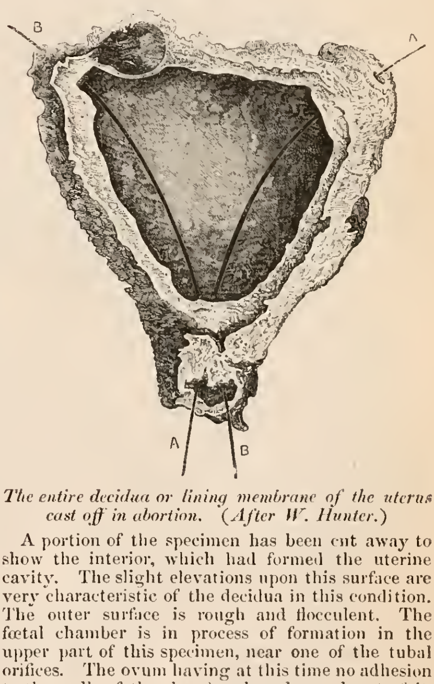
At this time all the uterine tissues have begun to expand and grow, and the uterine cavity, the walls of which were previously nearly in contact, to enlarge after the manner which in pathology constitutes eccentric hypertrophy. But, according to the foregoing description, this cavity now no longer forms one, but two compartments, the one partly inclosed within the other.

Of these two chambers, the newly formed and smaller one contains and supports the ovum, and subsequently the fœtus. It may therefore be termed the fœtal chamber; the other constitutes the original cavity of the uterus, and may be distinguished as the uterine chamber; according to the views of Breschet, it is the hydroperionic cavity. As the fœtal chamber enlarges, and the decidua reflexa becomes more expanded in consequence of the growth of the contained ovum, it gradually encroaches upon and finally obliterates the uterine chamber, which can no longer be distinguished as a separate cavity after the fifth or sixth month of gestation.

It will be necessary to examine separately the general characters of these two decidual coats. That which lines the uterine cavity may be first noticed. The parietal decidua, at the very earliest period of pregnancy in which it can be examined, forms a soft and spongy layer, 1—2‴ in thickness. That surface which looks towards the uterine cavity is elevated into numerous projections, which may be roughly compared to the cerebral convolutions, though relatively much flatter and less regular than these; between them are numerous little furrows or channels. The whole surface, both in the sulci and elevations, is covered by numerous minute perforations, corresponding with those formerly described as the orifices of the uterine glands in the unimpregnated uterus. But these orifices, from being enlarged, may now be easily distinguished by the unaided eye. They give to the surface a fine cribriform aspect. All these characters are more or less observable also in the decidua lining the uterus, in cases of extra-uterine (tubal) gestation. Along the marginal lines formed by the angles of the cavity, where the decidua is always thinnest, these apertures are large and expanded, but in the elevated spots they are often closed, apparently from lateral pressure, occasioned by the rapid growth of structure.

When early abortion takes place, the whole lining of the uterus, including the decidua reflexa, is often thrown off entire, forming a

Fig. 450.



The entire decidua or lining membrane of the uterus cast off in abortion. (After W. Hunter.)

A portion of the specimen has been cut away to show the interior, which had formed the uterine cavity. The slight elevations upon this surface are very characteristic of the decidua in this condition. The outer surface is rough and flocculent. The fœtal chamber is in process of formation in the upper part of this specimen, near one of the tubal orifices. The ovum having at this time no adhesion to the walls of the chamber, has dropped out of it. Bristles are introduced at the orifices corresponding with the Fallopian tubes, and pass out at the internal os uteri, the cervix not contributing to form the decidua.

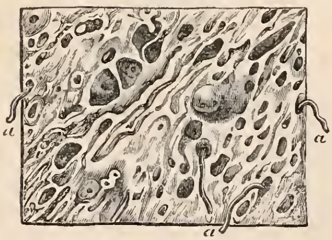
cast of the uterine cavity. If this occurs in the first fortnight of gestation, the mass retains the triangular form of the uterus. In each of the three angles is generally found an aperture corresponding with the points at which the membrane had been torn off from its continuity with the lining of the Fallopian tubes and cervix uteri.

The outer, or dorsal surface of the substance expelled, is always rugged. It exhibits numerous little papillary or club-shaped elevations, and between these much smaller cup-like or conical depressions, which are seen by transmitted light to lead, where the membrane is thinnest, directly into the apertures observable on the inner surface. At the thinnest points of all, these apertures are so wide, and the cup-like depressions so shallow, that the part has the appearance of a net, the meshes of which still consist of the enlarged orifices of the utricular glands. Hence the epithet "lace-like," often applied to the decidua in this condition.

The roughness of the dorsal surface of this, the parietal decidua, is occasioned by the membrane having been torn away from its connexion with the muscular coat of the uterus, in the act of abortion. The club-like projections are apparently the bases or blind ends of the hypertrophied utricular glands torn out entire from the substance in which they were previously embedded. When laid open, they are found to contain a small cavity. The cup-like depressions are the halves, or portions of similar, perhaps smaller glands, torn across, so as to leave other portions still attached to the uterus. The meshes are simply the orifices of such glands and of the channels leading to them.

At this and subsequent stages there may be often seen lying within and among these orifices, fine, thread-like ramified filaments, which some physiologists suppose to be utricular glands, or their epithelial lining, now becoming loosened out and falling away, — a view in which my own observations do not enable me to coincide. See *fig.* 451.

Fig. 451.

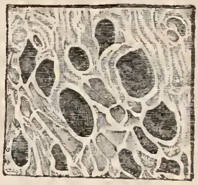


External surface of the decidua vera, from an ovum of about two months; showing the oblique channels in its substance. (*After Schrœder van der Kolk.*)

a a a, filaments supposed to be the loosened utricular glands (?)

As pregnancy advances to the third and fourth months, the uterine chamber expands, the decidua which lines it increases in thickness in parts to 3—4‴, and becomes at the same time more spongy, so that upon section it appears to be composed of flattened spaces or cells, communicating together by wide valvular orifices. These are best seen by examining under water the rough surface of an aborted ovum at that period, or the corresponding portion of the uterus from which it had been torn off. (*Fig.* 452.) These cells, or areolar spaces, continue to be seen, more or less distinctly, in the decidua throughout pregnancy, but are most conspicuous near the margins of the placenta.

Fig. 452.



Surface of the decidua vera more advanced. (*After Schrœder van der Kolk.*)

It is here represented as still attached to the walls of the uterus after the chorion, together with a layer of the decidua, have been peeled off from it. From a uterus at the sixth month of pregnancy, just beyond the margin of the placenta. The orifices and canals are much wider than in the first figure.

They are still divisions of the same ramified canals, or uterine glands, which have been described as found everywhere in the lining membrane of the uterus before impregnation, *fig.* 438., but now become so dilated and tortuous as scarcely to be recognisable as the same structures.*

In the latter months of pregnancy, the parietal decidua becomes thinner, and loses much of its spongy character, except immediately around the placenta, where this is still most distinct. It ultimately becomes blended with the outer surface of the fœtal membranes, and is partly thrown off with them in the act of birth, while a part remains, forming a honeycomb layer, attached to the uterine muscular coat.

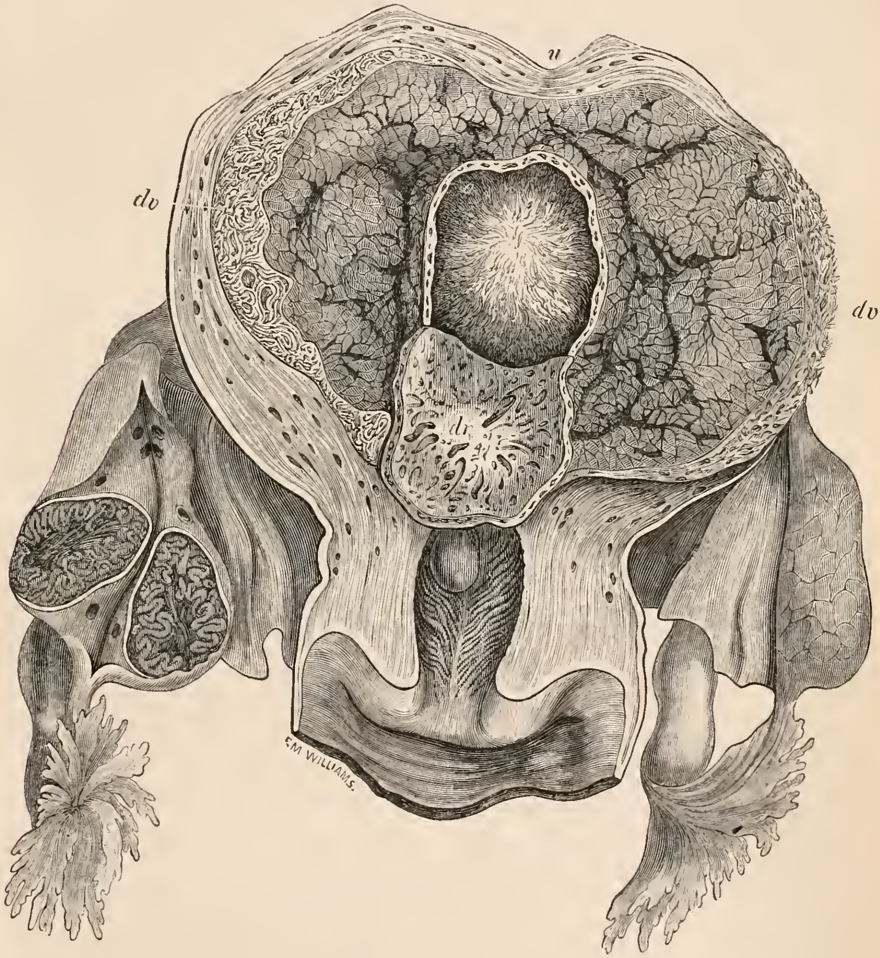
If next the growth of the *decidua reflexa*, or *decidua ovuli*, be traced, this will be found to undergo a development corresponding with that of the ovum, which it encloses and protects. The little chamber containing the ovum, which, as already stated, usually occupies a situation near one of the upper uterine angles (*fig.*450.), although it may also be found near the lower orifice (Hunter, "Gravid Uterus," *pl.* 34., *fig.* 4.), or elsewhere, appears at first like a small superadded cavity upon the outside of the larger one, or that formed by the parietal decidua. But as the development proceeds, the fœtal protrudes gradually into the uterine chamber, in the form of an incomplete sphere, whose upper pole rises free into the

* The four figures 450, 451, 452, and 453., showing the decidua or lining membrane of the uterus in different stages of development during pregnancy, should be compared with *figs.* 438, 439. and 443., which exhibit the same structure in different conditions of the unimpregnated state. These structures form a developmental series, the individual stages of which are often dislocated from their true and natural sequence by the employment of terms calculated to give an impression that the parts spoken of are different in structure and composition. "Mucous or lining membrane of the uterus," "Lymph," and "Decidua," when so employed, should be read as convertible terms representing the same part in different stages of development.

uterine cavity, but the lower forms an attached base of greater or less breadth, which is continuous in its entire circumference with the parietal decidua. The two chambers are totally distinct, and have no communication with each other. In aborted specimens, an aperture may be sometimes seen in the base or outer surface of the fœtal chamber, or that part which has been torn away from the uterine substance. In a very early specimen in my possession, and also in another which I have examined, one or more points are distinguishable also upon the upper or northern pole of the little spherical chamber, which have the appearance of apertures recently closed. Coste, in his beautiful series of illustrations*, directs attention, in several figures, to a similar spot in the same situation, having the appearance of a recently closed aperture, or umbilicus. These traces of openings in both the upper and lower poles of the sphere, are of consequence, in reference to the explanation which will be presently offered of the mode of formation of the decidua reflexa and fœtal chamber.

The outer surface of this chamber is nearly

Fig. 453.



Uterus in the first month of gestation; showing the formation of the fœtal chamber by the decidua reflexa, more advanced than in fig. 450. (*After Coste.*)

u, uterine walls laminated and traversed by numerous vessels; *d v*, decidua vera or developed lining membrane of the uterus, the uterine glands or canals being much enlarged; *d r*, decidua reflexa, in which lies *o*, the ovum, at this stage often still unattached; *c*, corpus luteum.

smooth. Upon it, however, are seen the orifices of numerous uterine glands. These are usually wanting near the centre, or umbilicus, but become more distinct towards the

* Histoire Générale et Particulière du Développement des Corps Organisés.

circumference, and are very numerous, large, and close set, in the decidual fold at the base, all round the line of apparent reflexion.

Numerous flat vessels, obviously veins, terminating in minute subdivisions, are seen ramifying over the whole surface, but becoming very scanty, or ceasing near the central point. They are continuations of similar vessels, which are still more conspicuous upon the parietal decidua. The capillaries in which these vessels terminate are exceedingly numerous, and may be sometimes seen deeply injected with blood. This is rendered the more conspicuous when the congestion is unequal, so as to form patches of a bright pink, alternating with other portions of a pale flesh colour.

The internal surface of the fœtal chamber, after the ovum has fallen out, or has been removed, presents a slightly uneven appearance, occasioned by numerous very shallow pits or depressions, occurring in close-set groups, and resembling, upon a small scale, the areolæ upon the inner surface of the heart.

When the body of the embryo begins to acquire length, the entire ovum exchanges the spherical for the slightly oval form, and to this the fœtal chamber also becomes adapted. Such is found to be the form of the fœtal chamber, sometimes in the latter half of the first, but generally during the second month, and from this period onwards the ovate figure prevails.

In the latter part of the first month, or at latest in the beginning of the second, the ovum, previously lying loose in the fœtal chamber, begins to be attached to the walls which surround it. This attachment is effected by the extremities of the villi, which from the first equally surround the chorion, everywhere becoming attached to the little pits and anfractuosities upon the inner surface of the fœtal chamber just described. In this way the embryo, surrounded by its amnion and chorion, becomes securely anchored in the midst of its little chamber, through the instrumentality of the villi, which, spreading in all directions, may be compared to the rays of the geometric spider's web.

Thus to receive, to protect, and support the ovum, and to prevent its escape from the uterus, appears to be the first object of the formation by the reflected decidua of a separate fœtal chamber (*fig.* 453.).

Ultimately, as the ovum grows, the base of its chamber expands, and here takes place a more dense and rapid growth of decidua. This is the part commonly termed the *decidua serotina*. Here the chorion villi, which now form large ramified groups, attach themselves, and from the margins of the collections of sulci just described, into which the villi penetrate, and which are now much extended, there proceed offsets or dissepiments of decidual structure. These dip down between the groups of villi sometimes as far as the surface of the chorion, and divide that which was formerly one continuous collection of ramified chorion fringes, into the separate lobes which characterise the mature placenta.

One or two points remain to be more explicitly stated. It may be asked, how does the ovum gain the interior of the fœtal chamber, or, in other words, how is the decidua reflexa formed around it? In reply to this, little beyond conjecture can be offered. Of the numerous explanations which have been attempted, few are found to meet all the peculiarities of the case. It is most probable that either the ovum becomes embedded in some of those folds of decidua which are found in it at an early period of pregnancy, and so the decidua becomes built up around it, as Sharpey and Coste suppose. Or, as it appears to me more likely, the ovum, on first reaching the uterine cavity, drops into one of the orifices leading to the utricular follicles, and in growing there draws around it the already formed, but soft and spongy decidua constituting the walls of the cavity. The chief support for such a conjecture, beyond its apparent probability, is the fact ascertained by Bischoff, who, in one case in the guinea-pig, found the ovum in precisely this situation at the bottom of a uterine follicle.*

The entrance of the ovum into the decidua being supposed, the rest of the growth of the reflexa is easily followed. The ovum now, in enlarging, raises the walls of the chamber, in which it lies, just as the skin becomes raised by the accumulating contents of a subcutaneous abscess. The process is probably in part purely mechanical, and in part in the nature of an excentric hypertrophic growth; for the actual substance of the chamber is much increased beyond the material of which it was at first composed. That some of this is borrowed from the parietal decidua, is very probable from the number of orifices of utricular glands seen upon its surface, which serve to show that the decidua reflexa is so far formed out of pre-existing structures; but much is also due to the further development of the elemental decidual tissues; and to the growth of these, the large vascular supply, which the reflexa at first receives, doubtless contributes. The little point, or umbilicus, observed sometimes at the upper pole of the fœtal chamber, may mark the spot at which, upon either of the foregoing hypotheses, the ovum first entered the decidua.

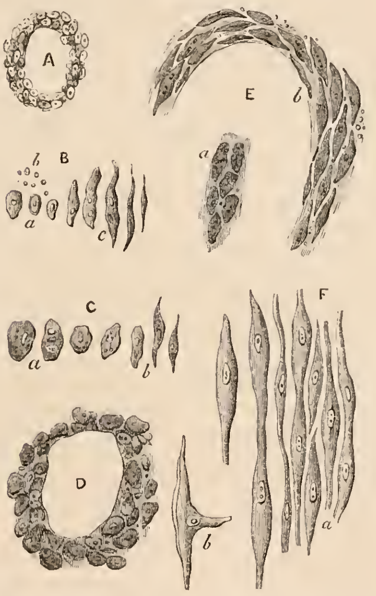
Another question which has never been satisfactorily determined, relates to the ultimate fate of the decidua reflexa. Dr. Hunter, from observing that, at the time of birth, only one layer of decidua can be found upon the secundines, supposed that, after a certain period of pregnancy, the decidua vera and reflexa, having come into contact, united to form one membrane. Doubting this explanation, I have made many observations, with a view to settle this point; and from these I

* While these sheets are passing the press, I have received the last part of Otto Funke's "Lehrbuch der Physiologie," 1857, in which the same suggestion is offered, exemplified by the same case, which, indeed, is the only one yet known.

am satisfied that no such union takes place; but that, when the decidua reflexa has fulfilled the offices already assigned to it, and has ceased to be vascular, so that no further addition of material to it can take place, it becomes, after the fifth or sixth month, so completely attenuated by distension from the growth of the ovum within, that it is reduced to a mere film, of which the only trace left at, or indeed before, birth, is a narrow frill still discoverable at the margin of the placenta between the decidua vera and the chorion. But the decidua lining the uterine walls continues vascular to the last; and this alone constitutes the membrane a part of which at birth is found adherent to the outer surface of the chorion, and which Dr. Hunter, from observing that it now consisted of only one layer, imagined was formed of the two deciduæ united together.

Histology of the decidua. — The morphological changes effected during pregnancy in the

Fig. 454.



Histology of the decidua. (*After Schrœder van der Kolk.*)

A, orifice of utricular gland of an unimpregnated adult uterus surrounded by round epithelial cells; B, cells of decidua in an ovum of about three weeks; *a*, round and oval nucleated cells; *b*, fat granulations; *c*, cells, from a deeper layer, elongated and beginning to form fibres; C, the same from an ovum of five weeks; *a*, round and oval cells, much enlarged, and containing nuclei and fat granulations from the surface; *b*, elongated cells from a deeper layer; D, orifice of a utricular gland from the same ovum, much enlarged as compared with A; E, margin of a valvular opening in a deeper layer of the decidua, from an ovum of two months; at *b*, the cells have become elongated, at *a* they are filled with fat granulations; F, long and broad cells from a decidua of nine months; *a*, the cells exhibit a nucleus, some having one and others two nucleoli; *b*, three-pointed cell.

decidua, and the chief purposes of these, having been stated, the histological peculiarities will now be briefly described. The lining membrane of the uterus, from infancy onwards, is composed, as already shown, of free elementary corpuscles or nuclei, contractile fibre cells, amorphous tissue and epithelium, together with capillary vessels, and the tortuous canals termed uterine glands. These undergo important modifications, which serve to explain the great and rapid growth of the decidua during pregnancy. According to Schrœder van der Kolk, who has traced and figured with great care the several stages of development of these elemental tissues, the cells of the decidua, surrounding an ovum of about three weeks, situated nearest the villi, have already undergone considerable enlargement. These occurred in the form of oval nucleated cells (*fig.* 454. *B a*), with fine nuclei and fat granules, *b*, intermixed; while in the layer of the decidua, still deeper, occurred longer cells, that were already beginning to form fibres.

In an ovum of five weeks, similar cells were found, in a further stage of development. In the superficial decidual layers, the oval cells, *C a*, were filled with granules, and contained a nucleus, and some a nucleolus. In the deeper layers, as before, the cells had become more elongated, *C b*. In and between all these cells were numerous minute fat granules, and among the cells lay fine nuclei. The openings of the utricular glands, *D*, which were surrounded by enlarged epithelial cells, were now considerably expanded, as compared with their usual condition previous to impregnation, *A*.

At two months, the increase in size of the oval cells, *E a*, now abundantly furnished with fat granules, was still more marked. These were developed into long cells, *b*, which were found composing those valve-like membranous septa formed now everywhere on the deeper decidual layer, as already described, *fig.* 452.

From this period onwards, the development of the cells proceeds more and more rapidly, until those in the deeper layers become transformed into fibres, which it is impossible to distinguish, under the microscope, from the peculiar contractile fibre cells of the true muscular structure.

In the ninth month are found colossal fibre cells, *F a*, which are rarely seen beyond the margin of the placenta. These were very transparent, and exhibited, some one, and some two, nucleoli. A remarkable three-pointed cell is sometimes also observed, *F b*. Fibres of fibrous tissue occur everywhere, and between them small cells and nuclei. The utricular glands have long ceased to be discernible in the advanced stages of pregnancy.

According to the observations, however, of Rolin, Robin, and Kilian, from the fourth or fifth month onwards, the decidua begins to lose the character of energetic life, which, up to that period, it had exhibited, and becomes atrophied, and less firmly adherent to the uterine walls; while, between it and the muscular parietes, there appears a new formation of decidua, at first soft and delicate, but which gradually acquires the peculiar characteristics of that membrane. This layer is not thrown off at birth, nor dispersed in the lochia, but remains attached to the inner uterine surface, and forms the foundation of the new mucous membrane, with which, after labour, the uterus is furnished. M. Robin supposes that this new soft layer is often mistaken for a product of inflammation occurring in puerperal and other uterine maladies.

e. The uterus after parturition.

Immediately after labour, the uterus, if entirely empty, occupies the whole of the pelvic cavity, together with the lower portion of the hypogastric region. The bulk of the organ varies in different individuals, and is considerably greater after twin or multiple pregnancy.

The tissues generally are of a redder colour, and softer, and more easily lacerable than in the unimpregnated condition; those of the cervix being usually more lax than those of the body, from infiltration of serum, and occasionally, in parts, of blood.

The cervical mucous membrane, which is retained*, after labour exhibits here and there sometimes slight lacerations, extending occasionally into, or through, the proper tissue of the part. In other respects, the internal aspect of the cervical canal resembles that of the same part in the last month of gestation, except that the large and voluminous plicæ (*fig.* 446.) have become folded out and flattened during the previous act of labour. Around the margin of the internal os uteri may be seen a thin ragged fringe marking the point from which the decidua, here usually much attenuated, had been torn away.

The entire uterine cavity is denuded; it presents everywhere, except at the placental space, a rough, flocculent, and sometimes honeycomb-like surface, caused by the detachment of a portion of the decidua and its discharge along with the fœtal membranes. Another portion remains covering the muscular structure of the uterus, but is in parts so thin, that the latter appears to be left nearly bare.

The surface to which the placenta had been attached forms usually one-third of the entire inner superficies of the contracted uterus. This, which is termed the placental space, is easily distinguished by its uneven, rugged, and somewhat nodulated appearance; caused chiefly by the presence of numerous large veins, whose truncated orifices obstructed by coagula here protrude slightly above the general level.

Upon section, the uterine walls exhibit everywhere the same laminated arrangement of the proper tissues, with numerous intermediately lying tortuous arteries and flattened veins and sinuses, already described as observable in the uterus during the latter periods of pregnancy (*fig.* 449.).

These flattened thin-walled veins are usually empty, or contain a few unadherent coagula. Those, however, which occupy the seat of attachment of the placenta, where they are much larger than in any other situation, are filled with dark or greyish-red clots adherent to their walls, and closing their mouths, which terminate directly upon the uterine cavity.

The peritoneal coat of the recently emptied uterus is of a pale pinkish-white colour, and presents a smooth, shining, and in parts a slightly wrinkled surface. It is thicker and less diaphanous than the same membrane before labour.

The process of involution. — No rapid or material alteration in the size or composition of the organ occurs during the first few days after labour. In the course of the first week, however, commences a series of important and interesting processes, continued during the greater portion of the two months immediately following labour, and having for their object the restoration of the uterus to a condition similar to, though not identical with, its state before impregnation. These changes consist in a gradual diminution in the weight and dimensions of the organ accompanied by a corresponding metamorphosis and ultimate reconstruction of its tissues. They together constitute the process commonly termed the involution of the uterus, which will now be examined.

Changes in dimensions and weight.—According to repeated estimates made by Heschl, the weight of the uterus, immediately after labour, ranges from 1 lb. 6—7 oz., ordinarily, to 2 lbs. 5—7 oz.; the latter being the weight after twin labour.

The dimensions depend upon the degree of contraction. Under ordinary circumstances, the entire length is 8—10 inches, and the thickness of the parietes 1 inch. These first changes in the dimensions of the organ, as compared with the state previous to labour, are effected solely by the contraction of the uterine fibre. They consist chiefly in a rearrangement of relative position in the component tissues, by which, while the entire substance of the uterus remains undiminished, its length and breadth are greatly reduced, and the thickness of the parietes correspondingly increased. In one respect, however, the entire bulk and weight are less than they were before labour, because a much smaller quantity of blood now circulates in the walls, but the solids remain unaltered.

At the end of the first week, the diminution of the organ is not very considerable. Its weight is merely reduced from 1 lb. 6—7 oz. to 1 lb. 3—4 oz. At the end of the second week, the rate of diminution is found to have been much more rapid; the organ now weighs only 10—11 oz. At the end of the fifth week, 5—6 oz.; and in the course of the second month, it is reduced to its ordinary weight of 1½ to 2½ oz.; but it never entirely regains the

* For the discussion of this question, see the works of Heschl, Robin, and Kilian, hereafter quoted.

small size and dimensions characteristic of the virgin state.

Metamorphosis and restoration of the component tissues. — The first and immediate reduction in size of the uterus, after parturition, has been just stated to depend upon mere contraction of the uterine fibre. But contraction alone will not account for those great and remarkable reductions in the dimensions of the organ which have been just described. The true explanation of these phenomena is furnished by a series of metamorphoses affecting more or less the entire uterine tissues, by which the greater portion of those structures which have been formed during pregnancy, become disintegrated and removed, while other and new tissues are developed in their place.*

In these metamorphoses, the colossal fibre cells, which form the great bulk of the newly added material, play the most important part. These have been traced, during their development in pregnancy, from the small fusiform cell of the unimpregnated uterus to the fully formed fibre of the organ at term. The growth of these proceeds *pari passu* with that of the fœtus, for whose expulsion they are destined; and this act being accomplished, their destruction and removal becomes a necessary prelude to the recomposition of the entire organ upon the same type as before impregnation. In this respect, the aggregate formation of fibre cell is comparable to the deer's horn, the placenta and other structures which, having served the purpose of their formation, and being incapable of suffering retrogression, become caducous, with this difference, however, that the one class of structure being thrown off in a mass, the act of separation is striking and obvious; while the deciduous process in the other is gradual and fragmental, and can only be discovered by the most patient and careful scrutiny.

The disintegration and removal of the uterine muscular fibre is effected, first, by the transformation of each fibre into molecular fat. This process does not commence earlier than the fourth or sixth day after labour, and not later than the eighth day. Certain differences are observable in the order of retrogression. Thus the process begins somewhat later in the inner than in the outer laminæ, while the cervix remains unchanged a few days longer than the body. In the individual fibres, the process of decay begins at many points simultaneously. The fibres lose their sinuous outline, and become paler; while within them appear yellow oil granules, commonly arranged in rows. The nucleus of the fibre is pale, but distinct, until it becomes obscured by the increase of the oil granules; while the extremities of the cells, on account of their tenuity, are the first to suffer disintegration.

Fig. 455.

Process of involution or disintegration, and renewal of the uterine fibre after parturition. (After Heschl.)

a, the old fibres filled with fat granulations 2 — 4 weeks after delivery; *b*, development of new fibres in different stages, about the fourth week.

During the second and third week, the process of disintegration continues; and it is probable that a considerable absorption of effete material now takes place, since it is not easy to explain otherwise that rapid diminution in bulk, especially in the second week, which the entire organ undergoes, as shown by the calculation of weights already given. As a result of these molecular changes, the uterus now loses its reddish colour, and becomes of a dirty yellow, and is at the same time more easily lacerable.

In the course of the fourth week, and possibly sometimes during the third, there appears, in the midst of the now degenerated fibres, the first traces of a new formation of uterine substance. These occur first in the form of cell nuclei, which are concurrently developed at several points; and gradually, while the last portions of the old muscular coat are being disintegrated and absorbed, acquire the character of the new muscular fibre cells (*fig.* 455. *b*). So that, by the end of the second month, the reconstruction of this portion of the uterine substance is often complete.

The disintegration of the remains of the decidua, and the reconstruction of the lining membrane of the uterus, which had been removed during the act of birth, is effected by a process very similar to that just described.

With regard, first, to that portion of the inner uterine superficies, which had been covered by the placenta, it is observed that this undergoes a somewhat slow retrogression. The veins, filled by thick clots in the normal state in consequence of the progressive involution of the intermediate uterine substance, occasion here a marked protrusion; so that very often, after four or six weeks, the placental space forms an elevated spot of twice

* On this subject the following may be consulted with advantage: — Dr. R. Heschl, "Untersuchungen über das Verhalten des menschlichen Uterus nach der Geburt," in the Zeitschrift der kais. kön. Gesellschaft der Aerzte zu Wien. 1852. B. ii. p. 228.; F. M. Kilian, "Die Structur des Uterus bei Thieren," *loc. cit.*; Schrœder van der Kolk, *loc. cit.*

the circumference of a dollar. Finally, however, these coagula are removed, and, together with the veins, disappear, while the place sinks to the level of the surrounding parts; and, after becoming smooth and receiving an investment of mucous membrane, is generally no longer discernible. The restoration of the placental space to its former condition does not, however, always proceed normally. Sometimes, in consequence of excessive activity in the process of reconstruction, hypertrophic growths of the new material take place; so that, several months after labour, a tumour of more or less considerable size, formed at the expense of the uterine tissues, is found to occupy the original seat of the placenta. I have satisfied myself by several microscopic examinations of the correctness of Heschl's opinion, that in this way are formed some of those anomalous-looking fleshy substances which are occasionally discharged from the uterus, and are regarded as moles.

The *histological* changes, which take place after labour in the tissues lying internally to the muscular coat, up to the complete restoration of the mucous membrane, have been examined by many observers, not always, however, with corresponding results. It appears certain that a portion at least of that layer of decidua which is still left attached to the uterine walls, is removed by fatty transformation, and that many of the products are discharged by the *lochia*. Schrœder van der Kolk has traced this process as it occurs in the nuclear cells and fibres, which form so large a portion of the decidua. Those very broad fibre cells, which are visible in it up to the ninth month of pregnancy, are no longer to be found four or five days after labour, when they appear to be transformed into long cells, through an abundant fatty transformation which progressively continues, until, by the increasing development of the oil granules and the corresponding diminution of the cells and fibres, the situation of the latter can ultimately only be discovered by the still existing longitudinal direction of the fat nuclei, while all traces of a cell wall have entirely disappeared.

Without the aid of the microscope, however, it may be seen that, a few days after labour, the entire inner surface of the uterus is covered by a more or less red soft pulpy substance, which has the same anatomical composition as the decidua. This, which is considered by some physiologists as identical with the layer of decidua already described, as formed, according to Kilian, Robin, and others, as early as the fourth or fifth month of gestation, is not discharged after labour, but becomes the seat of that reparatory process, by which the restoration of the mucous membrane upon the uterine body is effected. Between the twentieth and thirtieth day, this layer begins to resume the character of a mucous membrane. It is at first more pulpy, and softer, and thicker than mucous membrane in a normal state. The vessels become distinct in it about the third week, and sometimes still later. Previous to this, the blood appears to be contained in simple channels between the elongating cells.

The epithelium is as yet hardly formed. By scraping the inner surface of the uterus twenty days after labour, Schrœder found still only the remains of half decomposed cells. But no new cells with cilia could be yet with certainty discovered.

The utricular glands make their appearance last of all. In several cases, Heschl found them completely formed at the end of the second month; but previous to this, their development could not be traced.*

Finally, it may be said that the restoration of the mucous membrane, with all its peculiar structures, is completed about the sixtieth or seventieth day after delivery, *i. e.* by the time that the uterus is reduced to its normal bulk.

Thus it appears, that the act of involution consists in two processes, which are concurrently performed, yet with opposite purposes. For the act of reconstruction being commenced long before the retrograde metamorphosis is complete, the result of both is, that a restitution or reconstruction of certain tissues of the uterus, more or less complete, takes place.

With regard to the muscular coat, it is perhaps not any overstatement of the fact to say that each ovum is provided with its own series of fibres for the purpose of effecting its expulsion, and that these, after parturition, entirely disappear, or at least can no longer be recognised, while a new series of embryonic or undeveloped forms appears in their place. The same may also be said of the decidua, though with certain differences as to the time and mode of its destruction and renovation. Regarding the fibrous tissue of the uterus, little has been determined with accuracy; but enough has been observed to render it probable that this also, to a certain extent, becomes subject to fatty transformation. The blood-vessels appear to be likewise partly involved in a similar process, although their principal trunks probably suffer but little change beyond a material diminution of size. The peritoneum is that tissue which undergoes the least apparent alteration. It preserves, however, a thickness proportionate to the reduced bulk of the organ, and consequently it must suffer a corresponding involution.

Regarding the puerperal alterations in the nervous system of the human uterus, but little is known. Kilian†, after examining a specimen at eight, and another at twelve days after labour, as well as the uterus of many animals at different periods, arrived at no definite conclusions. He thinks it in the highest degree doubtful, that, in the puerperal state, the nerve fibres undergo the same involution process as the other tissues; viz. that the old fibres are entirely destroyed, and become replaced by a new, younger, or embryonal

* By Kilian they are said to be formed during pregnancy.

† *Loc. cit.*

form. He rather conceives that a reduction so takes place, that either the contents of the nerve fibre are partly or entirely removed by resorption, so that there remains, according to circumstances, a partly or entirely empty sheath; or that the contents of the fibre are transformed in the same manner that Günther and Schön (Henle, Allgemeine Anat. p. 771.) observed in divided nerves; viz. that the contents of the tubules become coagulated, as after death, and are then subject to resorption: the fibre appearing then to be perishing, and ribbon-like, and the contents to be disappearing. Regarding the human uterus, he thinks it in the highest degree probable, that the nerve fibre is included in the energetic resorption process that affects the puerperal uterus generally; that a reduction of the fibre follows; and that, in the next pregnancy, it again becomes developed *pari passu* with the development of the other tissues.

f. The uterus after the menstrual epoch, and in old age. — Whether the uterus has been employed, in its ultimate office, in the process of reproduction, viz. that of gestation, or whether it has proceeded only so far towards this as to have been limited to the repetition, in unvarying succession, of that preparatory stage which is expressed by the minor function of menstruation, in either case the period equally arrives at which the activity of the organ passes away. Ova are no longer discharged from the ovaries. These cease to be creative or developing organs; and with this cessation of the proper function of the ovary, there comes also a corresponding diminution, and finally a termination of the correlative offices of the uterus.

It is now interesting to observe how the uterus gradually resumes some of the peculiar features which it exhibited at an earlier period of life. It may be said to fall back again into its infantine condition. For with the shrivelling of the ovaries, and their reduction to a size as small sometimes as that of a child of two or three years, (*fig.* 456.) the uterus also gradually shrinks, not in all its parts, but principally in the body, or that portion which is chiefly employed in the processes of menstruation and gestation. This part becomes atrophied more than the rest; its walls become thinner, partly from diminished circulation in them, and partly from atrophy of the component tissues, which appear pale and nearly bloodless. Thus it happens that, in advanced life, the walls of the uterine body, no longer possessing that fulness which at an earlier period caused them to encroach upon the cavity, and to exhibit that incurvation of the sides and fundus which has been described as characteristic of the mature organ, again return to the straight and more attenuated condition which they had in early life. We may often observe, therefore, in the uterus of aged persons, a nearer approach to the form of the equilateral triangle, caused by the shortening of the body and the straightening of its walls, than is seen in the uterine cavity of mid-life; and it is this return to the form of the fœtal cavity, together with the now preponderating size of the cervix, which remains nearly unchanged, that gives to the aged uterus its greatest similitude to that of infancy or early youth.

Fig. 456.

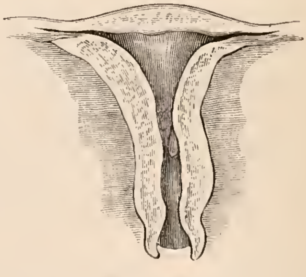
o, the shrivelled ovaries.
This figure exhibits the parts of half the natural size. (*Ad Nat.*)

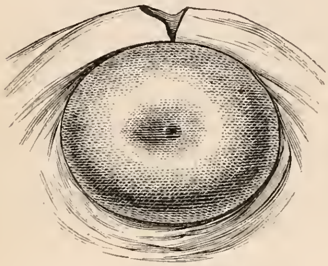
Fig. 457.



Thinning of the uterine walls in old age, and return to the triangular form of the cavity characteristic of the infantine (fig. 442.) and undeveloped uterus (fig. 465). (Ad Nat. Half the natural size.)

But these changes are not limited to the body of the uterus. The external uterine orifice being now no longer required to serve as a conduit for fluids to or from the uterus, or for the passage of more solid contents, becomes reduced in diameter, and may sometimes be observed to possess an aperture that would hardly admit the head of a moderate sized probe.

Fig. 458.



Os uteri in old age. (*Ad Nat.*)

Functions of the Uterus.

The uterus, in common with the rest of the generative organs, being concerned only in the reproduction of the species, its offices are limited to that period in which the animal functions are maintained in their highest state of efficiency. The growth of the body is nearly or quite completed before the sexual offices commence, and the power of reproduction continues as long as the frame is maintained in full vigour; but when the age arrives at which the animal functions generally begin to decline, their decay is anticipated by the total cessation of the power of procreation in the female. The period, therefore, is limited, yet not brief, during which the functions of the uterus can be exercised, and on either side of this epoch the organ remains passive, except under abnormal states.

The chief functions of the uterus are those which relate to — 1. Menstruation; 2. Insemination; 3. Gestation; 4. Parturition.

The office of the uterus in menstruation. — Although the uterus is the efficient instrument in the performance of menstruation, yet the power of initiating and regulating this function resides in the ovaries, which exert a powerful reflex influence, not only upon the uterus, but also upon the entire organism. Without the ovaries, menstruation has never been known to occur. Their artificial removal is followed by a permanent cessation of the catamenial flow, although the uterus may be left uninjured; while the congenital absence of both ovaries is always accompanied by an enduring amenorrhœa.

The external sign or evidence of menstruation consists in the occurrence of a sanguineous discharge, which escapes from the vaginal orifice of women in health, periodically, except during pregnancy and lactation. This discharge first appears usually between the fourteenth and sixteenth years, and continues to be repeated at intervals of a lunar month for an average period of thirty years. The time, however, of the commencement, as well as of the decline, of menstruation is very variable, and may be either much accelerated or retarded, according to individual peculiarities.*

Periods of duration and recurrence. — The catamenial period and interval together occupy a space of one lunar month. And in some women this function is performed with such regularity that the day, and very nearly the hour, of its expected return may be predicted. The natural duration of the flow varies from three to five or even seven days. An interval then occurs during which the flow entirely ceases. This occupies from twenty-one to twenty-five days; and it is during the first half of this interval that conception most commonly takes place.

It cannot, however, be asserted that this degree of regularity is observed even in the majority of women. Frequently the period of regular return is anticipated by one or more days; or, on the other hand, it may be retarded, without the occurrence of any concomitant disturbance of other functions, such as would justify the regarding of these examples as abnormal. But whatever may be the amount of variation — dependent in most cases upon idiosyncrasy, — still a law of periodicity is observed which, in all ages and countries, has been recognised, and more or less distinctly expressed by such terms as catamenia, menses, courses, periods, règles, mois, monatlicher Fluss, and the like.

No catamenial discharge takes place normally during pregnancy or lactation. Exceptions to both these rules, however, occur, and instances of the latter are sufficiently common. But with regard to the former, it is probable that many at least of the recorded cases of menstruation during pregnancy have been cases in which the placenta was implanted low down, or even over the os, under which circumstances it is well known that slight flooding will occasionally commence at an early period of gestation, and observe a certain rough periodicity. Upon *anatomical* grounds, a catamenial flux during pregnancy can only be supposed possible where the condition of the uterus is such as to admit of the discharge taking place from the vaginal portion of the cervix; an occurrence which is shown by Mr. Whitehead to have obtained in all the instances of supposed menstruation during pregnancy which he had investigated. For "on examining these cases with the speculum

* For much valuable statistical information relating to the periods of invasion and decline of the catamenia, and in refutation of the popular belief that these periods are greatly influenced by climate, &c., see Robertson's Essays and Notes on the Physiology and Diseases of Women; also, on the subject of menstruation generally, Whitehead, the Causes and Treatment of Abortion and Sterility; A. Brierre de Boismont, De la Menstruation, 1842; Raciborski, De la Puberté, 1844.

during the existence of the menstrual phenomena, the blood was invariably found issuing from diseased surfaces situated upon or about the labia uteri, none escaping from the interior of the organ." *

But in any case there is wanting a sufficient series of observations, taking cognisance of the exact duration and times of recurrence of such discharges, and comparing these with the normal periods and intervals of menstruation, to warrant an unhesitating belief in the occurrence of a true catamenial flow as a possible phenomenon during gestation.

Quantity. — The quantity of the menstrual fluid which escapes at each period has been so variously estimated at different times and by different observers, as to render it obvious that the calculations could not have proceeded upon any common data. Thus Hippocrates, and afterwards Galen who quotes him, states the quantity as two Attic hemina, equal to about eighteen ounces. In recent times it has been estimated by Magendie at several pounds, and Haller gives the average amount as varying from six to twelve ounces. But all these estimates are too high. Dehaen, who employed an ingenious method of measurement, calculated that some women lost three, others five ounces, and very few half a pound ; but that it was exceedingly rare for a woman who had no malady to lose as much as ten ounces.† Probably the only proceeding by which any definite result can be obtained, is that of observing the rate of escape of the discharge from the uterine orifice. According to the observations of Mr. Whitehead, this is generally so slow that no more than from ten to twelve grains could be procured during the time that the patient was able to endure the irksomeness of the proceeding. From these, and similar observations of my own, as well as from other estimates, I conclude that two to three ounces is probably the full extent of the natural flow, and that a discharge amounting to six or more ounces in the aggregate will generally produce for the time sensible effects upon the constitution, such as general pallor, and some feebleness of the muscular system.

Nature of the catamenial discharge. — There is no foundation for the belief once so prevalent, and even partially still retained, that the menstrual fluid contains materials of a noxious or poisonous nature, nor yet that it serves as a vehicle for the depuration of the blood of the female. The occasional fœtid odour of the discharge, and sometimes also of the breath of women during menstruation, arises from the decomposition of the fluid, as it slowly collects in the vagina, and doubtless also from its partial resorption into the system, producing in such cases a heavy or fœtid odour of the breath, the cause of which was pointed out more than two centuries ago by De Graaf.‡ The menstrual fluid has always, even in health, a peculiar and somewhat heavy odour which

* Whitehead, loc. cit. p. 24.
† Brierre de Boismont, op. cit. p. 68.
‡ De Mul. Organ. Lug. Bat. 1672, p. 134.

is as characteristic of it, as is the *gravis odor puerperii* of the lochial and other discharges in childbed.* But these circumstances afford no evidence that the excretion is, when first formed, necessarily unhealthy.

The menstrual fluid, when first formed, appears to consist almost entirely of pure blood ; but, in its course through the vagina, it receives in addition the secretions of that canal, whereby both its physical condition and chemical constitution are materially altered. Hence the differences of opinion which have so long prevailed regarding the real nature of this fluid, and the extent to which it differs from pure blood. These differences have been maintained chiefly by the well-known fact that menstrual blood seldom coagulates, and also by the difficulty of discovering fibrine in it. But a solution of this difficulty is found in the fact that the mucus of the vagina has always an acid reaction, and that in this acid the fibrine of the blood is so readily dissolved, that not only is its coagulation prevented, but chemical analysis fails usually to reproduce more than a trace of it.

The menstrual fluid, therefore, as escaping from the vaginal orifice, and that collected from the os uteri, are essentially two different products, and this distinction should be observed in all examinations having reference to its chemical or physical composition. But it would be perhaps arbitrary to designate either of these alone the menstrual fluid. Probably this term is most suitable to the first. Both the vagina and uterus are concerned in the production of this fluid in the form in which it is most familiarly known, and in this form it may first be examined, the pure and unmixed product of the uterus being reserved for subsequent consideration.

Composition of menstrual fluid according to M. Denis.

Water	82·50
Fibrine	0·05
Hematosine	6·34
Mucus	4·53
Albumen	4·83
Oxide of iron	0·05
Osmazome and cruorine, of each	0·11
Salts and fatty matter	1·59

Microscopic examination. — The menstrual flux exhibits three periods or stages ; viz. the periods of invasion, stasis, and decline. In the first the discharge is of a paler colour, and sometimes consists mainly or entirely of mucus — *menstrua alba.* But this stage is not always observed, the discharge often commencing at once of the deep red colour characteristic of the middle stage. This continues during the greater part of the period, and is succeeded by the third stage or that of

* Doubtless this led Pliny to draw up that dire catalogue of evils, in which he informs us, that the presence of a menstruating woman turns wine sour ; causes trees to shed their fruit, parches up their young shoots, and makes them for ever barren ; dims the splendour of mirrors and the polish of ivory ; turns the edge of sharpest iron ; converts brass to rust ; and is a cause of canine rabies.—C. Plinii, Nat. Hist. liber vii. § xiii. ed. Cuvier, 8vo. vol. i. Paris, 1827.

decline, when the discharge loses its deep red colour and assumes the hue of water in which raw flesh has been washed. This is very commonly the condition of the discharge during the last day or two of each period, especially in those women in whom the flow is of long continuance.

M. Pouchet* has examined with great care the menstrual discharge at each of these periods. The following are the results of his observations: 1*st invasion.* A very few blood globules mixed with mucus may be observed, together with mucous-corpuscles and scales of epithelium, mostly entire, floating in an abundance of limpid fluid. Almost all the mucous-corpuscles contain smaller globules or granules which form in them a central nucleus. 2. *Stasis.* Menstruation having reached its apogée, the blood-globules are much more numerous than at the onset. The plates of epithelium usually remain entire. 3. *Decline.* The fluid contains the same substances, and presents nearly the same appearances as at the time of commencement of the flow.

These observations agree generally with my own, and also with those of Donné, who found the menstrual fluid to consist of, 1. Ordinary blood-globules of the proper character, and in great abundance. 2. Mucus from the vagina mixed with epithelial scales. 3. Mucous-corpuscles from the cervix uteri.

The unmixed menstrual fluid.—But in order to determine the nature of the menstrual fluid as it issues from the uterine orifice, unmixed with the secretions of the vagina, it must be collected by a speculum accurately fitting the uterine neck. The fluid so obtained possesses properties very different from those of the flux already described. Its sensible characters, as observed in more than a dozen specimens, are well described by Mr. Whitehead. Thus procured, the fluid is never so dark in colour as ordinary menstrual blood, so called, nor so fluid always as that of the arteries. Its colour varies slightly, but whatever is its tint, this is not subsequently affected by intermixture with the vaginal mucus. It appears usually rather more viscid than systemic blood, probably on account of its slow exudation. When thus collected it invariably coagulates, the separation into clot and serum being complete in three or four minutes. It sometimes passes off in a continued stream as pure blood, but more often as a thin coloured serum mixed with small flattened clots, the size of orange seeds, which, becoming broken down and, as it were, dissolved in the vaginal mucus, appear at the external orifice in the usual uncoagulable fluid form. It is invariably alkaline.

In menorrhagia the discharge is as fluid as arterial blood, and not being delayed on account of the greater rapidity of escape, it trickles in drops along the tube.

On account of the great difficulty which is experienced in obtaining the pure fluid from the uterus in quantities sufficient for chemical analysis, the following results by Bouchardat are the more valuable. The woman, a multipara, was thirty-five years of age. To explain the large proportion of water Bouchardat states that she had subsisted chiefly on a vegetable and milk diet.

Bouchardat's analysis of pure menstrual blood.

Water - - - - -	90·08

Fatty matter - - - -	2·21
Salts - - - - -	5·31
Mucus - - - - -	16·79
	100·00

It will be observed that the proportion of fibrine is here much larger than in the former example. But chemical analysis is not needed to show that this element of the blood constitutes a part of the fluid exuded from the uterus. For in women who have died menstruating fibrinous clots have been found in the uterine cavity; coagula have also just been described as forming at the os uteri and mixing with the fluid collected by the speculum, and it cannot have escaped observation that clots sometimes form about the vulva, at times of menstruation, especially when the discharge is freer than usual.

But the notion that the menstrual discharge differs from ordinary blood "in containing only a very small quantity of fibrine, or none at all,"* which view has gained general currency of late, and in support of which the investigations of Brande or Lavagna are usually quoted, appears to be altogether a modern one. For the older writers considered the menstrual discharge as identical with blood. Hippocrates says in reference to it, "procedit autem sanguis velut à victimâ, et cito coagulatur, si sana fuerit mulier." Mauriceau† says that menstrual blood does not ordinarily differ in any way from that which remains in the woman's body. So also Haller and Hunter, both of whom regarded menstruation as a natural evacuation of blood.

The results of these careful investigations therefore warrant the conclusion that the menstrual fluid, at the moment of its effusion, consists of pure blood, mixed only with the small quantity of mucus and epithelium which it receives in passing through the body and neck of the uterus, and that at this point it always has an alkaline reaction. But that in the course of its passage through the vagina the original fluid becomes mixed with the mucus of that canal, which there exists in increased quantities, and that in the acid of that mucus the fibrinous portion is so far dissolved as to render the detection, by chemical means, of fibrine, as a constituent of the secretion, difficult or impossible. So much, however, of fibrine as belongs to the blood-corpuscles must always be present, for these bodies exist in

* Théorie Positive, Atlas, plate xii.

large quantities in every instance of a healthy menstrual flux.

Source of the menstrual fluid. — The vagina, the os and cervix, and the body of the uterus, have been severally regarded as the parts which furnish the menstrual flux. And so far as the mucous element is concerned it is probable that all these surfaces contribute a certain proportion; but that the blood in normal menstruation is derived mainly from the lining membrane of the body of the uterus, is placed almost beyond doubt by the following considerations: —

1. In the uterus of one who has died whilst menstruating, a remarkable difference is usually perceptible in the condition of the mucous membrane lining the cavity of the body and cervix respectively. That of the body is highly injected, of a deep red colour, the vessels distinct, and the capillaries numerous. That of the cervix exhibits a condition the opposite of this. It is pale, uninjected, and free from all appearance of distended vessels.

2. If such a uterus be injected, the same conditions are observed in a more marked degree. All the capillaries on the mucous membrane of the body are filled, but comparatively few of the cervix; an abrupt line of demarcation occurring sometimes at the internal os uteri.

3. If gentle pressure be employed, as by taking the uterus in the palm of the hand, and slightly approximating the two sides, blood is perceived to flow up from the little pores or orifices of the utricular glands, which are everywhere perceptible, upon the surface of the mucous membrane, until this collects in the cavity in a quantity sufficient to cover the surface.

4. If the same experiment be made under water, in a dish or shallow basin, with the aid of very gentle pressure on the sides of the uterus, such as could not apparently cause any rupture of uterine vessels, the little streamlets of blood are seen welling up from each pore, and mingling with the water. In neither of these cases is the blood seen to proceed from any part of the cervix, but only from the lining membrane of the uterine cavity.

5. The blood, in ordinary menstruation, is seen to flow from the os uteri into the speculum, but is never observed to proceed from the lips of the cervix, except the latter be in an abnormal state.*

6. The cavity of the uterus, after death during menstruation, has been frequently found to contain blood or a coagulum.

From these observations it may be concluded, that in normal menstruation the blood is furnished by the walls of the uterine cavity. Whether the lining membrane of the oviducts also contributes any portion of the fluid is not certainly known. But I have had reason to think this very probable, from observing that, in cases of death during menstruation, the tubes as well as the uterus contained blood, which may in some cases, however, have entered them by regurgitation from the latter. (See also p. 618.)

By what means does the blood escape from the uterine vessels in healthy menstruation? — The investigation of this question is attended by great difficulties, and data sufficient even for its approximate determination are yet wanting.

The explanations which have been offered are chiefly the following: —

(*a.*) The blood is supposed to escape in the form of a secretion.

So long as it was maintained that the menstrual fluid differed essentially from pure blood, the view that it was eliminated from the general circulating current by a process analogous to that which obtains in true secreting glands received ready acceptance, and the menstrual fluid was, in accordance with such views, denominated a secretion. But since it is now known with tolerable accuracy to what portion alone of the menstrual fluid the term secretion can, with any degree of truth, be applied, it seems useless further to argue the question of secretion or non-secretion, in reference to the main ingredient of this fluid, which has already been shown to be pure blood, unaltered in its physical and chemical constituents, until after it has become mixed with other and adventitious matters.

(*b.*) The blood is supposed to escape by transudation through the capillaries of the uterine mucous membrane.

This view, which is proposed by Coste * and others, need not be considered specially with reference to the uterus. Those who think that the blood-corpuscles, which microscopic examination proves to be abundantly present in the menstrual fluid, can pass by transudation, unaltered and entire, through the walls of capillary or other vessels without rupture of their coats, will find no difficulty in applying this explanation to the production of a like phenomenon, as it may be supposed to occur in the uterus.

(*c.*) The blood is supposed to escape through lacerated capillary vessels.

Many observed facts give to this view a certain amount of probability. Thus, in an injected uterus the capillary vessels, which form so fine a network upon its inner surface (*fig.* 439.), may be occasionally observed denuded, and hanging forth in detached loops. In such a condition I have found the vessels when death has occurred during menstruation.† Unless this is a post-mortem change, which is improbable, it may be assumed that this laying bare of the capillaries is the consequence of a vital action, whereby a portion of the epithelial and mucous surfaces are broken

* Whitehead, loc. cit. p. 24.

* Histoire du Développement, tom. prem., 1 fasc. p. 209. 1847.

† I am not prepared to assert that this condition is always present during menstruation, or that it is limited to such periods. A larger number of examples than those in which I have observed this feature would be necessary to establish such a fact; and the whole subject requires a closer examination than has yet been given to it.

down, and subsequently discharged, along with the menstrual fluid. According to the observations of Pouchet *, such an exfoliation of uterine epithelium takes place monthly in women and the mammalia generally. Pouchet, indeed, maintains that not only is there a monthly desquamation from the uterus, but that this extends to the separation and expulsion of a deciduous membrane on each occasion, and that this expulsion, which takes place in the form of the broken down elements of the deciduous lining of the uterus, constitutes the process described by him under the title of intermenstruation. Such an exfoliation, if it extended only to the epithelial cells surrounding the uterine capillaries, would simply leave them bare, but if proceeding to the extent of removing the whole deciduous uterine lining, would of necessity carry off with it the whole capillary network of vessels, (see *fig.* 539.) lying upon the face of this membrane, and consequently would leave a surface of torn capillaries, from which the hæmorrhage might occur †, and this in fact takes place in cases when dysmenorrhœal membranes are discharged (*fig.* 443.).

(*d.*) The blood is supposed to escape by permanent vascular orifices.

In the present state of our knowledge, the evidence in support of this view is not more conclusive than that upon which the preceding hypothesis is built: yet many circumstances lend colour to it. The question of a termination of the uterine vessels by open orifices has been occasionally, though obscurely, touched upon by different authors. Thus, Madame Boivin ‡, a most careful observer, after speaking of the "perspiratory orifices of extreme minuteness," visible upon the inner uterine surface, evidently meaning the orifices of the now well-known uterine glands, describes the manner in which the blood may be made, by pressure, to appear in droplets upon the inner surface of the uterus when death has occurred during menstruation; and, without giving a personal opinion, she elsewhere quotes the then prevailing views, that the blood is furnished by the exhalent extremities of arteries terminating upon the inner surface of the uterus. Dr. Sharpey § endeavoured, by various expedients, to determine what is the precise relation of the blood-vessels to these orifices in the decidua a little more advanced *, as, for example, in early pregnancy; but after expressing his conviction upon the subject, the precise anatomical connection between the two is left undetermined. Ordinarily, in injecting the uterus with fine coloured fluids, I have observed the cavity to become filled, the injection apparently escaping by the glandular orifices, which also themselves may be seen filled with injection. In some specimens a capillary branch may be observed passing to and stopping short at one of these canals or orifices, and having much the appearance of an open vessel. Without personally expressing an opinion upon this point until I have carried further some experiments now in progress, I may observe, that the idea of a permanently open termination of vessels here need not be set aside upon the objection that such an arrangement would produce a constant bleeding, because the vessels supplying the blood must first pass through a dense muscular tissue, amply sufficient to control or arrest bleeding, as indeed it does effectually after labour, when much larger mouths are laid open, and also occasionally when menstruation is suddenly arrested by powerful mental impressions, acting apparently upon the muscular fibre of the uterus; while many positive facts might be adduced in support of such a view, such as the frequent bleedings of uterine polypi, which are always invested by mucous membrane, the ready passage of fluids through the surface of the latter when their main vessels are injected, and the like.

What is the purpose of menstruation?—To this question no reply will be satisfactory which does not include the consideration of many other circumstances besides the mere escape of blood. Menstruation has evidently a much deeper signification than is declared simply by the flux, which is probably not the most important part of the function, although it constitutes the external sign or evidence of it.

Amid all the crude hypotheses of former times, such as that menstruation is due to fermentation, lunar influence, and the like, some of the older writers appear nevertheless to have had a dim perception of the truth when, under the form of an elegant type, they shadowed forth that which appears to be the real purpose of the menstrual act. The French term, "fleurs," and the English, "flowers," are now fallen into disuse; but they were employed in earlier times as designations of menstruation, for the purpose of suggesting that, after the example of trees, which do not bear unless the fruit is preceded by the blossom, so a woman does not become pregnant until she also has had her flowers.†

Menstruation is not established until the ovaries have reached a certain stage of development, and the maturation and discharge

* Théorie Positive, Huitième Loi.

† Pouchet, who does not enter upon the question of the effect which such a monthly denudation of the inner surface of the uterus would have upon its capillary vessels, nor, indeed, at all upon the consideration of the precise mode in which the menstrual fluid escapes, makes this supposed exfoliation and expulsion of the menstrual decidua occur at the periods intermediate between those of the menstrual flux. Thus the idea of a separative process, which might have been made comparable with that occurring in labour, when the entire ovum is thrown off and a bleeding surface is left, from which the lochial discharge takes place, loses its significance from the circumstance that this phenomenon is said to happen at periods when there is no bleeding.

§ Müller's Physiology by Baly, p. 1579.

* It must be observed that throughout this article the terms "decidua" and "mucous or lining membrane of the uterus" are employed as strictly synonymous.

† Mauriceau, Malad. des Femmes grosses. 1681.

of ova has commenced.* It continues to be performed as long as the process of ovulation is continued; but when the latter ceases, and the ovaries have become shrunken, their tissues attenuated and wasted, and Graafian follicles can be no longer distinguished, menstruation ceases to be performed.

These facts show that menstruation and ovulation proceed *pari passu;* but they do not alone prove that the one function is dependent upon the other.

If, however, both ovaries are congenitally deficient, no attempt at menstruation is ever observed; while, on the other hand, in cases where the ovaries are present but the uterus is deficient, puberty becomes established in due course, and then a regularly recurring menstrual molimen may be observed, although for the want of the uterus this function cannot be carried out. See note §.

Or if, under ordinary circumstances, after the regular establishment of menstruation, both ovaries become extensively diseased, or both are removed by operation†, menstruation is from that moment permanently suspended.

Hence it appears that the presence of the ovary in a healthy state is essential to menstruation.

But something more also is needed; for the ovaries may be present and healthy, yet if they cease for a time to mature or emit ova, as for example during pregnancy and lactation, when they are passive‡, then, so long as those processes endure, menstruation is also commonly suspended, but returns after the completion of one or both of them.

A series of facts so consistent appears to admit of but one interpretation: namely, that a menstruating condition of the uterus bears a direct relation to the active operations of the ovaries, and that this function is only performed under circumstances which render pregnancy possible so far as the ovaries are concerned; but if the conditions are such that impregnation cannot take place, then the uterus, although it may be healthy, does not menstruate.

But, in addition to this general relationship between menstruation and ovulation, it is necessary to determine further if any direct correspondence exists between each separate act of menstruation and the maturation or discharge of one or more ova from the ovary, so that these two acts shall be coincidentally performed.

The following evidence supports this view.

The ovaries at the menstrual periods are not unfrequently the seat of pain and tenderness, indicating some unusual activity of this part. This is most remarkable in the rare case of hernia of the ovary.§

In women who have died during a menstrual period the ovaries have been frequently observed to present unmistakable signs of the recent rupture of one or more Graafian follicles. Some examples of this fact have been already given. In one case the ovum itself was found in the Fallopian tube (p. 567.).*

Conception is supposed to take place most frequently within a few days after a menstrual period, and therefore during the time which an ovum, if it were emitted from the ovary during menstruation, would occupy in passing down the Fallopian tube and perhaps in arriving at the uterus.

Menstruation corresponds in many particulars with the œstrus, or rut, in the mammalia, and in them it is only during the œstrus that ova are emitted from the ovaries, and that conception can take place.

The foregoing facts constitute evidence bearing upon two distinct points. The first series proving that a menstruating condition of the uterus is maintained only so long as the ovaries continue in the active performance of their function of preparing and ripening ova. The second series affording a certain amount of presumptive evidence, that each separate act of menstruation is connected with or is dependent upon a corresponding act of maturation, and perhaps of spontaneous emission of one or more ova from the ovaries.

The accuracy of the first conclusion will probably not be questioned; but if the second point is to be regarded, as at present, more than an hypothesis having many facts and probabilities for its support; if, as M. Pouchet believes, we are justified in considering as established laws of generation that in man ova are emitted from the ovary at fixed epochs and at no other times, and that these occa-

* The views of Dr. Ritchie in dissent from this statement have been already noticed, p 572.

† See Mr. Pott's case, p. 573.

‡ Négrier's, loc. cit.

§ In a case of this kind recorded by Dr. Oldham (Proceedings of the Roy. Soc. vol. viii. p. 377.), both ovaries had descended through the inguinal canals, and were permanently lodged in the upper part of the external labia. At intervals of about three weeks one or both ovaries were observed to become painful and tumid, the swelling augmented for four days, remained stationary for three days, and then gradually declined; the whole process occupying generally from ten to twelve days. It happened, unfortunately, that in this case the uterus and vagina were deficient, so that menstruation could not take place; but the case in one respect is the more interesting on that account, for notwithstanding the absence of the uterus, all the external signs of puberty were present, and the evidence of a periodical activity and excitement of the ovaries, and of a menstrual molimen affecting the organs which were not malformed, were here unmistakable. These circumstances forcibly call to mind the painful condition of the ovaries which, in a similar case, induced Mr. Pott to extirpate those organs.

* Upon the connection between the discharge of ova from the ovaries, and the phenomena of heat and menstruation, the following should be consulted, viz.:—*E. Home,* Lectures on Comparative Anatomy, vol. iv., and Phil. Trans. 1817 and 1819; *Power,* Essays on the Female Economy, 1821; *R. Lee,* Cyclopædia of Practical Medicine, art. Ovary, 1834; *Gendrin,* Traité Philosophique de Médecine Pratique, t. i. 1839; *W. Jones,* Practical Observations on Diseases of Women, 1839; *Paterson,* Edinb. Med. and Surg. Journ. vol. liii; *Girdwood,* Lancet, 1842–43; in addition to the works of *Bischoff, Raciborski, Négrier, Coste,* and *Pouchet,* already quoted under the title OVARY, p. 568., where will be found a full account of the process of ovulation.

sions, which furnish the sole opportunities for impregnation, bear the same constant relation to menstruation that the acts of ovulation and the times of conception in the mammalia bear to the œstrus, it becomes necessary to examine more closely the grounds of this belief; and for this purpose the circumstances as yet ascertained regarding the times of conception in women, the condition of their ovaries, not only during menstruation but in the intervals also, and the actual relation which the œstrus, or period of conception in mammals, bears to menstruation, may be briefly passed in review.

The precise period at which conception in the human subject occurs in most cases cannot, for obvious reasons, be determined, but whenever conception can be traced to a single opportunity, the process of impregnation, or the fertilisation of the ovum by contact with the spermatozoa, may be assumed to take place within a few hours after the act of insemination; for the spermatic fluid rapidly traverses the generative canal, while here spermatozoa cease to have motion within thirty hours at latest from the time of emission.

From various methods of computation it is supposed that in a large majority of cases conception occurs during the first half of a menstrual interval, and most commonly during the first week. In sixteen instances noted by Raciborski conception occurred as late as the tenth day after menstruation in only one case.*

The number of instances in which conception can be ascertained, or may be fairly assumed, to have taken place in the latter half of a menstrual interval is comparatively small. Nevertheless impregnation may unquestionably occur during this time, and even within a day or two of the next menstrual flow, which is then usually diminished in duration and quantity, or is reduced to a mere show.

Now if we endeavour to explain these facts, relating to the times of conception, by the aid of an ovular theory of menstruation, the question may be brought within very narrow limits. One of two postulates may be assumed. An ovum emitted at or soon after a menstrual period either remains susceptible of impregnation through the whole of the succeeding interval, or it loses that susceptibility, and perhaps perishes before the recurrence of the next menstrual flow.

The first hypothesis would sufficiently account for impregnation taking place at any part of a menstrual interval; but it has little or no evidence for its support. Nothing, indeed, is known regarding the length of time during which the human ovum remains susceptible of impregnation after it has escaped from the ovary. The period of susceptibility in the mammalia generally is variable. In the bitch, as already stated (p. 606.), the ovum, after quitting the ovary, is supposed to remain in the tube during six or eight days. Its passage is probably quite completed in ten days. In the guinea-pig the period is much shorter, as the ovum enters the uterus at the end of the third day. In the rabbit also the period does not extend beyond the beginning of the fourth day. But by the time that the ovum reaches the uterus, or sometimes even the lower end of the oviduct, in most of the mammalia yet observed, the œstrus is past, and with it also the opportunity for impregnation. The evidence therefore obtainable from the mammalia fails to support the conjecture, that in man an ovum detached during menstruation can remain susceptible of impregnation through the whole of a menstrual interval, consisting of twenty-three or more days, although the period of this susceptibility *may* be longer in man than in the other examples cited.

But if this first hypothesis fails, the second appears inevitable, viz., that an ovum emitted during menstruation loses its susceptibility of impregnation before the termination of the succeeding menstrual interval. M. Pouchet supposes, that in the human subject the duration of this susceptibility does not exceed fourteen days. Consequently if, according to the strict formula of the latter physiologist, ova are emitted only at or shortly after the menstrual periods, there must remain a portion of each menstrual interval, during which every woman is physically incapable of conception. And this alternative M. Pouchet* does not hesitate to adopt.

But since this conclusion is incompatible with the facts already stated regarding the occasional, though probably rare occurrence of conception during the latter portion of a menstrual interval, and especially towards its conclusion, M. Coste, who shares with many others a belief in these facts, has proposed an explanation which constitutes a very considerable modification of the ovular theory of menstruation. To account for impregnation at a later period than usual of a menstrual interval, M. Coste supposes that a ripe or distended Graafian follicle, having failed in reaching the point of rupture, may remain stationary, as it sometimes does in mammals †, and that the influence of the male is sufficient to determine the dehiscence of a follicle in such a state. And in order to anticipate the obvious objection, that if the emission of an ovum from the ovary is the cause or occasion of menstrua-

* These and similar facts have been commonly regarded as showing a greater *aptitude* for conception shortly after menstruation; but the influence of mere *opportunity* has not perhaps been sufficiently considered; for if, as in the case of the Jews under the strict requirements of the Levitical law, the whole of the first week, or that period which is commonly regarded as most favourable to conception, be withdrawn from the opportunities for impregnation, no diminution whatever of prolific power results.

* Théorie Positive. — M. Pouchet believes that a slender decidua is always formed at the decline of each menstruation, which, together with the ovum, whenever the latter is not impregnated, is cast off from the uterus between the tenth and fourteenth day, and that after this event every woman remains incapable of conception until the next menstrual period, when the detachment of another ovum from the ovary renews her capacity for impregnation.

† For a fuller statement of this view, with illustrative examples, see p. 568.

tion, the latter phenomenon ought to be repeated whenever the former event occurs; and consequently in the case now under consideration M. Coste suggests that the same cause which provokes the discharge of the ovum in this case, also occasions fecundation, which arrests the menstrual flux before this has time to manifest itself.

Thus, if even the foregoing explanation could be deemed satisfactory, it appears necessary occasionally to fall back upon the old doctrine of the detachment of ova coincidently with fecundation, in order to supply the deficiencies of the newer theory of their spontaneous emission independently of it. It must however be confessed, that every view yet offered of the direct dependence of each separate act of menstruation upon a corresponding act of ovulation, disappoints expectation by leaving some condition relating to conception unexplained, or explainable only by raising an additional hypothesis; while many circumstances of common occurrence, such as the sudden reappearance of menstruation under mental emotion and the like, are left unaccounted for upon any hypothesis of ovarian dominance.

If next the ovular view of menstruation be tested by the evidence derived from anatomy, although many facts will be found in proof of the statement that ova are often emitted at the menstrual period, these cases have not been yet sufficiently collated to form a series capable of affording unquestionable conclusions as to the precise relation which the emission of ova bears to each menstrual act. That ova may pass spontaneously from the ovary during the menstrual flow is proved by cases already given at p. 567. and 605. M. Pouchet, however, supposes that it is the *maturation* of the ova which takes place during menstruation, and that their *emission* follows immediately or within four days after the cessation of the flow. M. Coste found the period of *rupture* of the Graafian follicle to be very variable. In one case the follicle was already burst on the *first* day of menstruation. In a second instance, although *five* days had passed from the cessation of the flux, the follicle was still entire, though the slightest pressure sufficed to cause its rupture. In a third case *fifteen* days had elapsed, and yet rupture had not taken place. In the example represented by fig. 380. *ten* days had passed since the last menstruation began, and the follicle was entire, though perfectly ripe, and apparently upon the point of rupture.

These examples, in the same degree that they favour a belief in the occurrence of impregnation at indefinite periods of the menstrual intervals, by showing how conception is then possible, discourage the view that the *emission* of ova is necessarily limited to the precise times of the menstrual flow. But until a larger number of examples than yet exists, showing the condition of the follicles during both the menstrual periods and intervals, has been collected and carefully compared, no definite conclusions as to the exact relation which the *emission* of ova bears to each act of menstruation can be arrived at, so far as anatomical evidence is concerned. For the attention of observers having been directed more to the condition of the ovaries at the time of menstruation than in the interval, much more has been ascertained of their state at the former than at the latter periods. Yet it is during the intervals of menstruation that conception in man normally takes place, while mammals become impregnated only during the œstrus.

It is important, therefore, to determine, thirdly, how far the œstrus or rut in the mammalia may be regarded as comparable with the act of menstruation in the human female; for if, as is commonly supposed, these two functions are identical, or nearly so, then the facts to be derived from comparative anatomy may assist further in determining the nature and extent of the relation between menstruation and ovulation in man. But if the phenomena attendant upon the rut do not, in all respects, coincide with those accompanying menstruation, the conclusions which are legitimately deducible from observation of the former function must not be too strictly applied to the latter.

In the mammalia the periods of emission of the ova from the ovary, and of their passage down the Fallopian tube, are undoubtedly coincident with the œstrus. It is only on these occasions that the female manifests an instinctive desire for copulation. She is then said to be in heat. The vulva is congested, swollen, and bedewed with an increased secretion, which is generally odorous, and is sometimes tinged with blood. This condition is of brief duration. At the longest it continues for a few days. But whatever be its duration it is the only period during which the female can be impregnated.

In the human subject the periodical return of congestion of the reproductive organs, the menstrual flow, and the corresponding spontaneous emission of ova, so far as this point has yet been ascertained by post-mortem examination, accord with the phenomena displayed by the mammalia during the œstrus. It is also believed that in some instances conception has taken place *during* menstruation*, a circumstance which is clearly reconcilable with the anatomical evidences already produced, and is so far in accordance with what normally occurs in the mammalia during œstruation.

But here the analogy ceases. And from this point onwards the more closely the two functions are compared, the more plainly does it appear that although the œstrus and menstruation possess many circumstances in common, yet the resemblance endures only for a certain period, more or less brief, while, after this is past, there follows in man an intermediate condition which is not only not comparable with the corresponding intermediate

* Some of the few authorities for this fact extant are quoted in the works of Pouchet and Coste, *loc. cit.*

state in animals, but is in many of its essential features the direct converse of this.

For, as already stated, in the mammalia usually by the time that the ovum has reached the uterine extremity of the oviduct, or has entered the uterus, the opportunity for impregnation is lost, the œstrus is over, and the animal refuses the male: all the conditions immediately necessary to procreation then pass away, and an interval of perfect inaptitude ensues, which is sometimes so remarkable that not only are no ripe ova to be found in the ovaries, but even the male organ ceases to secrete semen. In this series of recurrent periods, marked by irresistible impulse, alternating with total inappetence for congress, nothing is more evident than that each corresponds with an internal physical condition, of which it affords a most intelligible explanation. The appetency occurring and remaining only as long as congress would be fruitful; the inappetency returning whenever this would be necessarily infertile.

Now, with regard to the human subject, whatever may be *possible* during menstruation, yet essentially the intervals of the menstrual acts are the times of fertility in women. And the only question that can arise upon this point is, whether the power of conception extends over the whole or over a part only of this interval—a question that has been already considered.

In all that relates, therefore, to the coincidence of the ovipont with the œstrus of mammals, the evidence derived from comparative anatomy serves to strengthen the belief in a corresponding correlation between the emission of ova and the act of menstruation in the human subject. But in respect of the interval, the great divergence of the facts here displayed tends to embarrass and perplex rather than to elucidate the question as it relates to man. For it is precisely in this interval that all the circumstances occur which, for want of a consistent explanation, have often thrown a doubt over the whole theory of the direct dependence of menstruation upon ovarian influence; and in elucidating these points, comparative anatomy affords little or no help.

In taking a retrospect of these several facts relating to menstruation and its connection with a corresponding ovipont, an essential distinction should be made between the influence of the ovaries in determining the power of the uterus to perform the menstrual act, and any influence which they may have over the periodicity of that function. In all that relates to the former faculty, the power of the ovaries may be regarded as indisputably established. In much that is connected with the latter, there is obviously room for more information than we at present possess.

If each separate act of menstruation is determined by certain modifications periodically occurring in the ovary, it is probable that the essential part of the process is the *maturation* of an ovum within the follicle, while the process of its *emission* may be an accidental feature, not always occurring, sometimes happening spontaneously, and sometimes caused in the way already suggested, but having nothing necessarily to do with the menstrual act, although the time of its occurrence may materially affect the period of a resulting impregnation.

The purpose of the *flux* remains to be considered. If the quantity of fluid escaping at each recurrence of menstruation be estimated at three, or possibly five, ounces, and the process is repeated, without interruption from pregnancy, lactation, or disease, once in every lunar month, or thirteen times annually for thirty years, then an aggregate quantity of seventy-two pounds or nine gallons on the former supposition, or of a hundred and twenty-two pounds or fifteen gallons upon the latter estimate, will have passed from the system in the course of menstrual life, and, so far as this is composed of blood, will have been apparently entirely wasted.

It is difficult to arrive at a perfectly satisfactory conclusion regarding the purpose of this large loss. For the external escape of blood must be regarded as, to a certain extent, an accidental feature in the process of menstruation. That it is not essential to fertility, is proved by the fact that women sometimes, though very rarely, breed who do not menstruate; that the temporary suspension of the menstrual flow during lactation is no certain preventive of conception; and that, occasionally, young girls become pregnant before the menstrual age has arrived.

The blood which escapes is certainly converted to no positive use. No office can be assigned to it, such, for example, as has been suggested for the analogous escape of blood into the ripe ovisac — an effusion that has been termed the menstruation of the follicle.* But although the blood, after it has passed the uterine epithelium, is altogether lost, it may, by escaping, fulfil the negative purpose of affording relief to the congested capillaries of the uterus. For we find, from various kinds of evidence, that, at each menstrual period, all the uterine tissues become charged with a more than ordinary quantity of blood, and, therefore, with the materials necessary to those rapid growths which have been shown to commence as soon as impregnation has taken place. From the moment that the latter occurs, the mucous and other tissues of the uterus begin rapidly to expand, and the current of blood is diverted to new channels. There is then no overplus, until the whole cycle of generative acts, including lactation, is complete. The only observable break happens at parturition; but after the balance of the uterine circulation has been restored by the escape of blood at the time of labour, and by the lochia, there is again usually no redundance until the office of the mammary glands has ceased. Then, the activity of the ovaries recommencing, the periodical hyperæmia of the uterine vessels returns, and the overplus is emitted in the form of menstrual

* See p. 556.

blood. And thus, by each act of menstruation, the uterus is placed in a state of preparation for that profuse development of its tissues which impregnation may at any time of the succeeding interval call forth.

The office of the uterus in insemination.— After menstruation, which is to be regarded as a process preparatory to impregnation, the next office of the uterus is that of receiving the seminal fluid, and apparently of conducting it to the Fallopian tubes, by which again it may, in rare instances, be carried as far as the ovary. To this office the form of the uterus appears to be well adapted in all its parts. For, first, the cervix uteri is so constructed as to lie in the centre of the upper dilated portion or fornix of the vagina, into which it projects to a distance of 3—4‴. This dilated extremity of the vagina forms a pouch which receives the extremity of the intromittent organ, and in this receptacle the seminal fluid is deposited. But, on account of the natural position of the uterus, which lies in the axis of the pelvic brim, while the course of the vagina corresponds with that of the cavity and outlet (*fig.* 433.), the cervix uteri is so directed (downwards and backwards) as to cause the os uteri externum to be maintained in the very centre of this pouch, so that the seminal fluid will be retained in a situation in which it is most certain to flow through this orifice into the cervix.* But the cervical canal is traversed by numerous furrows, which will act as so many channels, conducting the semen to the internal os, while the dilated central portion of that canal (*fig.* 424.) serves the purpose of a second reservoir.

It may also be readily believed that the ejaculatory act on the part of the male will suffice to carry the seminal fluid thus far, although the impetus with which it is propelled having been checked by the constriction caused by the external os uteri, would hardly suffice to carry it much beyond the more narrow barrier existing at the internal os. Or if it should pass this second obstacle, the almost complete apposition of the walls of the uterus would prevent any considerable penetration of the semen further into the uterine cavity, so far as this is dependent on the act of ejaculation.

But this very apposition of the uterine walls may, in another manner, assist the onward progress of the semen, by inducing a kind of capillary attraction, such, for example, as will cause water to rise, to a certain distance, between two plates of glass placed in close contact. The rigid walls of the human uterus, which are normally in such close apposition that sections made in certain directions scarcely suffice to display any appreciable cavity (*figs.* 426. and 427.), seem admirably adapted to favour this gradual rise of the seminal fluid between them towards the Fallopian tubes; and thus a compensation is provided for that peristaltic movement, which, in some mammalia with a more intestiniform and less rigid uterus, appears, under the influence of the coitus, to affect alike the vagina, uterus, and Fallopian tubes*, and to suffice for the conveyance of the seminal fluid from one extremity to the other of the generative track.

The action of the cilia of the uterine epithelium cannot, in any way, contribute to this result, if those observations are correct which agree in assigning to them a movement such as would create a current from within outwards; for it is obvious that such a motion would tend to retard rather than to advance the progress of the seminal fluid towards the Fallopian tubes.

If therefore any other power is needed to account for this movement, it must be sought in the action of the spermatic particles themselves. For, little adapted as their motions appear to anything like onward progression, yet they have been observed to continue long after ejaculation, in the fluid found within the uterus and tubes, and even upon the ovary.† It has been also proved beyond doubt that by this power the spermatozoa penetrate the ovum itself‡, and therefore to it may be attributed a certain share in the progress of the seminal particles through the uterus towards the oviducts, although this may not be a very considerable one.

Finally, it is possible that in man and the mammalia some such remarkable property may be possessed by the spermatozoa as that which I have observed in certain annellides. If a portion of the contents of the testis of the common earth-worm (*Lumbricus agricola*, Hoffm.) be placed under the microscope between two slips of glass, in about ten minutes the whole mass is seen to heave and writhe with astonishing energy, the form of the movement being that of the peristaltic action of the intestines (*fig.* 459.). Everything in contact with the spermatozoa becomes ciliated by them, one end of the filament fixing itself while the other vibrates free. The result is, that if the body to which the spermatozoa attach themselves is fixed, such as the glass, or the margin of a mass of granules, a line of cilia is formed whose action creates a strong current, and everything movable is drawn into the vortex, and is seen drifting rapidly along. But if the body to which they attach themselves is movable, then this soon becomes clothed with spermatozoa,

* Dr. James Blundell has described a peculiar movement which he observed in the vagina of the rabbit, and which serves to explain the mode of introduction of the seminal fluid into the uterus:— "This canal during the heat is never at rest; it shortens, it lengthens, it changes continually in its circular dimensions; and when irritated especially will sometimes contract to one-third of its quiescent diameter. In addition to this action the vagina performs another," which "consists in the falling down, as it were, of that part of the vagina which lies in the vicinity of the wombs; so that it every now and then lays itself as flatly over their orifices as we should apply the hand over the mouth in an endeavour to stop it. How well adapted the whole of this curious movement is for the introduction of the semen at the opening it is needless to explain." —Researches Phys. and Pathol. p. 55. 1825.

* Blundell *loc. cit.*; see also p. 611. of this article.

whose free ends moving rapidly, cause the whole to rotate. A most remarkable object

Fig. 459.

Spermatozoa of Lumbricus agricola in motion and forming cilia. (*Ad Nat.*)

is thus formed, which continues for a considerable time in motion, clearing for itself a free area, and in this it revolves, whilst its revolutions are apparently assisted by the action of other spermatozoa, which, having attached themselves to the periphery of the cleared space, keep up a perpetual vortex, in which the central body is partly a passive and partly an active agent.*

Whether any similar effect is capable of being produced by the spermatozoa in the human subject, or how far this property may be general in spermatozoa, I am not aware; but the circumstance is altogether too remarkable to be passed over without mention here, as it may serve to explain how the onward movement of spermatozoa can, in some cases at least, be aided by this peculiar property of the spermatic filaments to attach themselves to surfaces with which they were in contact, and to clothe these surfaces with a fringe of cilia capable of producing the ordinary effects of cilia in motion.

The office of the uterus in gestation.— The process of gestation may be considered to commence from the moment that the ovum, which has been subjected to the fertilising influence of the male generative element in the Fallopian tube †, is received impregnated into the uterine cavity. If no such contact of the generative elements as is necessary to the development of the ovum takes place, then the latter suffers no further change beyond that slight alteration in its condition during its passage through the oviduct, which has been already described; and ultimately it becomes lost, probably suffering decomposition, but at least giving no evidence of its presence in the uterine cavity. But if the ovum has been fertilised, then commences that remarkable series of changes in the physical condition of the uterus whereby this organ is fitted for the protection and nutrition of the ovum during the usual period of forty weeks in which the latter is normally retained within its cavity. As these changes involve very considerable alterations in the form and composition of the entire uterus, as well as of its several parts, they have been considered as a part of that series of metamorphoses which the uterus undergoes in its progress from infancy to old age, of which a description has been already given, (p. 644.).

The office of the uterus in parturition.— The act of parturition, or that process by which, in normal cases, the product of conception, after due development, is spontaneously separated and expelled from the parent body, constitutes the last chief office of the uterus.

The labour process may be regarded as essentially a contest between two opposing forces, which are *resisting* on the one hand, and *propulsive* on the other. Resistance is necessary to preserve the fœtus in its place. Propulsion is requisite to detach and expel it from the parent body. The resisting force is chiefly passive in its operation. It is that which is offered by the membranes enclosing the fœtus, by the os and cervix uteri, by the soft parts lining and closing in the pelvis, and lastly by the osseous and ligamentous structures of the pelvis itself. Naturally, these are sufficient to counteract any tendency to the escape of the fœtus from the operation of gravity upon it, in various changes of posture, or under any impulsive movements of the parent body. Their combined resistance is such as to require the operation of powerful muscles to overcome them before the child can be expelled. This power is supplied by the uterus, aided subsequently by the diaphragm and other muscles, abdominal and pelvic. Labour constitutes the performance, and birth the end of the process, for the accomplishment of which in a natural manner the forces should be nearly evenly balanced. The preponderance of power being, however, at first, on the side of resistance, and finally on that of propulsion. Whenever the forces are thus proportioned, the act of parturition is, *cæteris paribus*, natural. Whenever they are greatly disproportioned, the process is abnormal; whether the error be on the side of too much resistance, or too little propulsive force. In these last two particulars may be comprehended the history of every unnatural labour in which the mechanism* is at fault.

* These observations were first made by me at the time when the late Dr. Martin Barry announced his discovery of the penetration of the ovum by the spermatozoa in the rabbit, and were communicated to him, and subsequently for publication to Prof. Owen, in whose lectures on the invertebrata this account appears. Lectures on the Comp. Anat. and Phys. of the Invertebrate Animals, by Richard Owen, F.R.S., 2nd edit. p. 257.

† See p. 609.

* The mechanical operation of the parts concerned in labour having been reserved for con-

When labour is about to commence, the uterus having previously taken a lower position in the pelvis, begins to contract gently, and often without pain, so that the only or chief evidence of its action is an occasionally recurring tension and hardness of the organ.

These contractions commence apparently at the cervix, so far as it is possible to analyse them, and travel onwards towards the fundus *: the whole organ soon becoming firm and resisting to the touch, and its upper part rising and assuming a more prominent position in the abdomen. This hardness and tension is occasioned partly by the rigidity of the whole fibre, in a state of tonic contraction, and partly by the resistance offered by the incompressible contents of the organ, for which there is no exit so long as the cervix remains closed.

The contraction having overspread the uterus, a sense of pain is now first felt; the pain, like that of cramp, being usually proportionate to the sensible tension and hardness of the organ.

After enduring for a time the state of contraction gradually subsides, and is replaced by one of relaxation. In subsiding, the contraction observes the same order as in commencing, the os and cervix yielding first, while the upper portion and fundus remain longest tense and hard. From this it results that the antagonistic force, exerted by the two extremities of the organ, not being throughout contemporaneously and equally employed, the excess of the fundal over the ostial contraction will represent the measure of the unopposed, and consequently efficient, propelling power.

The period of action is followed by one of repose, in which the organ remains relaxed, and no pain is experienced.

After an interval of variable duration contraction returns, and continues to recur in rythmical order, but with a gradually diminishing interval, while at the same time the contractions, especially at the fundus, increase in intensity and duration.

As a result of these successive contractions, the os and cervix slowly yield, and a portion of the fœtal membranes, containing some liquor amnii, protrudes, in the form of a pouch. This, as the os uteri becomes still further opened, is followed by the head or some other portion of the child, which, having entered the vagina, ultimately fills up the pelvis, and distends the perineum.

At this period the abdominal and pelvic muscles are brought powerfully into play. Their cooperative action is occasioned by the parts of the child occupying the pelvis irritating structures which are abundantly supplied by spinal nerves. And now the chief use of spinal reflex action, in relation to labour, becomes manifest, not so much in regard to the uterus itself, whose contractions are probably still mainly dependent upon its own sympathetic nerves, as in that correlation with other parts, between which and the uterus it is essential that consentaneous action should be occasionally established.

The powerful cooperation of the abdominal muscles, which form as it were an additional sheet of contractile fibre, nearly surrounding the uterus, being thus enlisted, the passage of the child is completed with greater rapidity and certainty; and, after a pause, the placenta and membranes are expelled, the liquor amnii having, either altogether or in part, escaped at some earlier period of the labour.

This general sketch of the operations of the uterus in labour will suffice as an introduction to a more detailed and critical examination of the nature of the forces employed, and of the manner in which these are called forth.

Of the peristaltic action of the uterus, and its cause. — From direct observation upon many mammalia, it is known that the action of the uterus is in them peristaltic, *i.e.*, the contractions commence at certain points, and pass on from segment to segment slowly, and in a vermicular manner. If a single point of an organ so composed is irritated, the action starts from the point of irritation, and spreads outwardly, and by irritating different points, other peristaltic centres may be obtained.

Although the human uterus does not admit of the same direct methods of observation which can be employed in animals, yet from all that is known, we may conclude that its mode of contraction does not differ in any important particular from that of other similarly constructed hollow muscles, when engaged in propelling or expelling their contents.

The principal circumstances bearing upon this point in regard to the human uterus are the gradual and slow contraction, followed by an equally slow return to a state of relaxation —phenomena easily observed, when the hand is placed upon the abdomen of a woman in labour—a certain tremulous motion of the os uteri, when contraction is commencing, followed by a sensible gradual hardening of the uterus, before the woman is herself conscious of pain; the longer abiding of the contraction at the fundus than at the cervix; and the occasional segmental contraction of the organ after labour, commonly termed *hour-glass contraction* *, which may occur at any point intermediate between the fundus and cervix, and which resembles similar contractions of common occurrence in other hollow muscles, whose action is peristaltic. These several circumstances, added to the general analogies, suffice to show that the action of the human uterus is peristaltic.

Peristaltic action, as it occurs in vertebrate animals, is found to depend upon the structure of the organ displaying it, rather than

sideration in a separate article (Parturition, Mechanism of, Vol. III. of this Cyclopædia), the vital endowments only of the uterus, as far as these relate to the parturient act, are here examined.

* Wigand, Die Geburt des Menschen. Berl. 1820.

* See p. 702.

upon the mode of its innervation or excitement. So that if in a situation where organic fibre is usually found, the intestine, for example, of *cyprinus*, the part is composed of striated muscle, then no organic or peristaltic action can be produced in it; but upon excitement, contractions of the kind usually seen in striated muscular fibre ensue.*

In the same way the peristaltic action of the uterus, although exhibiting certain differences, according to the manner in which it is evoked, is nevertheless to be referred to the peculiar composition of unstriated fibre, and not to the mode of innervation or excitement of the organ.

For the muscular fibre of the uterus is not bound up in separate sheaths, as voluntary muscles are, nor do the fibres run principally in one direction, nor are they long and continuous — conditions all favourable to that quick transmission of nerve influence, and rapid action which occur in voluntary muscle — but the fibre cells are for the most part distinct, lying in apposition, or imbedded in a matrix of amorphous tissue (*fig.* 436.), and forming by their combination intricate laminæ.

Through a tissue so composed, the influence of a stimulus can only be propagated slowly, and the organ formed of it can only contract after a vermicular or peristaltic manner. Nevertheless, the power, the endurance, and the orderliness of the action that ensues, will be, to a certain extent, dependent upon the nature and mode of application of the excitant. It cannot be questioned that, under many circumstances, the direct application of a stimulus to the uterine muscular structure excites its contractions in the same manner that the food does those of the œsophagus and intestines, without any intervention whatever of nerve. This happens when the hand is passed into the bare uterine cavity after labour, or when the membranes are separated from the inner surface of the uterus by a catheter.

To bring such an organ into *co-ordinated* action, all that appears necessary is, that nerve fibres should enter its tissue at a certain number of distinct points or centres, whence the irritation excited at these spots being propagated from fibre to fibre, may spread through the mass, until the whole is brought into harmonious operation.

And it need not excite surprise if these centres of excitement are few, and the nerves of the gravid uterus consequently not numerous; for a more abundant supply of nerve force, and more rapidly recurring contractions, would be prejudicial in labour, by bringing the uterine walls more constantly and violently into contact with the fœtus, and by driving out the blood passing through them so rapidly as to cause dangerous regurgitation, or so frequently as to produce fœtal asphyxia, through too constant interruption of the placental circulation.

* Weber, in the article *Muskelbewegung*, in Wagner's Handwörterbuch. 1856.

It is in favour of the views of Wigand, who maintains that uterine action begins at the cervix, and travels upwards, that the cervix receives a larger supply of nerves than the fundus, so that the action may be here first established, and the fundus afterwards excited. But however this may be, it is known that unless all parts of the organ are eventually brought into consent, the labour does not proceed regularly, for if one portion is felt to be hard, and another at the same time soft, irregular action and spurious pains ensue. To ensure, therefore, consentaneous action between the respective points of the uterine fibre at which the nerves enter its tissue, and to establish and regulate the movements, appear to be the offices of the nerves in relation to the uterine structure.

Of the rythmic action of the uterus, and its cause. — The uterus, like the heart and the respiratory muscles, is time-regulated or rythmic in its action. In this action the usual three rythmic periods are noticeable, viz., a period of contraction, a period of relaxation, and one of repose.

The sensible phenomena which accompany the first period are, a gradually increasing and sustained hardness of the uterus, a gradual approach and continuance of suffering, and, after a time, a certain advance of the presenting part of the child. These occurrences do not commence coincidently, but each overtakes the other in the order enumerated.

The phenomena of the second period are, the gradual subsidence of the hardness, the gradual passing away of the pain, and the retiring of the presenting part, and these are more nearly coincident than the former.

The third period is marked by an absence of all sensible signs.

These three periods together constitute the uterine rythm, which observes certain laws, that are in some respects different from those which govern the rythmic action of other parts, as for example, of the circulatory and respiratory organs respectively.

In the action of the uterus, the repeats take place more slowly than in either of the instances just named, although between these two, also, there is a proportionate difference, nearly, or quite as great. The heart's rhythm being quickest, the respiratory rythm slower, and that of the uterus slowest of all.

But the rythm of the uterus does not observe a constant or uniform rate. At the commencement of labour, the order of sequence of the rythmic motion remains for a time tolerably constant; but as the process advances the rythm becomes modified, so that, like the example of the heart under violent emotion, the interval shortens, while the force and vigour of the contractions increase.

It is a matter of great interest to discover, if possible, the determining cause of this rythm; that which constitutes the regulating as well as the disturbing force. The latter should be rather termed the accelerating force, for it is beyond question a healthy necessity which, for the purpose of advancing the process, demands this graduated change of the uterine rythm throughout labour. Rythm plainly does not, like peristaltic action, depend upon the structure of the organ which displays it, for the three examples here taken, viz., respiratory muscles, heart, and uterus, differ from each other materially in composition. The first consists of striated voluntary fibre; the second of striated involuntary fibre; the third of unstriated involuntary fibre. It may therefore be concluded, that something else than structure determines rythm. This appears to depend rather upon the manner in which the contractions are evoked, and hence upon the mode of innervation, which is different for each organ. The heart and respiratory muscles each admit of more easy observation than the uterus, and referring to them for aid in the elucidation of this question, we find that each of these organs, or sets of organs, is provided with a nervous rythmic centre, upon which its rythm depends, and upon the injury or destruction of which the rythm immediately ceases, — the rythmic centre of respiration being in the medulla oblongata, and that of the heart in its own proper ganglia. Which of these divisions of the nervous system furnishes the rythmic centres of the uterus has not been determined, but from the analogies just quoted, we may select by preference the heart, because its actions most nearly resemble those of the uterus, in being purely involuntary, while the case of the respiratory muscles constitutes an example of mixed movements wherein volitional can be superadded to unconscious rythmic motion.

If therefore the rythmic action of the uterus is regulated in like manner with that of the heart, we must, upon the strength of this analogy, look for its rythmic centres among the sympathetic ganglia which lie nearest to the organ.

And this view does not necessarily exclude a certain influence of the spinal nerves over the rythmic action of the uterus. For just as under emotion or bodily excitement both the cardiac and respiratory rythms are accelerated, so, as labour advances, and more parts become irritated, the uterus appears to receive an addition of nerve force which may be possibly acquired from other and more distant centres than its own proper ganglia.

The heart's rythmic centres have been regarded by some physiologists as so many "magazines" of nerve-force, whence at regulated intervals this force is discharged, causing the muscular structure to contract in accordance with the rate of supply of the stimulus. The influence of these nerve-centres is best shown by placing a ligature upon them, or by cutting them away. When hindered in their operation by tying, the *rythm* ceases, though the motor power is not lost. When they are cut away, together with certain portions of the heart, the other portions cease to have rythmic motion, though they may still be artificially excited to repeated single actions.*

But an inconstant stimulus thus furnished to the muscular structure being powerless to produce a permanent or tonic contraction, the effect after a short time passes away to be reproduced upon a fresh application of the excitement. In this way rythm, so far as it is dependent upon nervous supply, is apparently determined.

But in the case of the uterus we observe that the *rate* of the rythm must be to a certain extent limited by the peculiar nature of the uterine fibre. For this, as already shown, is of a kind which cannot be excited to *rapidly repeated action* like the heart. In this form of fibre the response to the stimulus is slow, and often does not take place until after the excitant is withdrawn. Hence the meaning of that slow repetition of uterine action which is observed in ordinary labour.

When this point is further examined, it will be found that, according to the degree or kind of excitement employed, the uterine rythm may be merely accelerated, or a rythmic may be converted into a more continuous action. The influence of the passage of the child during labour over successive surfaces in quickening uterine action has been already shown. Another example may be drawn from the effects of ergot. When ergot is given by the stomach some time usually elapses before the ergotine mixes with the blood sufficiently to excite the rythmic centres, but that being done, the action is simply augmented, or else occasionally it becomes so violent that the intervals are obliterated, and one contraction becomes merged in another, so that an intermittent is converted into a continuous uterine action.

But that which more certainly demonstrates that the rate of the motions, whether rythmic or constant, is dependent on the kind and extent of irritation, is the variation in the results obtained by different modes of inducing premature labour. If, according to the method of Kiwisch, water is injected simply against the cervix, after several repetitions, rythmic action is slowly excited. If the cervix is distended by the introduction of a sponge tent, rythmic action ensues more quickly and certainly. But if the first proceeding is so varied that the water, instead of being merely thrown against the cervix, is introduced between the membranes and the uterine walls for a very short distance, so as gently to effect their separation from the inner surface of the uterus, labour is induced with greater certainty and speed than in any other way; but should the separation be carried still further, some such tumultuous form of labour results as ergot produces when acting in the manner just specified. The uterus acting continuously and very energetically rather than intermittingly.

Influence of the different nervous centres upon the uterus in parturition. — In the present unsettled state of neural physiology, especially in

* Paget, Croonian Lecture; Proceedings of Roy. Soc. vol. viii. No. xxvi. 1857.

relation to the powers of the different nerve centres, it is scarcely possible to arrive at any satisfactory conclusion regarding the relative degrees of influence which these may be supposed to exercise over the movements of the uterus. The marked differences of opinion still existing upon this subject* afford sufficient evidence of the uncertainty of the data upon which definite conclusions can be based. In this uncertainty, however, all points of the nervous system are not equally involved.

The amount of influence of the cerebrum upon the act of parturition can be determined with tolerable accuracy. That the uterus is in communication with the brain is proved by the fact that the woman is conscious of the fœtal movements, and that she suffers pain when the uterus contracts. Emotion may excite, and may also for a time delay, uterine action. The will cannot operate directly upon the uterus, either in the way of producing, or of restraining its contractions, but a slight indirect influence may be occasionally perceived, when by voluntary changes of posture, or by the use of those muscles which assist labour, the force of the uterus is slightly increased; or conversely, when, by carefully restraining all such movements and actions, this result is avoided.

It is further shown by the occurrence of labour in cases of complete paraplegia, and also during states of unconsciousness, induced by anæsthetics, that the uterus contracts while it is withdrawn from all volitional and like cerebral influences.

These several examples serve to show to what extent the contractions of the uterus may be influenced by the cerebrum, and also how that influence may be withdrawn. It is obvious that psychical influences are neither necessary nor accessory to the simple act of labour. They may often be regarded as disturbing, but not as regulating forces. Hence the dominant power over the contractions of the uterus, which is exercised during labour, must have its seat in some of those nervous centres that are placed lower than the cerebrum.

We may therefore proceed next to inquire what are the attributes which from direct observation and analogical reasoning the uterus may be supposed to derive respectively from the ganglionic and spinal systems, regarded as separate sources of motor power. But here, on account of the intimate manner in which the nerves derived from each of these centres are bound up together, great difficulty arises in distinguishing between the operations of each, and these difficulties can be only in part surmounted.

The circumstances which point more particularly to the influence of the ganglionic system will be first considered.

The uterus derives a greater proportionate supply of nerves from the ganglionic than from the spinal system. This appears from the researches of both Snow Beck and Kilian. The actions therefore of those parts or organs having like endowments, which are in other respects also comparable with the uterus, may be here examined.

Of all organs the heart is that which most nearly resembles the uterus. It constitutes, after the uterus, the largest hollow muscle. Like the uterus, it acts with rhythm, and, in a certain degree, peristaltically. It continues its contractions, with little, if any, interruption, for a long time after its principal cerebro-spinal connections have been destroyed, as by tying the pneumogastric nerves. It continues to contract rhythmically in many animals for a variable time after death, or when cut out of the body Its contractions are regulated mainly by sympathetic ganglia, while the cerebro-spinal fibres which it receives serve to establish relations between it and other parts.

The uterus exhibits many like peculiarities. It acts with rhythm and peristaltically. It continues these actions, in numerous species of animals, for a variable time after death. Even in the human subject, a post-mortem power of contraction seems to be occasionally retained, as in the case of women whose spontaneous delivery has taken place some time after all evidences of somatic life have ceased.* In these several offices we may conclude that the uterus also, so far as its operations are under the dominion of the nervous system, is, like the heart, chiefly influenced by sympathetic ganglia and nerves.

That this is the case is also further shown by the occurrence of delivery under circumstances in which *all* spinal influence appears to be abrogated. The following is an example.†

A woman was attacked with paraplegia in the eighth month of pregnancy. She had neither sensation nor motion in any part below the umbilicus. No reflex movements whatever could be produced by tickling the soles of the feet. The fæces passed involuntarily, and the urine was drawn off daily. About the ninth month, her medical attendant, when about to pass the catheter, found a full-grown fœtus in the bed (dead). The uterus was contracted, and the placenta in the vagina. The

* See *Tyler Smith*, Parturition and the Principles and Practice of Obstetrics; and Lancet, 1856. *Scanzoni*, Lehrbuch der Geburtshilfe. *Brown-Séquard*, Physiology and Pathology. *Carpenter*, Principles of Human Physiology; and *Todd*, art. Nervous System, in this Cyclopædia.

* A large number of these cases has been collected by Dr. W. H. Wittlinger, "Von der nach dem Tode der Mutter von selbst erfolgenden Geburt," in the Analekten für die Geburtshülfe, Bd. I. 1849. All cases of *post-partum* delivery are probably due to one of three causes, viz., to a contractile power or irritability remaining in the uterus after death, and comparable to that which in voluntary muscles produces the now well-known *post-mortem* cholera movements; to *rigor mortis;* or to the development of gases within the abdomen or uterus, causing the expulsion of the child by pressure. The first is probably the cause of birth within a few hours, and the last several days, after the death of the mother, and the second of the expulsion of the fœtus before decomposition has set in, yet at a later period than can be accounted for upon the first hypothesis.

† For this case I am indebted to Mr. Paget.

woman was entirely ignorant of what had occurred. Scanzoni and Chaussier relate similar examples of birth taking place notwithstanding complete paralysis of the sensitive and motor functions of the lower half of the body. In Chaussier's case the pressure was occasioned by a hydatid cyst which involved the chord on a level with the first dorsal vertebra.*

On the other hand, that the uterine movements are also *capable* of being influenced by spinal fibres, appears from the following considerations. Uterine contractions may be excited by the application of cold to the general surface of the body, or by placing the child at the breast; by injecting warm and stimulating fluids into the rectum, and in other like modes.

Again: the uterus, under various circumstances of health and disease, is observed to react upon all or several of the parts just named.

Hence it appears that a mutual relationship is established, by virtue of which the uterus may be either the excitor of actions in these parts, or may through them be itself excited to action. And there can be no doubt that the spinal cord is the agent through whose reflex operations these several effects are produced.

From this evidence it may be concluded that the double supply of nerves answers different purposes. That the *spinal* system furnishes nerves for the purpose of bringing into harmonious relations all those organs whose cooperation with the uterus is essential or accessory to various steps of the reproductive process. While the organ deriving also a similar or even larger supply from the *ganglionic* system, these nerves serve to regulate the functions which the uterus itself is capable of discharging without cooperative aid. In this view the offices of the spinal system, as a system of relations, and of the ganglionic, as a system presiding over the direct acts of the parts which it supplies, may be separately exhibited. It is doubtless also a chief office of the ganglionic system to regulate and control the action of the blood-vessels with which the uterus is so largely supplied.

What is the exciting cause of labour?— This question carries us only one stage further in the preceding course of inquiry: and the reply to it will be nearly found in the facts already stated. For if these serve to throw light upon the causes of the rhythmic and peristaltic movements of the uterus, then the conditions which determine the first rhythm and first peristalsis, or, in other words, the beginning of labour, cannot lie very remote from these.

Many circumstances may evoke the first rhythm, which being followed by others, labour becomes established. Thus, irritation of incident nerves in various parts and organs may so force those sympathies with the uterus which, for other uses, are established by the spinal system of nerves, as to bring on an unnatural and premature form of labour; — but this is not the present question.

The determining causes of natural labour can be only satisfactorily sought among that class of phenomena which causes the separation of the ripe fruit from the stem which bears it: in a perfecting, namely, of the fruit or product of conception, so that it becomes fitted for an independent existence, and as a step preparatory to this, in a gradual metamorphosis of those tissues which, having served for a time the purpose of connecting the two together, are now no longer required by either. This connecting medium in the human subject is the decidua, which lines the whole uterus. Its metamorphoses during pregnancy have been described. Already as early as the middle of that period, the preparation has begun for a new tissue, which, after labour, is to reconstruct the lining membrane. The old attenuating and perishing decidua, now no longer needed, except at the spot where it

* Cases of paraplegia have sometimes occurred in which artificial aid appears to have been needed to complete the delivery, as in a case cited by Brachet (Fonctions du Système nerveux ganglionaire, p. 266. 1830). By those who contend for a preponderance of spinal influence over labour, such cases are cited in proof. It is said that notwithstanding the complete loss of sensation and motion in the extremities, independent reflex operations may still be preserved in the uninjured portion of the chord. But the motions which may be occasionally excited by irritating paralysed limbs are "disorderly and purposeless," and are in no way comparable with those co-ordinated actions that characterise natural labour. Moreover, the argument is entirely inapplicable to the case cited in the text, in which no reflex action whatever could be produced. It has also been supposed that an essential distinction may be drawn between cases in which the disease is situated high up, and those in which it occupies a lower situation: in the latter cases the portion of chord supposed to furnish spinal nerves to the uterus being involved in the disease, and in the former not. But such conclusions can be of little value until the precise limits of the chord, whence spinal fibres can be derived to the uterus, have been anatomically determined. (See the account of the origin of these nerves at p. 641.)

For like reasons it does not appear that in the present state of neural physiology in relation to the uterus, satisfactory conclusions can always be drawn from experiments upon animals. For although it might seem probable that in a case of mixed nerves, by destroying the centre or origin of one of the sets, the functions of the other might be left unimpaired; or by stimulating one of the nerve centres alone, their actions would be exclusively called forth, while the rest would remain passive; still, absolute conclusions cannot always be arrived at, even in these ways. For in the latter case, on account of this very intermixture of nerves, whenever we attempt to stimulate ganglionic centres, or plexuses, we are dealing at the same time with the spinal fibres which pass through them. Or contrariwise, when we endeavour to destroy extensive tracks of spinal centres, we do not know if the arrest of labour that may follow is not due to the violence which, in most of these experiments, has caused the death also of the animal within a few hours or days after, rather than to the destruction only of the portion of spine whence uterine fibres are supposed to be derived. In this way, perhaps, we can explain those discordant results of experiments, in some of which labour has been arrested, and in others has not apparently been interfered with, so far as uterine action alone is concerned, after greater or less injury or destruction of the chord.

covers the placenta, loses by degrees the character of active vitality, and its tissues are converted into molecular fat.

Other and corresponding changes, of which an account will be hereafter given (see PLACENTA), occur in those structures in which the fœtal blood circulates. The profusely developed capillaries which ramify within the villi during the early and middle periods of gestation begin to suffer retrogression as the time of separation approaches, and the fœtal blood flows in more simple and relatively fewer channels, while, not unfrequently, entire villi become obliterated by calcification.

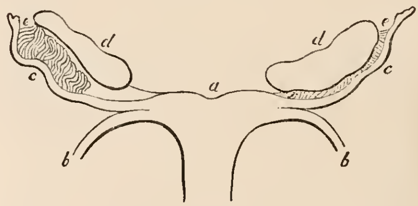
While these changes are proceeding in the temporary structures that serve to connect the fœtus with the uterus, structures which begin in part, at least, to become effete, even before the offices for which they are formed have been fully carried out,—the tissues which are to be employed in the process of expulsion are as yet only ripening into full strength, although they also, in turn, are about to suffer a like retrogression, but not until the object of their formation has been accomplished. The contractile fibre, which constitutes the principal portion of the uterine tissue, has gradually, during pregnancy, advanced to that more complete form which is reached commonly about the sixth month. From this period probably no new development of muscular fibre takes place, although that which is already formed appears to increase somewhat in size and power. It constitutes now a contractile tissue, capable of exerting great expulsive force. How easily, and in how many ways, the contractile power may be evoked, has been already shown. It is probable that by the series of metamorphoses already enumerated as occurring in the parts which connect the fœtus with the uterus, the entire ovum becomes gradually placed in the position of a foreign body within that organ; a position which may be compared to that of the food within the alimentary canal. And just as the food is propelled onwards, peristaltically, by irritation of successive portions of the containing surfaces, until, with the subsequent cooperation of muscles acting under the dominion of the spinal cord, it becomes finally ejected; so the ovum is itself apparently the excitor of those first peristalses in the uterus which initiate labour. How these become coordinated and established, and how the rhythmic periods are probably determined, has been already considered, as well as the means by which, during the further advances of the child over successive portions of the generative track, other nerve and motor forces are added to those with which the process commenced.

ABNORMAL ANATOMY OF THE UTERUS.

A. *Defective development.* — Imperfect or defective development of the uterus may occur under two circumstances. There may be either an original defect in its organisation, arising from a failure of growth or imperfect formation of those portions of the generative canal out of which the uterus is developed; or else the organ, having been regularly formed during embryonic and fœtal life, may not have proceeded in its development, but may have retained the infantile character after the usual age of puberty has arrived and passed.

1*st Class. Congenital defects.* — Defects of this class may affect the uterus alone, or may be conjoined with corresponding imperfections of other organs. In order that their nature and origin, as well as the possibility of their occurrence, independently of any malformations of the other reproductive organs, may be clearly understood, it is necessary to remember the mode in which the uterus is originally constructed. Formed by the coalescence of

Fig. 460.



The entire internal generative organs, from a fœtus of three months. (*After J. Müller* × 8.)

a, uterus; *b*, round ligaments; *c*, Fallopian tubes; *d*, ovaries; *e*, remains of Wolffian bodies.

the inferior extremities of the ducts of Müller*, the uterus will be materially modified in its construction according to the degree of perfection of those ducts, as well as by the amount of union which has taken place at their lower terminations.

Taking these particulars as affording a basis for classification the malformations of the uterus which are dependent upon original vices of formation may be arranged in four groups, viz.: —

Group 1. The ducts of Müller being both imperfect or undeveloped, there results a more or less complete absence of the uterus. The examples of total absence of the uterus which have been recorded are probably cases in which the rudiments exist, but have been overlooked, on account of their slight development; for generally there may be traced a more or less distinct fold of peritoneum lying behind the bladder and representing the broad ligament, within which are found some indications of a uterus. These rudiments consist of two uterine cornua, either conjoined at their lower extremities, or remaining separate in their whole course. They usually occur under the form of two hollow rounded cords or bands of uterine tissue, extending upwards towards the ovaries, and united perhaps at the usual seat of the uterus by cellular tissue, with which some uterine fibres are intermixed. Sometimes one or two little masses of uterine tissue are found. These are either solid, or they contain a small cavity

* See p. 642.

lined by mucous membrane. This constitutes the condition designated by Mayer the *uterus bipartitus*. The concomitants of this condition may be a short vaginal cul-de-sac, together with rudimental Fallopian tubes, and perhaps well developed ovaries. In the latter case the external organs may be well formed, and there may be no deficiency of sexual character, or the vagina may be entirely wanting.

The coexistence of this rudimental uterus with ovaries well developed is easily explained. For the ovary is formed out of a separate portion of blastema from that from which the Wolffian bodies and excretory duct of the generative apparatus are developed, *fig.* 400. and 416., so that the failure in growth of the one does not necessarily involve a corresponding defect in the other.

Group II. If one uterine cornu retains the imperfect condition last described, while the second undergoes development, the one-horned uterus or *uterus unicornis* is produced. So that the organ here consists of a developed and an undeveloped half combined.

The developed uterine horn may be either the left or the right. It then consists of a cylindrical or fusiform canal or body, curved outwardly in the form of an arch which exhibits various degrees of deflection from the meridian. To its upper extremity is usually attached a tube leading to the seat of a well-formed ovary.

The second or undeveloped cornu, with its tube, is not always entirely deficient ; but there often exists a rudiment in connexion with the developed horn, which, according to the degree of malformation, is either solid or hollow, or is traversed by a canal opening into the cervix of the developed half.

In the case of the uterus unicornis, notwithstanding the imperfection of one uterine half, both ovaries may be found alike developed.

The type of this condition of uterus exists as a normal formation in the class aves, where one side only of the generative apparatus proceeds in its growth, and the other remains undeveloped from an early period of fœtal life.*

Group III. If, instead of an unsymmetrical growth of the two uterine cornua, such as occurs in the last example, both sides are alike developed, yet without any, or with only an imperfect, junction of their lateral borders there is produced a *uterus bicornis*, falsely termed a double uterus (uterus duplex). Here however there is no evidence of plurality, or true duplicity of the uterus, but only a deficiency of that union of the two separately formed halves by whose subsequent conjunction the organ is normally constituted.

This conjunction should naturally commence from the level of the point of attachment of the round ligaments, and the variations in the degree of malformation will be according to the height at which the union of the uterine halves stops short of that point.

The highest degree of malformation in this group, or the greatest departure from the normal form, is that in which the two uterine halves do not coalesce at all, but remain completely divided in their whole extent. This happens very rarely, and is co-existent with other malformations, such as fissure of the abdominal and pelvic walls. The division is here so complete that certain of the pelvic or abdominal viscera may occupy the space between the two uterine halves.

In the next degree of this kind of deformity a horizontal commissure occupies the angle in which the two uterine halves meet, and serves to unite them together (*fig.* 461.). The horizontal commissure is composed, like the cornua, of uterine tissue, and represents the fundus uteri. According to the height at which it is placed, the external form of the uterus approaches or recedes from the normal type. Rokitansky* has pointed out how the situation of this commissure affects the angle in which the two cornua meet, and consequently the relative mutual position of the two uterine halves. The nearer the point of co-

Fig. 461.

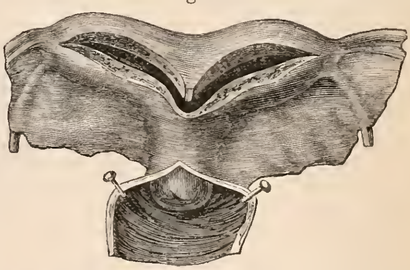
Fig. 462.



The vagina, os uteri, and cervix, single. (After Busch.)

The body of the uterus forming two cornua, which are still nearly horizontal, but are united by a commissure at a higher point than in *fig.* 461.

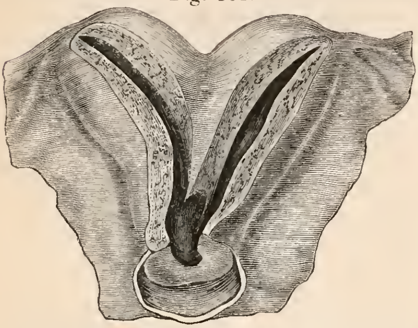
* See Fallopian tube, p. 613.

* Loc. cit. p. 274.

alescence of the two halves approaches to the external orifice, the more obtuse will be the angle at which their junction takes place, and the more extensive will be the fissure (*fig.* 461.). On the other hand the higher the point of union, the more acute will be their angle.

This becomes obvious in the lesser degrees of deformity represented in *figs.*462. and 463. In *fig.* 462., although the commissure is placed at a higher point than in *fig.* 461., so as to be much further removed from the external os, there is still a considerable separation of the two cornua, and their direction is still mainly horizontal ; but in *fig.* 463., where a more perfect coalescence of the two halves has taken

Fig. 463.



The cornua more completely united externally, and the two halves becoming more nearly parallel. (*Ad Nat.*)

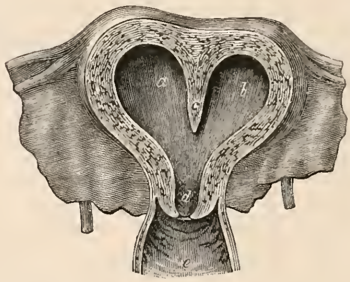
The body is still divided by an internal septum which descends from the commissure as far as the commencement of the cervix, where it ends in a thin falciform edge.

place, and, consequently, where the commissure approaches nearer to the points of attachment of the Fallopian tubes and round ligaments, the angle has become so much smaller, that the two halves begin to lie nearly parallel with one another, and the horns, or ununited portions, exhibit only a slight divergence.

In this, as well as in the following group of malformations, there often proceeds from the commissure an internal septum which descends to a variable depth, and exercises a corresponding influence upon the separation of the two halves. In cases where the commissure representing the fundus lies very low, there may be no septum, and a single cervix conducts into two uterine halves which lie right and left of it. In cases where the fundus is higher, if the septum extends downwards only in a slight degree, as in *figs.* 462. and 464., the cervix is still common to both sides of the uterus. Where the septum begins to divide the cervix, as in *fig.* 463., the separation of the two uterine halves is more complete, but there is still a common os externum, leading to the two canals. The highest degree of division, and consequently lowest type of structure, is that in which the septum extends not only through the cervix, but even to the extremity of the vagina, dividing the latter, *fig.* 461., together with the hymen in the virgin state, so that there are two complete canals leading to corresponding uterine halves.

Group IV. In this group the external form of the uterus differs but little from the normal character. The breadth of the organ, especially between the points of entrance of the Fallopian tubes, is usually greater, and the fundus, though arched, is more shallow than usual. Here also a slight notch, extending into a shallow furrow, running along the posterior uterine wall, may indicate the seat of that internal vertical septum which more or less completely divides the uterine cavity into two halves, and constitutes the *uterus bilocularis* (*fig.* 464.).

Fig. 464.



The body of the uterus showing only a slight indentation externally. (*After Busch.*)

An internal septum *c*, divides it into two loculi, *a* and *b*. The cervix, *d*, is single.

The extent of this septum, and consequently the more or less perfect formation of two separate loculi, exhibits the same varieties as in the former group. The partition may stop short at the cervix, or extend in rare cases completely through that canal, and even divide the vagina. Where the septum is rudimental, and extends only to the cervix, the lower free border is usually thin and falciform (*fig.* 463.), having its concavity directed forwards, the lower extremity being that which is connected with the posterior uterine wall.

These several deviations from the normal form of the uterus will more or less influence the manner of performance of all its functions.

The acts of *menstruation* and *insemination* are those perhaps which are the least disturbed. Regarding this former function, wherever the ovaries are perfect and a channel exists for the menstrual fluid, as, for instance, in the one-horned uterus, the external escape will occur as usual ; but in the case of atresia of the vagina, and in those examples of a hollow rudimental uterus, the menstrual blood collects, and distending the closed sac forms there a hæmatometra.* Where the parts representing the uterus are entirely solid,

* See p. 697.

the menstrual molimen may not be thereby hindered, but the escape of blood can only take place, if at all, from some unsuitable situation producing the so-called *menses devii*, or vicarious menstruation.

Regarding the influence of these malformations upon insemination and a resulting impregnation, much of necessity depends upon the condition of the vagina; for this canal may be in so rudimental a state as not to admit of intromission. The canal leading to the ovary also may be either open or closed. In the case of the rudimental tube attached to one side of a single developed cornu, the passage may open into the cervix of the developed half, and thus a channel for the seminal fluid will be established in connexion with an ovary that may be normally formed, and thus impregnation and gestation, even in an undeveloped cornu, is possible.*

Greater difficulties and considerable danger indeed to life arise, during the progress of *gestation*, in the higher deformities of this class. Pregnancy in a rudimental horn would probably be attended by rupture and fatal hæmorrhage at an early period, as happened in Rokitansky's case quoted in the last note, and as usually occur also in the not dissimilar example of ordinary tubal gestation. But even in the case of pregnancy occurring in the developed horn of a uterus unicornis, the undeveloped half will exercise a marked influence upon the progress of gestation, by impeding the due expansion of the developed side; while the supply of blood usually furnished in pregnancy being here provided by only one set of vessels, the course of the pregnancy will probably suffer in a corresponding degree.

In the cases of the uterus bicornis and bilocularis, either horn, or either uterine half, may become separately or alternately the seat of gestation, or pregnancy may proceed simultaneously in both. There is even reason to suppose that twins have been developed in one half, and also that superfœtation has obtained in such a condition of parts.

In those cases where the vagina is partitioned into two canals impregnation may take place more frequently or even exclusively on one side, in consequence of the one channel or half being more favourably formed for intromission than the other.

Regarding the influence which these anomalies may have over the last office of the uterus, viz. *parturition*, it is only necessary to observe that in both the uterus bicornis and bilocularis the organ will be deprived of the advantageous use of the fundus, which so materially aids expulsion in a normally formed uterus, while in the case of the uterus unicornis and bicornis, where the impregnated half usually forms an acute, or even nearly a right angle with the axis of the body, the effect, as Rokitansky has shown *, will be, that during the act of parturition the axis of the impregnated half meeting with the vaginal axis in an obtuse angle, the direction of the uterine force and of the expulsion of the fœtus will cross the axis of the pelvis, and fall upon the pelvic parietes that lie opposite to the vertex of the pregnant half of the womb, and thus the act of parturition will be rendered correspondingly difficult in such cases.

2nd Class. Defective development after birth. The pre-pubertal uterus. — The ordinary age of puberty may have arrived and

Fig. 465.

passed, and yet no corresponding enlargement or growth of the uterus may have taken place; the organ retaining the form and size which

* See a remarkable case of pregnancy in the rudimentary half of a uterus unicornis, ending in rupture of the sac and death in the third month, by Rokitansky. (Pathol. Anat. Syd. Soc. vol. ii. p. 277.) The preparation is preserved in the Viennese Museum.

* Loc. cit.

characterise it in infancy or childhood. Such may be the condition of the entire internal organs, as in the accompanying example (*fig.* 465.) of the undeveloped uterus from a female aged 19, who had never menstruated. In these cases, the body generally exhibits a corresponding feebleness of growth, and the sexual attributes are little, if at all, displayed.

The infantine condition of the uterus is here exhibited in every particular. The proportionately large size of the cervix, *b*, the small triangular uterine cavity, *a*, with a raphé extending into it, and the thin parietes, are precisely such as are usually found in the infantine organ.

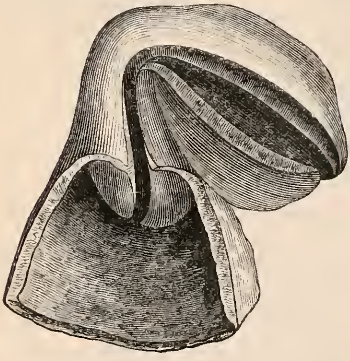
In the last case, the ovaries exhibit also their ordinary infantine proportions; but these may become developed, and the functions of menstruation may proceed naturally, while the external characteristics also are those of a well-formed female, but the uterus remains small, the vagina is short, and instead of terminating in the usual fornix, with a projecting cervix, this canal ends in an aperture, which just admits a sound or probe, and is not furnished with the usual lips of the os tincæ. These cases usually result in sterile marriage, and may be easily detected during life.

Anomalies of form. — Deviations from the ordinary form of the uterus which are acquired during life, and do not proceed from original malformation, or imperfect development, such as that last noticed, will be here considered.

The angular flexions of the uterus which take the definite forms of a forward or backward curve, or of an inflexion towards either side, are distinguished as anti- and retroflexion and lateral inflexion.

a. Antiflexion of the uterus is that condition of the organ in which, without any material change of position in the cervix, the body is bent forwards, so that the fundus, lying more or less horizontally, is directed towards the symphysis pubis, while, according to the degree of inflexion, the anterior wall of the uterus is brought near to, or in contact with, the cervix in front, while the posterior wall looks upwards, corresponding more or less with the plane of the pelvic brim. The point of curvature is always at the line of junction of the body with the cervix uteri, and here an angle more or less acute is formed.

Fig. 466.



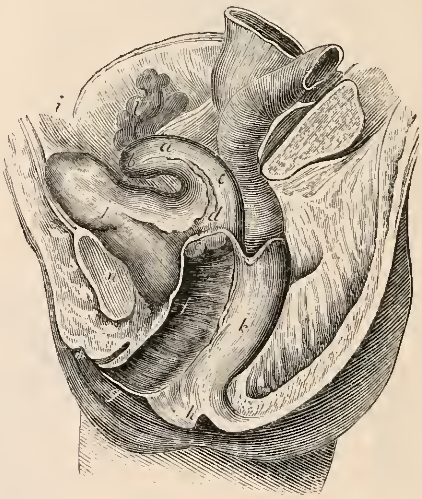
Antiflexion of the uterus. (*After Boivin and Dugès.*)

The point of flexure is at the junction of the body with the cervix. Both canals are laid open. (The figure is viewed from the right side.)

Fig. 466., giving a lateral view of the antiflexed uterus, exhibits the relative situation of its various parts when this deformity exists in the highest degree.

Now a slight amount of antiflexion of the body upon the cervix has been shown by *figs.* 426. and 433. to be natural to the uterus; and it is not until one or two pregnancies have supervened, that this forward tendency, when excessive, is lost, and hardly even then, for the uterus may still retain that correspondence in form, with the curvature forwards of the pelvic cavity, which is so prominently expressed in the curve of the sacrum, and is in accordance with the normal form of the uterine canal. In the fœtus (*fig.* 467.), and during early infancy, antiflexion exists as a

Fig. 467.



Natural state of antiflexion of the uterus in fœtal and infantine life. (*After Bourgery.*)

a, body, and *b*, fundus of the uterus; *c*, point of junction of body and cervix; *d*, cervix; *e*, os tincæ; *f*, vagina; *g*, hymen; *j*, bladder; *k*, rectum; *l*, Fallopian tube; *n*, symphysis pubis; *m*, labium.

normal state, and it appears to me that this bias towards a forward inflexion of the uterus at the early periods of life is given by that remarkable bending forwards of the lower extremity of the spine which is observable in the early embryo. The part containing the structures that are afterwards developed into the uterus exhibits then an abrupt curve, which at this early period will probably be impressed upon the organs within, and being abnormally retained by them after the pelvis has changed its form, may give rise to the malformation under consideration.*

b. Retroflexion exhibits the converse peculiarity, the body of the uterus being bent backwards upon the neck at such an angle that the fundus occupies a position more or less deep between the cervix and rectum, filling and distending the pouch of Douglas. This condition of the uterus ought not to be confounded with retroversion or with those retro-uterine tumours produced by inflammation, and effusion into the cellular tissue (*fig.* 433., G) at the back of the cervix, of which an account will be presently given. See p. 688.

c. Lateral inflexion. — The uterine body exhibits occasionally an inclination to lateral curvature, so that the fundus is directed towards one or other side. A curvature outwards, in the form of an arch more or less deflected from the meridian, has been shown to be the usual condition of the uterus unicornus. But where a tendency towards either side is shown in the otherwise normally formed organ, this appears to arise from some inequality in the development of the two uterine halves; or it may depend upon one half undergoing hypertrophy, so that in either case one uterine angle lies higher than the other, and a vertical line would divide the organ into two unequal parts. The cervix is here curved as well as the body, or the latter may remain perpendicular while the body is bent so as to form an angle with the cervix. The former variety has been designated the retort-shaped uterus.

Anomalies of Position.

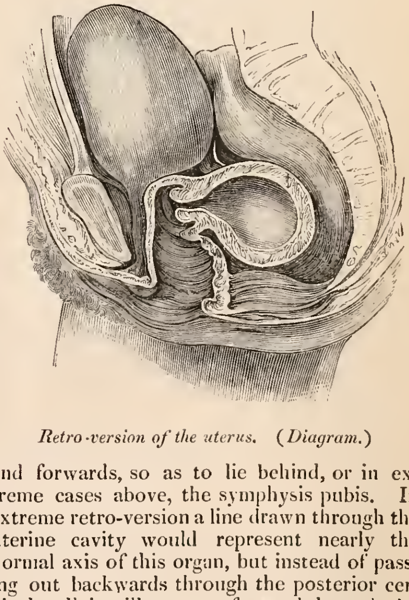
Obliquity of position, Hysteroloxia, Metroloxica, Obliquitas uteri.—The foregoing defects should not be confounded with those deviations in position, without alteration of form, which constitute the various obliquities of the uterus; — like the inflexions of the uterus they are distinguished according as the organ is directed forwards or backwards in the median line, or laterally in the transverse diameter of the pelvis.

a. *Anti- and retro-versions. Situs uteri obliquus anterior et posterior.* — Anti-version of the uterus is by no means so common as retroversion. Both affections differ from the corresponding anti- and retro-flexions of the organ in this respect, that while in the two latter cases the point of flexion is usually at the seat of junction of the body with the cervix uteri, in the former the uterus remains straight or nearly so, while the entire organ is directed forwards or backwards, and the seat of flexion is at the junction of the cervix with the vagina. The displacement of the uterus is here far more considerable than in the former cases.

In *anti-version* the degree of uterine displacement is limited by the bladder and anterior wall of the pelvis, which generally prevent the fundus from sinking so far forwards, as to give the entire uterus in the unimpregnated state more than a horizontal direction. An extreme degree of anti-version however sometimes occurs at an advanced period of pregnancy in multiparæ, on account of an unusual laxity of the abdominal walls permitting the whole uterus to fall forwards, so as to occupy the artificial pouch formed by the pendulous abdomen, the fundus filling the bottom of the pouch, while the cervix and os uteri are tilted upwards and backwards, the latter being lifted out of the pelvis, and pointing above the promontory of the sacrum. This malposition materially impedes labour by reversing the natural direction of the uterine axis, so that the propelling force is expended upon those parts that lie opposite to the os, and the fœtal head is prevented from entering the pelvic brim.

Retro-version occurs in conditions of the uterus otherwise normal, or it may happen when the organ is enlarged by disease or pregnancy. When unimpregnated the displaced organ lies entirely, and when pregnant chiefly, within the pelvic cavity. In retro-version, on account of the excavation of the sacrum, the fundus readily descends so low as to admit of the normal relations of position of the os and fundus being nearly reversed. The latter being directed downwards and backwards towards the coccyx, while the former is tilted upwards

Fig. 468.



Retro-version of the uterus. (*Diagram.*)

and forwards, so as to lie behind, or in extreme cases above, the symphysis pubis. In extreme retro-version a line drawn through the uterine cavity would represent nearly the normal axis of this organ, but instead of passing out backwards through the posterior cervical wall, it will pass out forward through the anterior wall, because the stretching of the vagina in these cases will cause a slight degree of flexion of the cervix downwards. The sequelæ of this displacement in the case of the gravid uterus, when artificial or spon-

* See a paper in the Trans. Micr. Soc. vol. v. pl. 7.; Quarterly Journ. Microscop, Scien., July, 1857, in which I have figured a human embryo of four weeks, exhibiting this peculiarity in a marked degree.

taneous reposition cannot be effected, are usually premature expulsion of the ovum or sloughing of the uterine parietes and slow discharge of the contents by fistulous openings into the vagina, rectum, or other parts.

b. *Hernia of the uterus. Hysterocele, Metrocele.* — This displacement is rare. The uterus may escape from the pelvis by some of the natural openings which ordinarily admit of hernia, or by an aperture artificially formed, as, for example, between the muscular fibres of the abdominal walls. In uterine hernia, the displaced organ is often accompanied by other parts, almost always by its own appendages, and commonly by a portion of intestine, or omentum. Uterine hernia may be congenital or acquired. It may occur to the unimpregnated or the gravid organ, and in the latter case the development of the fœtus may proceed to the full extent while the organ occupies this unusual situation.

A careful examination of the recorded cases of uterine hernia leaves it doubtful if the precise form of the hernia has been, or indeed could be, determined in every instance.

Ventral hernia has been observed only of the gravid uterus, which may become, in part at least, included in a large umbilical hernia, or it may result in cases of separation of the recti muscles where the uterus has ascended sufficiently high to fall forwards over the brim of the pelvis. And it has been supposed to occur after the cicatrisation of a supra-pubic abscess, and as a consequence of a Cæsarian section.

Of *crural hernia* an interesting example is given by Lallemand *, in a woman aged eighty-two, whose body he examined. The hernia appeared at the age of forty, after labour. It remained as an irreducible tumour in the right groin, and was twice accompanied by symptoms of strangulation. After death, the sac of the hernia was found to contain the uterus, ovaries, Fallopian tubes, and upper part of the vagina, together with two folds of omentum.

Inguinal hernia. — Chopart † relates a case of hernia in which the uterus with the Fallopian tube and left ovarium occupied a sac beyond the inguinal ring. The uterus was small, flabby, and elongated. Lallemand ‡ gives a corresponding case where the uterus and right tube and ovary were found in a hernial sac on the right side in a woman who lived to the age of seventy-one.

The most remarkable examples are those in which the uterus either became pregnant while so situated, or was protruded during pregnancy.

In two examples of this kind, related by Sennert, the precise nature and situation of the hernia is, perhaps, doubtful, but they are nevertheless very interesting.

In the first, a swelling in the left groin followed the blow of a stick. Soon the swelling expanded, and it became in time evident that this was caused by the presence of a gravid uterus. The tumour, covered by integument, hung forward like an oblong gourd; by degrees movements of the fœtus were perceived, and the woman having at length reached her term of pregnancy, the integument and uterus were laid open, and the child and placenta extracted.

In Sennert's second case, some injury had been received in the first confinement, but it was not until after the ninth delivery that a swelling appeared in the left groin, and gradually increased to the size of a cow's bladder; finally it hung down to the knees. The tumour was opened, and a living child extracted. Both cases ended fatally to the mothers.

The best authenticated case is one which occurred at Salamanca, and is related by Professor Ladesma. A woman, age 42, mother of seven children, and the subject of an irreducible inguinal hernia, when 3 to 4 months pregnant experienced a sudden increase of the tumour after stooping. The swelling, now of a different consistence, could not be reduced, and after a time fœtal movements were perceptible within it. Labour ensuing in the usual way, the liq. amnii escaped per vaginam, but it was necessary to extract the child by incision into the sac. The tumour contracted ultimately to the size of an ordinary scrotum, and formed a permanent hysterocele in the inguinal ring.*

In addition to these forms of uterine hernia, a partial displacement of the organ through the obturator foramen or ischiatic notch appears possible. This latter is distinguished by the not very appropriate title of *hernia dorsalis* uteri.

Prolapsus.—Falling of the Womb.—Bearing down.—Two degrees of this displacement are recognised. In the first the uterus occupies a situation lower than usual, the cervix resting upon or near the floor of the pelvis, yet without any protrusion of the organ externally. In the second, the uterus is protruded partly or completely through the vulva. The former is distinguished as partial, and the latter as complete prolapsus or procidentia uteri.

Prolapsus in the first degree is not necessarily accompanied by any material change in the condition of the uterus itself. The following alterations, however, in its relations to surrounding parts usually result. The whole organ occupies a lower position than usual in the pelvis. The vagina is more or less completely filled, its upper part becoming folded upon itself like the half inverted finger of a glove. The cervix is abnormally directed forwards. The uterine appendages become in part displaced in following the descent of the uterus, while the neck and posterior wall of the bladder, and sometimes a small portion of the rectum, are likewise drawn down on account of their attachments to the cervix uteri.

In extreme prolapsus or procidentia, the

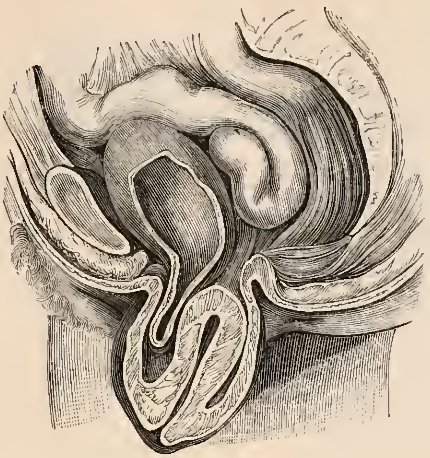
entire uterus, or a great portion of it, hangs forth beyond the vulva, forming there a pyri-

Fig. 469.



Extreme prolapsus or procidentia uteri. (Diagram.)

form tumour of considerable size. At the bottom of this is the os uteri, greatly exceeding in dimensions in chronic cases the ordinary condition of the part. (*Fig.* 472.) The lips are swollen and hypertrophied, and usually present a sore and granular surface on account of the friction to which they are continually exposed. The external covering of this tumour, in all but its lower part, consists of the inverted vagina, the horizontal rugæ of which are very conspicuous anteriorly between the cervix and pubic arch, where a fluctuating swelling is observed, caused by the presence of a portion of the displaced urinary bladder. (*Fig.* 469.) In chronic cases the surface of the inverted vagina gradually loses the character of a mucous membrane, and puts on the ordinary appearance of common integument. After replacement, however, an extensive shedding of epidermal scales ensues, and the surface resumes in time the condition of a mucous membrane.

In cases of great elongation of the cervix, the latter alone may protrude, while the body of the uterus remains within the pelvis. Such a combination of hypertrophy with displacement has passed with the ignorant for an example of hermaphrodite formation.

Prolapsus is the most common displacement to which the uterus is subject. It is frequent in multiparæ, and in women who follow fatiguing occupations, especially those of a relaxed habit of body; but it also happens in nulliparæ. In the latter, when it occurs at an early period of life, it is often associated with enlargement of the uterus or its appendages, whereby both the weight of the organ is increased, and a broader surface is offered for pressure from above.

Elevatio uteri. Dislocation upwards.—This is the converse displacement to the foregoing. The uterus, in consequence of some enlargement of the parts appended to it, as the ovary, or on account of the formation of morbid adhesions, may be drawn upwards to such an extent that no portion of it, or only a part of the cervix, is retained within the pelvic cavity. This displacement is also occasionally observed during pregnancy, and in multiparæ, whose abdominal walls are relaxed, and permit the uterus to incline forward, so that at the beginning of labour the os cannot be reached by the finger.

Inversion. Eversion. — The uterus, either in the unimpregnated or gravid state, may become partially or completely inverted. The conditions which appear ordinarily to combine in producing this displacement, are, first, a distension of the uterine cavity*, as by pregnancy or the presence of a tumour; and secondly, a force applied in the way of pressure from above, or traction from below, whereby the distended uterine walls become folded within each other, somewhat after the manner of the intestinal walls in intussusception. Inversion of the uterus appears always to begin at the fundus which is first depressed into the uterine cavity, and then, under the continued operation of the disturbing forces, the part is gradually protruded through the cervix and os uteri, *fig.* 470., until it emerges in an inverted form into the vagina followed by the reversed walls of the uterine body, and ultimately by those of the cervix. The inversion of the uterus is now complete. The greater part of the organ lies beyond the vulva as a pyriform tumour, the base of which, formed by the fundus, is below, while above the narrower neck of the tumour consisting of the inverted cervix lies in part within the vagina, the upper portion of which canal is also drawn down and partly inverted. The vagina is thus materially shortened, and terminates in a circular fold marking the point of reflexion or inversion, while the usual seat of the os uteri, which is necessarily obliterated, is occupied by the now inverted cervix (*fig.* 471.).

Inversion constitutes the highest degree of displacement of which the uterus is susceptible, for it is both prolapsed and inverted, so that the relative situation of the entire organ to surrounding structures, as well as of all its parts to each other, is completely changed. Inversion does not, however, always proceed to the highest degree, but may stop short at any of the intermediate stages just described.

When inversion occurs to the gravid uterus, the accident usually happens during the efforts of the organ to expel the placenta. In this way, inversion may occur spontaneously, or it may be favoured or produced by injudicious attempts to extract the placenta, or by too much traction applied to the funis. In the unimpregnated uterus, a polypus attached by a stem to the fundus may by its weight slowly produce the same results. That a sudden and spontaneous inversion of the unimpregnated uterus is possible, was proved to

* Boyer, and some others consider that distension of the uterine cavity is not an essential preliminary to inversion.

me in a case which I witnessed of an aged woman whose uterus became completely inverted during a convulsion. In this instance, the only apparent predisposing cause was the

dilatation of the uterine cavity by a tumour the size of a flattened apricot, which was expelled at the moment when the uterus came

Fig. 471.

Complete inversion of the uterus. (*Diagram.*)

down completely inverted, — the violent action of the abdominal muscles and diaphragm probably here producing or aiding the eversion.

After complete inversion, the uterus may remain incapable of replacement. Under these circumstances, the external surface of the protruding portion loses much of its original character of a mucous membrane, and becomes covered by a thicker epithelial layer. It continues, however, more vascular than the surface of an ordinary procident uterus, and is especially liable to abrasion and ulceration, from the friction to which it is exposed. When this displacement occurs during menstrual life, and is permanent, the menstrual fluid may be observed at the periods exuding from the surface of the inverted organ.

The internal relations of an inverted uterus depend upon the extent of the inversion. In extreme cases the interior of the tumour consists of a sac lined by the peritoneum, which originally formed the outer covering of the uterus. The centre indeed of the broad ligament may be said to be inverted so as to form a pouch in which are contained the Fallopian tubes and ovaries, and occasionally a portion of small intestine (*fig.* 471.).

In minor degrees of inversion the uterus remains within the vagina, and the peritoneal pouch in its interior contains only the roots of the uterine appendages (*fig.* 470.).

Anomalies of Size.

a. *Atrophy.* — Under this head may be included those examples in which the uterus appears to have been originally well developed, but has since suffered atrophy of its tissues. Such cases are to be distinguished on the one hand from the imperfectly developed and prepubertal forms already described; and on the other from examples of senile atrophy as it occurs in its ordinary course. Whenever atrophy attacks the uterus before the climacteric change the condition is to be deemed abnormal. Such a wasting may affect the entire uterus or some of its parts. In either case the tissues become pale, soft, and nearly bloodless. In atrophy of the uterine body the walls may not exceed in thickness or density those of the urinary bladder. Such a condition may occur under dilatation of the uterine cavity, which however is more commonly attended by an increase in the thickness of the uterine parietes. The atrophy of the uterine walls which is accompanied by dilatation of the cavity, is distinguished as *excentric*, and that which occurs in combination with a diminished cavity as *concentric* atrophy.

Atrophy of the cervix may be combined with partial atresia of its canal, and is often associated with some malposition or morbid growth of the uterine body or its appendages.

b. *Hypertrophy* is of far more frequent occurrence than uterine atrophy. According as this condition affects the entire uterus or only some of its parts, the organ either presents the ordinary figure but upon a larger scale, or else a greater preponderance is given to one portion, so that the uterus becomes malformed. Hypertrophy of the entire uterus commonly results from frequent pregnancy, from the growth of tumours, or from accumulation of fluid within the cavity. In the latter cases the uterine walls may acquire the same thickness as in pregnancy—and the hypertrophy is due also to the same cause, viz. to a development of smooth muscular fibre, such as ordinarily takes place in the gravid uterus.

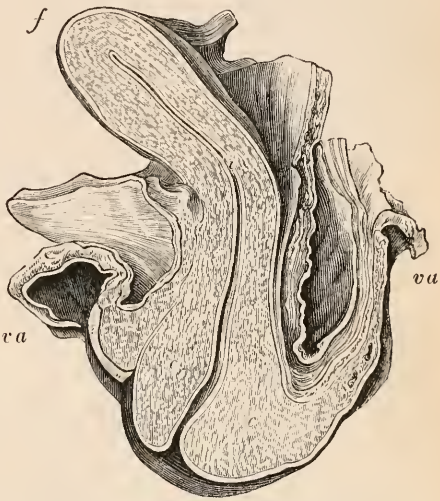
Hypertrophy of the cervix is most frequently observed in extreme prolapsus, of which in the chronic stage it appears to be a constant sequence. Here the hypertrophy produces usually a uniform enlargement of both lips, which form together an annular tumour divided transversely by a wide os tincæ, *fig.* 472.

Fig. 472.

Hypertrophy of the os and cervix in prolapsus uteri. (*Ad Nat.*)

But the cervix may become hypertrophied in the longitudinal direction also. From this there results a remarkable elongation of the uterine neck, which may protrude to a considerable distance beyond the vulva without a corresponding degree of displacement or descent of the body of the uterus. In the accompanying illustration, *fig.* 473, the manner of growth of the elongated cervix is shown. The body of the organ being only partially displaced, a gradual addition to the length of

Fig. 473.



Elongation of the cervix uteri from longitudinal hypertrophy. (*Ad Nat.*)

f, fundus; *i o*, internal os uteri; *c c*, cervix; *v a*, vaginal walls.

the neck occurs until the vaginal portion protrudes at the vulva. The canal of the cervix may now measure several inches in length. By degrees the protruded part undergoes in addition the concentric and excentric hypertrophy which is common to all cases of procidentia, and the lips gradually acquire the same appearance as in *fig.* 472.

Among the anomalies of size may also be included those examples of imperfect involution of the uterus after pregnancy, in which the organ retains for several months the ordinary size characteristic of it shortly after labour.

Pathological conditions of the separate tissues of the uterus.—Reserving for future notice the affections of the gravid uterus, those morbid states which are observed in the unimpregnated organ will be at present considered. These may be divided into such as belong to (1) the peritoneum; (2) the subperitoneal tissue; (3) the parenchyma; and (4) the mucous lining of the uterus.

1. *Pathological conditions of the peritoneal coat.*

a. The external position of the peritoneal coat, and the small amount which it contributes to the bulk of the uterus, combine to render the morbid conditions of this coat, regarded singly, of less pathological importance than the abnormal states of the other tissues. The pathological conditions of the serous coat are chiefly those of *acute or chonic metroperitonitis*, terminating often in exudative processes and the subsequent formation of adhesions between those portions of the uterus which are invested by peritoneum and adjacent structures, such as the Fallopian tubes, ovaries, *fig*. 420., small intestines, and the like.

These adhesions are occasionally so extensive as to affect the figure of the uterus, and in most instances they deprive it of its natural mobility, and impede or destroy the functions of the parts or organs appended to it, so that an abiding sterility frequently results. The ovaries becoming invested by a capsule of false membrane, are tied down and atrophied, while the tubes lose their power of motion or their canals become obliterated.

The uterine peritoneum is sometimes alone affected, while the appendages escape. If the inflammation has not proceeded to the formation of bands of adhesion, there may result only some slight processes of false membrane which remain and fringe the surface of the organ. These little fringes or processes, consisting of delicate folds of membrane, often contain vessels which are easily injected.

The peritoneum suffers considerable distension with correlative hypertrophy in the case of tumours which project from the outer surface of the uterus. These become invariably covered by an extension of the peritoneum, which is especially strong about the base of the peduncle occasionally acquired by such tumours.

2. *Pathological conditions of the sub-peritoneal fibrous tissue.*

a. *Perimetritis. Partial chronic metritis. Peri-uterine phlegmon. Retro-uterine tumours.* — The subperitoneal fibrous tissue which connects the peritoneum with the uterine substance, like the peritoneal coat itself, is subject to inflammation. In those situations where the union of the outer and middle coats of the uterus is very intimate, the distinction between a peritoneal and a subperitoneal inflammation may not be possible, but where this connexion is very loose, and is effected by the interposition of a lax fibrous tissue, inflammation may apparently have an independent seat without affecting at all, or with only a partial inclusion of the uterine parenchyma, and sometimes of its peritoneal investment.

The term "*peri-uterine*" has been employed by some authors*, with a view perhaps of avoiding confusion, though at the cost of a solecism, to distinguish these affections from others commonly termed *perimetrial*. In this article, however, inflammation of the subperitoneal fibrous tissue will be designated *perimetritis*, while inflammation of the peritoneum itself, which some include in the latter term, is distinguished as *metro-peritonitis*.

Perimetritis consists in an acute, or more often a chronic inflammation of the tissue, which loosely attaches the peritoneum forming the base of the broad ligament to the proper substance of the neck and lower portion of the body of the uterus. The relation of the peritoneum and of the loose fibrous tissue surrounding the cervix uteri have been described at page 631., where also attention was called to the peculiar lax tissue of this kind which unites the posterior cervical wall with the portion of peritoneum forming the retro-uterine pouch (*fig*. 433. G.). Here, particularly, this inflammatory affection has its seat, although it occasionally extends around the sides of the cervix, so as partially to encircle that part, or more rarely it may involve only the fibrous tissue connecting the anterior cervical wall with the posterior surface of the bladder (*fig*. 426. *b b*, and *fig*. 433. F.).

The anatomical conditions of these perimetrial inflammations are deep congestion of the vessels, accompanied by serous, and occasionally by sanguineous, and possibly fibrinous infiltration of the loose tissue of this part, which, on account of its extreme laxity, readily admits of a great degree of distension. In this way is rapidly formed a tumour which almost invariably occupies the space between the peritoneum and the posterior wall of the uterus, at the point where the body joins the cervix (retro-uterine tumour).

The recognition of such a tumour or swelling during life, by physical signs, is not difficult. The finger introduced into the vagina, so that its extremity reaches the point of reflexion of the posterior wall of that canal forwards on to the uterine neck, discovers, just above this spot, a hard or semi-elastic projection, which seems to grow out of the cervix just at its point of junction with the body of the uterus. The surface of the tumour towards the rectum, upon which it encroaches, is convex, and is either smooth or irregularly nodulated, while between the tumour and the neck of the uterus is usually perceived a notch more or less deep, and comparable in form to that which separates the body from the neck of an ordinary retort. Hence this condition may easily be mistaken for the retorted uterus, which it closely resembles in many particulars. The surface of the tumour is exquisitely tender, while the adjacent uterine structures are free from tenderness.

The comparative frequency of this affection*, and the constant and severe suffering which result from it, especially in married women, in whom it is usually found, may justify here a brief exposition of the peculiar anatomical condition and relation of parts which appear to me to conduce to its production. From the view of the pelvic viscera given in

* Monat, Observation Médicale (Gazette des Hôpitaux, 1850.) Bernutz et Goupil. Recherches Cliniques sur les Phlegmons péri-utérines. (Archives Générales de Médecine. Mars 1857.)

* I believe that it is often confounded not only with retroflexion, but also with retroversion, fibrous tumour, and hypertrophy of the posterior uterine wall, and that hence the frequency of its occurrence has not been commonly recognised.

(*fig.* 433.) it will be seen, that while the normal cervix projects obliquely into the upper part of the vagina, the fornix or blind extremity of that canal forms the actual termination of the tube, so that this arrangement, while it tends materially to the preservation of the os and cervix uteri from injury during congress, at the same time exposes the cul de sac of the vagina to a certain amount of pressure, which various circumstances, such as relative shortness of the vagina and other obvious conditions, may render injurious. But exactly over this spot lies the mass of lax fibrous tissue in question, the meshes of which become easily infiltrated under inflammation by serous or fibrinous fluids supplied by the vessels, which sections of this region show to be so abundant in the neighbourhood. (*Fig.* 429.)

Perimetrial inflammation occasionally reaches the suppurative stage, and in this way are formed some of those abscesses which burst through the cervix, or form collections of matter between the folds of the broad ligament.

3. *Pathological conditions of the muscular or proper coat.*

a. *Diminished and increased consistence* of the uterine substance, although generally resulting from obvious morbid processes, is yet sometimes found without any apparent disease of the tissue.

Diminished consistence may be found in various degrees, from a slight friability or softness to a nearly complete pulpiness (*marciditas*). In these cases the texture of the uterus may be pale and exsanguine, or in a state of hyperæmia, with occasionally apoplectic effusion. Rokitansky associates the latter condition with thickening, and sometimes ossification of the uterine arteries.

b. *Parenchymatous inflammation of the uterus. Metritis. Metritis parenchymatosa.*—Inflammation of the substance of the uterus, which in the puerperal state is so commonly fatal, seldom leads to death in the unimpregnated. Hence opportunities for investigating the anatomical condition of the organ in the non-gravid state under conditions of inflammation are of comparatively rare occurrence. From such opportunities, however, aided by what may be observed during life, the following may be concluded as to the changes which inflammation produces in the muscular and fibrous coat.

Under acute parenchymatous inflammation the whole organ becomes increased in bulk, and at the same time redder and softer. On section blood flows freely from the divided vessels, and the tissues are found permeated by serous infiltration. Sometimes the highly congested vessels have in parts given way, and ecchymoses or larger apoplectic collections have resulted.

If no commensurate resorption of these effusions takes place the organ continues of abnormal size. This is more particularly observable when a portion of the uterus, as the body or cervix, has been repeatedly inflamed. The latter, especially, remains enlarged. The os tincæ is patulous, and one or both lips of the cervix present an œdematous hardness, and occupy a larger space than usual in the fornix of the vagina.

Occasionally inflammation of the uterine parenchyma reaches the suppurative stage, resulting in collections of matter which may escape into the peritoneum between the folds of the broad ligament, or externally by the vagina or rectum.

Chronic inflammation produces likewise a general enlargement of the uterus, but more commonly the cervix is principally or exclusively involved, and the resulting enlargement is especially observable in its vaginal portion, the lips of which become increased in breadth, or elongated and prominent.

When chronic inflammation affects, on the other hand, the parenchyma of the body of the uterus chiefly, the walls of this part become thickened and indurated, while the cavity undergoes enlargement such as is exhibited by the ventricles in excentric hypertrophy of the heart. Under chronic inflammation the uterine tissue becomes indurated, so that upon section it grates beneath the knife. This induration is occasioned chiefly by hypertrophy of the fibrous element of this coat of the uterus.

c. *Fibroid. Tumor fibrosus uteri. Fibro-muscular tumour. Hard fleshy tubercle of the uterus* (Baillie).—These and numerous other titles have been employed by different authors to designate a form of degeneration of the uterine tissue which is so common that, according to the often quoted calculations of Bayle, it may be found in every fifth case of women who die after the age of thirty-five.*

Fibroid of the uterus has for its basis the same structure as fibrous tumours in general.† The surface of a section presents to the naked eye a peculiar mottled appearance, caused by the presence of numerous white lustrous bands intersecting in all directions a more homogeneous basis substance, which in these uterine formations has always a greyish or light brown colour, the latter being especially distinct in spirit preparations. The difference between these two, however, is more apparent than real, consisting, as Paget suggests, rather in the mode of arrangement than in an actual differentiation of the component structures. These consist chiefly of very slender filaments of fibrous tissue "undulating or crooked," and exhibiting various degrees of development in different specimens, being in some large and wavy, and in others very short, and often intermixed with cytoblasts and nuclei. Along with this fibrous basis is found a variable amount of smooth muscular fibre, which in some cases, especially in the polypi hereafter noticed, forms the chief bulk of the

* Dr. West has furnished some interesting statistics upon this subject. (Lectures on the Diseases of Women, Pt. i. p. 277. 1856.)

† For an account of these see Paget's Surgical Pathology, Vol. II. Lect. V.; and also for those of the uterus, Bidder, in Walter ueber firbröse Körper der Gebärmutter.

mass, so that a muscular rather than a fibrous tissue results. A small quantity of elastic fibre is also occasionally found in these uterine formations.

Fig. 474.

Section of fibroid tumour of the uterus. (*Ad Nat.*)

The structural variations observable in fibroid of the uterus, are dependent chiefly upon the peculiarities in arrangement of these component elements. In the more dense formations, the white shining fibrous bands enclosing little pellets of the browner substance, form numerous small compact masses, which are again closely united together by a somewhat looser fibrous tissue that serves to combine the whole into lobes or lobules, varying in size from a pea to that of a man's head. The variation in density of these masses depends, further, upon their vascularity. In the softer kinds, bloodvessels that may be injected permeate the mass, running along the bands and layers of fibrous tissue connecting the lobules. Such tumours are sometimes of a deep red colour. The denser masses, on the other hand, are apparently nearly bloodless; at least, injections cannot be made to penetrate them.

The different configurations which these masses of uterine fibroid assume, appear to depend in a great measure upon accidental conditions. In this particular three varieties may be noticed.

1*st var.* *Interstitial fibroid.* — The mass here forms a growth, sometimes of immense size, but still contained within the proper boundaries of the organ, occupying one or other uterine wall, but neither encroaching upon the uterine cavity, nor protruding externally. Such is the case represented in *fig.* 475., in which the external appearances were those of the ordinary gravid uterus in the seventh month. Such masses appear occasionally at their periphery to merge gradually into the healthy tissues of the uterus, but more commonly there exists a distinct boundary formed by loose cellular tissue with which the tumour is so lightly connected that it may be easily detached and turned out of its investing capsule (*fig.* 475).

Fig. 475.

Interstitial fibroid of the uterus. (*Ad Nat.*)

The tumour is formed in the substance of the posterior wall, which is so attenuated at one spot as to be nearly broken through. The cavity of the uterus is shown in the lower part of the figure unaltered in size.

2*nd var.* *Subperitoneal fibroid.* — In this variety the fibroid mass or masses protrude from the external surface of the uterus. Here one or several round or oval tumours are formed which seem to grow out of the uterine substance by a narrower or broader base, or they remain attached to it by a peduncle. These masses consist entirely of fibroid, having either simply an investment of peritoneum, or beneath that also, in many instances, a layer more or less thick of uterine substance which is usually laminated, so that a capsule composed of the natural tissues of the uterus is formed around the tumour (*fig.* 476.).

3*rd var.* *Sub-mucous fibroid.*—In this variety the fibroid mass quits its bed in the uterine walls, and projects into the cavity of the uterus; it becomes covered by an extension of the lining membrane of the uterus, and sometimes also beneath this by a layer of healthy uterine tissue. These tumours, when they possess a peduncle, constitute the fibroid polypi of the uterus.

A distinction has been made in these polypi between such as form continuous outgrowths from the substance of the uterus, and those in which the polypous mass forms a discontinuous tumour, connected only by a narrow stem of mucous and muscular tissue.

The original position of the fibroid growth in the uterine walls, whether in the middle or nearer to their inner or outer surfaces, probably determines, in a great measure, the direction and form which these growths ultimately take, and is consequently productive of the three varieties above noted.

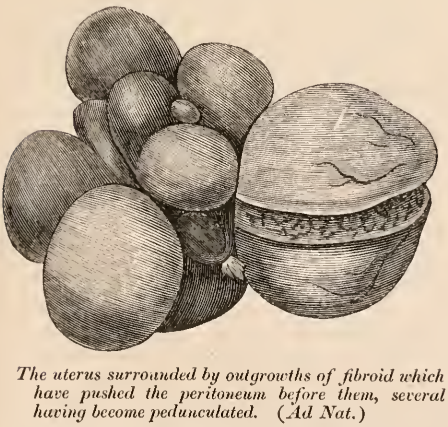
The different forms which fibroid assumes are in accordance with these varieties of position. Fibroid growths retained within the uterine walls, are at first almost invariably spherical, but in course of growth become ovate or flattened. Those which project from the outer surface are usually nearly round, while the polypi of the cavity, and those which extend into the vagina, are pyriform, and possess longer or shorter peduncles. The greater part proceed from the fundus, comparatively few from the walls of the body, and scarcely any of this kind from the cervix. The latter are usually of a more spongy or cellular character than the former, which consist of a denser fibrous tissue.

The power of growth of fibroid tumours appears to be nearly unlimited. The known extremes in such cases are, in point of number, from one to forty; and in respect of weight, from a few grains to seventy pounds.

Fibroid exercises a considerable influence upon the form and position of the uterus. Tumours within, or external to it, change the position of the organ in various ways, producing elevation, prolapsus, lateral obliquity, and especially retroversion, according to the seat which they occupy. Polypi distend the cavity of the body and cervix, and the os uteri, and sometimes produce prolapsus and inversion of the uterus.

The influence of fibroid upon the thickness of the uterine walls is also considerable. Generally a marked hypertrophy, equal sometimes to that of pregnancy, takes place, while in parts a thinning of the walls occurs. The latter is especially observable in cases where the tumours are numerous, as in *fig.* 476. These sometimes appear to grow at the expense of the whole uterine substance, so that the original organ is with difficulty discovered among the hypertrophied mass.

Fig. 476.



The uterus surrounded by outgrowths of fibroid which have pushed the peritoneum before them, several having become pedunculated. (*Ad Nat.*)

The uterus, at the expense of whose tissues the tumours are formed, can scarcely be discovered in the midst of the mass.

Important consecutive changes take place during the process of growth of fibroid. So long as the structure retains its original hardness, the increase is comparatively slow, consisting in a simple and uniform multiplication of the elements already described. Occasionally an increase of density is produced by calcification of certain portions of the mass, and in this way the so-called bony tumours of the uterus are formed. Or, on the other hand, under rapid growth, the tumour may become softer, in consequence of serous infiltration into its tissues; the fluid occasionally collecting in the centre of the tumour and forming there a species of dropsy. Or, a process of inflammation being set up, suppuration, and sometimes sloughing, result. In the more vascular fibroids the vessels may dilate and burst, and the tumour then becomes infiltrated with extravasated blood. It has been doubted whether fibroid ever undergoes absorption. I have reason to think, from occasionally witnessing a marked diminution in bulk, that this may sometimes occur. The explanation of this is indeed easy when the mass of the tumour consists of hypertrophied muscular tissue, which in such cases has been found to undergo fatty degeneration, and so its dispersion may be effected.

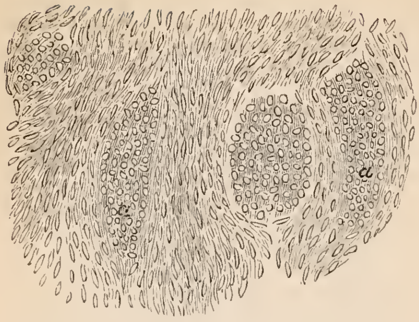
Subperitoneal and interstitial fibroid, when extensive, interferes with pregnancy, and also renders labour difficult or perilous, by weakening the expulsive power of the uterus and predisposing the organ to rupture. Submucous fibroid, in the form of polypi, may prevent impregnation or shorten gestation. In the unimpregnated uterus, all forms, but especially the submucous and interstitial, are apt to be accompanied by severe recurrent hæmorrhage, producing excessive anæmia and occasionally death.

Lastly, it may be observed, in reference to tumours which are commonly termed polypi, that the present state of pathology demands a separation of these, according to their structural differences, such as has long been established, upon a similar basis, among those objects of the animal kingdom whose supposed resemblance, distant indeed, and at the best fanciful, has given a name to this form of tumour. For, as in that prototypal group of animal forms, once termed polypi, three widely separated classes at least are now known to have been combined, so those pathological formations, which are still familiarly termed polypi, exhibit a more than equal number of varieties, each marked by distinct differences of structure. These may be distinguished as the *fibrous*, including the cellular, which are composed of a looser fibrous tissue; the *muscular;* the *mucous*, also frequently containing much fibrous tissue, and the *cancerous* or *malignant* polypi. And to these have been added the so-called *fibrinous* or *blood* polypi.

The fibrous polypus has been already described, and the second, or muscular, may here also be classed with it, as having its origin in the middle coat of the uterus, but consisting of muscular rather than of fibrous tissue.

These muscular polypi are comparatively rare. Their structure, as exhibited in the accompanying *fig.* 477., is precisely that of the proper muscular coat of the uterus.

Fig. 477.



Section of a polypus formed of the muscular tissue of the uterus. (After Wedl.)

The fibres, arranged in bundles, run in different directions. At *a a*, they have been divided transversely, and in other parts obliquely. Compare with *fig.* 436.

The malignant polypi, and those which are formed of hypertrophied mucous structure, belong to another category, and will be described hereafter.

4. *Pathological conditions of the mucous coat.* — *a.* First under this head may be noticed *simple hypertrophy* of the uterine mucous membrane, followed often by a partial shedding of that structure in the form of the so-called

Dysmenorrhœal membrane.—The term *menstrual decidua* would probably form a more appropriate title for these structures, which consist of a greater or less thickness of the mucous membrane lining the uterus, differing in no respect from that membrane in its ordinary condition *, except in the one particular, that it has undergone a certain degree of hypertrophy. (*Fig.* 443.) The hypertrophies which the mucous membrane of the uterus undergoes in various circumstances form a most interesting subject for study, but all of them are not pathological. The most familiar example of normal hypertrophy of the uterine mucous membrane is that which occurs in ordinary pregnancy. Here, no sooner does the uterus begin to enlarge, than the mucous lining also expands, and its tissues become opened up by an increased flow of blood, and a consequent rapid development of the simple elements composing this structure. This hypertrophy occurs in every pregnancy where the ovum enters the uterus. But it also happens very generally in those cases where the ovum never enters the uterus at all, but is developed externally to that cavity (extra-uterine gestation). Here a most perfect decidua is usually found lining the uterus. The exceptions are few in which the uterine mucous membrane, under these circumstances, does not exhibit any increase of thickness, but retains or nearly so, its ordinary characters

* See on the structure of the uterine mucous membrane, p. 635. of this article.

But a state of pregnancy is not necessary to produce evolution of the uterine lining, for this may occur when the body of the uterus is enlarged from other causes. Thus, in an example in my possession of uterine fibroid, in which the body of the uterus has undergone the hypertrophy already described (p. 491.), as common in that state, the hypertrophy has extended to the mucous membrane, so that the uterine cavity, which had also been occupied by one of these tumours, exhibits a delicate decidual lining.

The decidual membranes occasionally cast off from the uterus under circumstances of dysmenorrhœa, consist of fragments, or, more rarely, of entire membranes forming casts of the uterine cavity. The structure of all these is nearly similar, and they differ chiefly in the greater or less thickness of membrane detached. All present upon their inner surface the peculiar cribriform markings already described as constituting the orifices of the uterine glands, while their outer surfaces are rough and shaggy, like the outer surface of aborted ova, for this surface has been detached or torn off from the uterus. *Fig.* 443. represents a portion of such a membrane, as seen from its inner or cribriform surface. The microscopic characters of these membranes are precisely those of ordinary decidua.

b. Hypertrophy of the follicular structures of the uterine mucous membrane. Follicular polypi. Mucous polypi. Cysts. — The pathological formations which take their origin in the mucous membrane lining the uterus, consist chiefly in hypertrophic growths of that membrane, and of its follicular structures. They present usually two varieties, according as the follicular or the ordinary mucous tissue abounds in their composition. Many of these growths acquire a peduncle, and then constitute the mucous or follicular polypi.

The follicular structure is most apparent in those growths which spring from the body, and especially from the fundus uteri near the orifices of the Fallopian tubes. These vary in size from a pea to a small plum. They have usually a rounded or oval form, and become partially flattened by the external pressure of the uterine walls. A short and narrow peduncle connects them with the spot from which they arise. Externally they are smooth and covered by a layer of epithelium, beneath which is a thin extension of the uterine mucous membrane. This is often sufficiently transparent to render visible numerous opaline spots, indicating the seat of groups of uterine follicles distended and elongated, and containing a semitransparent gelatinous fluid. Between these elongated follicles there is a loose fibrous tissue connecting them together, and giving substance to the mass. These tumours possess little resistance, and are usually soft and elastic.

The more solid mucous tumours very generally acquire a stem, and early take the form of polypi. These mostly arise from between the folds of the lining membrane of the cervix, and are evidently mere hypertrophies of that structure, including a variable proportion of the sublying cervical fibrous tissue. In size they range from a pea to a walnut, and occasionally their peduncle measures several inches in length, so that they may pro-

Fig. 478.

Pedunculated polypus of the cervix uteri. (*After Boivin and Dugès.*)

trude to a considerable distance beyond the vulva. Their form is generally that of an elongated pear. The surface is smooth, though not uniform, being usually nodulated or lobed, and in parts roughened by minute papillary growths. Sometimes one or two of the cervical folds or rugæ, scarcely altered in character from their ordinary condition in the healthy cervix, are distinctly visible upon them. These more solid tumours are covered by cylinder or pavement epithelium and hypertrophied mucous membrane. Internally they are composed of loose inelastic fibrous tissue, containing a few enlarged and obstructed follicles, one or two of which may grow more than the rest, and form a cavity distended by a slimy fluid.

The growth of both these forms appears to be limited, and they never attain to the size which the fibrous polypi often reach. With the hypertrophies of the follicular structures are also to be classed those single cysts, of the size of a pea, or larger, and sometimes pedunculated, which are very commonly found lying between the cervical folds, or protruding from the os uteri. These consist almost exclusively of distended Nabothian follicles.

c. Hypertrophy of the filiform papillæ of the cervix. — A variety in the condition of the filiform papillæ upon the vaginal portion of the cervix has been described at p. 639. These papillæ, nstead of being short, and covered by pavement epithelium up to the very margin of the os uteri, as they are upon the rest of the cervical lips, may present the same condition which they have within the cervix, where they are longer and larger, and are not bound down by a continuous layer of covering epithelium. These papillæ often appear at the margin of the os, and form there little tufts, or extend over the lips of the cervix in the crescentic manner already described at p. 639. They then constitute one of those conditions to which, in the present day, the term ulceration is very frequently applied; yet there is no more reason for asserting that these are pathological formations or conditions, than there is for asserting the same of the villi within the canal, for both are identical in form. They can only be regarded as pathological structures when they obviously exceed the natural conditions already described. Then, indeed, they may be classed among the hypertrophies of special structures of the cervix, and they will bear the same relation to the natural papillæ, that the hypertrophied follicular structures, forming the cysts and polypi recently described, bear to the cervical follicles in a healthy condition. Both the hypertrophied and the natural papillæ give to the finger that peculiar velvety or mossy sensation which is usually classed among the diagnostic signs of ulceration of the os uteri.

d. Simple inflammatory hypertrophy, with extroversion of the cervical mucous membrane. — The mucous membrane lining the canal of the cervix uteri under chronic inflammation becomes frequently partly everted, so that a portion of the inner surface of one or both walls of the neck is rendered visible at the lower orifice, taking here the place ordinarily occupied by the inner border of the lips of the os tincæ. This affection is usually combined with a corresponding hypertrophy of the proper tissue of the cervix, and may be compared in its effects to that thickening of the upper lip common in strumous children, which causes the part to become everted.

Figures 7. and 8. Plate IX. in Boivin and Dugès' Atlas represent an extreme degree of this affection, in which the cervical mucous membrane protrudes to an unusual extent, so that the palmæ plicatæ and middle raphé on both sides are seen. In the more common minor degree of hypertrophy with eversion, a crescentic protrusion only of the cervical mucous lining occurs. The unevenness of the surface, caused by the slightly swollen and prominent rugæ, and as often by the numerous little depressions consisting of enlarged mucous crypts, according as one or the other of these is the predominant normal structure in the cervix *, gives to the part during life the appearance of a raw or granular surface, while

* For a description of these varieties, see p. 640.

the natural boundary between the lower edges of the cervical canal and the lips of the os tincæ being now transferred on to the latter in consequence of this eversion, an abrupt semicircular line becomes visible, which, while it only indicates the natural termination here of the vaginal epithelium (see p. 640.), is frequently mistaken for the margin of an ulcer.

This condition may be observed upon only one lip, or upon both simultaneously. It requires special notice here, not so much for its pathological importance, which appears to me to have been overrated, as on account of certain views of late connected with it, under the belief that it constitutes another form of ulcer of the os or cervix uteri.

c. *Catarrhal inflammation of the mucous coat. Endo-metritis. Metritis catarrhalis. Metrorrhœa. Catarrhus uteri. Acute and chronic catarrh. Leucorrhea. Fluor albus.*

The ordinary inflammatory affections of the uterine mucous membrane in the unimpregnated state, which were formerly known only by the discharges to which they give rise, and which were consequently confounded with similar affections of the vagina, have in recent times been more accurately examined, and traced to their real seat. That the lining membrane of the uterus, and its cervix in a state of acute or chronic inflammation, is the principal source of many of these discharges, is now well ascertained, and the similarity of these affections to the catarrhs of other mucous surfaces is now also generally admitted. Hence the term uterine catarrh, under the various forms above quoted, has been employed in most recent works on uterine pathology to designate these affections. Inflammation, whether acute or chronic, may involve the entire uterine mucous membrane, or it may be limited to that of the body or cervix.* The ordinary anatomical conditions of this membrane under inflammation are, first, deep hyperæmic congestion, so that the surface presents a uniform florid red colour, or it is mottled with patches of red, intermixed with paler and less vascular parts. In congestion of the mucous membrane lining the body of the uterus, the superficial capillaries, whose healthy forms are represented in *figs.* 439 *a* and *b*, become intensely loaded, so that rupture occasionally takes place, followed by effusions into the substance of the membrane. A serous or sero-sanguinolent, and in more advanced stages, a muco-purulent fluid, covers the surface, while the entire mucous membrane becomes swollen, softened, and infiltrated with serum. An abrupt line of demarcation, when the congestion is limited to the uterine body, marks the boundary between that cavity and the cervix, the lining membrane of which may retain its natural pale colour,—just such an abrupt line of demarcation between the highly congested membrane of the uterine body and the paler lining of the cervix, as occurs during menstruation or in early pregnancy.*

When inflammation affects chiefly or exclusively the cervical mucous membrane, this becomes turgid and swollen, and its vessels congested. The congestion affects more particularly the capillaries of the vaginal portion of the cervix, and of the interior of the canal near the orifice. The lips of the os tincæ are at the same time tumid, the os is enlarged, and the cervical canal expanded; changes which indicate that the structures immediately beneath the mucous membrane are then also involved. A loss of epithelium in the neighbourhood of the external orifice, more or less extensive, may occasionally accompany the severer forms of this affection. From this it results that the turgid and vascular papillæ beneath becomes exposed, and when these are also hypertrophied, the surface acquires the condition commonly termed granular.

The natural or healthy secretions of the cervix become materially altered under catarrh. In a normal state the cervical secretion is sufficient in quantity to cover the mucous folds, and to fill the crypts and furrows, and occasionally to block up the entire canal. It consists of a viscid, tenacious, and nearly transparent fluid, enveloping numerous mucous corpuscles, granules, and epithelial scales.

When the catarrhal state ensues, this fluid is greatly increased in quantity, and, according to the severity of the affection, it passes through the various conditions of a viscid transparent jelly, resembling clear starch or white of egg, of a thicker cream-like fluid, or of a puriform mucus, in colour nearly resembling pus. Blood also is occasionally found mixed with these secretions.†

The ordinary secretions of the cervix, as shown by Dr. Whitehead, have an alkaline reaction within that canal, but they speedily become acid when mixed with the vaginal secretions, which also cause the previously transparent cervical products to become opaque as they pass through the vagina.

Acute specific catarrh of the vagina (gonorrhœa), as well as simple catarrh of that canal, may be associated with the foregoing affections.

Ulceration of the mucous coat. Metro-helcosis. Granular ulcer. Simple erosion, abrasion and excoriation.—These terms have been severally employed to designate certain conditions of the os and cervix uteri, regarding the nature, frequency and pathological importance of which, as is very well known, great diversities of opinion are in the present day entertained.

The affections of the cervix uteri, which

* This distinction, not usually observed by continental authors, has been emphatically made by Dr. H. Bennet. A Practical Treatise on Inflammation of the Uterus. 3d edit. 1853.

* This point, under both these conditions, is illustrated with great fidelity in the coloured delineations of Boivin and Dugès. See Atlas, Pl. I. fig. 4., and Pl. II. fig. 6.

† A descriptive account of some of these fluids, accompanied by illustrations, will be found in the paper of Dr. Tyler Smith, in Vol. XXXV. of the Med. Chir. Trans.

are commonly deemed ulcerative, are admitted by those who so describe them to possess certain characteristic and exceptional features by which they are distinguished from ulcers of other parts. For it is truly asserted, that "whatever the character of an inflammatory ulceration of the cervix the ulcerated surface is never excavated; it is always on a level with, or above the non-ulcerated tissues that limit it, and its margin never presents an abrupt induration."*

Further, with regard to the position of these "sores," two principal circumstances have been almost invariably noticed. As seen by the aid of the speculum, they either present the appearance of a red and apparently raw surface commencing, within the cervix, or at the margin of the os tincæ, and spreading outwardly to a limited extent over one or both lips; or they form numerous isolated red spots, or sometimes depressions dotted at nearly regular intervals over the whole surface of the vaginal portion of the cervix, and varying in size from a pin's head to a millet seed.

It will aid description to take advantage of these peculiarities for the purpose of arranging in two groups or classes the various pathological and other states of the uterine cervix, which severally exhibit the characters just mentioned. Many of these, however, when minutely examined, and tested by the aid of the microscope, so little fulfil the conditions of true ulceration, as to make it appear that such a term could only have been applied to them under, in some instances perhaps a misapprehended, and in others a strained, view of their real nature.

In the first class may be included those cases in which the filiform papillæ of the cervix are in an uncovered state, and either of their natural size or hypertrophied; eversions of the cervical mucous membrane; and hypertrophic growths of the same. All, or nearly all the non-excavated ulcers, so termed, are referable to one or other of these conditions.

Beginning with the normal variety of structure already described, in which the central columnar folds of the cervical mucous membrane take a perpendicular direction (*fig.* 424.), and after running down to the very margin of the os tincæ terminate there in a narrow border, or tuft of filiform papillæ, the simplest form which has been viewed as abrasion, excoriation, or ulcer, is thus produced. The velvety pile, constituting one of the most common features of pseudo-ulcer, being formed by these slightly prominent papillæ, fringing the margins of the os.

In a more marked degree of the same condition, instead of a narrow line or margin, a broader crescentic patch of uncovered filiform papillæ extends outwardly over either or both lips. The papillæ are gathered into little groups, whose appearance, when magnified by a common hand lens, may be compared to miniature wheat-sheaves heaped together. Each papilla is perfectly free and possesses its own proper epithelial coat.* This little group, which may cover half the circumference of the cervical lip, is encircled or semi-encircled by a thin non-elevated margin, where the ordinary pavement epithelium covering the rest of the cervical lip terminates. There is no appearance of any loss of tissue here, beyond that occasioned by the absence of a portion of that dense layer of epithelium, which, like a sheet cast over the papillæ, usually invests them, as far as the inner borders of the cervical lips, with one common covering, in addition to their own proper coat.

These papillæ may retain their normal size, or they may be hypertrophied. On account of the large number of capillaries which they contain, and from the circumstance that they are uninvested by vaginal epithelium, they present a florid and often turgid aspect.

When such a part is brushed over with nitrate of silver, a line of demarcation is instantly produced, the mucus entangled among the naked villi is coagulated, and a cloud of white chloride of silver is precipitated among them, while the parts adjacent which are covered by pavement epithelium are less affected, and exhibit only a pinkish white opalescence, that contrasts with the dead white within, and with the abruptly marked border of the epithelial edge. In this way is produced another effect commonly quoted as a test of ulceration.†

Those bolder and more marked projections of a florid red colour which begin also from the inner margins of the os, and spread outwardly, looking like granulations, consist of hypertrophies of pre-existing structures intermixed occasionally, though more rarely, I believe, with pathological new formations.

Such hypertrophies are chiefly the following, viz. eversion of the cervical lining as described at p. 693.; hypertrophies of the crested folds of that membrane, which when everted, enlarged, and inflamed, constitute the condition termed "cockscomb granulation;" and lastly, distended and closed muciparous follicles gathered in groups around the os and intermixed with the hypertrophied structures just noticed. These latter add to the irregularities and nodosities of the surface, and together with fissures formed by deepened natural folds, and varicose distensions of vessels, constitute the more irregular forms of hypertrophies which have been termed ulcers.

The second class of pseudo-ulcers termed commonly aphthæ and granulations, viz. those which are dotted at regular intervals over the lips of the cervix, but are often more enduring than herpes, and do not usually in their progress coalesce as herpetic spots when contiguous almost invariably do; these consist of

* J. H. Bennet, *loc. cit.* p. 79.

* Regarding the nature of this coat see p. 639.

† Precisely such an effect may be produced upon mucus scraped with a piece of glass from the tongue, and touched with argenti nitras.

enlarged muciparous follicles*, which in three different conditions or stages correspond with three varieties of pseudo-ulcers of the aphthous kind. In the first variety the follicles are closed and project like millet seeds above the general level of the cervix. They contain a little glairy fluid, and may be compared to the distended closed follicles described at p. 640., as occurring within the cervical and uterine cavities. They are almost always placed at such regular intervals apart, that they must be regarded as natural structures enlarged, rather than as pathological new formations.

The second variety consists not of closed but open follicles similarly arranged. Within and at the bottom of many of these may be seen the filiform papillæ enclosed, cup-like, and resembling the stamens in a half opened flower. Similar follicles to these occur sometimes within the cervix under ordinary circumstances.

When these papillæ become hypertrophied and sprout out above the cup-like level of the containing follicles they form florid-looking and elevated spots resembling granulations in appearance, and these constitute a third variety — the "granulations simples sans ulcerations" of Pichard.†

The foregoing examples have been here passed in review for the purpose of illustrating the principal anatomical and pathological conditions of the uterine cervix, which when viewed by the speculum during life exhibit appearances that are regarded by many observers in the present day as affording unmistakeable characteristics of ulceration. With this object they have been here grouped together, but they do not form a class; many of them indeed have no pathological relationship, and to few can the term ulceration be regarded as appropriate. In order, therefore, to eliminate from the category those conditions which have no title to be considered as ulcers, it is needful to apply to them the test of a definition. With this view, and also for the purpose of avoiding the confusion which from the time of Hunter downwards has attended the employment of various terms for the designation of ulcerative processes, of those at least by which the particles of open or exposed surfaces are removed, it may be well to adopt some such distinction as that proposed by Mr. Paget, namely, to regard as abrasions or excoriations those conditions in which the epithelium or epidermis of an inflamed part is alone removed, and those only as ulcerations in which the removal extends further to the vascular or proper tissues beneath the epidermis.‡

Judged by this test, there may be excluded, first, all those apparent sores which, beginning invariably from within the margins of the os, and appearing to spread outwardly more or less over the cervical lips, present a florid and often granular aspect, and being on a level with surrounding parts, and without definite edges or raised border, fulfil all the conditions commonly assigned to ulcers of the uterine neck. These, almost without exception, consist of the inflammatory conditions already described as hypertrophies and eversions of the cervical mucous membrane. The apparently raw surface exposed to the eye is not usually any portion of the outer cervix, but the swollen inner surface of the walls of the cervical canal now everted and brought into view, just as the interior of the lip is brought into view in common strumous thickening about the mouth. The margin of this apparent ulcer is the normal boundary of the os, or line of demarcation between the vaginal and cervical mucous membrane, now disturbed and thrown out of its natural place. The granulations upon this surface are the thickened and inflamed papillæ, follicles, and rugæ of the cervical canal. The edges are not raised because they simply form the boundary between the vaginal and cervical epithelium, and the centre is not depressed, because there is no erosion nor any loss of tissue.

These conditions of the uterine cervix in respect of their true pathological relations are exactly allied, in their different degrees, to the inflammatory conditions of the eyelid termed respectively Lippitudo, Ectropion and granular lid. Both are attended by like hypertrophies of structure and corresponding depravements of their healthy secretions. Both are reduced to their normal condition by similar or even identical methods of treatment, and both are alike entirely removed from the category of ulcers.

Next to these may be enumerated the conditions of the uterine neck which are distinguished by loss instead of hypertrophy of tissue. When this loss consists solely in detachment of epithelium the term "epithelial exfoliation" appears to be a more appropriate designation and preferable in many respects to "excoriation or abrasion," — terms which seem to imply something of violence in the mode of production of these conditions.

Exfoliation of the tesselated epithelium covering the vaginal portion of the cervix appears to take place under some circumstances with great ease. In uterine catarrh for example, this shedding of epithelium commences at the borders of the os, and extends outwardly. Or it may involve the entire epithelium of the vaginal portion of the cervix together even with that of the vagina itself, these being sometimes thrown off like a cast. In such cases, a fresh epithelium is formed beneath the old one that has been detached.*

But if the epithelium is not renewed the villi remain denuded. This condition may be precisely imitated after death by macerating the part for a few days, and then peeling off

* See p. 640.

† Excellent representations of the varieties described above will be found in Boivin and Dugès' Atlas, pl. 25. 27. and 33., and in Pichard, Mal. des Femmes, pl. 3.

‡ Surgical Pathology, vol. i. p. 419.

* See also page 707. and note.

the epithelial covering. And it is probable that profuse discharges lying in constant contact with these parts during life may similarly assist in softening and detaching this structure. But it is deserving of consideration that the papillæ of the outer surface of the os by this uncovering are merely reduced to the same anatomical condition as those of like form within the cervical canal. Whether this deprivation of a natural covering usually found here renders the villi of the outer cervix, which are probably specially sentient structures, more susceptible of irritation, particularly when in a hypertrophied state, is a matter for consideration that would extend the present inquiry beyond its proper limits here. But it is probable that in this way may be explained those constitutional and local erethisms which often accompany faulty states of the uterine cervix; and which have led to such conditions being invested with a degree of importance often in excess of their true pathological value.

But the villi may be found in some specimens denuded of vaginal epithelium, yet without any evidence of inflammatory or other changes. Such a part may appear quite natural. The villi upon the cervical lips, and those within the canal being in every respect identical and alike natural in appearance, so that the strictest microscopical investigation may fail to detect any difference between them. The examination of such specimens has satisfied me that the vaginal epithelium does not always normally terminate precisely at the inner borders of the uterine lips, but may cease at some point short of this.*

In the third place are to be noticed those cases in which the process of removal extends to tissues deeper than the epithelium, *i. e.* to the villi, the vascular and fibrous, and other tissues. The removal of such tissues here necessarily produces excavation with definite borders, and all the characters of a true ulceration. Ulcers of the uterine cervix exhibiting these features are almost exclusively either syphilitic, phagedenic, cancerous, or cancroid, and such as occur upon the surface of a prolapsed uterus. They are seldom, I believe, scrofulous, and more rarely if ever do ulcers occur upon the uterine neck as the result of simple inflammation, fulfilling the conditions that would entitle them to be admitted into the category of true ulcerations.

Distensions of the uterine cavity, by liquid or gaseous contents, constitute the affections termed respectively *hydrometra*, *hæmatometra*, and *physometra*. These collections result usually from narrowing or atresia of some portion of the vagina or cervix, whereby the natural or morbid secretions of the uterus become pent up in its cavity. They are generally accompanied by hypertrophy, but sometimes by atrophy of the uterine walls.

* Some of these morphological varieties have been described in a preceding page; and such, together with many of the hypertrophies already noticed, have been repeatedly submitted to me during life as examples of ulcers of the uterine neck.

Hydrometra results usually from a combination of chronic uterine catarrh with obliteration, absolute or relative. of the lower uterine orifices. Such obliteration, for example, may be caused by chronic disease of the cervix, by the presence of a submucous fibroid or a cervical polypus obstructing the cervical canal, or by the pressure of an enlarged neighbouring viscus, as the ovary *, or of a chronic abscess. If, with these or similar conditions, uterine catarrh co-exists, the secretion from the mucous membrane collects in, and gradually distends, the cavity; the walls of the uterus becoming at the same time hypertrophied, or sometimes atrophied.† The fluid which accumulates in such cases may be thin and watery, but it is more often puriform, and in some instances, as in Dr. Hooper's example, which resulted from the opening of an abscess into the uterine cavity, it consists of pure pus. To these cases, the term *pyo-metra* would be perhaps more appropriate. Collections of these kinds amount usually to several ounces, or may reach one or two pounds. The uterus enlarges to the size of a fist, and, in rare examples, to the bulk of the gravid uterus at term.‡ Pure hydrometra, *i e.* without hæmatometra, can only occur after the climacteric period, or in combination with amenorrhœa.

When the inner and outer os uteri are both closed, and the cervical and uterine cavities are at the same time distended, the organ resembles an hourglass in form. This constitutes the *uterus bicameratus vetularum* of Mayer.

Hydrometra is to be distinguished from *hydrorrhœa uteri*, in which there is no obstruction, but a continual escape of a thin, watery fluid, often to a large amount. This condition, which may occur both in the unimpregnated and gravid uterus, is apparently dependent upon excessive activity of the follicular structure of the cervix, and may be viewed as a coryza of that part.

Hæmatometra consists in a collection of blood, usually menstrual, in the uterine cavity. It is commonly associated with atresia of the vagina at some point, generally at the orifice, as when the hymen is imperforate, or when the orifice has become closed by inflammation of the vulva in early infancy. Under these circumstances, when the menstrual age arrives, the fluid, for which there is no outlet, collects in, and distends, the cavity of the uterus, whose walls at the same time become hypertrophied, as in pregnancy; or occasionally attenuated, as in the case of hydrometra just stated. The fluid, which is generally dark-coloured, and of the consistence of treacle, may, if not artificially evacuated, escape spontaneously in various ways, viz. into the abdominal cavity, by travelling along the oviducts, or through lacerated or ulcerated open-

* Scanzoni, *loc. cit.* p. 165.
† Hooper, Morbid Anat. of Uterus, pl. III.
‡ Case. Dr. A. T. Thomson, Med. Chir. Trans. vol. xiii.

ings in the uterine walls; or, if previous adhesions are formed, the fluid may escape by the vagina or rectum. Hæmatometra may occur also in certain malformations of the uterus, as already described (p. 680.).

Physometra. Pneumatosis s. tympanites uteri.—This affection, known to Hippocrates* and Aretæus†, consists in a collection of air in the cavity of the uterus, which makes its escape from time to time by the vagina, with or without explosion. The air may be dry, or accompanied by more or less fluid (*physometra humida*). In ordinary cases it is inodorous, but occasionally it possesses a most offensive odour. In these latter cases (*physometra putrida*), the gas appears to be generated by decomposition of some substance within the uterus, as a putrid fœtus, the remains of a placenta left in utero, and the like, while the generation of an inodorous gas, on the other hand, without the presence of any such substances, within the uterus, can only be compared with those sudden developments of air in the stomach and intestines which often take place in hysterical women.

Hydatids.—A case of acephalocysts within the ovary has been given at p. 584., but this is so rare an affection of the uterus that no anatomical collection, I believe, in this city contains an example of it. Rokitansky's often-quoted case‡ appears to be the only certain instance of acephalocysts in the uterine cavity which pathologists in the present day are able to adduce.

In the "Lancet" of 1840, vol. i. p. 691., a case is reported as one of uterine hydatids, the nature of which is not very clear. That they were not acephalocysts (echinococcus vesicles) may be inferred from the description. This case, which is quoted here as an example of the more doubtful instances of hydatids, was probably one of interstitial pregnancy (see p. 621.) combined with the vesicular degeneration of the chorion described in the next paragraph.

Those vesicular masses and groups or strings of watery vesicles, falsely termed hydatids, which are so frequently expelled from the uterus accompanied or preceded by abundant serous discharges, combined with rapid distension of the abdomen and some symptoms of pregnancy, consist invariably of moniliform enlargements of the villi of an imperfectly developed chorion or placenta.

It is almost needless to observe that the presence of a true chorion structure, which these substances invariably exhibit, even in their most degenerated and abnormal forms§, constitutes unquestionable evidence of a prior act of impregnation. Connected with these, when the degeneration is not much advanced, may be sometimes found an embryo perfectly or incompletely developed*, but in higher grades of this abnormal state the embryo invariably perishes or is unformed.

* De Morbis Mulierum.

‡ Loc. cit. vol. ii. p. 291.

§ For descriptions and illustrations of these structures see Wedl, Pathological Histology (Syd. Soc.), p. 172.

Narrowing and obliteration of the uterine cavity. Atresia.—The defects which come under this head may be either congenital or acquired. They may consist in a simple narrowing, or stricture of the cavities of the uterus, or of the apertures leading to them, or in a complete obliteration of some or all of these. Probably most of the cases of atresia which do not originate in the malformations already described, have resulted from the organisation of the products of inflammation affecting these parts.

Obliteration of the *external os uteri*, either partial or complete, is the most common of these conditions. In minor degrees, where the form of the parts is not lost in adhesions with adjacent structures, the os is found closed by narrow membranous threads or bands. If the closure is not complete, pregnancy may ensue, but labour is obstructed, and the original seat of the os is then with difficulty traced, or it cannot be found.

The *cervical canal* may be entirely obliterated by the formation of fibrous tissue, in which smooth muscular fibres have been sometimes found.

Obliteration, or narrowing of the *inner uterine orifice*, may occur in the progress of senile atrophy, or as a result of the same processes that cause obliterations lower down. All the foregoing atresiæ may result in the collections of fluids within the uterine cavity recently described.

Lastly, the *cavity of the uterine body* may be so completely closed that no trace of it can be found. Such an example is delineated in Pl. 13. of Boivin's and Dugès' Atlas, which contains also the figure of another uterus, the original seat of whose cavity is indicated only by a narrow triangular band of white tissue nearly as hard as cartilage.

Pathologic conditions which may involve several of the uterine tissues.

Cancer.—The two main disorganising processes by which the structure of the uterus is metamorphosed or disintegrated and ultimately more or less destroyed, are those under which cancer and fibroid are respectively developed in its tissues. Of these, regarded as destructive agents, cancer ranks second in point of frequency, but first in potency.

Cancer occurs in the uterus as in the ovaries, under the three principal varieties of encephaloid, scirrhous, and colloid. But while in the latter organ colloid as a primary disease is certainly more common than either of the other two; in the uterus, on the other hand, both scirrhous and colloid are rare, while encephaloid constitutes the chief form under which cancer is found.

The development of cancer may undoubtedly commence in any portion of the uterus, but the number of instances in which it occurs,

* Granville, Graphic Illustrations of Abortion pl. iv. and v.

first, in the cervix, and especially in the vaginal portion, is so preponderating, that this may be regarded as mainly the seat of origin of uterine cancer.

The comparative rarity of opportunities for examining uterine cancer in the incipient stage, has limited to a certain extent our knowledge of this part of the subject.

The cervix in the incipient stage, smooth, tense and hard, or exhibiting upon its surface here and there knotty projections, is found upon section to have its tissues infiltrated in parts by the cancerous structure, which differs in the character and relative proportions of its elements, according to the form which the cancer assumes. In the medullary variety a white cream-like or lardaceous semi-fluid matter, composed of the usual cancer constituents, is found interspersed among the meshes of a loose reticulum, in the softer portions of which few if any of the normal uterine fibres can be traced. The larger preponderance of the encephaloid matter, compared with the fibrous stroma, occasions that semi-elastic feel which the part early acquires, and at the same time constitutes the main difference between encephaloid and scirrhous cancer.

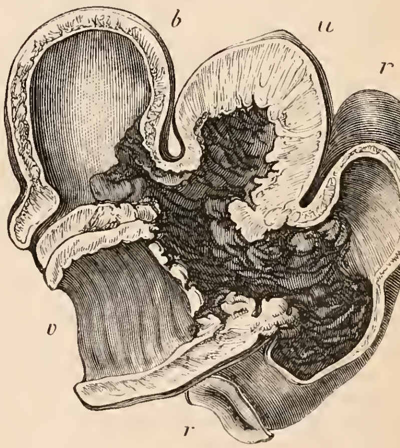
In the scirrhous or fibrous variety the greater hardness of the structures is dependent upon the presence of a large proportion of a coarser fibrous stroma, composed of dense white fibres, the minute interspaces of which are occupied by a greyish or reddish softer and often pulpy substance, which may be obtained by scraping, or may be squeezed from the part. In the harder forms of scirrhous but little fluid is so obtainable; but in some specimens here and there, softer portions are found from which a fluid cream-like matter exudes, differing in no respect from the pulp of encephaloid cancer. These and the softer portions obtained by scraping are composed of cancer cells with molecules, granules, and disintegrated fibrous tissue.

The irregular nodulated projections occasioned by the unequal development of the cancer structure rapidly increase in the encephaloid variety, and the cervix becomes much enlarged. The surface of the more projecting portions becomes florid and vascular, and these portions pass first into ulceration by thinning and absorption of their mucous covering. The creamy or cheese-like contents of these tuberculated portions then escape, and being sometimes of a yellow colour may be mistaken for tuberculous matter.

This stage is followed by the formation of one or more corresponding ulcers upon the outer cervix, which coalescing destroy the remaining portions of the mucous membrane, and spreading up the cervical canal, convert it into an irregular funnel-shaped cavity, bounded below by hard rugged margins. Or fungous vascular growths, friable and easily bleeding, sprout from the part and entirely destroy its natural configuration. A yellow or greenish-brown sanious discharge, of a highly fetid odour, mixed occasionally with florid blood and ultimately with fragments of putrid tissue, dates from the commencement of ulceration, and increases in proportion to the extent of surface denuded. The fragments of putrefied tissue which hang from the ulcerated surfaces, and occasionally pass away in the discharges, consist mainly of connective tissue fibres, which are more slowly disintegrated, stained of a dirty brown colour by infiltration with decomposed blood.

By these disintegrating processes both lips, and finally the cervix itself, are destroyed and removed; the cancer structures being continually deposited in advance of the ulceration, while the fundus and even the body of the uterus may still remain sound. In like manner cancerous deposits take place in the fibrous tissue surrounding the uterine neck, and attaching it to adjacent parts. Thus the uterus becomes fixed in the pelvis, and at the same time a way is paved for the further extension of destructive ulceration, by which first the bladder and then the rectum are penetrated, and the disease further extending down the vagina, the whole is laid open into one ulcerous cloaca (*fig.* 479.). If life is

Fig. 479.



Cancer of the neck of the uterus (*u*), extending to the bladder (*b*), rectum (*r*), and upper part of the vagina (*v*). (*Ad Nat.*)

maintained beyond this point the pelvis becomes lined with cancerous matter, and, the peritoneum inflaming, all the adjacent parts become agglutinated together, until finally the ulceration may extend into and lay open the peritoneal cavity itself.

The penetration of the bladder earlier than the rectum, which almost uniformly obtains, is explained by the different modes of connexion of the cervix with these two parts. Since nothing but fibrous tissue intervenes between the bladder and the anterior cervical wall (*fig.* 426. *b b* and 433 F), the cancer elements are readily deposited, and extended in this direction, while the posterior wall being separated from the rectum by a double fold of peritoneum (*fig.* 426. 433. G), the cancer matter does not so easily penetrate through this, not at least until adhesions have formed.*

But cancer may commence in the fundus or body, instead of in the cervix, although this is rare; or it may extend to the uterus from the ovary. In this way extensive disorganisation of the adjacent parts may occur, the cervix remaining intact.†

Cancer, when thus developed, especially in the encephaloid variety, assumes often the form of distinct masses or tumours, rather than of an infiltration of the tissues.

These tumours may be imbedded in the uterine walls, or form numerous irregular rounded and sometimes pedunculated masses, variously attached to, or projecting from their surface. On the other hand such a distinct mass formed in the substance of the uterine walls, or beneath the mucous membrane, may in the course of growth push the latter before it, and, subsequently acquiring a stem, may fill the uterine cavity or protrude into the vagina, and constitute a malignant polypus.

In most cases of uterine cancer the uterus is the primary, and except in those instances where the disease has spread by direct extension to adjacent parts, it may remain throughout the sole organ attacked. Or uterine cancer may be associated with like formations in the stomach, mamma, ovary, &c., and be developed concurrently with or consecutively to these.

Cancroid. Epithelial cancer. Cauliflower excrescence.— Cancroid of the uterus is limited in its commencement to the vaginal portion of the cervix, and presents the following principal varieties. It may appear under the form of papillary growths, resembling condylomata, which spring from the mucous surface, and form little compact masses that gradually, by the growth and elongation of the papillæ, become soft, pulpy, and brittle, and easily bleed on being touched. After a time a basis of cancroid is developed in the cervical tissues, or the papillary growth appears upon a larger scale, forming a hard, knotty, and brittle mass, which grows with tolerable rapidity, and ultimately more or less fills the vagina or protrudes from the vulva. In form the growth often resembles a cauliflower, to which it was likened by Dr. John Clarke. The surface is of a bright flesh colour, and is covered with small projections or granules. These again are united into larger masses or lobes, set upon short and broad stems, that ultimately coalesce into a common basis formed by one or both lips of the cervix. The whole tumour has a certain firmness and solidity; but the superficial granules are so brittle that slight handling causes some to break away, a free hæmorrhage resulting. Or the cancroid, after being developed in and beneath the mucous membrane of the cervix in the form of little granular masses, gradually breaks through the surface; while in the course of time ulcerations form upon the most prominent portions, and these coalescing, while increased deposits of cancroid take place in the sublying tissues, which in turn are also destroyed, a sore, more or less extensive, is formed that in its further aspect and progress very nearly resembles encephaloid cancer.

Regarding the structure of these cancroid formations, they are, according to Virchow, at the commencement simple papillary growths, and later assume the characters of cancroid. At first they appear in the form of small villous projections from the surface, composed of an outer very thick layer of peripheral epithelial plates, and an inner one of cylinder ephithelium, the interior of the villus consisting of large blood-vessels. These vessels are chiefly colossal thin-walled capillaries, which either form simple loops at the extremities of the villi between the layers of epithelium, or ramify in compound loops over the surface, or lastly, present a retiform arrangement. The great size, tenuity, and superficial position of these vessels explains the profuse discharge of watery fluid, and frequent bleedings, which constitute such striking features in the progress of the cauliflower excrescence, as well as the entire collapse and almost total disappearance of those tumours after death, so that only slight traces of them are found on post-mortem examination.

At the commencement the papillæ are single and close-set, so that the surface, as Clarke describes it, is merely granular. The peculiar cauliflower form is occasioned by the branching of the papillæ, which ultimately form fringes an inch in length. After this superficial process of growth has continued for a certain time, cancroid alveolar spaces begin to be formed at the base, between the fibrous and muscular layers of the organ. At first these appear as simple spaces, with epithelial contents, but later are found alveoli, from whose parietes new papillæ spring, which also become ramified, constituting arborescent proliferous growths.

Corroding ulcer.— Here may be noticed an affection of the uterine cervix, whose exact pathological relations have not been determined with sufficient accuracy. The corroding ulcer, first described by Dr. John Clarke, and compared by Rokitansky to a phagedenic (cancerous) sore of the skin, differs mainly from cancer in the absence of a cancer basis, or of cancerous infiltration of adjacent tissues, while it resembles the destructive march of cancer in its mode of gradually disintegrating, and destroying the os and cervix, and even portions of the body of the uterus, and extending to the bladder, rectum, and adjacent structures. The characters of this ulcer are those of a ragged, irregular-margined sore, with a brownish or greyish base, from which issues a thick purulent or copious watery secretion. The margins and base may be thickened by inflammation, but there are no granulations.

* Dr. West is, I believe, the only author who has hitherto pointed out the true cause of this difference.

† See case, p. 593.

Upon the question of the nature of this form of ulceration Foerster gives a useful hint. After describing a case which fell under his notice, and where he could find no traces of either encephaloid or epithelial cancer in the base of the ulcer, he mentions another which also to the naked eye appeared to have no cancerous basis, and yet on microscopic examination the entire base of the ulcer, to the depth of a line, was found to consist of cancer structure.* May not the thinness of this layer, by limiting the pabulum which feeds the progress of the ulcer, explain the slow advances of the latter observable in some cases of corroding ulcer?

Tubercle rarely effects the uterus, and still more rarely is it a primary disease of that organ.

Tubercle of the uterus exhibits the following peculiarities. The tuberculous deposit is limited in the first instance to the mucous membrane of the body of the organ. Here it occurs either in the form of tuberculous granulations, isolated or collected in groups, or more often as a uniform infiltration, limited at first to the mucous membrane, but ultimately penetrating more or less deeply the sublying uterine parenchyma, and accompanied by hypertrophy of the muscular coat. In the subsequent metamorphosis of the tubercular formation the infiltered membrane softens and melts down, so that the cavity becomes filled by a purulent pulpy fluid. The tubercular infiltration terminates abruptly at the inner uterine orifice†; or if rarely it penetrates the cervical canal or appears upon the vaginal portion, it is then only in the form of isolated tubercular granulations, which latter may probably pass into tubercular ulcers.

Tuberculosis of the uterus is usually associated with a corresponding condition of the mucous membrane lining the Fallopian tubes. These latter are found distended and their canals filled by caseous tuberculous matter.

Solutions of Continuity.

Laceration of the walls of the uterus occurs under various circumstances. It happens rarely in the unimpregnated organ, more frequently during pregnancy, and most commonly during labour.

Rupture of the walls of the unimpregnated uterus can only occur under abnormal conditions of the organ, as from considerable growths of fibroid, or from great distension of the cavity by watery, puriform, or sanguineous fluids, such as occur in hydro- and hæmatometra. See p. 697.

Rupture during pregnancy may happen at almost any period, but chiefly during the latter half, although it may take place even as early as the second month, as from vomiting.‡ Or it may be occasioned by violent spasmodic contraction, or from contusion or sudden concussion. It is most likely to happen in the case of the imperfectly developed uterus, as in the uterus unicornis, of which a description has been already given (p. 679.), or in the case of gestation in the uterine portion of the Fallopian tube (graviditas interstitialis, p. 621.).

Rupture of the uterus may occur upon only very slight exertion, as in the act of stooping*, or even without any obvious cause, as during sleep.† Most of the recorded cases, however, of spontaneous rupture of the uterus have occurred during labour, under violent uterine action, combined with some unusual resistance to the passage of the child, such as is occasioned by a distorted or fractured pelvis, a tumour, an unyielding state of the os and cervix uteri, or by some malposition or unusual bulk of the child. It may also occur from violence in instrumental delivery, or from injudicious efforts to turn the child.

The seat of rupture is most commonly the neighbourhood of the cervix, the laceration extending very often through the os to the vagina, or upwards, so as to involve more or less of the body of the uterus. It occurs oftenest at the sides, less frequently in the anterior or posterior walls, and least of all at the fundus.

The course of the laceration is generally oblique, rarely in the horizontal direction. It may, however, extend round the whole circumference of the cervix, the lower segment of the uterus being forced off in a single piece, before the presenting part of the child.‡

The length of the rupture may be such as to admit of the child escaping into the abdomen, among the intestines, or it may be only very slight. All the coats of the uterus are not necessarily involved. The peritoneum alone may be torn, numerous rents (40—60) occurring in this coat, without extending to the muscular tissue.§

These lacerations occur in most instances where the uterine tissues are perfectly healthy. In some cases the walls of the uterus have been apparently attenuated, the attenuation being attributed to pressure upon the spine or pelvic bones, or there has been more or less evidence of antecedent inflammation near the seat of the accident.

Perforation of the uterine walls occurs in cancer, (*fig.* 479.) followed by the establishment of fistulous communications with the bladder and rectum; or from penetrating abscess at the surface of the uterus; or as a consequence of adhesions formed between the uterus and an ovarian cyst, the contents of

the latter being discharged through the uterine cavity.

Pathological conditions of the Uterus after Parturition.

Irregular contraction. — After tedious and exhausting labours, or those in which the uterus has been rapidly emptied, or under other circumstances which tend to the production of a general or partial atony of the organ, its post-partum contractions are often imperfect. The whole uterus may remain relaxed and undiminished in size, or a portion only of the walls may contract while the rest remain inactive. From the latter combination result the hour-glass and other irregular forms of the organ when the cavity of the uterus is partitioned into two chambers, in the upper of which a part or the whole of the placenta may be imprisoned. The seat of constriction being either near the fundus, or the centre of the uterus, or the neighbourhood of the cervix. This condition is often attended by hæmorrhage from the uncontracted portions of the uterine walls.

In explanation of these irregular contractions, it has been usually assumed that the contracted portions consist of the fibres that have retained their vigour, and the relaxed parts of those that have been exhausted. Numerous observations, however, have satisfied me that this is but an imperfect and, in some respects, an erroneous interpretation of this phenomenon. It appears to depend rather upon arrested peristaltic action, which may indeed be, and probably is, the result of exhaustion; not, however, of a particular set of fibres, but of the ganglionic nerves which especially govern this movement of the organ. So that the peristaltic contraction in travelling along the uterus from os to fundus, is stopped in some part of its course. This explanation is consistent with the fact that these constrictions are not confined to any special region, but may occur at any point between the cervix and the fundus, and particularly with the circumstance that in some cases the constricted part may change its seat, the contraction being sometimes felt to travel onwards towards the fundus, while the hand is employed within the uterus in removing the placenta. See p. 673.

Rokitansky describes a remarkable result of partial contraction, with relaxation of the rest of the uterine fibre. When this occurs at the placental region, the part that gave attachment to the placenta being relaxed is forced into the cavity of the uterus by the superior tonicity of the surrounding tissues, and there constitutes a kind of tumour which, on account of its form and the protracted hæmorrhage that usually ensues, may be mistaken for a polypus or a hæmatoid growth.

Retarded and incomplete involution consists in an arrest of those metamorphic processes by which the uterus after parturition is restored to its ordinary condition. All inflammatory puerperal processes are attended by this condition in a greater or less degree. But involution may be arrested without inflammatory action, so that the uterus remains undiminished in bulk, its fibre uncontracted, and its tissues unrenovated for several weeks or months after labour. The soft flabby organ is easily distinguished above the pubes, reaching sometimes as high as the umbilicus; while its cavity, tested by the uterine sound, may measure several inches in depth.

Puerperal inflammations.—The puerperal or post-partum inflammatory affections of the uterus may be noticed according as they involve the peritoneum, the proper tissue together with the blood-vessels and absorbents, or the lining membrane of the organ.

Puerperal endometritis.—Inflammation of the internal surface of the uterus occurs, as a primary affection of that organ, shortly (within a few hours or days) after labour. It takes the form usually of plastic inflammation, whose first seat is either the surface which has been exposed by the separation of the placenta, or certain portions that have suffered injury, such as lacerations and contusions, occurring during forced or spontaneous delivery. From these points, the inflammatory action may spread over the entire inner superficies of the organ, or it may involve more or less deeply the uterine parenchyma, and ultimately extend by contiguity to the peritoneum itself. The form of inflammation, and the nature of the exudative products, exhibit great variations in different instances, variations which are especially observable in respect of individual and epidemic influences, and are directly connected with corresponding conditions of the blood to be hereafter noticed. Endometrial inflammations have been accordingly distinguished by some pathologists, as croupy, dysenteric, catarrhal, and the like.

The exudations of the fibrinous or croupous kind, which are found upon the inner surface of the inflamed uterus, exhibit sometimes great plasticity. These may occur in the form of isolated patches, or of more extensive investments of a dense yellowish or greenish lymph, either firmly agglutinated to, or lying loosely upon, the sublying tissues. In inflammations of a less sthenic type, the exudation is softer and more gelatinous, and is often intermixed with serous and purulent fluids. Or the fibrinous matter may be wholly wanting; the inflammatory products consisting then entirely of purulent discoloured and sanious exudations, which, in cases that have been distinguished as putrescence of the uterus, assume usually a greenish or dirty-brown coffee-coloured aspect.

The condition of the tissues, which are brought into view by removing or wiping away the above-mentioned products, exhibits corresponding variations. Beneath the coating of firm lymph, characteristic of uterine croup, the uterine tissue is merely softer and more spongy, and redder than usual; but in those forms of inflammatory action which rapidly pass into the puriform stage, the subjacent tissues become infiltrated and softened, so that they may be easily scraped away in the form of a discoloured flocculent pulp. This condition, in its highest degree, where the tissues appear macerated and deeply penetrated by the dirty-coloured fluids already described, at the surface, constitutes uterine putrescence.

In addition to these products and results of inflammation, there may be found attached to the uterine surface fragments of an imperfectly detached placenta, or blood clots and shreds of the deciduous lining, lying free within its cavity. These, by their decomposition within the uterus, whose cavity, from the moment of parturition, has ceased to be completely closed against atmospheric contact, play an important part in the production of those septic and other infections of the blood which appear to form an essential part of all or nearly all puerperal inflammatory processes.

Puerperal metrophlebitis.—Inflammation of the veins of the uterus occurs most frequently in combination with, and is, to a certain extent, secondary to, the conditions last described; but it may occur also as a primary affection, and continue for a time the chief or only morbid state of the organ. The inflammation is seldom confined throughout to the veins of the uterus. It appears to commence in some of the orifices of the venous sinuses, which, after labour, terminate open mouthed upon the inner surface of the uterus, over the placental place, and thence spreading through those sinuses which occupy the uterine walls, it may extend to the spermatic and hypogastric veins and their tributaries, either upon one or both sides, and ultimately involve more distant vessels.

The condition of the veins in uterine phlebitis varies according to the intensity and duration of the inflammation. The inner coat may be pale or stained with the colouring matter of the blood. It may have lost its polish, or have become adherent to the contents of the vessel, where these are of a solid nature. The coats of the vessels affected may be thickened and opake, and the surrounding tissues infiltered by various colouring fluids, or softened and in a state of putrescence.

Regarding the contents of the vessels, these consist sometimes of firm plugs of fibrine coagulated from the blood, but more often of these in a softened grumous state, intermixed with portions of a yellow grey or whitish colour. The interior of such coagula may consist of a fluid not easily distinguishable from pus, but resulting from metamorphic changes in the fibrine, subsequent to its coagulation within the vessels. Or the veins may be distended by a brownish sanies, or a yellow or greenish yellow viscid pus, so that upon section of the uterine walls numerous collections of the latter, resembling separate abscesses, are displayed.

In the more severe cases of metrophlebitis the proper tissue of the uterus is deeply involved, being discoloured and in a state of disorganisation and putrescence throughout its entire thickness; or exhibiting at different points smaller or larger abscesses, the contents of which may have been discharged into the general cavity, or form ramified sinuses or fistulæ in the uterine substance. Such abscesses most probably arise from the suppurative inflammation extending beyond the coats of the veins, and involving the surrounding parenchyma.

Uterine phlebitis is often associated with inflammation of the uterine lymphatics (*Lymphangioitis*). These vessels, like the veins, become distended and varicose, and filled with a yellow or greenish puriform fluid, so that their course, together with that of the Fallopian tubes and ovaries, which are generally conjointly affected, may be easily traced into the corresponding hypogastric and lumbar lymphatic plexuses and glands.

Puerperal metro-peritonitis, or inflammation of the peritoneal coat of the uterus, is associated with either or both of the foregoing affections, or it occurs as the primary local disease, and sometimes constitutes throughout the sole apparent morbid condition of the uterus. The inflammation may be limited to the peritoneal covering of the uterus and its appendages, or it may involve that of the entire pelvic and abdominal regions. The membrane itself, which often exhibits little vascular congestion, may have retained its polish, or may be covered by exudative products of very various characters. These may be only small in amount, and partially distributed, or abundant and copious. They consist of firm fibrinous concretions, or softer and more pulpy yellow or greenish exudations, consisting of coagulable lymph loosened by serous or purulent infiltration, or thick purulent fluid, or semi-fluid matter, or lastly serous or sanious fluids, the latter being often discoloured and rendered turbid by intermixture with the before-mentioned products, especially with fibrinous flocculi and puriform and sanguineous effusions.

These several pathological conditions of the uterus, which appear to be incompatible with the progress of those normal changes in the condition of the organ that constitute the process of involution (see p. 658.), are accompanied almost invariably by a marked interference with those processes, so that the act of retrogression is either altogether arrested, or is in a high degree retarded.

The foregoing puerperal affections of the uterus exhibit numerous points of great pathological interest. These, even in their milder forms, cannot be generally regarded as purely topical affections, for they commonly, in their progress, become associated with like conditions of other and often distant organs, whose connection with the original, or at least principal, seat of disease, can only be explained upon the hypothesis of a general dyscrasis of the blood. It is probable that in some cases, of those, for example, whose commencement is apparently dependent upon miasmatic influences, inoculation with cadaveric matter and the like, a primary infection of the blood precedes the development of the topical condition, which may be viewed as the local expression of the former. In a large number of instances, however, the affection of distant parts may be considered as the result of a secondary blood infection, *i.e.* of a poisoning of the blood by the introduction of some products from the original nidus of disease, and particularly of venous pus and sanies in metrophlebitis.*

The occurrences which immediately ensue upon the act of parturition, offer a ready explanation of the mode in which these and other extraneous matters may gain access to the general circulating fluid. For by the separation and removal of the placenta, together with a large portion of the decidua, the contents of the uterine cavity, consisting of various puerperal products now exposed to the direct influence of the atmosphere, are brought into immediate relation with the patent orifice of the uterine veins terminating upon the placental space. Through these a copious reception of the exudated products of inflammation or of septic matters resulting from decomposition within the uterus, or of infecting matter derived from sources still more external, may readily take place, and so produce either the primary or secondary dyscrases of the blood just noticed.

It is also to be observed that independent of external sources of a blood dyscrasis, the latter may be occasioned by an accumulation of effete material, resulting from the arrest of those eliminative processes which constitute so large and important a part of the act of involution, and are always more or less impeded during puerperal inflammation; or commonly by a reflux of pus and sanies formed in the larger venous channels in the case of metrophlebitis already mentioned; while some of the worst forms of sepsis of the blood are those which result from deep prostration of the nervous system, occasioned by exhausting forms of parturition.

The more important associated morbid processes occurring in connection with puerperal inflammation of the uterus, which it may be necessary here to notice, consist in exudations into the larger serous sacs and synovial bursæ, upon the mucous membranes, and in the parenchyma of various parts and organs; and of deposits within the larger vessels, chiefly the veins leading from the uterus, or in the capillaries of organs often far removed from the original seat of inflammation.

The effusions upon the peritoneum and pleura, and less frequently upon the pericardium, consist of fibrinous and croupous exudations, combined often with copious effusions of serous, purulent, or sero-purulent fluids, the latter being, perhaps, often the result of a breaking down or liquefaction of the croupous fibrine, and its conversion into a pus-like fluid. Similar collections are found in the synovial membranes of the larger joints, especially of the knee, shoulder, and hip. While upon the mucous surfaces, particularly of the intestines, which are later affected than the serous structures, a less sthenic form of exudation is usually found, the effusion consisting here of serous, gelatinous, or purulent exudations (the former contributing largely to the production of puerperal diarrhœa), and of infiltrations into the mucous and submucous areolar tissues.

These various exudative processes, whose preference for particular tissues is probably in part determined by textural peculiarities, must be considered as efforts to eliminate the dyscrasial materials from the general blood mass, and they will continue until the exhaustion of the crasis is complete.

The qualitative variations observable in the products bear exact relation to the nature of the previous infection, and of the dyscrasis arising out of it. The character and mode also of the first effusions may materially affect those which occur at a later period; for when the plastic products have been very abundantly and rapidly formed, and the defibrination of the blood consequently very considerable, the extensive discharge of the fibrinous element leaves the blood so attenuated, that the serous portion may then speedily transude through the walls of the capillary vessels, and in this way are produced those enormous collections of serous or sero-purulent fluids which sometimes rapidly form in the advanced stages of puerperal inflammations, occasionally with but slight evidences during life of their occurrence.

Of equal or greater interest are those associated pathological phenomena which are connected with secondary phlebitis, having its seat either in the larger veins, or in the capillary system of vessels. The veins nearest to the uterus are commonly first involved; and from this point the inflammatory action may spread either by direct or interrupted continuity to more distant vessels, following, however, the reverse order of the circulation; or it affects vessels remote from the original seat of inflammation, as in the capillary congestions, and inflammations of distant parts producing the lobular infarctions, and in more advanced inflammatory stages, the so-called metastatic abscesses and sloughs of various organs and tissues. The obstruction to the circulation arising in these cases from coagulation of fibrine within the vessels, and viewed by some pathologists as the cause, and by others as an effect only of inflammation, may be perhaps regarded as a provision for limiting the spread of the infecting fluids, and preventing, to a certain extent, their introduction into the general circulation.

In the larger vessels, especially in the veins nearest the point of primary infection, the fibrine is found under various conditions of coagulation, forming long cylindrical plugs, as in crural phlebitis, or shorter clots, whose red coloration depends upon the degree in which the blood corpuscles may have been incorporated in its several laminæ, or their paler yellow colour, upon the absence of the same, and the consequent greater purity of

* Rokitansky, *op. cit.* vol. ii.

the (perhaps effused) fibrine. The centre of these coagula may be found softened, and containing the creamy pus-like fluid which results from the molecular disintegration and liquefaction so commonly observed in fibrinous clots. Frequently the clots are of a less consistent texture, being of a dark brown or chocolate colour, or reduced to the consistence of a soft pulp. The coats of the veins may be thickened and adherent to the contained coagula, or covered by fibrinous laminæ or merely blood-stained, or presenting no deviation from the natural state.

LIGAMENTS OF THE UTERUS.

These terms are applied to several duplicatures of peritoneum, containing variable quantities of fibrous and muscular tissue, which serve to connect together the uterus and its appendages and to limit the motions of these parts within the pelvis. They are distinguished as the *broad*, the *round*, the *utero-sacral*, and the *utero-vesical* ligaments.

The broad ligament.— The fold of peritoneum in which the uterus is contained, after investing the fundus and anterior and posterior walls of the organ, passes off laterally in the form of a double lamina that extends from each uterine border horizontally outwards as far as the sides and base of the pelvis, to which it is attached. Thus a vertical septum is formed, which divides the cavity of the pelvis transversely into two chambers; the anterior and shallower one containing the bladder, the posterior and deeper holding the rectum and a portion of the small intestines. The uterus occupies the middle of the septum, while the lateral extensions of it form the *broad ligament* of either side. *Figs.* 368. and 404. *f.*,

Attached to the upper border of the broad ligament are three folds, termed lesser wings. The central and superior of these, which is the largest, contains in its free falciform edge the Fallopian tube, and at its base a portion of the parovarium. It has been already described as the mesentery of the tube. The smaller posterior fold invests the ovary together with its proper ligament; while the third or anterior fold is inclined obliquely towards the body of the uterus, and constitutes the covering of the round ligament. Between the laminæ which form the principal or lower portion of the broad ligament, as well as within the alæ, are found the blood-vessels, lymphatics, and nerves which supply the uterus and its appendages, together with a variable amount of fibrous and unstriated muscular tissue that serves to connect the alminæ together.

This structure should be regarded as a mesentery rather than a ligament of the uterus. It serves to invest the uterus and its appendages with a common peritoneal covering, and to protect these parts and attach them to the pelvis, as the mesentery attaches the intestines to the spine; while the interspace of the folds suffices for the conveyance of vessels and nerves. The resemblance to a mesentery is more obvious in the bicorned and intestiniform uterus of the mammalia generally, as well as of many other vertebrata in which it forms the *mesometrium.*

The utero-sacral ligaments.— From the posterior wall of the uterine neck two falciform folds of peritoneum proceed towards the rectum. These are most easily seen when the parts are stretched. Between them lies the depression of variable depth known as the retro-uterine pouch, or space of Douglas. When the peritoneum is removed, these folds are seen to be occasioned by two corresponding bands of fibrous tissue, extending from the substance of the cervix backwards towards the sacrum, to which they are attached. Their strength varies considerably in different subjects; so that when not much developed they may be overlooked. The importance of these ligaments, or rather fibrous bands, has perhaps not been generally sufficiently appreciated. From their position and connections it cannot admit of doubt that they are intended to restrain the motions of the uterus, — to prevent it from being forced upwards in the act of conjunction, and especially to limit the descent of the organ in erect postures of the body.

The utero-vesical ligaments. — Opposite to the point of junction of the body and neck of the uterus, where the peritoneum is reflected forwards on to the bladder, are commonly observed two slighter lateral folds, containing bundles of fibrous tissue. These constitute the anterior or utero-vesical ligaments.

The round or sub-pubic ligament: ligamentum rotundum, ligamentum uteri teres. — This ligament consists of a flattened chord or band of muscular and fibrous tissue, which, traced from below upwards, proceeds from the internal inguinal ring in a curved direction towards the superior angle of the uterus on either side, where it is inserted in front of and a little below the commencement of the Fallopian tube. (*Figs.* 404. and 418.) The ligament of the right side is commonly shorter than that of the left: hence it happens that in pregnancy the uterus more often inclines to that side. According to Mr. Rainey*, the round ligament arises by three fasciculi of tendinous fibres: the inner one from the tendons of the internal oblique and transversalis muscles near the symphysis pubis; the middle one, from the superior column of the external abdominal ring, near its upper part; and the external fasciculus, from the inferior column of the ring, just above Gimbernat's ligament. From these attachments the fibres pass backwards and outwards, soon becoming fleshy: they then unite into a rounded chord, which crosses in front of the epigastric artery, and behind the lower border of the internal oblique and transversalis muscles, from which it is separated by a thin layer of fascia continuous with the fascia transversalis: it then gets between the layers of peritoneum forming the broad ligament, along which it passes backwards, downwards, and inwards to the point of insertion already described.

* On the Structure and Use of the Ligamentum Rotundum Uteri, Phil. Trans. p. 515. pt. ii. 1850.

The round ligament is composed of smooth muscular fibre, derived from the uterus, and arranged in bundles, surrounded by connective tissue, of striated muscle, continuous with that of the abdominal parietes, and of blood-vessels, lymphatics and nerves.

The peritoneal covering of the round ligament is occasionally prolonged in young subjects at its lower part through a portion of the inguinal canal, where it forms the *canal of Nuck*. This is usually obliterated in adults, where the arrangement of the *tendinous part* of the round ligament just described serves to close the internal ring, and to prevent, in a great measure, the occurrence of inguinal hernia in the female. The persistence of this canal probably leads to the abnormal descent of the ovary into the labium, constituting hernia of the ovary (see p. 574.);—an occurrence exactly comparable with the normal descent of the testis into the scrotum of the male.

VAGINA.

Normal Anatomy.

Syn. Vulvo-uterine canal. — The vagina constitutes a flattened cylindroid, extending from the vulvar orifice to the neck of the uterus. It lies entirely within the pelvis, between the bladder and rectum, running very nearly in the direction of the axis of the pelvic outlet, but having a slight curvature forwards. The orifice of the vagina is bounded anteriorly by the vestibule, laterally by the nymphæ, and posteriorly by the hymen. The upper or blind extremity, termed the fornix, receives the vaginal portion of the uterine neck, which is not placed exactly at the termination of the canal, but appears as if it were let into its upper wall (*fig.* 433.).

Dimensions.—The vagina is capable of considerable extension. It varies in dimensions in different subjects. In the ordinary virgin state, the anterior wall, which is the shorter, measures, from the median tubercle of the vagina to the anterior lip of the uterus, less than two and a half inches; and the posterior wall, from the centre of the vulvar orifice to the end of the fornix, three inches. The transverse diameter, in the natural state of the canal, which is flattened from before backwards, so that the anterior and posterior walls are in contact, measures ordinarily one inch and a quarter. But when the canal is distended, and after the birth of many children, these dimensions may be much exceeded.

External surface.— The following are the relations of the external surface of the vagina. *Anteriorly*, it is connected to the urethra and base of the bladder by areolar tissue. *Laterally*, it is in relation with the root of the broad ligament and the pelvic fascia. *Posteriorly*, in the first part of its course, it is covered by the peritoneum, forming the anterior wall of the retro-uterine pouch, or space of Douglas; secondly, where the peritoneum ceases, and for about half its course, it is united to the rectum; and lastly, it is separated from the latter by the thickness of the perineum.

Composition. — The walls of the vagina are of variable thickness in different parts, the average being 1‴. They are composed of three coats. The outermost of these is formed of fibrous tissue, intermixed with an abundance of elastic fibre. Beneath this is a second or muscular coat, containing unstriped muscular fibre and fibre-cells, which, during pregnancy, undergo a development similar to that of the uterine fibre. The third, or innermost, is the mucous coat, composed of a dense connective tissue, with much admixture of elastic fibre, to which is due a great part of that elasticity and distensibility with which the vagina is endowed. Imbedded in the substance of the mucous membrane, which is covered by squamous epithelium, are numerous muciparous follicles.

Internal surface.—Upon the inner surface of the canal the mucous membrane is thrown into folds, which, in the virgin, form numerous closely-set transverse rugæ, that are arranged with a certain approach to regularity, and sometimes exhibit a central connecting line or raphé, forming the *columnæ rugarum*, upon the anterior and posterior walls. At the sides of the vagina these folds are less prominent, and take an oblique or longitudinal direction. In some subjects the rugæ are covered by, or are chiefly composed of, short, crowded verrucose papillæ, intermixed with others more filiform. They become larger towards the vaginal orifice, where they sometimes take the form of little leaflets, resembling the smaller fimbriæ of the Fallopian tube, especially about the meatus urinarius. After numerous acts of parturition, as well as from frequent intercourse, the folds become obliterated, and the inner surface of the vagina is rendered nearly or entirely smooth.

Arteries.—A special artery usually exists for the vagina, which may arise either from the hypogastric, internal pudic, middle hæmorrhoidal, or even from the obturator. From one of these origins the artery descends along each side of the vagina, giving off in its course numerous branches, which inosculate in the recto-vaginal septum with those of the opposite side. Near its extremity, the artery sends off a considerable branch to the bulb of the vagina, and after supplying the external organs, it terminates by inosculating with the artery of the opposite side, between the vagina and rectum. One or two separate branches are generally found to arise from the uterine artery. These descend between the bladder and the vagina, supplying branches to both those parts. An abundant and intricate network is formed in the vaginal walls by the ramifications of the smaller vessels derived from these sources, which interpenetrate the several coats down to the mucous membrane.

Veins.— The veins which collect the blood from the labia, constrictor muscles, and mucous membrane of the vagina, and from the erectile tissue forming the vaginal bulb, unite to form a considerable plexus, especially around the vulvar orifice termed the vaginal plexus. From this plexus branches pass to the vesical, and hæmorrhoidal, and uterine plexuses; the blood being finally collected by large veins which empty themselves into the internal iliacs. *Figs.* 482. and 483.

The *Lympatics* are those which are common to the bladder, cervix uteri, and lower part of the rectum. They terminate in the pelvic glands.

The *Nerves* are derived from the pelvic plexus, which contains a large proportion of tubular fibres, derived from the fourth and fifth sacral nerves.

Uses of the vagina. — The vagina, during copulation, serves for the reception of the male intromittent organ, and for the lodgement of the seminal fluid in such a position as to facilitate the introduction of that fluid into the uterus.* During menstruation the vagina gives passage to the catamenia. In labour it transmits the fœtus and secundines, and subsequently the lochia.

Abnormal Anatomy of the Vagina.

Anomalies. — Congenital absence of the vagina is not very rare. The entire vagina may be wanting; so that on separating the labia no trace appears of a canal leading to the uterus; or the canal may be so narrow as only to admit a probe or quill; it may be very short, terminating in a *cul de sac*, or it may open into the urethra or rectum. The latter malformation has not always prevented pregnancy, even when combined with an entire absence of the external organs.

A vertical septum occasionally divides the vagina through a greater or less portion of its course. This, when complete, produces the double vagina with double hymen (*fig.* 461.). The septum may cease at a variable distance from the vaginal orifice, the fornix and upper part remaining single; or, contrarily, the fornix may show signs of division, while the lower part of the tube remains single. The septum is almost invariably in the median line, but the more frequent use of one or other channel in parturition or sexual conjunction may give to them an appearance of unequal development.

Transverse membranous septa sometimes pass across and obstruct the vagina more or less completely. These, though they do not necessarily prevent impregnation, for they are seldom absolutely imperforate, may so far impede labour as to require division. They occur at various points within the canal; at a short distance from the orifice, or as high up as the level of the utero-sacral ligaments. They consist, for the most part, of natural folds unusually developed, or they result from accident, as inflammation or injury consequent on difficult labours. Some of those constrictions which occur near the orifice are doubtless the consequence of inflammation of the vulva and vagina in infancy.† Atresia of the vagina may thus be acquired, or it may be congenital. When the obstruction is complete, retention of the menstrual fluid results.

Displacements. — The vagina may be altogether displaced from the pelvis, or it may simply have its normal direction altered within that cavity. Prolapsus of the vagina occurs sometimes alone, but it is more often combined with procidentia or inversion of the uterus (*fig.* 469.). In any of these cases, if the prolapse is permanent, the vaginal surface loses altogether the character and appearance of a mucous membrane, acquiring a thick cuticular covering, and assuming the condition of ordinary integument. In retroversion of the uterus, the vagina is drawn upwards and forwards, its extremity lying behind the pubic symphysis. (*Fig.* 468.) In hernia of the uterus, the vagina is diverted from the median line towards one or other side of the pelvis, and may be partly included in the hernial sac.

Solutions of continuity. — Laceration of the vaginal walls may occur during obstructed labour, and is then frequently associated with rupture of the uterine cervix. Fistulous openings into the bladder, and sometimes into the rectum, are occasioned by sloughs consequent on protracted labour. Fistulous cloacæ are also commonly formed in advanced stages of cancer (*fig.* 479.).

Inflammation of the vagina. — *Vaginitis.* — This occurs both in the acute and chronic form. It may present the character of benignant catarrh, or of a specific blenorrhœa (*gonorrhœa*). In the more acute form the mucous membrane is highly vascular, and is sometimes excoriated, from excessive shedding of epithelium. The discharge presents variable characters, from the viscid yellow puriform mucus, to the creamy, milk-like, or thin, nearly watery, fluid (*leucorrhœa*).

Croupous exudations occasionally form upon the vaginal mucous membrane, chiefly in connexion with typhoid exanthematous or puerperal processes.

Epithelial desquamation. — Occasionally the entire epithelial coat of the vagina is thrown off, forming a membranous cast of that canal. Several of these casts may be found, one contained within another. Their discharge may be accompanied by symptoms resembling those of dysmenorrhœa; but more particularly by an intolerable itching or sensation of crawling in the vagina. They are composed entirely of dense vaginal tesselated epithelium.*

Serous and sanguineous infiltration into the mucous and fibrous coats of the vagina takes place occasionally during protracted labour, producing considerable tumefaction, and consequent narrowing of the canal. In this state

* See Insemination, p. 671.

† These cases are sometimes recorded as examples of imperforate hymen.

* I have given a description, with several illustrative figures, of these epithelial casts of the vagina, some of which include also the epithelium of the vaginal portion of the cervix uteri, in Beale's Archives of Medicine, for April, 1858. I suspect that the nature of these has been overlooked, and that they have been confounded with the true dysmenorrhœal membranes which consist of the lining membrane of the uterus. See *fig.* 443.

the vaginal walls are easily lacerable, or if subjected to continued pressure pass readily into gangrene.

Abscess forms occasionally in the vaginal walls, but many of the abscesses which burst into that canal have their origin in pelvic cellulitis, or in inflammation of other structures external to the vagina.

Ulceration. — The minute aphthous ulcers which are dotted over the surface of the vagina originate in follicular inflammation. The more extensive and irregular ulcers, except those which form upon the more exposed parts when the vagina is inverted, as in procidentia uteri, are usually either syphilitic or cancerous.

Gangrene of the vagina occurs in conjunction with gangrene of the vulva in septic puerperal processes; or it results from pressure in protracted labour. Spontaneous gangrene occurs also occasionally in infants and young children.

Cysts and tumours. — The former, if of small size, may result from obstructed mucous follicles; but more often the larger cysts arise in situations external to the vagina, and protrude into its canal. In the same way, fibrous or osseous tumours growing from the periosteum or ligaments of the pelvis, ovarian, or even uterine tumours may, by pushing before them the walls of the vagina, protrude into the canal. Vaginal cystocele and rectocele occur in a similar manner. The tumours which lie free within the vagina are chiefly uterine polypi, or cancerous tumours of the cervix or of the vagina itself. The uterus, when partly inverted, also forms a tumour occupying the vagina.

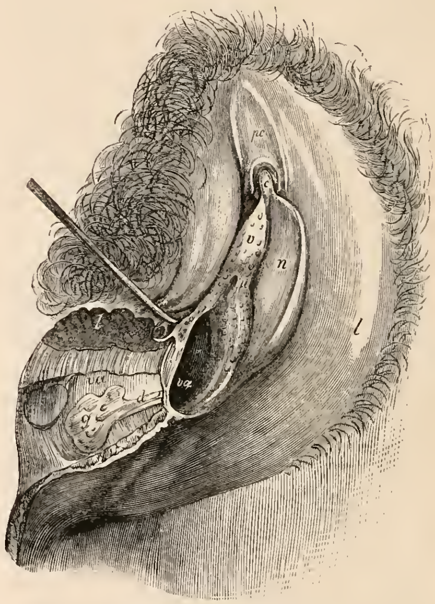
Cancer may originate in the vagina, although it more often constitutes an extension of the same disease from the uterus. In either case it appears most commonly as medullary cancer, taking the form of tuberculated masses or ridges, which narrow or obstruct the passage, and quickly pass through the stages that characterise the ordinary progress of uterine cancer. The surrounding parts become infiltrated with cancer matter, and the vagina is fixed in the pelvis, ulceration of the walls and fistulæ resulting. Occasionally, at the commencement, this disease appears in the form of soft, rapidly-growing papillary structures, springing from the upper and posterior wall of the vagina (*villous cancer*).

EXTERNAL ORGANS OF GENERATION.

Syn. *Vulva. Pudendum.*— These parts perform subordinate offices in the act of reproduction. They are in no way concerned in gestation, and only slightly in menstruation and parturition. They are associated with the vagina in the act of copulation, which has for its object insemination, or the conveyance of the seminal fluid to the internal or formative organs. The parts which serve to establish this relation between the sexes, with the exception of the vagina, are placed external to the body, and are attached to the front of the pelvis. They are included under the general term *vulva* or *pudendum*, which extends from the mons veneris to the perineum. The vulva consists of the following parts, viz. labia, clitoris, nymphæ, vestibule, vaginal orifice, and hymen.

The Mons Veneris forms a slightly rounded or flattened eminence, of triangular outline, covering the symphysis and horizontal rami of the pubes. In fat subjects it is separated from the abdomen by a transverse furrow. It is composed of adipose and fibrous tissue, covered by integument. The latter contains many sebaceous and hair follicles. The hair is not developed until the age of puberty.

Fig. 480.



External organs of generation, and commencement of vagina. (*After Huguier.*)

l, labium of left side (that of the right side is divided and partly removed to expose the vagina and vulvo-vaginal gland); *n*, nympha; *c*, glans clitoridis; *p c*, preputium clitoridis; *v*, vestibule; *u*, orifice of urethra; *v a*, vagina; *g*, vulvo-vaginal gland, or gland of Bartholin and Duvernay; *d*, duct of the same.

The Labia, termed also *labia majora*, to distinguish them from the lesser labia or nymphæ, are two symmetrical tegumental folds (*fig.* 480. *ll*), placed one on either side of the *rima* or fissure which leads to the vagina. The labia vary considerably in size and form in different subjects. In stout adults they are full and fleshy, closing the vulvar orifice, and concealing the rest of the generative organs, which they serve to protect. In the aged the labia become shrivelled and the nymphæ protrude between them, as they also commonly do in infants and young subjects. The outer surface of each labium is composed of common integument, which at the age of puberty becomes covered with hair. Along the line of apposition of the two labia, where the rima is formed, the hair and integument cease, and the mucous membrane common to the rest of the generative canal commences. From this point inwards the surface of the labium is smooth, of a reddish or pink colour, and is here furnished with numerous muciparous and sebaceous follicles, which bedew the parts with an odorous secretion, and preserve their constant moisture. The labia are united above by a slight frenulum, termed the *anterior commissure*, while below they are connected, at the anterior margin of the perineum, by a broader *posterior commissure*. When the parts are here drawn asunder, a second fold appears within the former, just below the entrance of the vagina. The transverse boat-shaped furrow between these constitutes the *fossa navicularis*. Beneath the cutaneous and mucous covering of the labia is found a layer of *dartoid* tissue, the rest of their substance being formed of loose *fibrous and adipose* tissue.

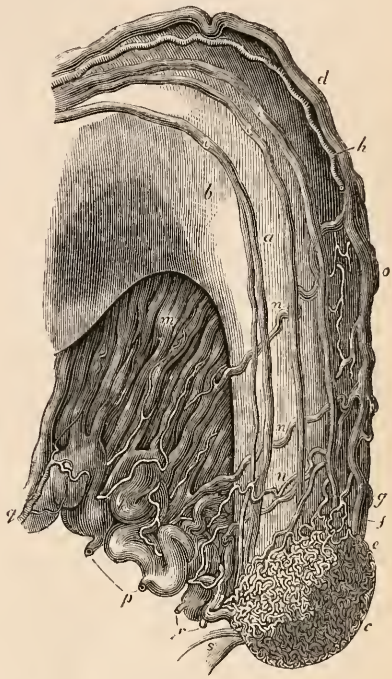
The labia represent the scrotum, which in the early fœtus is divided into two halves. A raphé indicates in the male the line of their subsequent confluence. In the female the two halves remain permanently separate. The normal descent of the testis into the scrotum in the male, about the seventh month of intra-uterine life, is represented by the abnormal descent of the ovary into the labia of the female which constitutes ovarian inguinal hernia. (See p. 574.)

When the labia are drawn asunder, the clitoris, the vestibule, nymphæ, and vaginal orifice are brought into view.

The Clitoris (*figs.* 481. and 482.), in general form and composition, resembles, on a diminutive scale, the penis, but it is deficient in some of the parts which compose the latter organ. The clitoris lies in the upper part of the vulvar fissure, concealed between the labia, and encased in a fold of mucous membrane, the lower border of which forms a hood or prepuce (*preputium clitoridis*) (*fig.* 480. *p c*), that terminates just above the superior commissure of the nymphæ, and allows the extremity only of the organ to appear. When this covering is removed, the clitoris is seen to consist of the following parts: viz. a small imperforate *glans* (*fig.* 481. *c*), composed of spongy erectile tissue, and covered by a highly sensitive mucous membrane, which is abundantly supplied with nerves; this terminates the free extremity of the organ: a *body* (*fig.* 481. *b*), consisting of two *corpora cavernosa*, united along the median line, and invested by a fibrous tunic. The body extends upwards and backwards to a point a little above the centre of the pubic arch. Here it makes a sudden downward curve, and, after dividing into two *crura*, is attached by these beneath the iscio-pubic rami of either side. Opposite the point of curvature, a flattened *suspensory ligament* attaches the body of the clitoris to the pubic symphysis. Two ischio-cavernous muscles (*erectores clitorides*), composed of striped muscular fibre, are inserted into the crura. They have the same relations, and, according to Kobelt, are fully as long as in the male (*fig.* 483. *n*).

Blood-vessels.— Two *dorsal arteries* (*fig.* 481. *h*), running along the upper surface of the clitoris, supply the glans, from which the blood is again collected by superficial veins, emerging from the root of the glans at *e*, and by others having a deeper origin at *f*. These transmit the blood to the *vena dorsalis*, *d*. From the cavernous bodies the blood is also collected by a series of vascular canals, of which an account will be presently given.

Fig. 481.



The clitoris (enlarged 4 diameters.) (After Kobelt.)

a, body; *b*, angle or curvature; *c*, glans; *d*, vena dorsalis; *e*, superficial veins emerging from the root of the glans, and *f g*, veins of deeper origin. These transmit the blood to the vena dorsalis; *h*, dorsal artery; *i i i*, dorsal nerves; *k*, the venous plexus, termed pars intermedia (shown also at *d*, *fig.* 482., and *e*, *fig.* 483.); *l*, communicating venous branch between the glans clitoridis and pars intermedia; *m*, ascending venous canals proceeding from the pars intermedia (*k*) to the under surface of the body of the clitoris; *n n* and *o*, lateral branches of communication between the vessels last named and the vena dorsalis; *p*, veins from the labia, and *r*, from the nymphæ and frenulum clitoridis, which enter the pars intermedia; *q*, arterial branches corresponding with the pars intermedia and communicating veins; *s*, frenulum clitoridis.

Nerves.— The clitoris is richly endowed with *nerves*, *i i*, which are *relatively* three or four times larger than those of the penis. They pass along the sides of the clitoris, each dividing usually into three branches, the ultimate ramifications of which lose themselves partly in intricate plexuses within the glans, and partly in terminal loops upon its mucous covering.

Development. — In the fœtus of three to four months, the clitoris is scarcely distinguishable from the penis. But about the latter period the proportionate retrocession of the one organ, and the increased development of the other begin to be apparent. In the male, the groove along the under surface of the penis is closed in, and at the same time the raphe of the scrotum is formed; while in the female, the parts corresponding with the bulb and corpus spongiosum urethræ remain open, and constitute a portion of the rima. These lie in two halves on either side of the entrance of the vagina, while the urethra is developed independently of them.

Nymphæ.—*Labia minora v. interna.*—These consist of two thin and slightly fleshy folds of mucous membrane (*fig.* 480. *n*), somewhat resembling a cock's comb, which lie on either side of the entrance to the vagina, extending from the clitoris downwards, as far as the middle or lower border of that orifice. The nymphæ commence above by two roots. The inner one, thin and membranous, is inserted beneath the glans clitoridis, and forms with its fellow a kind of *frenum.* The outer one, more fleshy, passes round the glans, and by its junction with the corresponding portion of the opposite side constitutes the *preputium clitoridis* (*fig.* 480. *p c*) already described. From these two roots or origins each nympha extends downwards and outwards, forming a thin prominence, of variable extent in different subjects, until it becomes merged in the labium of the corresponding side, near its posterior extremity.

The nymphæ are composed almost entirely of mucous membrane, which on their outer side is continuous with that of the labia, and upon their inner surface with the lining membrane of the vagina.

Various uses have been assigned to the nymphæ. One of these is that they serve to direct the stream of urine issuing from the urethral orifice, as suggested in the classic allusion to the sea nymphs pouring water from a vase which is implied in their name. Another supposition is that the nymphæ aid the enlargement of the vaginal orifice, by becoming unfolded at the time of labour, although no such unfolding can be absolutely observed. It is more probable that their office is that of extending the secreting and sensitive surfaces at the entrance of the vagina.

The nymphæ correspond with that part in the male which forms the tegumental covering of the urethra, but which remains ununited in the female along the median line.

The Vestibule. — This term has been employed in two senses. In its widest sense it includes all the parts which immediately surround the vaginal orifice. In a more restricted meaning, it is limited to that triangular patch of mucous membrane (*fig.* 480. *v*) which fills up the summit of the pubic arch. In the latter sense the apex of this triangle is formed by the clitoris, the sides by the upper halves of the nymphæ, and the base by the roof of the vaginal orifice. In the centre of the base is situated the *meatus urinarius*, which forms here a slight prominence (*fig.* 480. *u*), at a distance of one inch behind the clitoris. Immediately below this point the anterior column of the vagina terminates in a prominent bulb or tubercle, marked usually by numerous transverse folds.

Orifice of the Vagina, and Hymen.—Immediately below the vestibule, and between the nymphæ, is the orifice of the vagina (*fig.* 480. *v a*), which, in its undistended state, has the form of a vertical fissure, especially in women who have borne children, but in virgins it is more constricted and circular, and is further narrowed by a fold of the vaginal mucous membrane, the *hymen*, which either encircles or semi-encircles the orifice. As some important questions in obstetric and forensic medicine relate to this membrane it will receive here a more particular examination.

The hymen, regarded in an anatomical point of view, possesses no peculiarity or speciality by which it is essentially distinguished from many like structures in other parts. It belongs to the same class of formations as the valvulæ conniventes of the intestines, and the frill-like folds of mucous membrane which not infrequently surround the terminal orifices of mucous tubes. In the fœtus such folds are seen with various degrees of distinctness at the termination of the urethra, vagina, and often of the rectum. The lower end of the vagina, in the fœtus *invariably* terminates in a marked projection outwards of the mucous lining of the tube. It takes the form of a laterally compressed conical fold, the base of which is continuous all round with the vaginal walls, but the apex is directed forwards. Its centre exhibits a vertical slit-like orifice, the direction of which is apparently due to the lateral compression of the nymphæ and labia, between which it lies. This is the hymen. In advanced fœtuses it is scarcely distinguishable in form, and only to a certain extent in size, from the similar conical termination of the cervix uteri, which projects into the vagina, as the hymen does between the nymphæ. The vaginal portion of the cervix uteri and the hymen both constitute invaginations or intussusceptions at two different points of the same mucous tube, —the one marking the division between the uterus and the vagina, the other between the latter and the external parts. The chief difference between them is that the direction of the orifice in the former is transverse, and in the latter vertical.

Such is the condition of the hymen during fœtal and infantile life. But as growth advances the posterior half becomes much more developed than the anterior, just as the posterior half of the uterus, the posterior lip of the cervix, and the posterior wall of the vagina, are commonly larger and more developed than the corresponding anterior halves. Thus it happens that in adults the hymen presents usually the form of a crescentic or semilunar fold, the concave border of which is directed upwards or forwards, while that which had been in the fœtus, the upper half, has now become unfolded or lost among the plaits of mucous membrane, situated at the upper part of the vaginal entrance. This, because it is the most constant, has been usually regarded as the typical form of the hymen. But the fœtal form is also often retained, namely, the circular fold of mucous membrane, which, as the parts become more expanded, acquires a round rather than a slit-like aperture. If, however, the folds of the mucous membrane lining the vagina are profusely developed, then the hymen also exhibits the form not so much of a distinct membrane as of an irregularly constricted orifice, the sides of which are puckered or gathered into plaits, so as nearly to close the vaginal entrance. And this also is a very common condition of the part, especially in young subjects.

The varieties, therefore, in the hymen which anatomists recognise, such as the crescentic, circular, cribriform, and the like, become easily explicable. They all proceed apparently from a common starting point, but differences in the degree of development, or accident, may determine the permanent form. The *half-circle* and *crescent* result from a normal development of the posterior, and a corresponding retrocession of the anterior, moiety of that conically projecting mucous fold which is more or less distinct in every fœtus. The hymen with a *central* or nearly central circular orifice, results from a flattening down and retiring within the vaginal orifice of the cone; the retiring naturally following upon an expansion of the vaginal walls as growth advances. The appearance of a *notched margin* to the central aperture is produced by the prominent edges of the terminal vaginal folds, which are in some subjects more profusely developed than in others. The *cribriform* hymen probably results from an abnormal cohesion of these notched edges, in such a manner, that small apertures are left between them, and the completely *imperforate* hymen by an entire adhesion of the margins of the orifice, the result sometimes of inflammation in infancy.

The hymen, however various its forms may be, consists of a double layer of mucous membrane, containing between its laminæ a small quantity of fibrous tissue and blood-vessels. It is of variable degrees of thickness, being in some subjects very strong and tough, and in others forming a very slender lamina. Its situation is at the entrance of the vagina. Although the depth at which it is placed within the vulva varies in different subjects, according to the thickness of the labia, and the size of the nymphæ and vestibule. Occasionally, as already stated, one or more plicæ of the vaginal mucous membrane, more than usually developed, form constrictions at a higher point within the canal, but the term hymen cannot with propriety be applied to any of these.

The presence of the hymen, although it raises a strong probability of virginity, yet affords no certain evidence upon that point, nor does its absence establish the contrary.

The hymen is commonly said to be ruptured on the occasion of a first complete intercourse, but the expression unfolded would probably, in many instances, more accurately represent the mode of its disappearance. Whenever the hymen presents any considerable membranous surface, doubtless a real laceration occurs, but in the cases in which it takes the form of a crescentic fold, or of a puckered rosette, instead of being lacerated, it probably becomes unfolded or flattened out, and so disappears, just as the ordinary vaginal folds are obliterated, by frequent intercourse or by parturition, without any rupture.

Upon the presumption that the hymen is always *lacerated* a certain hypothesis has been raised, namely, that the little fleshy bodies occasionally observed near the orifice of the vagina, termed *carunculæ myrtiformes*, constitute the remains of that membrane. But, notwithstanding a great amount of evidence that has been collected regarding the myrtiform bodies, it cannot be shown that these are anything more than accidental and uncertain formations, having nothing necessarily to do with the hymen.

The hymen may be broken by accident, or may become obliterated by the frequent employment of vaginal injections, and in other like modes. Or, from constant leucorrhœa, the parts may become so relaxed that a distinct membranous fold can be no longer discerned at the vaginal orifice, although there may have been no loss of virginity.

On the other hand, impregnation may take place without destruction of the hymen, which has frequently been found entire at the time of labour, and even in women affected by syphilis.*

Sebaceous and Muciparous Glands and Follicles of the Vulva. — The *sebaceous* follicles correspond with the male preputial follicles. They are scattered over the nymphæ, clitoris, and inner surface of the labia. Their secretion contains butyric acid and has a strong and somewhat ammoniacal odour. This occasionally becomes highly irritating, especially when cleanliness is neglected.

The *muciparous* follicles are arranged in groups, the principal ones being situated upon the vestibule (*vestibular follicles, fig.* 480. *v*), around and upon the sides of the meatus urinareus (*urethral follicles, fig.* 480. *u*), and at the sides of the entrance of the vagina (*lateral follicles of the vaginal orifice, fig.* 480. *va*).

The muciparous follicles are composed of a delicate vascular mucous membrane arranged in the form of short mucous crypts, or consist of simple or branched tubules ending

* In a case of extensive syphilitic periostitis which came under my notice, in a woman thirty years of age, who had previously been a prostitute, a tough membranous circular hymen closed the orifice of the vagina so completely that the tip of the fore finger could scarcely be inserted within it.

in a *cul-de-sac*. The vestibular follicles are of the former kind and the urethral of the latter.

All these vulvar follicles secrete a viscid mucus, the quantity of which becomes considerably increased under excitement or irritation. It serves to lubricate the several parts of the vulva.

The *vulvo-vaginal glands*, termed also the glands of Bartholin and of Duvernay, consist of two conglomerate glands of the size of a haricot bean, variable in form, and of a pale reddish yellow colour, which are placed one upon each side of the vagina near the entrance (*fig*. 480. *g*). They are lodged beneath the superficial perineal fascia, having their inner side united to the vagina by areolar tissue, and their outer surface in relation with the constrictor muscle of the vagina. The lobules composing this gland send off tubules which at its upper and fore part unite to form an excretory duct that proceeds horizontally forwards as far as the vaginal orifice, upon the side of which it terminates just within the nymphæ and externally to the hymen. The orifice of the duct (*d*) is covered by a falciform fold of mucous membrane, which renders its discovery sometimes difficult.

This gland secretes a viscid fluid resembling somewhat the prostatic fluid and having a peculiar odour. Under excitement its secretion is rapidly formed and, like the contents of the salivary duct, is sometimes emitted in a jet. This gland is probably homologous with Cowper's gland in the male. In infancy and early life it is very small, attaining its full development in the adult, and again diminishing and even disappearing in old age.

When the labia and nymphæ are abscised a series of vascular erectile structures are brought into view, which, together with a special muscle, surround the vaginal orifice. These are the *vestibular bulb*, *pars intermedia*, and *constrictor vaginæ muscle*.

Pars intermedia.—From the dorsal vein of the clitoris (*fig*. 481. *d*) several branches (*n*,*n*) pass downwards round the sides of the organ to communicate with a double row of closely-set venous canals, which commencing anteriorly at the glans extend backwards to the root of the clitoris in the form of a frill that completely occupies the angle contained in the curvature of the organ (*fig*. 481. *m* and *fig*. 482. *f*). These venous canals enter the body of the clitoris by a double row of apertures along its under surface. They represent the communicating veins between the corpus spongiosum urethræ and the corpora cavernosa penis. After receiving branches from the glans clitoridis (*fig*. 481. *l*), nymphæ (*r*), and labia (*p*), they form on either side a series of convoluted veins (*k*), which spreading downwards and outwards ultimately terminate below in the bulb of the vestibule (*fig*. 482. and 483. *a*). This is the structure termed by Kobelt the *pars intermedia*. It corresponds with the corpus spongiosum urethræ of the male, which in the female remains divided into two halves. The arteries of this structure (*fig*. 481. *q*) are derived from the pudendal.

Fig. 482.

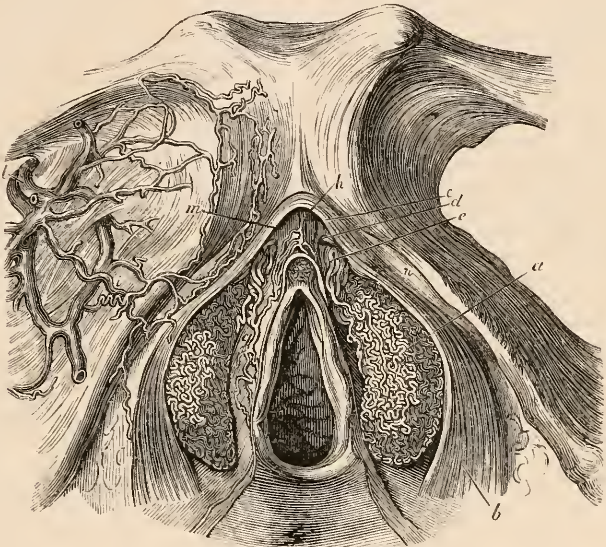
Lateral view of the forepart of the pelvis, attached to which are the clitoris and the vascular and erectile structures connected with it. (*After Kobelt.*)

a, vestibular bulb of the left side; *b*, veins passing off from the lower and posterior border of the bulb, to the pudendal vein; *c*, similar veins communicating with the hæmorrhoidal; *c'*, the spot at which the veins of the vestibular bulb pass off to the vagina; *d*, pars intermedia; *e*, glans clitoridis; *f*, ascending communicating veins proceeding to the body of the clitoris; *g* and *i*, lateral communicating branches between the vena dorsalis clitoridis and pars intermedia; *h*, vena dorsalis; *k*, bend of the clitoris; *l*, crus clitoridis; *n*, vulvo-vaginal gland.

Bulbus vestibuli (Kobelt). *Plexus retiformis v. reticularis* (De Graaf). *Crura clitoridis interna* (Swammerdam). *Plexus cavernosus* (Tabarranus). *Corpus cavernosum* (Santorini). *Semibulb* (Taylor). *Bulb of the vagina*.—Lying one on either side of the entrance to the vagina, and behind the nymphæ and labia, are two masses of vascular parenchyma, composed almost entirely of tortuous veins enclosed in a fibrous membrane. These in their collapsed state are of the size and form of an almond; but when injected may be compared to a filled leech (*fig*. 482. and 483. *a*). Anteriorly they are directly continuous with the structures last described, while from their sides communicating branches pass back to the obturator veins (*fig*. 483. *l*), and from their lower ends to the pudendal and hæmorrhoidal veins (*fig*. 482. *b* and *c*). The bulb of the vagina, now commonly regarded as the homotype of the bulb of the urethra which is here bipartite, forms the principal portion of the erectile tissue surrounding the vaginal orifice.

Constrictor vaginæ.—The clitoris together with its bipartite pars intermedia and vestibular bulb is encased in a thin sheet of muscular structure (*fig*. 483. *b* and *c*), which has been usually regarded as the constrictor of the vaginal orifice, but which Kobelt considers to be more particularly employed as a compressor of the parts just named. This muscle takes its origin in a broad flattened base (*b*) from the perineal fascia midway between the anus and tuber ischii. The inner fibres interlace with those of the sphincter ani, while the outer ones reach to the corresponding ascending ischial ramus. Thence the muscle becomes gradually smaller as it ascends, and after embracing the entire length and breadth of the vestibular bulb, it converges forwards to meet its fellow at the clitoris, where it terminates in two little flattened portions of which the posterior passes as a narrow tendon (*fig*. 483. *d*) to unite with its fellow between the upper end of the bulb and the root of the clitoris, while the anterior looser portion (*c*) mounts over the dorsum of the clitoris, forming the *musculus attrahens clitoridis*. This serves to depress the organ and compress the dorsal vein, at the same time that the lower portion of the same muscle, by compressing the rest of the vascular apparatus, forces the blood out of the vestibular bulb and pars intermedia upwards into the body of the clitoris, and thus aids in producing congestion and erection of all these parts during coition.

Fig. 483.



Anterior view of the parts represented in Fig. 482. (*After Kobelt.*)

a, vestibular bulb; *b*, constrictor vaginæ muscle, according to Kobelt the compressor of the bulb. It is here represented as drawn back behind the bulb, which in the natural position is covered by it. *c*, anterior division of the muscle which passes over the body of the clitoris, serving to depress the organ, and to compress the dorsal vein; *d*, posterior tendinous division of the same muscle; *e*, pars intermedia; *f*, glans clitoridis; *g*, veins proceeding from the nymphæ; *h*, dorsal vein of the clitoris; *i*, branches communicating with the obturator veins; *k*, branches ascending to the epigastric veins; *l*, obturator veins; *m*, corpus clitoridis; *n*, crus clitoridis of the left side.

Blood-vessels of the external organs. — The *arteries* are supplied by the terminal branches of the internal pudics and from branches of the femoral.

The pudic sends off two branches: the first, or lower (*superficial perineal branch*), terminates in the labium after supplying the sphincter vaginæ and some of the perineal muscles. The second, or superior, mounting along the ischio-pubic rami to the division of the crura clitoridis, sends off a branch (*artery of the bulb*) to the bulbus vestibuli, and then separates into two terminal twigs, the one (*profunda branch*) entering the cavernous substance of the clitoris, while the other forms the *dorsal artery* of that body (*fig*. 481. *h*).

The femoral supplies the *external pudics*, two in number on each side, which arise by a common trunk or singly from the inner side of that vessel. The superior of these branches (*superior pudenda externa*) arises near the crural arch and, passing inwards, sends off two branches, one to the mons veneris and lower part of the abdominal integuments, the other, terminating in the labium, sends also twigs to the nympha and preputium clitoridis. The inferior branch (*inferior pudenda externa*), arising a little below the former, or from the profunda, passes obliquely towards the labium in which it terminates, anastomosing also with the superficial perineal branch of the pudic.

Veins.—The veins of the clitoris and the venous plexuses surrounding the vaginal orifice, together with their communicating branches, have been already described. The *external pudic veins*, collecting the blood from the mons veneris and the interior of the labia, take a course similar to that of the corresponding arteries, and empty themselves into the saphena.

The lymphatics of the external organs terminate in the inguinal glands.

The nerves.—The external parts are abundantly supplied with nerves derived chiefly from the pudic. The pudic nerve arising from the lower part of the sacral plexus passes through the sacro-sciatic foramen and accompanying the pudic vessels divides into two branches.

The *inferior, or perineal branch*, sends twigs to the labia, nymphæ, and roots of the clitoris, and then gives off the *superficial perineal branch*, which is distributed to the constrictor muscle of the bulb of the vagina.

The *superior, or branch of the clitoris*, corresponds with the dorsal nerve of the penis. Beneath the pubic arch it passes between the roots of the clitoris and is distributed along the side of that organ in the manner already described (*fig.* 481. *i i*). Some of its ramifications are distributed upon the prepuce and in the nymphæ and upper parts of the labia.

The labium also receives nerves from the branches of the *inferior pudendal* nerve, a division of the small sciatic nerve. These communicate with the superficial perineal branches.

Abnormal Anatomy of the External Organs.

Labia.—The labia, together with the whole of the external generative organs, may be deficient, or they may retain through life an undeveloped or fœtal condition, consisting only of a very narrow fold of integument. In rarer cases, the labium of one side only has been developed. The labia may, on the other hand, present the form of a double or even a triple fold. In cases of deficiency of the lower part of the abdominal integument and anterior wall of the bladder, with separation of the pubic symphysis, the labia are imperfectly formed, and are set wider apart than usual, inclining somewhat outwards. The labial commissure is then also deficient. The posterior commissure of the labia may be much hypertrophied, projecting unusually forward, and covering more or less the entrance to the vagina. The labia are occasionally so completely coherent along the median line, that the vulvar fissure is obliterated, leaving only an aperture sufficient for the passage of urine. This condition is commonly the result of inflammation of the vulva in early infancy.

The diseases affecting the tissues of the labia may be superficially seated, or may involve more or less their entire substance. The principal superficial affections are erythematous inflammations, often accompanied by vesicular, chiefly herpetic or eczematous, and sometimes pustular eruptions; enlargement of the follicles, increased secretion, occasionally watery, and in excessive quantity, occurring in combination with a solid œdematous condition of the part (oozing tumour of the labium), excoriations, aphthous or specific (chancrous) ulcers; and condylomata, especially of the softer and syphilitic kind. The deeper seated affections are acute, and chronic inflammation of the fibrous and cellular tissue; induration and hypertrophy, sometimes of considerable extent (*elephantiasis*); serous infiltration, associated with pregnancy, or cardiac disease; suppuration producing large collections of pus within the labium; sloughing and gangrene. The veins of the labia frequently become varicose in multiparæ, and hæmorrhagic effusions take place into their substance. These effusions may be produced during straining efforts, or by external violence, but are especially apt to occur during labour, from pressure of the child's head upon the veins returning the blood from the venous plexuses that surround the vaginal orifice, whereby the latter become over-distended and ruptured, a considerable interstitial hæmorrhage often resulting. Cysts enclosing a glairy fluid, and adventitious growths of a more solid kind, such as are common to fibrous and cellular tissue, are not unfrequently found within the labia. Cancerous degeneration is more rare, but it may occur, either alone, or in combination with vaginal or uterine cancer. The labia may suffer laceration during labour, from forcible violation of the person, and in other ways. Fistulæ, communicating with the rectum, and permitting the passage of fœcal and gaseous fluids, occasionally form in the labia as sequelæ of suppurative processes. Lastly, these parts are occasionally the seat of hernia of the intestine, and, more rarely, of the ovary.

Clitoris.—Entire absence of the clitoris probably seldom or never occurs alone. But the clitoris and nymphæ may be deficient even when the labia are present. The clitoris is sometimes so small that its presence may escape detection. More often it is of unusual size, projecting beyond the labia. Such enlargements, though occasionally occurring without degeneration of the tissues, are more commonly the result of inflammatory hypertrophy, or are occasioned by profuse condylomatous (syphilitic) growths, in which the prepuce also may be included. The clitoris is also subject to cancerous degeneration, sometimes attaining an enormous size.

Nymphæ and vestibule.—The protrusion of the nymphæ between the labia, which occurs as a normal condition in infants, is not unfrequently observed in adults, when these parts, exceeding their ordinary dimensions, hang down below the posterior commissure: their lower extremities may in rare cases be prolonged as far back as the anus. The number of the nymphæ may be increased to two (Morgagni), or even three pair (Neubauer). Excessive hypertrophy of the nymphæ is common in certain climates. It may be associated with corresponding enlargement of the clitoris. The nymphæ are subject to the same inflammatory and specific disease as the labia, but they more commonly affect the surfaces than the substance of these parts, which, being of a denser texture than the labia, are not so easily infiltered with the venous, sanguineous, or puriform fluids, that readily collect within the latter.

The morbid conditions of the *vestibule* consist chiefly in inflammatory hypertrophy of the vestibular follicles, especially of those which immediately surround the urethral orifice and line the sides of the ostium vaginæ. They present the appearance of small red granulations. A more decided spongy vascular growth often springs from the border of the urethral orifice, where it forms either a bright red fringe, or a soft tumour, varying in size from a pea to a cherry (vascular tumour of the meatus). The vulvo-vaginal gland and its duct may be the special seat of blennorrhœa, sometimes of an infecting kind. This may be made to ooze from the orifice of the duct, by pressure behind the labium.

The most frequent varieties in the conditions of the *hymen and ostium vagina* have been already noticed.* The vaginal orifice may be nearly or completely obstructed by an adventitious membrane, or by the hymen preternaturally developed. Some of these states are congenital, but others are acquired. In either case, attention is often not called to them until after the establishment of puberty. According to their degree, they interfere with the functions of the vagina, partly or altogether preventing intromission, and rendering insemination imperfect or impossible. They impede the exit of the products of conception and the escape of the menstrual fluid. In the latter case, when menstruation is established, the fluid collects in and dilates the vagina and cervix uteri, and lastly the body of the uterus, and even the Fallopian tubes. Spontaneous rupture of the hymen, or membrane, may then occur, liberating the fluid.

PLACENTA.

The placenta is the organ provided in each pregnancy for the nutrition and respiration of the fœtus. To this it is connected on its free side by the umbilical cord, while its opposite or attached surface is united to the fundus, sides, or lower part of the body of the uterus by a layer of the decidua. A placenta exists only in the mammalia and in some of the cartilaginous fishes. It is composed of structures derived partly from the ovum and partly from the uterus. The fœtal or embryonal portion is not always furnished by the same portion of the ovum. It is sometimes constructed from the yolk sac, as in certain sharks, and the vessels which ramify in it are then the branches of the omphalo-mesenteric artery and vein. In other cases, as in the mammalia, the chorion supplies the fœtal portion, which is here rendered vascular by the umbilical vessels derived from the allantois. The maternal or uterine portion of the placenta is furnished by the decidua or lining membrane of the uterus. These two portions, viz., the fœtal and the maternal, originally distinct, and, even in their subsequent union, preserving a certain independence, become more or less closely connected together by interdigitating the one with the other. Their union may be one of mere contact, the fœtal portion forming numerous projecting vascular folds which in the form of laminæ or tufts, or single villi, are received into corresponding depressions or sulci, equally vascular, formed in the lining membrane of the uterus. Or it may consist in a more intimate conjunction of these parts, such as takes place in man, where the decidua or maternal portion forms a lamina which is spread over and united to the groups of villi that constitute the fœtal portion. In the former case at the time of parturition the two portions are separated, the fœtal processes being simply drawn out of the recesses which contained them without laceration of either of the tissues. But in the latter, the one part cannot be expelled without carrying a considerable portion of the other with it.

Form. — The mammalian placenta exhibits numerous varieties of form. In most Ruminants it is composed of numerous detached placentulæ constituting groups or bosses of vascular villi that project from the surface of the chorion, and are received into corresponding cotulæ upon the inner surface of the uterus. In the Carnivora the placenta encircles the fœtus in the form of a broad flat belt. In Pachydermata, Cetacea, and many other families, the villi are nearly evenly distributed over the whole surface of the chorion, so that the fœtus is everywhere surrounded by placenta. In some Rodentia and Quadrumana the placenta is double.

In man the placenta forms a single discoid organ, which in its natural position is slightly convex upon the outer, and concave upon the inner superficies. Its outline is generally *circular* or *oval;* it is sometimes *reniform*, *cordate*, or more or less *triangular*. It is rarely *bilobed* or *multilobed*.

Dimensions and weight. — The size of the placenta is exceedingly variable, bearing usually a certain proportion to the bulk of the child. A full-sized oval placenta measures 7—7½″ in its shorter, and 8—9½″ in its longer diameter, and measures 23—24″ in circumference. The thickness is generally greatest opposite to the point of entrance of the funis, where the organ measures commonly 1—1¼″, but it becomes gradually attenuated towards the margin, which is slightly rounded, measuring here only 2—4‴ in thickness. The weight of the placenta ranges from 15—30 oz. or more.

Fœtal surface.—Upon the fœtal surface of the placenta are observed portions of the amnion and chorion, together with the root of the funis and the principal branches of the umbilical arteries and vein.

Amnion.—The amnion (*fig.* 484. *am*), after furnishing the outer covering of the funis,

* See VAGINA and HYMEN.

passes off in all directions at the root of the cord, and spreads in a thin opaline lamina over the fœtal surface of the placenta, to which it slightly adheres. In some cases, especially when the umbilical vessels divide before entering the placenta, the amnion has no attachment at all to the latter. The amnion of the placenta does not differ in any respect from the rest of the amniotic sac, of which the placental portion constitutes about one third. Upon its fœtal surface is a single layer of flattened polygonal cells filled with delicate fat granulations.

Chorion. — The same proportion of chorion as of the amnion, namely, about one third of the entire superficies, is appropriated to the placenta. This, however, is not, like the amnion, simply an apposed membrane. It enters into the composition of the organ, and gives strength to it (*fig.* 484. *ch*). It sustains and transmits the branches of the umbilical vessels (*v f*), which adhere to, and ramify upon, its fœtal surface, between it and the amnion. This face of the chorion is united to the amnion by a thin and easily separable layer of soft pulpy tissue, constituting a portion of the *tunica media* of the ovum, while the reverse surface, which forms, as it were, the base or floor of the placenta, bears the numerous tufts or villi that make up the bulk of this organ.

Fœtal blood-vessels. — The blood-vessels of the placenta which belong to the fœtus are branches of the two umbilical arteries, and of the single umbilical vein. These, as just stated, ramify in large trunks over a considerable portion of the fœtal or under surface of the placenta, before they penetrate the chorion to gain the interior of the organ. When the fœtal vessels have been injected from the funis, their course upon this surface of the placenta is easily traced. Within the root of the cord, and at a distance of one inch from its insertion, the two umbilical arteries communicate together by a cross branch half an inch in length. Immediately on reaching the placental surface, each artery bifurcates, the branches passing off in opposite directions. A second bifurcation takes place, in the same manner, about half or three quarters of an inch from the first. And lastly, a third, at distances ranging from one to two and a half inches. Each of these dichotomous divisions is at first more or less abrupt and opposite, the vessels afterwards bending, and taking a slightly divergent or parallel course, or even somewhat approximating. After the third bifurcation, the vessels again divide and subdivide, but now at acute angles ; their extremities become lost, when they are reduced to the size of a crow quill, by dipping down suddenly, and passing through the chorion, to enter the substance of the placenta at distances varying from an inch to an inch and a half from its border. A small branch, however, in continuation, often runs on nearly to the edge. Lateral branches, of the same size as the terminal subdivisions, also leave the main vessels in all parts of their course, and dip down into the placental substance.

The branches of the veins, about sixteen in number, which return the blood from the interior of the placenta, emerge from its substance close to the points of entrance of the arteries, and take a less tortuous course than the latter. They, however, accompany these vessels, but more in the form of radiating lines, which proceed towards the root of the funis, passing under the arteries, and ultimately uniting in the single umbilical vein.

The varieties in the form of the placenta already noticed are apparently dependent upon certain modifications in the development and arrangement of these vessels, which are likewise very variable, although the same primary divisions are noticeable in all. In the *circular* placenta the root of the cord is inserted into, or near, the centre. In the *oval* form it is attached to the smaller extremity forming the *placenta en raquette*. In the *reniform* and *cordate* placenta, the insertion is likewise more or less lateral. Lastly, when the vessels of the cord divide before arriving at the surface, they form the *placenta en parasol.*

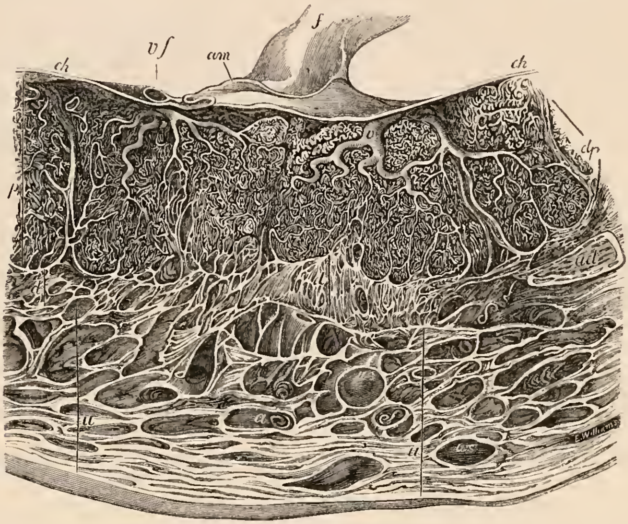
Uterine surface. — The reverse or uterine surface of a placenta which has been separated from its attachment, as in natural labour, is rough, and is divided into numerous rounded oval or angular portions, termed lobes or cotyledons. These vary from half an inch to an inch and a half in diameter. The whole of this surface consists of a thin, soft, and somewhat leathery investment of deciduous membrane, which dips down in various parts to form the sulci that separate the cotyledons from each other. This layer is a portion of the decidua which, as long as the parts are *in situ*, constitutes the boundary between the placenta and the muscular substance of the uterus, but which at the time of labour becomes split asunder, so that while a portion is carried off along with the placenta, and constitutes its external membrane, the rest remains attached to the inner surface of the uterus. This layer serves as a medium by which the uterine arteries (*fig.* 484. *a a*) and veins pass from the uterus into the placenta. Numerous valve-like apertures are observed upon all parts of the surface. They are the orifices of the veins which have been torn off from the uterus. A probe passed into any of these, after taking an oblique direction, enters at once into the placental substance. Small arteries, about half an inch in length, are also everywhere observed embedded in this layer. After making several sharp spiral turns, they likewise suddenly open into the placenta. These are the uterine vessels, which convey the maternal blood to and from the interior of the placenta.

Circumference. — The margin of the placenta is bordered all round by the united membranes which enter into its composition. Here the amnion and chorion, after lining the fœtal or concave surface, come into contact with the decidua which covers its uterine face, and the three membranes then pass off together to enclose the liquor amnii and fœtus. At this part the decidua is always most dense.

Partly within its substance is formed an incomplete sinus, the circular vein or sinus. This constitutes an interrupted channel, which more or less encircles the placenta. Several orifices are observed in its walls. Some communicate directly with the interior of the placenta, and others with the uterine sinuses.

Substance.—When a clean section has been made through the placenta (*fig.* 484.), the two surfaces already described are observed to enclose between them a soft spongy substance, which is made up principally of countless ramifications of the fœtal villi. These are attached at their base to the chorion, from

Fig. 484.



Vertical section of the walls of the uterus with the placenta attached. From a woman in the thirtieth week of gestation. (After Wagner.)

The length of the lines *u u*, serves to distinguish the uterus; *p*, the placenta, and *d d*, the decidua. To the right of the figure the decidua is separated into *ud*, uterine decidua, and *dp*, decidual prolongations which form the dissepiments dividing the placenta into lobes; *f*, funis; *am*, amnion; *ch*, chorion; *v f*, fœtal blood-vessels (divided) upon the surface of the placenta; *v v*, villi; *u s*, uterine sinuses; *a a*, curling arteries in the substance of the uterus.

which they spring, while their opposite extremities are united to the decidual layer forming the uterine boundary of the placenta. The interspaces left between the villi and their ramifications form what have been termed the cells of the placenta. They are widest between the roots of the villi, and much smaller between their extremities. In these spaces the maternal blood circulates. When injections are thrown into the placenta from the uterine arteries or veins, these spaces become filled, and the mass, when broken, exhibits a peculiar granular appearance. Dipping down among the villi, and reaching in some cases as far as the fœtal surface of the placenta, are numerous sheet-like prolongations of decidua (*fig.* 484. *dp*). These constitute the dissepiments which separate the entire mass into its several lobes or cotyledons. At the placental margin, the decidual layer generally dips under the villi, forming a return end or border, which is directed inwards, and is attached at a distance of 3—4‴ from the margin to the outer surface of the chorion. The exact relation of the decidua to the villi, in various parts of the placenta, will be better understood after a more minute description has been given of each of these structures.

The tufts and villi. — A placental tuft has been often compared to a tree. It consists of a trunk giving off numerous branches, which ultimately end in finer subdivisions or villi (*fig.* 484. *v v* and *fig.* 485. *a*). The trunks may be said to take root in the chorion, from which they spring, while the branches and finer subdivisions spread laterally and upwards, until they come into contact, at their sides, with the adjacent tufts and villi, and above with the decidua which bounds the placenta towards the uterus. Many of the villi, instead of branching like trees, proceed thread-like from the floor to the roof of the placenta, only sending off short knotty side branches. The tufts are so closely set, that their forms cannot be readily discerned until they are floated out in water. The stems are tough and fibrous, or coriaceous, while the branches and finer villi, though strong, are of a more brittle texture. When one of these is broken off, and examined by the microscope, it presents the following characteristics — the subdivisions are abrupt, contorted, and singularly devoid of symmetry; from all parts of their surface spring numerous short pullulations, which render them knotty and uneven.

Every villus is composed of two distinct parts, viz. an outer leathery sheath, and an inner softer and vascular structure, which is contained within the former like a finger encased in a glove. The distinction between these two structures is not easily observed, except in parts where the outer sheath has been accidentally broken off, leaving the more pulpy internal substance exposed. Or in cases where the placenta has become stale by keeping for a few days, when the inner portion by shrinking has retired from the end of the villus, so that a small interspace has been here left (*fig.* 485. *b*).

When a terminal tuft so prepared is viewed by transmitted light, under slight compression, the outer case is seen to consist of a transparent non-vascular structureless membrane, embedded in the substance, or attached to the inner surface of which are numerous flattened spheroidal cells, forming generally a single layer. In the apex of a growing tuft, or forming a distinct bud projecting from its extremity, may be often observed a group of similar cells which appear to be passing off from a spot in the centre of the mass.* These cells perform important parts in the growth and offices of the villi, which will be presently noticed.

The internal portion (*fig.* 485. *b*) consists of a soft and pulpy structure which envelopes the blood-vessels of the villi. In its substance also are embedded numerous cells of a similar nature to those observed in the structureless sheath.

Termination of the fœtal vessels. — The arrangement and terminal divisions of the blood-vessels within the villi varies considerably according to the age of the placenta. The following distribution is observed from the third to the sixth month (*fig.* 485. *a*). Each villus contains one or more arteries and veins, together with numerous capillaries. The arteries pass up the centre of the stem, and divide into branches according to the number of the terminal subdivisions. Within these the branches split up into numerous capillaries, which present various forms of arrangement, in some parts resembling Malpighian bodies, and in others the arrangement of pulmonic capillaries. From these capillaries the blood is collected by veins which pass back through the tufts accompanying the corresponding arteries. All these vessels, with their subdivisions, are enveloped and supported by the pulpy granular substance that forms the interior of every villus (*fig.* 585. *b*).

Towards the end of pregnancy, the true capillaries of the villi gradually disappear, so that in a placenta at term the blood-vessels present the condition accurately described by C. H. Weber and Goodsir. A single vessel generally enters each terminal tuft, and after forming an open loop, it returns again, either dividing within the villus, or leaving it as it entered. Or a single vessel may enter, and retire from two or more villi, before it terminates in a principal vein. Many modifications occur in the forms of the loops, which may be simple, compound, wavy, or much contorted, and in parts varicose.*

Fig. 485.

a, terminal villus of a fœtal tuft, from a placenta of six months. The arteries, veins, and capillaries are minutely injected. The latter, which disappear towards the end of gestation, are here very abundant. The arteries and veins occupy the centre, and the capillaries the surface, of the tuft, immediately beneath the non-vascular sheath. The nucleated non-vascular sheath is shown at *b*, separated from the internal softer structure in which the vessels ramify. (*Ad Nat.*)

Such, then, are the structures belonging to the fœtus which are brought into contact with the maternal blood in the interior of the placenta, viz. the portion of chorion that forms the floor of the placenta, and the tufts or villi which spring from its surface. The office of the former is simply mechanical in confining the maternal blood to its proper course, and preventing rupture of the organ; the latter constitutes the potential portion of the placenta.

On the other hand, the sole parts belonging to the mother, the existence of which can be anatomically demonstrated in the substance of the placenta, are formed out of the decidua.

The decidua.—A general description of this membrane, as it forms the roof of the placenta, and sends off dissepiments into its substance, has been already given. It only remains to

* J. Goodsir. Anatomical and Pathological Observations, 1845.

* These are the only terminations of the fœtal vessels of the placenta which have been hitherto described. The true capillary system disappears towards the end of gestation, and apparently, on this account, has escaped the attention of observers, as far as I am aware, except Schrœder van der Kolk, who, in his recent work, has described and figured them in a placenta of three months. Scanzoni also (Lehrbuch der Geburtshilfe, *fig.* 99.) reproduces the figure of Meckel and Gierse, in which the capillaries have evidently been injected; but this is given as an example characteristic of a dropsical placenta, and not as representing a normal state.

explain the exact relations of this structure to the villi, within the placenta. All the extremities of the villi which are sufficiently long to reach across the placenta from the chorion to the opposite surface formed by the decidua, become firmly attached to the inner side of the latter. This attachment takes place not by any actual perforation of the decidua, but by the ends of the villi being simply inserted, in an early stage of the formation of the placenta, into little shallow pits or cup-like depressions in the decidual substance, into which they are received, and from which they may be withdrawn.* In other cases, the ends of the villi become blended with the decidua, to which they are apparently fixed, by a growth of decidual cells. These attachments are for the purpose of giving strength to the placenta, and of mechanically supporting the villi. They take place not only between the ends of the villi and the decidua forming the roof of the placenta, but also wherever decidua and villi come into contact. Hence similar attachments are also formed between the villi and the septa or dissepiments (*fig.* 484. *d p*), which divide its substance into separate lobes. Upon the floor also of the placenta all round the margin, where the decidua turns downwards and inwards to become united with the chorion, and to form the placental margin, the decidua is found for a short distance attached to the bases of the villi. And this arrangement gives to the parts an appearance as if the decidua had been here penetrated by the villi, but one which is actually occasioned by the former having, in the course of growth, become extended around the roots of the latter long after these were first formed. Occasionally also decidual cells may be found upon the surface of villi, connecting together their extremities, or forming here and there rough irregular belts upon their stems.

Termination of the maternal vessels. — No extension of the maternal blood-vessels into the substance of the placenta among or between the villi, can be demonstrated to take place. So far as anatomical evidence goes, the maternal vessels all terminate at once and abruptly upon the inner surface of the decidua. The curling arteries, after passing from the muscular coat of the uterus, obliquely for the most part, through the layer of decidua which forms the roof of the placenta, open directly into the interior of the latter; while the veins commence by equally abrupt openings which conduct through the decidual layer to the venous sinuses in the uterine walls. These venous orifices occupy three situations. The first and most numerous are scattered over the inner side of the general layer of decidua which constitutes the upper boundary of the placenta; the second form openings upon the sides of the decidual prolongations or dissepiments, which separate the lobes from each other; while the third lead directly into the interrupted channel in the margin, termed the circular sinus.

Development of the placenta. — The early steps in the formation of the placenta have been described in the account which has been already given of the development of the *decidua* during gestation (p. 653.). These first steps consist in the formation out of the decidua of a perfectly spherical chamber, in the centre of which lies the impregnated ovum.

The surface of the ovum is at this time covered everywhere by short club-like villi of equal size. The extremities of these villi are simply in contact with, but are not as yet attached to the walls of the containing chamber. Subsequently both the villi and the decidua forming the fœtal chamber undergo considerable metamorphoses. Certain portions of these become intimately united, in order to form the placenta; while other portions suffer retrogression, and take no part in its construction. The following are the principal features in these metamorphoses.

Fœtal portion. — The surface of the ovum does not long retain the peculiarity just mentioned, of being equally covered by villi. During the second month at least, if not earlier, those villi on the side furthest from the uterus cease to grow, and in consequence of the increasing expansion of the ovum become more widely scattered over this part of its surface, while those nearest to the uterus rapidly increase in size and extent, so that this portion of the ovum soon exhibits a profuse growth of villous processes, which send out their ramifications in all directions.

According to Professor Goodsir, the development and growth of the villi proceed from the groups of cells already described as occupying their bulbous extremities. These swellings on the sides and ends of the villi are their germinal spots, and are the active agents in the formation of these parts. The villus elongates by the addition of cells to its extremity, the cells passing off from the germinal spot, and the spot receding on the extremity of the villus, as the latter elongates by the additions which it receives from it.

As the villi increase in size, their strength is gradually augmented by the conversion of the membrane and cells forming their stems and larger branches into a tough white fibrous texture; while frequently, towards the end of gestation, calcification is observed to begin within the finer villi, and to proceed sometimes to so great an extent that a considerable number of them become filled up and obliterated by solid matter. While these changes are going on in the outer portion of the villi, or

* The difficulty of understanding the early steps in the construction of the placenta has arisen from the belief commonly prevalent, that the ovum on first reaching the uterus remains upon the outside of the decidua, and that the villi of the chorion penetrate its substance or enter the uterine glands in order to form the placenta. But there is no actual penetration of the decidua at any period, except that which consists in the *entire* ovum gaining a situation in the interior of this membrane shortly after its arrival in the uterus. The *tips* of the villi at a certain stage, as above described, become superficially imbedded in the walls of the fœtal chamber, which is formed of decidua; but this is not a penetration of the decidua, as commonly understood, but only a means of fixing the ovum.

that which is derived from the chorion, important modifications occur in the interior structures. Up to a certain period of gestation, the chorion and its villi contain no blood-vessels. According to the author last quoted, blood-vessels first appear in these parts when the allantois reaches and applies itself to a certain portion of the interior surface of the chorion. The umbilical vessels then communicate with the substance of the villi, and become continuous with loops in their interior. Those villi in which the blood-vessels do not undergo any further development, as the ovum increases in size, become more widely separated, and lose their importance in the œconomy. The villi, again, in which vessels form, in connection with the umbilical vessels, increase in number, and undergo certain changes in the arrangement of their constituent elements. As the blood-vessels increase in size, the cells diminish in number, but are always found surrounding the terminal loop of vessels in the situation of the germinal spot.

The injections of Schrœder van der Kolk * show a profusion of capillaries within the villi as early as the third month. And at later periods of gestation, up to the sixth month, I have succeeded without difficulty in displaying, by the aid of fine injections, such an abundant development of these vessels, as is exhibited in *fig.* 485. Before the end of gestation, however, the greater part or all of these fine capillaries have disappeared, and the vessels within the villi then show only the long tortuous varicose loops which Goodsir has so well described.

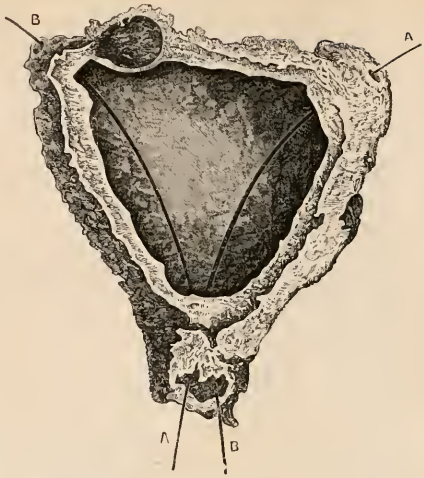
Such are the principal modifications which normally take place during the development and growth of the fœtal portion of the placenta. The changes occurring in the maternal portion, or that which is supplied by the decidua, are not less remarkable.

Maternal portion. — Four principal stages may be observed in the formation of this portion of the placenta.

The first stage is that in which the decidua constitutes a perfectly spherical chamber † surrounding the ovum, but having as yet no structural connection with it (*fig.* 486.). This is the condition of the ovum in the early part of the first month of gestation.

The second stage is marked by the commencing attachment of the villi all round to the inner surface of the containing chamber, so that now the ovum becomes fixed, and can no longer be turned out, except by breaking off the villi, or drawing out their ends from the little pits, or anfractuosities, already described in the walls of the decidua, in which they have become embedded. At this period (latter half of the first month), the decidua forming the walls of this chamber is sufficiently firm to admit of dissection, and already there may be traced, upon its inner surface,

Fig. 486.



Decidua at the beginning of gestation, exhibiting the fœtal chamber in the first stage of its formation. The ovum, being at this time unattached, has dropped out of it. (*After W. Hunter.*)

orifices communicating with canals in the decidua that lead into the uterine sinuses. The maternal blood already flows freely into the fœtal chamber, and, after passing everywhere among the villi, is returned into the uterine veins. Thus a *temporary placenta* is formed, which, as in Pachydermata, Cetacea, &c., entirely surrounds the ovum (*fig.* 487.).

The third stage is the most important. It marks the transition from the temporary to the permanent form of the placenta. Coincidently with the increased development of the villi on one side of the chorion, and their corresponding arrest of growth on the opposite surface, there occurs an increase of the space between the decidua and the ovum on one side, and a corresponding decrease of it upon the opposite side. The increase is always on the side next the uterus, where the villi are most abundant, and the decrease upon the opposite surface, where they are fewest. And this change continues progressively, until, upon the bald side of the ovum, the decidua reflexa and the chorion come into so close contact that the interspace is obliterated, and the blood, which formerly flowed freely among the villi, is now no longer admitted to this part of the circumference of the ovum ; while, upon the side which is directed towards the uterus, a large space is left which now takes the form of a meniscus. In order more effectually to confine the blood within this limited space, an increased development of decidual cells now takes place, which pass off from the uterine walls, and attach themselves to the chorion all round the circumference of this space, and thus is formed the margin of the permanent placenta. During all this time, the ovum, by its growth, has been gradually raising the decidua above and around it, just as the common integument becomes raised dur-

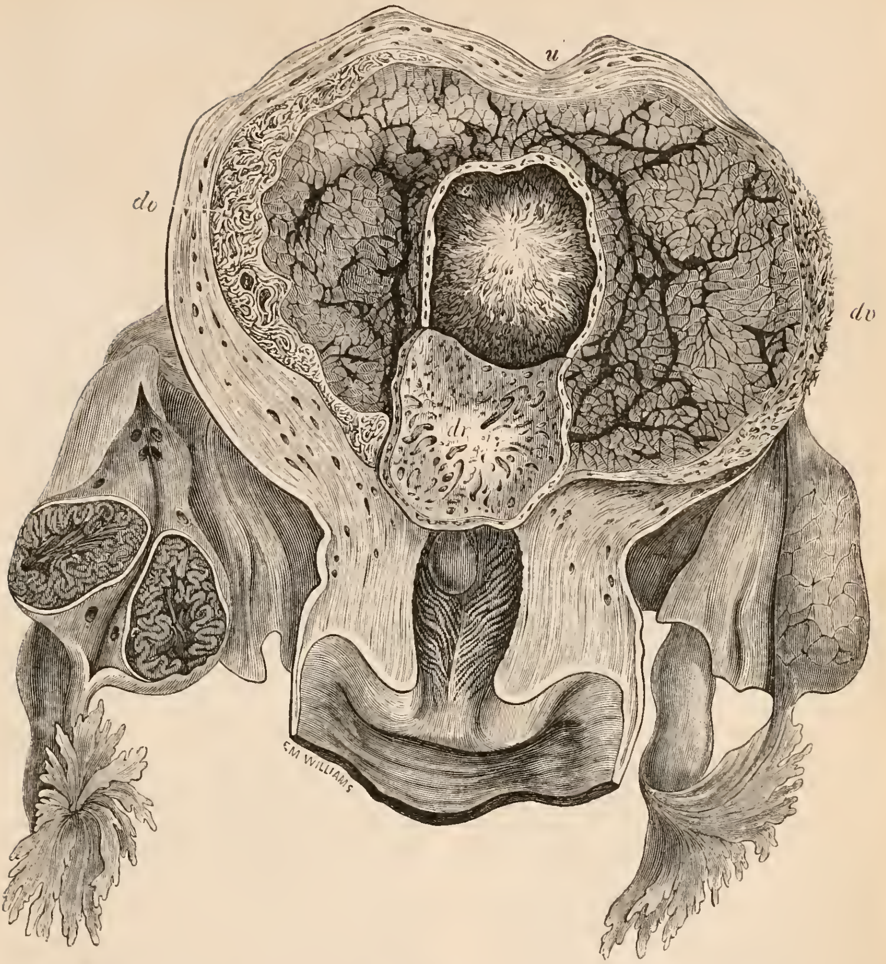
Fig. 487.



The formation of the fœtal chamber more advanced than in fig. 486. *The ovum is still evenly covered by villi, the ends of which, about this time, begin to be attached to the walls of the chamber in which the ovum is contained.*

o, ovum; *d r*, decidua reflexa, forming the fœtal chamber; *d v*, decidua vera; *u*, uterine walls.

ing the formation of a subcutaneous abscess; while in proportion as the base of the chamber becomes extended by the gradual retiring, from the centre, of the line of reflexion of the decidua, like waves receding from a central point, so, at the same time, an increasing surface is produced by the expansion of the uterus itself; and the layer of decidua here formed, commonly termed the decidua serotina, is simply the mucous membrane reproduced to supply the place of that which had been consumed or pushed off in forming the decidua reflexa.

The fourth or final stage consists in the partitioning of the permanent placenta into smaller portions or lobes by the extension of the layer of decidua (serotina) which lies opposite to the developed villi inwards at various points towards the chorion. In this way are constructed the dissepiments already described as bounding the several lobes or cotyledons. This partitioning of the placenta commences about the fourth month.

Thus, during these several stages in the formation of the placenta, two processes may be said to be concurrently carried on which tend in opposite directions — a process of positive enlargement and growth combined with one of relative retrogression or limitation. For while the bulk of the placenta is progressively increasing up to the completion of pregnancy, the relative amount of surface of the ovum appropriated to it is, on the other hand, diminished. The entire surface of the chorion being, in the first stages of development, employed as a placenta; while in the latter half of gestation, one third of it suffices for that purpose.

Functions of the placenta. — By means of the placenta, the blood of the mother is brought into mediate relation with that of the fœtus. Two currents, the one fœtal, and the other maternal, are continually flowing into and from this organ, yet in channels so perfectly distinct that no direct commingling of the streams can ever take place. Nevertheless, though no passage of the form-elements of the blood can occur, yet through the partition-walls which separate these two currents, all the materials necessary to the growth of the fœtus are conveyed by endosmotic processes, and all the changes necessary to the respiration of the fœtus, and to the elimination of effete materials, are effected. The mechanism by which these ends are accomplished is of two kinds. The one consisting of means for bringing the two constantly flowing streams of blood into juxtaposition, the other of instruments for carrying on the nutritive and eliminative processes which are the objects of this conjunction.

The fœtal blood conveyed by the branches of the two umbilical arteries, is distributed to the villi, whence, after being exposed, in the finer vessels and capillaries which ramify upon their inner surface, to the influence of the maternal blood, it is returned to the funis by the branches which terminate in the single vein. The propelling power by which the blood is moved resides in the heart of the fœtus, and the whole of its circulating fluid is thus carried in successive portions through the placenta.

The maternal blood, after having its impetus diminished by the spiral course which the arteries take in passing through the walls of the uterus, as well as through the decidua, is delivered at once into the placenta, where it becomes immediately separated into fine streamlets by the villi which are so closely set as to break up the interior of the organ into countless channels. After flowing everywhere among the villi, the blood escapes back into the uterine system * by the venous orifices upon the surface of the decidua, and upon the dissepiments and marginal furrows from which it is conducted, through the decidual coat, to the sinuses in the substance of the uterus, and thence is returned to the mother's body by the uterine and spermatic veins.

During the flow of these streams through the interior of the placenta, the surface of the villi is constantly bathed by the maternal blood. Nevertheless the blood of the fœtus is separated from that of the mother — first, by the walls of its own capillaries; secondly, by the gelatinous membrane in which these ramify; and thirdly, by the external non-vascular nucleated sheath derived from the chorion. With the latter alone, the maternal blood is brought into direct contact.

Each of these structures has its distinct office. The use of the external layer of cells (*fig.* 485. *b*) has been happily illustrated by Goodsir. They are to the ovum what the spongioles are to the plant: they supply it with nourishment from the soil in which it is planted. Thus their action is selective, and they transmit to the interior of the villus the materials necessary for fœtal growth. These again are taken up by the internal layer of cells (*fig.* 485. *b*), and by them brought into direct contact with the fœtal capillaries. By a similar process, the interchanges necessary to respiration are effected through the membranous surfaces which separate the maternal and fœtal blood. And these processes, respiratory and nutritive, are continued without intermission from the moment that the two separate currents are established until the final separation of the fœtus in the act of birth. Yet, throughout pregnancy, the form of the mechanism by which these changes are effected is continually altering, either in its greater or lesser parts. The greater changes have reference chiefly to mechanical, and the lesser to vital necessities. The changes in form exhibit a beautiful series of adaptations in the capacity and strength of the placenta to the increasing amount and force of the maternal current. The original plan of the placenta, that of an interspace between two spheres (a lesser one contained within a greater) filled by maternal blood, could not be long preserved with the materials out of which the temporary organ is constructed. For as the ovum grows, the decidua reflexa, which alone confines the blood

* I can arrive at no other conclusion than that the blood in the interior of the placenta, is as much external to the maternal vascular system as it is while passing through a quill inserted between the divided ends of a vein in a living animal. Although, in this belief, I find myself opposed to the views of Weber, Müller, J. Reid, Goodsir, and Schrœder van der Kolk, who, with certain differences maintain that the blood is still retained within the maternal system. The views of these and of many other physiologists, who more or less agree with them, are divisible into two classes. According to one view, the uterine vessels either form a network in the substance of the placenta (Weber), or become expanded into an enormous sac, composed of the inner coat of these vessels, which envelopes everywhere the surface of the villi (J. Reid), so that the blood after circulating within the placenta is returned to the uterus without having been extravasated. According to the other view (Goodsir and Schrœder van der Kolk), the decidua throws a close investment over every villus, and forms that outer covering of cells which I have ascribed to the chorion; so that in this view a lamina of uterine structure still separates the maternal blood from the exterior of the villi.

On this and other points relating to the minute structure and composition of the placenta, consult *Von Baer*, Untersuchungen über die Gefässverbindung zwischen Mutter und Frucht in den Saügethieren. 1828. *Ritgen*, Beiträge zur Aufhellung der Verbindung der Menschlichen Frucht mit dem Fruchthälter. 1835. *Sharpey*, in Müller's Physiology by Baly. 1837 and 1848. *Eschricht*, De organis quæ respirationi et nutritioni fœtus mammalium inserviunt. 1837. *E. H Weber*, in Hildebrandt's Anatomie, b. iv., and in *Wagner*, Elements of Physiology. 1841. *J. Reid*, Edinb. Med. and Surg. Journ., No. 146. *J. Dalrymple*, Medico-Chirurgical Trans., vol. xxv. 1842. *Goodsir. J.* and *H.*, Anatom. and Pathol. Observs. 1845. *Schrœder van der Kolk*, Waarnemingen over het Maaksel van de Menschelijke Placenta, en over haren Bloods-omloop. 1851.

that flows around it, becomes thinner, and finally gives way by extension. But long before this stage arrives, the whole of this portion is shut out from the maternal circulation, and the subsequent metamorphoses are directed to the strengthening of the more limited space which remains. It is on this account that the strong border of decidua is formed around the margin of the now restricted area. The base of the placenta now consists of the tough and resisting chorion; while that portion alone of the decidua which is strengthened externally by the uterine walls is retained to form the opposite boundary. Ultimately, as the current of maternal blood flows with increasing force into the placenta in proportion to the growth of the latter, this becomes subdivided by the decidual septa, which apportion the entire organ into separate placentulæ, and thus the larger supplies necessary to the increasing exigencies of the fœtus are disposed of without danger of rupture to any portion of the organ.

The changes in the more minute structures which belong to the fœtus are not less interesting. The profuse development of fine capillaries within the fœtal tufts, which is so conspicuous from the third to the sixth month, is connected not only with the functions of respiration and nutrition of the fœtus, but also with the growth of the villi themselves. But when the period of viability of the fœtus has arrived, the proportionate amount of capillary vessels within the villi becomes greatly reduced, until finally only the original stems of the vessels are left. And this relative reduction of the channels through which the fœtal blood flows, becomes more marked, until, as the time of birth approaches, many of the villi become more or less obliterated, and cease to admit blood, often in consequence of that calcareous degeneration which, from the frequency of its occurrence, may be regarded rather as a normal process significant of natural decay than as an evidence of any morbid or preternatural change.

The series of metamorphoses is closed by the degeneration of the materials which bind the placenta, and consequently the fœtus, to the uterus. The layer of decidua forming the connecting medium between the uterus and the fœtal structures, in common with the rest of this membrane, suffers slow disintegration, and its component cells are converted into molecular fat. And now the strength of the adhesion being gradually diminished, it only remains for the contractile power of the uterus to be evoked in order to accomplish the separation together of the fœtus and placenta, like ripe fruit detached from the parent bough.

The illustrations of this article marked, "ad naturam," are from original drawings and preparations in the possession of the author. For the rest of the figures the authorities are given.

The usual signs are employed: for an inch ″; for a line ‴; and for the amplification ×.

The following tabulated arrangement of the principal contents will facilitate reference to the several subjects, as well as to the books quoted in the foot notes of this article.

UTERUS AND ITS APPENDAGES.
